As with other medical issues, to assess a brain tumor, nurses and other health-care professionals should first obtain the patient's medical history. This history should identify whether patients could be at risk for a brain tumor because of factors such as obesity, age, family history, and certain radiation exposure. It should also determine whether patients are exhibiting symptoms of a brain tumor, such as frequent headaches and nausea. Patients should receive a physical examination to check their vision, hearing, speech patterns, coordination, and other physical behavior, including the patient's ability to walk. The examination should also include an assessment of the patient's deep tendon reflexes.

Diagnostics and Laboratory Values

Diagnostic procedures for brain tumors typically include imaging studies such as MRI or CT scans, tissue biopsies, and magnetic resonance spectroscopy (MRS) testing. MRI and/or CT scans will show whether a tumor exists. A tissue biopsy can determine the type and grade of the brain tumor. MRS testing can provide further analysis of the tumor by examining its chemical profile and providing more details about lesions found on MRIs.

To gauge their severity, tumors are graded on a four-point scale, with one being the least aggressive tumors and four being the most aggressive. The characteristics associated with each grade of tumor include the following (AANS, n.d.; Johns Hopkins Medicine, n.d.):

- Grade I—slow-growing, benign tumors that may appear as normal cells, are noninfiltrating, and typically pose no life threats
- Grade II—reasonably slow-growing tumors that are usually benign, appear as slightly abnormal cells, may be infiltrative, and may recur if removed
- Grade III—malignant tumors that grow reasonably fast, appear as abnormal cells, infiltrate into neighboring tissues, and tend to recur as a grade 4 tumor
- Grade IV—malignant, aggressive tumors that grow rapidly, appear as very abnormal cells, infiltrate easily into other parts of the brain, and rapidly recur if removed

Nursing Care of the Patient with Brain Tumors

Brain tumors, whether benign or malignant, are critical conditions requiring nursing care tailored to address the patient's needs based on the grade of their tumor. By recognizing the cues of brain tumors, nurses can help to

identify patients with a brain tumor. Nurses also need to understand how to provide effective nursing care to patients with a brain tumor.

Recognizing Cues and Analyzing Cues

To recognize when patients may have a brain tumor, nurses use data about patients' vital signs and neurological status to identify and analyze cues (Table 17.3).

Cues Found in Nursing Assessment	Analysis of Cue
Environmental triggers, such as exposure to radiation, head traumas, and medical history, such as a family member with neurofibromatosis or another genetic condition that puts some patients at greater risk of developing a brain tumor. Also, patients with another type of cancer, such as lung or breast, are at greater risk for developing a brain tumor as a secondary site to their primary cancer diagnosis.	May indicate risk of brain tumor
Headaches, vertigo, confusion, memory loss, fatigue, poor reflexes, numbness or paralysis, seizures, nausea, changes in appetite, behavioral changes	General symptoms that may indicate a brain tumor
Personality changes, disinterest in normal activities, forgetfulness, balance issues, and difficulty walking	May indicate a frontal lobe tumor
Difficulty with the senses, particularly hearing and vision problems	May indicate a tumor in the parietal or occipital lobe
Memory loss, tasting or smelling something that doesn't exist	May indicate a tumor in the temporal lobe

TABLE 17.3 Brain Tumor Assessment Cues

REAL RN STORIES

Nurse: Aarti
Years in Practice: Fourteen
Clinical Setting: Oncology
Geographic Location: Ohio

In my role as a registered nurse, I had the honor and pleasure of providing care for Mr. Anderson, an inspiring 55-year-old German male facing an insurmountable brain tumor diagnosis. From day one, I knew that providing clinical care wasn't enough; providing emotional support was also critical. As my patient underwent surgery to remove his brain tumor, I stood with him every step of the way, explaining each procedure with kindness and making him as comfortable as possible despite uncertainty. Postoperatively, I closely monitored his neurological status so as to act immediately if any signs of complications arose. Crafting an individualized pain management plan required working closely with Mr. Anderson's health-care team. I listened carefully and responded accordingly with empathy and professionalism to his fears, providing education on his treatment plan and offering guidance for at-home care. My holistic care commitment extended further by supporting his family as they planned to be present during his treatment and by offering advice about at-home care arrangements. As we transitioned into his recovery journey, I collaborated closely with therapists in devising an individualized rehabilitation plan and celebrating each small victory along the way. Facilitating open dialogue with Mr. Anderson, his family members, and members of his health-care team enabled me to foster a trusting and healing environment. As challenging as brain tumors may have been, my dedication was motivated by the desire not just to provide nursing care but to have an impactful role in those lives served. Through expertise and genuine concern, I worked hard to be an integral member of Mr. Anderson and

his family's support network through every phase of his condition with grace and determination. It doesn't always happen, but he did well, and it was wonderful to see him smile again."

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Nurses should prioritize brain tumor symptoms based on severity experienced by patients, such as frequency and intensity of headaches, vertigo, and seizures. Brain tumor symptoms should also be prioritized based on whether the symptoms result from tumors that are benign or malignant, as well as whether the tumors are grade 1, 2, 3, or 4. When taking action to care for patients with brain tumors, as appropriate, nurses should implement the nursing interventions in Table 17.4.

Nursing Care	Rationale
Complete focused neurological assessments.	Changes in LOC, pupillary response and shape, motor function, speech, and vital signs indicate health issues.
Provide after-surgery care.	Patients may need assistance as the effects of anesthesia wear off, which may include suturing incisions, emptying drains, changing dressings and bandages, and applying heat/cold packs to assist with any swelling.
Provide care associated with radiation therapy.	Patients may need help to understand what to expect with radiation, and they may experience side effects such as nausea.
Administer chemotherapy as ordered.	The patient may need help to understand the treatment and chemotherapy drugs that may need to be administered. Patients should be monitored because they may experience side effects, such as nausea and fatigue.
Manage pain.	Patients may experience pain, including headaches. They may need pain medications, such as analgesics.
Avoid Valsalva maneuvers.	Avoiding or minimizing bowel straining, coughing, or bearing down will reduce the risk of increases in ICP.
Implement seizure precautions.	Because brain tumors can cause seizures, keep the bed in a low position with the side rails up and provide bedside padding if needed. Ensure basic suction equipment is set up and ready for use.

TABLE 17.4 Nursing Interventions for Patients with Brain Tumors

Evaluation of Nursing Care for Patients with Brain Tumors

The desired outcomes for patients with brain tumors include the successful removal of brain tumors if possible. For patients who must learn to live with their brain tumors, the desired outcome is to relieve symptoms and restore as much quality of life as possible. For patients whose brain tumors are terminal, the desired outcome is to help patients navigate end-of-life challenges. Examples of successful outcomes for patients with brain tumors include pain that is satisfactorily controlled, physical therapy that results in a decreased risk for falls, and range of motion exercises that restore or sustain the patient's mobility.

Medical Therapies and Related Care

Treatment strategies for brain tumors depend on whether the tumor is benign or malignant, the grade of the tumor, its location and size, and the patient's health. Common treatments for tumors may include the following:

- Surgical procedures
  - craniotomy—involves removing a bone flap from the skull to access a tumor

    - neuroendoscopy—uses an endoscopy to enter the skull through small holes and access a tumor
    - laser ablation—uses heat to destroy tumor cells
    - laser interstitial thermal therapy—uses a laser inserted through a tiny incision in the skull to kill tumor cells
- Radiation therapy
- Chemotherapy drugs to kill existing cancer cells and inhibit the growth of new cancer cells
- Immunotherapy to strengthen immunity by recognizing and destroying cancerous cells as soon as they appear

LIFE-STAGE CONTEXT

Brain Tumors in Children versus Adults

Brain tumors in both children and adults may differ in many aspects, from their types, symptoms, and treatment approaches to how quickly the cancers may grow back over time. In pediatric cases, medulloblastomas, ependymomas, and low-grade gliomas, such as an astrocytoma are more prevalent. In comparison, adults more commonly have gliomas, meningiomas, and metastatic tumors. Whereas tumors in children have a large genetic component, brain tumors in adults develop more commonly due to environmental triggers over time. Treatment approaches also differ as pediatric oncologists may be less inclined to do surgery and rely more on chemotherapy for younger patients, compared to the surgical option more commonly seen with adults. Long-term effects of brain tumors and their treatment are seen more dramatically with pediatric patients compared to adults.

Guillain-Barré Syndrome

Guillain-Barré syndrome (GBS) is a rare autoimmune disease in which the immune system attacks the peripheral nervous system, affecting motor functions. Patients usually recover fully from GBS, but the syndrome duration tends to cause severe symptoms, which can include temporary paralysis. Occasionally, GBS is fatal, and some recovered patients may have lingering symptoms, such as fatigue, numbness, or weakness.

Pathophysiology

The exact cause of GBS remains unknown, but people who develop GBS often experience respiratory illness or diarrhea in the days, or even weeks, before they develop GBS. GBS may follow infection with *Campylobacter jejuni* or influenza viruses such as H1N1, and on rare occasions, vaccinations for the flu may lead to the development of GBS (Centers for Disease Control and Prevention, 2023). Surgeries can also trigger GBS, which occurs when an immune response damages myelin sheaths or nerve axons of peripheral nerves, causing muscle weakness, especially in the arms and legs. This muscle weakness may affect other bodily functions, such as swallowing and breathing (muscles in the throat and diaphragm are affected), and some patients with GBS may have difficulty walking. Some patients with GBS experience near complete paralysis.

GBS comes in different forms. The four primary types of GBS include the following:

- acute inflammatory demyelinating polyradiculoneuropathy (AIDP)—most common form of GBS characterized by muscle weakness that begins in the lower parts of the body and spreads upward
- Miller Fisher syndrome (MFS)—begins with paralysis in the eyes
- acute motor axonal neuropathy (AMAN)—characterized by paralysis and the loss of reflexes but the senses remain intact
- acute motor-sensory axonal neuropathy (AMSAN)—characterized by sensory deficiencies as well as a loss of reflexes and motor weakness

Clinical Manifestations

The symptoms typical of GBS include the following:

- muscle weakness progressing upward from feet to the hands and head
- tingling and weakness from lower body to upper body
- loss of deep tendon reflexes
- progressive paralysis from legs to respiratory muscles
- pain and aching of limbs

- difficulty speaking and swallowing
- autonomic dysfunction of heart rate, temperature, and bowels
- cranial nerve disorders causing blurred and double vision
- **paresthesia**, which is abnormal sensations such as burning, prickling, and tingling

In addition, because GBS affects patients' nerves and bodily functioning, patients with GBS may experience breathing difficulties, blood pressure and heart issues, blood clots, bladder and bowel dysfunction including incontinence, and pressure injury as the condition progresses.

Assessment and Diagnostics

To assess and diagnose GBS, nurses and other health-care professionals should review a patient's medical history and conduct a physical examination that focuses on GBS symptoms, such as vision problems, muscle weakness, paralysis, and loss of reflexes. If GBS is suspected based on the physical examination findings, medical tests to confirm the diagnosis may include a lumbar puncture, nerve conduction study, and/or electromyography (EMG).

Diagnostics and Laboratory Values

The analysis of CSF obtained by a lumbar puncture for a patient with GBS may show an infection and/or high protein in the spinal fluid. Nerve conduction studies may show slower speeds in nerve signals. EMG measures nerve activity and may reveal GBS symptoms such as slower nerve conduction and reflex abnormalities. EMG may also find abnormal changes in nerve patterns and absent or prolonged F-wave motor responses.

Nursing Care of the Patient with Guillain-Barré Syndrome

GBS is a serious condition that requires emergency medical treatment and hospitalization. Without immediate care, patients with GBS are more likely to experience long-term effects, such as muscle weakness, pain in the limbs, and difficulty with balance and coordination. Some patients with GBS may even die without medical treatment.

Recognizing Cues and Analyzing Cues

To recognize the cues of GBS, nurses should gather the patient's medical history to learn about indicators, such as recent surgery or exposure to infections or viruses that can trigger GBS. As noted previously, symptoms that may be cues of GBS include muscle weakness, loss of reflexes, pain and aching in limbs, paralysis, difficulty speaking and swallowing, and sensations of burning and tingling. Nurses should also review the results of tests performed on the patient with GBS, which may include a lumbar puncture, nerve conduction study, and/or EMG. To analyze these cues, nurses should determine if the examination and test results deviate from normal for the patient.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Because GBS is a serious condition that requires immediate care, prioritize GBS as critical and provide emergency interventions. Once the patient is stable, collaborate with the patient's health-care team members to address GBS symptoms, which may include loss of reflexes, muscle weakness, and difficulty speaking and swallowing. The actions that nurses should take to treat patients with GBS may include the interventions in Table 17.5.

Nursing Care	Rationale
Complete focused neurological assessments.	Changes in motor functions, reflexes, speech, and nerve functioning may be cues of GBS.
Monitor vital signs, muscles, and skin.	Blood pressure, heart rate, muscle strength, and skin issues such as bedsores indicate health issues.
Monitor for blood clots.	Symptoms such as pain, redness, and swelling may indicate blood clots, which may occur with GBS.
Monitor for bladder and bowel dysfunction.	Irregular urine outputs and bowel movements indicate health issues.

TABLE 17.5 Nursing Interventions for Patients with GBS

Nursing Care	Rationale
Prevent and monitor for aspiration and position the patient upright during meals.	Patients may experience swallowing and aspiration difficulties.
Manage pain.	Patients may require analgesics and complementary pain relief measures.
Support oxygenation and ventilation.	Patients may require respiratory care, including deep breathing exercises, to ensure adequate oxygenation and ventilation.
Assist with mobility exercises.	Physical therapy may assist patients with mobility exercises and positioning changes to minimize risk for impaired physical mobility.
Assist with plasma exchange.	Patients with GBS may need a plasma exchange to purify their blood.
Assist with immunoglobulin therapy.	Patients with GBS may need immunoglobulin therapy to strengthen their immune system.

TABLE 17.5 Nursing Interventions for Patients with GBS

Evaluation of Nursing Care for the Patient with Guillain-Barré Syndrome

The desired outcome for patients with GBS is recovery that results in a fully functioning peripheral nervous system. Ideally, patients with GBS should also not have lingering symptoms, such as fatigue, numbness, or weakness. Table 17.6 provides more specific details about evaluating outcomes for patients with GBS.

Nursing Diagnosis	Nursing Evaluation
Impaired gas exchange	• Evaluate improved oxygen saturation levels.
Risk for aspiration	• Observe for successful swallowing without aspiration. Evaluate the patient's ability to tolerate oral intake.
Impaired physical mobility	• Assess improvements in range of motion. • Monitor the patient's ability to ambulate independently or with assistance.
Risk for impaired physical mobility	• Assess improvements in mobility and range of motion. Evaluate the patient's ability to perform activities of daily living.
Ineffective airway clearance	• Assess the patient's ability to clear secretions effectively. Monitor for improvements in breath sounds and respiratory effort.
Sleep disturbance	• Assess improvements in sleep duration and quality. Monitor for signs of daytime alertness and energy levels.

TABLE 17.6 Evaluating Outcomes for Patients with GBS

Nursing Diagnosis	Nursing Evaluation
Swallowing impairment	• Observe for successful swallowing without signs of aspiration. • Assess the patient's tolerance of oral intake.
Verbal communication impairment	• Assess improvements in the patient's ability to articulate and communicate. • Evaluate the use of alternative communication methods.
Malnutrition risk	• Evaluate weight gain or stabilization. • Monitor for improvements in nutritional markers.
Acute pain	• Assess for a reduction in pain intensity or frequency. Evaluate the patient's comfort level during activities.
Impaired skin integrity risk	• Assess the skin for the absence of pressure ulcers or improvement in existing ones.

TABLE 17.6 Evaluating Outcomes for Patients with GBS

Medical Therapies and Related Care

Many patients with GBS are treated with intravenous immunoglobulin therapy (IVIG). This process provides patients with healthy antibodies intravenously. IVIG modulates immune response and decreases inflammation by blocking damaged antibodies in the patient's body. Plasma exchange (plasmapheresis) is another treatment regimen often used for patients with GBS. This procedure removes harmful antibodies by replacing old plasma with fresh plasma taken from another source, such as a donor.

Meningitis

Meningoencephalitis, also referred to as **meningitis**, is an inflammation of the meninges, which are the membranes covering the brain and spinal cord. Typically, meningitis is caused by bacteria, viruses, fungi, amoebae, or parasites. Less frequently, meningitis may be caused by noninfectious factors such as certain medications, such as antimicrobials or anti-inflammatory drugs, or by autoimmune conditions, such as rheumatoid arthritis or lupus. Meningitis varies in its incidence and prevalence depending on its cause. Viral meningitis is more common than bacterial meningitis but tends to be less severe; patients with bacterial meningitis are more likely to require medical treatment.

Pathophysiology

Meningitis can affect anyone, including children, but people with weakened immune systems are at greater risk. People who live in crowded conditions, such as dormitories, military barracks, or immigration camps have a higher risk of contracting meningitis. Also, those who have not been fully immunized are more likely to contract meningitis. Children are eligible to receive their initial meningococcal vaccination at age 10, with a booster at age 15. When there is an outbreak of infected individuals, exposure can elevate the risk for those who are not fully immune. Head injuries, such as skull fractures, and surgical procedures that break the protective barriers of the meninges increase the risk of introducing a pathogen into the meninges. In addition, people who travel to areas with a higher prevalence of meningitis risk contracting it (National Institute of Neurological Disorders and Stroke [NINDS], 2024).

Clinical Manifestations

The symptoms of meningitis are varied and range in intensity depending on severity of the case. Common clinical manifestations include sudden onset fever, severe headache, neck stiffness, **photophobia**, which is an increased sensitivity to light, and **phonophobia**, which is an aversion to loud noises.

If the infection progresses, patients may experience neurological symptoms, such as altered mental status, confusion, difficulty focusing, irritability, and seizures. Individuals who have bacterial meningitis may exhibit

additional symptoms such as hearing loss and a skin rash associated with *Neisseria meningitidis* pathogens. They may also experience **petechiae**, which are round spots on the skin caused by bleeding in the skin; they may be red, brown, or purple. Typically, symptoms in patients with viral meningitis are less severe than in patients with bacterial meningitis (Figure 17.5).

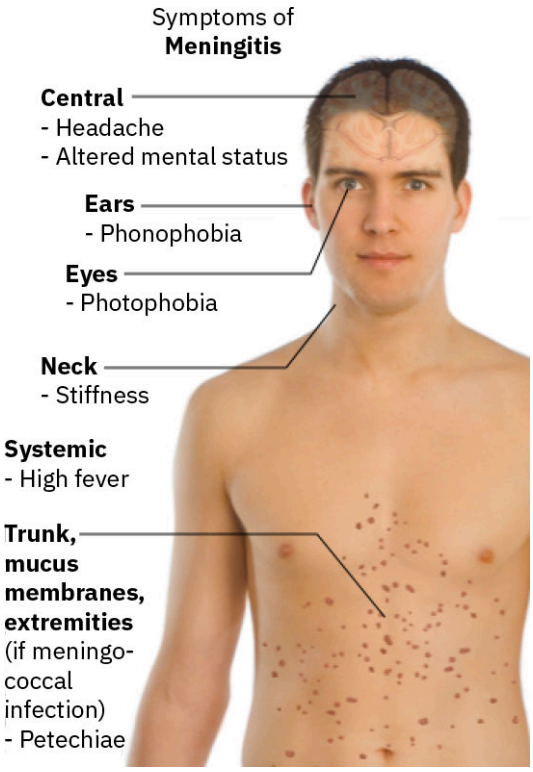

FIGURE 17.5 Clinical manifestations of meningitis include sensory symptoms, skin, and musculoskeletal changes. (credit: modification of "Symptoms of Meningitis" by Mikael Häggström/Wikimedia Commons, Public Domain)

Assessment and Diagnostics

Meningitis can be diagnosed through blood tests, lumbar punctures of CSF, and imaging with CT scans or MRIs. When assessments of patient's medical history and symptoms indicate that the patient may have meningitis, nurses or other health-care professionals should draw samples of blood and/or cerebrospinal fluid for laboratory testing. They may also order CT scans of the sinuses or chest or MRI scans of the head.

Diagnostics and Laboratory Values

Blood tests for patients with meningitis will show bacteria known to cause meningitis. Lumbar punctures may reveal bacteria that cause meningitis, as well as increased protein, elevated WBC count, and a low glucose level. Imaging may show inflammation and infection, including bacterial and viral.

Nursing Care of the Patient with Meningitis

Meningitis is a serious disease that can be deadly for some patients. Thus, patients with meningitis need immediate medical attention. Nursing care should focus on treating the bacterial and/or viral infection that has caused meningitis and should strive to relieve patients' symptoms, such as fever and pain.

Recognizing Cues and Analyzing Cues

To recognize the cues of meningitis, nurses should obtain the patient's medical history and determine if the patient is at risk for meningitis and has symptoms of meningitis. Nurses should check patients for skin rashes and petechiae. In addition, a physical examination may reveal a positive Brudzinski's sign or a positive Kernig's sign. A positive **Brudzinski's sign** occurs when pressure applied to the pubic symphysis elicits a reflex hip and knee flexion and abduction of the leg (Stribos & Jones, 2023). To elicit **Kernig's sign**, the patient is kept in a supine position, the hip and knee is flexed to a right angle, and then the knee is slowly extended by the examiner. The appearance of resistance or pain during extension of the patient's knee beyond 135 degrees constitutes a positive Kernig's (Karl et.al., 2022) (Figure 17.6). If the physical examination indicates the patient may have meningitis, patients should

receive testing, such as blood tests and lumbar punctures, to confirm the diagnosis. Meningitis is contagious. Thus, when drawing blood from patients with meningitis, nurses should take necessary precautions, such as wearing appropriate PPE equipment such as gloves and face masks.

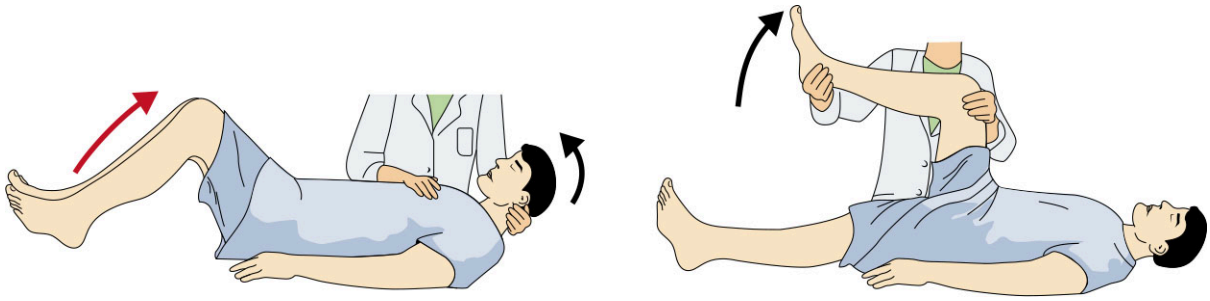

FIGURE 17.6 The (left) Brudzinski's and (right) Kernig's signs can be indicative of meningitis. (credit: attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Meningitis has the potential for rapid disease progression and can cause serious complications, such as brain damage, hearing and/or vision loss, seizures, and even death. Given the seriousness of meningitis and the threats it poses, meningitis should be prioritized as a critical disease that requires immediate, emergency intervention. Work with the patient's health-care team to develop solutions to address each patient's meningitis case. The appropriate nursing interventions may include the actions listed in Table 17.7.

Nursing Care	Rationale
Complete focused neurological assessments.	Changes in the patient's neurological symptoms, including cognitive issues and confusion, as well as problems such as headaches and fever are cues of meningitis.
Administer medication.	Antibiotics and possibly corticosteroids can help patients with bacterial meningitis. For patients with both bacterial and viral meningitis, pain medication can help relieve body aches and reduce fever.
Monitor vital signs.	Changes in blood pressure, heart rate, temperature, and other vital signs indicate how the patient is doing.
Drain fluids.	Patients with bacterial meningitis should have infected mastoids or sinuses drained. Nurses may assist with these procedures.
Monitor and maintain fluid and electrolyte balance.	Interventions such as intravenous fluids and potassium supplements may be needed to ensure patients stay hydrated and have the appropriate electrolyte balance.
Implement skin care.	Lotions, antibiotic creams, and other skin care treatments may be needed to care for rashes, wounds, and damaged skin.
Support oxygenation and ventilation.	Patients may have breathing difficulties and need assistance to maintain adequate oxygenation and ventilation.

TABLE 17.7 Nursing Interventions for Patients with Meningitis

Nursing Care	Rationale
Implement seizure precautions.	In some patients, meningitis can cause seizures. These patients need a quiet room, including limited visitors and dim lights. They also need airway supplies at the bedside, and the bed should be in a low position with the side rails up, as well as bedside padding if needed. Basic suction equipment should be set up and ready for use.
Maintain patient isolation.	Until diagnosis confirms the type of meningitis, patients may need to be isolated. If diagnosis confirms that the patient is contagious, the patient should continue to be isolated and patients must use the appropriate PPE equipment when treating the patient.

TABLE 17.7 Nursing Interventions for Patients with Meningitis

Evaluation of Nursing Care for the Patient with Meningitis

The successful treatment of meningitis should result in the removal of infection and alleviation of symptoms such as fever, headache, and neck stiffness. Patients should no longer experience issues such as seizures, photophobia, or phonophobia. If the treatment is not prompt, the patient is at risk for long-term issues, such as permanent nerve damage or hearing loss.

Medical Therapies and Related Care

Immunizations are essential in protecting against various forms of meningitis. Although vaccination schedules differ by country, they most often target specific pathogens associated with meningitis, such as *Hemophilus influenzae*, *Neisseria meningitidis* or *Streptococcus pneumoniae*. Patients with bacterial meningitis are more likely to require hospitalization, whereas those with viral meningitis may be treated as outpatients and provided supportive care while they remain at home. Patients who experience permanent damage from meningitis, such as nerve damage, may need long-term care such as anti-inflammatory medications and physical therapy.

LINK TO LEARNING

Meningitis can affect anyone, and although the infection can be serious, most people recover. But even with medical treatment, meningitis (https://openstax.org/r/77Meningitis) can be serious and even deadly.

17.3 Chronic Disorders of the Nervous System

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations for multiple sclerosis and myasthenia gravis
- Describe the diagnostics and laboratory values in the diseases of multiple sclerosis and myasthenia gravis
- Apply nursing concepts and plan associated nursing care for the patient with multiple sclerosis and myasthenia gravis
- Evaluate the efficacy of nursing care for the patient with multiple sclerosis and myasthenia gravis
- Describe the medical therapies that apply to the care of multiple sclerosis and myasthenia gravis

Multiple sclerosis (MS) and myasthenia gravis (MG) are chronic neurological diseases and complex disorders that profoundly affect lives. Multiple sclerosis is more common and typically initially affects people between the ages of 20 and 40 years old (NINDS, 2019). Myasthenia gravis (MG) is an uncommon disorder that usually affects females under 40 and males older than 60 years of age (NINDS, 2024b).

The autoimmune condition of the central nervous system characterized by inflammation, demyelination, and

neurodegeneration that manifests with diverse neurological symptoms, such as difficulties with coordination, slurred speech, and cognitive problems is called **multiple sclerosis (MS)**. MS is an incurable illness.

The autoimmune neuromuscular condition that manifests due to the body's production of hyperreactive antibodies that block acetylcholine receptors on muscle fibers, prohibiting communication to the nerves is called **myasthenia gravis (MG)**. MG primarily affects the **neuromuscular junction**, which is the point where nerve impulses meet muscles to create movement. Fewer nerve signals make it to the muscles, resulting in muscles that do not contract and move. Once a patient develops MG, it is a chronic condition.

Multiple Sclerosis

MS has the potential to be disabling. Although the exact cause of MS is still unknown, various genetic and environmental elements are believed to play a part, including family history, certain infections, vitamin D deficiency, and smoking (NINDS, 2019). Females tend to be affected more frequently than males, with symptoms typically appearing in early adulthood (NINDS, 2019).

Pathophysiology

MS is a neurodegenerative disease that has no cure. It is caused by antibodies attacking and damaging the protective layer of myelin sheath covering nerve fibers in the brain and spinal cord. This process creates scar tissue called "sclerosis." MS disrupts nerve signal transmissions, creating communication issues between the brain and other parts of the body.

Clinical Manifestations

MS manifests through a variety of symptoms, including the following:

- muscle weakness
- fatigue
- tingling and numbness
- lack of coordination
- a sensation that causes patients to feel dizzy, sometimes as if they are spinning or in motion while still, known as **vertigo**
- balance issues, which may include the inability to walk
- cardiovascular disease
- suppressed immune system
- eyesight issues, including blurred and/or double vision
- hearing loss
- difficulty breathing
- bladder, bowel, and sexual dysfunction, including infertility
- speech disorders as well as difficulty with swallowing
- cognitive issues, including confusion, memory problems, and difficulty concentrating
- personality and mood changes

The severity of MS symptoms varies among patients (Figure 17.7). Some patients go through periods of **remission**, when symptoms are minimized or even disappear, before facing **exacerbation**, a period when symptoms manifest again. Some patients do not have periods of remission and are continuously affected by MS symptoms. This may include symptoms so severe that patients are immobile, without the ability to walk independently.

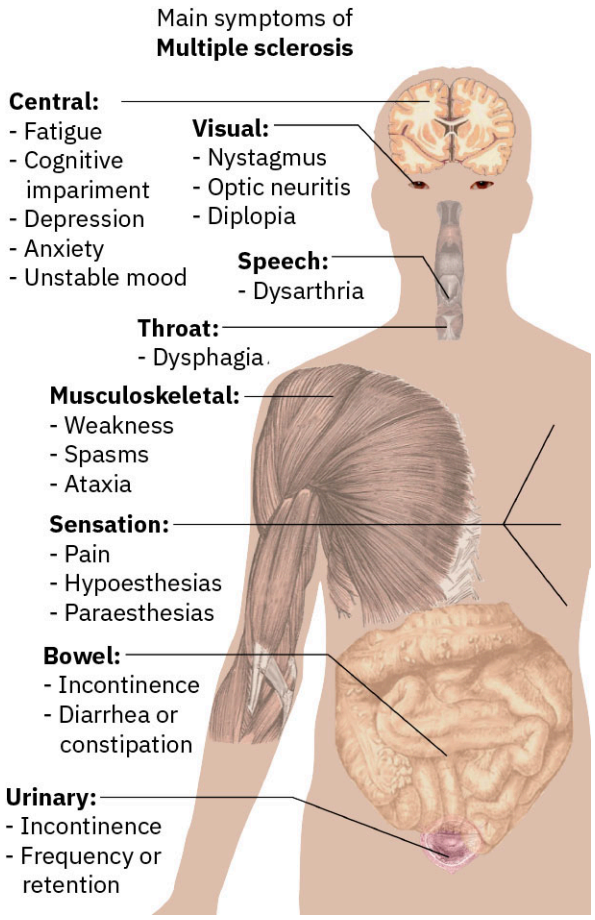

FIGURE 17.7 MS can affect various parts of the body. (credit: modification of "Symptoms of multiple sclerosis" by Mikael Häggström/ Wikimedia Commons, Public Domain)

Assessment and Diagnostics

MS is diagnosed by gathering a patient's medical history to determine if they have risk factors for MS. Such factors include a family history of MS; autoimmune diseases, such as type 1 diabetes or thyroid disease; vitamin D deficiencies; infections, such as Epstein-Barr (the virus that causes mononucleosis); obesity; and smoking. The medical history should also determine if patients have symptoms of MS, such as lack of coordination, cognitive issues, and hearing loss.

Diagnostics and Laboratory Values

If patients have symptoms of MS along with risk factors, additional assessment can be done through diagnostic testing. Blood tests, lumbar punctures, evoked potential tests, and MRIs may be useful to confirm an MS diagnosis.

Blood test results cannot show if a patient has MS, but they may show if a patient has another condition, with symptoms that are similar to MS, such as Lyme disease. If blood tests determine that a patient has a condition other than MS, health-care professionals can rule out MS as a diagnosis for the patient. Blood tests can also show the patient has a problem that is a risk factor for MS, such as a vitamin D deficiency.

A lumbar puncture can rule out infections that may be causing symptoms that mimic MS, as well as show if a patient has antibody abnormalities typical in MS. Evoked potential tests show how quickly nerve signals travel through the body, and in patients with MS these signals are defective. An MRI may show lesions that indicate MS.

Nursing Care of the Patient with Multiple Sclerosis

MS is incurable, but treatment can help patients manage the disease. Nursing care for patients with MS focuses on empowering them to participate in their care while supporting them to maintain the maximum independence and functioning levels possible.

Recognizing Cues and Analyzing Cues

To recognize the cues for MS, nurses should assess the patient's neurological status, with attention to motor functioning, coordination, and sensory perceptions. Nurses should be alert for muscle weakness, tremors, and gait issues, as well as problems with fine or gross motor skills. Other cues include sensory disturbances such as tingling or numbness, as well as problems such as fatigue, memory lapses, difficulty with concentration, and mood shifts. As part of this process, nurses should be aware that some patients with MS go through periods of remission and exacerbation, so some cues may be visible only part of the time. Nurses should also consider the results of blood tests, lumbar punctures, evoked potential tests, and/or MRIs performed on the patient. To analyze the cues of both symptoms and test results, nurses must evaluate how the findings deviate from normal ranges for both body functioning and test results.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

For patients with MS, prioritize health problems according to severity of symptoms, recognizing that some symptoms may be mild and require no treatment. Although there is no cure for MS, patients still need treatment to help them manage symptoms, recover from attacks, and slow the disease's progression. Coordinate with each patient's health-care team to generate solutions and develop the best plan of care to address the patient's case. The appropriate nursing interventions may include the actions in Table 17.8.

Nursing Care	Rationale
Complete focused neurological assessments.	Changes in the patient's neurological symptoms, including cognitive issues such as memory and confusion, personality and mood changes, vertigo, muscle weakness, tingling, numbness, and lack of coordination may indicate MS.
Monitor vital signs.	Changes in the patient's vital signs such as heart rate and blood pressure may indicate health issues.
If patient has an MS exacerbation, provide medications and monitor for side effects.	Patients may need corticosteroids to reduce nerve inflammation. Patients may experience side effects, such as elevated blood pressure, insomnia, and mood swings.
Monitor if patients receive a plasma exchange.	During the healing process after a plasma exchange, the plasmapheresis machine must be monitored and patients need care to prevent infections. This may include administering intravenous methylprednisolone.
Medication for ongoing MS management	Patients may need medication to manage ongoing MS symptoms, including injectable, infusion, or oral treatments of drugs such as monoclonal antibodies, interferons, and teriflunomide.
Administer other medications.	Patients may need additional medications to address problems such as fatigue and pain. Some patients may need muscle relaxants.

TABLE 17.8 **Nursing Interventions for Patients with MS**

Nursing Care	Rationale
Assist with mental health support.	Patients may need consultation with a mental health professional to help them cope with the challenges of living with MS. Some patients may need prescription medications to help with issues such as anxiety and depression.
Collaborate with physical therapist.	Patients may need assistance with mobility, including exercises to strengthen muscles and help with coordination and balance problems. Coordinate with the physical therapist as needed.

TABLE 17.8 Nursing Interventions for Patients with MS

REAL RN STORIES

Nurse: Layne
Years in Practice: Seven
Clinical Setting: Outpatient facility
Geographic Location: Reno, Nevada

At one point in my career as a registered nurse, I encountered an exceptional patient whose journey toward accurate MS diagnosis was challenging. Mrs. Gardner was in her 40s when she visited our health-care facility for answers about symptoms she'd been dealing with for over a year. Fatigue, muscle weakness, and intermittent sensory disturbances had become part of her everyday existence, making even routine activities an arduous struggle. She stated she had begun dropping glasses and cookware and tripping on flat surfaces. However, her previous efforts at communicating her symptoms had been met with dismissive comments from health-care providers who failed to recognize its complexity. Frustrated and distressed, Mrs. Gardner found herself caught up in a negative cycle of self-doubt as her genuine concerns were overshadowed by an overwhelming sense that they might just be an invention of her mind. In other words, she was made to feel that she was just making up the symptoms for attention. Months of proper treatment were delayed because of the delayed correct diagnosis. Our team persevered despite initial setbacks to solve Mrs. Gardner's mystery. At first, our assessment process started by listening carefully to her experiences and documenting any subtle cues we detected. Over time it became apparent that dismissals she had experienced had both dismayed her as well as prevented timely interventions. Advocating on her behalf, we coordinated comprehensive diagnostic evaluations, such as MRI scans and lumbar punctures. As advocates on Mrs. Gardner's behalf, we successfully coordinated the results that confirmed her MS diagnosis. Witnessing Mrs. Gardner's journey from uncertainty to clarity highlighted the essential importance of empathy listening, persistent advocacy, and an unshaken trust in patient experience.

Evaluation of Nursing Care for the Patient with Multiple Sclerosis

Because MS is incurable, the desired outcome for patients with MS is symptom management that enables the patient to have a better quality of life. This should include improvement, and even abatement, of symptoms as much as possible. If symptoms cannot be abated, the goal should be to modify the disease and increase the amount of time that elapses between periods when symptoms occur. Patients should also have the support system needed to help them overcome any psychological challenges, such as anxiety and depression, that they may experience as they manage MS.

Medical Therapies and Related Care

See the medical therapies used for patients with MS in Table 17.9.

Medical Therapy	Explanation of Care
MS exacerbations should first be treated with corticosteroids.	May include drugs, such as intravenous methylprednisolone and oral prednisone
If corticosteroids do not work, MS exacerbations may be treated with plasmapheresis.	The plasma exchange process should include removing the patient's plasma, mixing it with a protein solution, and putting it back into the patient's body. For some patients with MS, the protein solution can help treat MS symptoms.
Disease-modifying therapies may include injectable treatments.	Examples include monoclonal antibodies, interferons, and glatiramer acetate.
Disease-modifying therapies may include infusion treatments.	Examples include monoclonal antibodies such as natalizumab and alemtuzumab.
Disease-modifying therapies may include oral treatments	Examples include teriflunomide, monomethyl fumarate, siponimod, cladribine, ponesimod, and dimethyl fumarate.
Physical therapy	Should include exercises to help patients stretch and strengthen their muscles
Additional medications	Patients may need muscle relaxants and pain relievers to help with pain issues. Patients may also need medications, such as modafinil and methylphenidate, to help with fatigue. Other medications may be needed to help with problems such as constipation, sexual dysfunction, and insomnia.
Mental health support	Support may include counseling as well as medication to treat issues such as anxiety and depression

TABLE 17.9 Therapies for Patients with MS

Myasthenia Gravis

Myasthenia gravis (MG) is a chronic autoimmune disorder that occurs when the nerves and muscles fail to communicate. MG causes the skeletal muscles to become weak, affecting muscles that patients control voluntarily to do things such as swallow, make facial expressions, blink eyes, and move the arms and legs. MG generally affects females under age 40 and males over the age of 50 (Johns Hopkins Medicine, 2024c).

Pathophysiology

MG occurs when the immune system produces antibodies that target and block **acetylcholine** receptors at the neuromuscular junction. Acetylcholine is a key neurotransmitter essential in muscle contraction. When acetylcholine is blocked, it inhibits communication between nerves and muscles, hindering normal nerve-muscle connection, and leading to muscle fatigue and weakness.

Individuals with an autoimmune condition, such as lupus or rheumatoid arthritis, may be at risk for MG. Also, in some cases, MG may result when patients have a tumor in their **thymus gland**. The thymus gland produces and trains T cells, which are white blood cells that assist the immune system to fight infections and disease. The thymus gland can produce antibodies that block acetylcholine, so if the gland has a tumor and malfunctions, it may contribute to MG.

Clinical Manifestations

Typically, the symptoms of MG may include difficulty breathing, chewing, swallowing, and/or speaking; facial movement difficulties, including the inability to smile; vision problems, including double vision and drooping eyelids

known as **ptosis**; neck, limb, and/or muscle weakness; and fatigue. Nurses should be aware that the symptoms of MG are likely to worsen when patients are tired. In particular, a repetitive activity such as working the jaw muscles and chewing a plate of coarse foods, such as a steak or crackers, can be wearisome for patients with MG if the disease affects their **bulbar nerve**s, which hold the jaw in place and control swallowing, chewing, and speaking processes. The symptoms of MG are likely to lessen after periods of resting the affected muscles.

Assessment and Diagnostics

MG is assessed and diagnosed by conducting a physical examination focused on patients' coordination, balance, reflexes, senses of sight and touch, and muscle strength. Neurological assessments may show that patients have symptoms, such as breathing difficulties, muscle weakness, balance and coordination problems, poor reflexes, and vision problems.

Diagnostics and Laboratory Values

Tests that can be used to identify MG include blood analysis, ice pack tests, single-fiber EMG, repetitive nerve stimulation, imaging, and pulmonary function tests. Blood tests may show the presence of antibodies that block acetylcholine receptors. Ice pack tests may show that droopy eyelids do not respond to cold therapy. EMGs may reveal limited electrical activity occurring between the patient's brain and muscles. Repetitive nerve stimulation measurements may show that nerves have a limited ability to send signals to muscles. Imaging may illustrate a tumor in the patient's thymus gland. Pulmonary functioning tests—which measure a patient's lung capacity, volume, gas exchange, and flow rates—can determine whether MG affects a patient's breathing.

LINK TO LEARNING

For patients with MG symptoms, the ice pack test (https://openstax.org/r/77IcePackTest) is a useful bedside tool to help confirm a MG diagnosis.

Nursing Care of the Patient with Myasthenia Gravis

For patients with MG who are struggling to breathe, nurses should alert patients' providers that they need medications and other inventions, such as mechanical assistance to restore breathing. Nursing care should focus on following providers' orders to provide immediate medications and other assistance needed to restore breathing. Because MG is incurable, other nursing care for patients with MG should focus on alleviating symptoms as much as possible and helping patients manage the disease. For example, nurses can help patients conserve energy by modifying the way they eat meals and perform other tasks, such as learning to walk with a cane. Nurses should help patients identify which medications alleviate their symptoms and should provide education and support to ensure that patients understand the disease and the challenges that it poses for them.

Recognizing Cues and Analyzing Cues

To recognize the cues for MG, nurses should assess the patient's neurological status, with focus on the patient's coordination, balance, reflexes, senses of sight and touch, and muscle strength. Nurses should be alert for the symptoms of MG, such as shortness of breath, speaking difficulties, drooping eyelids, trouble swallowing, attempts to smile that appear as a scowl, fatigue, and muscle weakness, particularly in muscles that are used repetitively.

Nurses should consider whether patients have risk factors for MG, such as a thymus gland tumor or an autoimmune condition, such as lupus. To analyze the cues of the patient's symptoms and test results, nurses must evaluate how the findings deviate from normal ranges for both body functioning and test results. For example, a patient's blood test may reveal nontypical antibodies that disrupt communication between the patient's nerves and muscles.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

MG can be life-threatening. Specifically, if MG affects the muscles that enable patients to breathe, patients may need immediate intervention to restore breathing. For other symptoms, because there is no cure for MG, treatment should focus on helping patients manage symptoms, and, as much as possible, slow the disease's progression. Nursing interventions include those in Table 17.10.

Nursing Care	Rationale
Complete focused neurological assessments.	Changes in the neurological symptoms of a patient with MG including muscle weakness, vision issues, difficulties with swallowing and speaking, facial movements, and particularly shortness of breath indicate health issues.
Monitor vital signs.	Changes in the vital signs of a patient with MG, such as heart rate and blood pressure, may indicate health issues.
Maintain breathing.	Patients with MG with breathing difficulties may need medications, such as inhaled bronchodilators and/or inhaled steroids, to restore breathing. They may also need a ventilator, using either endotracheal intubation or a BiPAP.
Assist with bed positioning.	Patients with MG with breathing difficulties should be placed in Fowler's position while they are in bed. This is a semi-sitting position with the head of the bed elevated 45 to 60 degrees.
Administer medications for ongoing MG management.	For ongoing MG symptoms, patients may need medications such as corticosteroids, immunosuppressants, and cholinesterase inhibitors.
Administer intravenous therapy.	If patients with MG have symptoms that suddenly worsen, intravenous therapy may be useful. This includes therapies such as plasmapheresis, intravenous immunoglobulin (IVIG), and monoclonal antibodies that nurses administer by vein.
Assist with mental health support.	Patients with MG may need consultation with a mental health professional to help them cope with the challenges of living with MG. Some patients may need prescription medications to help with issues such as anxiety and depression.
Prepare for surgery and provide aftercare.	For patients with MG who have a thymus gland tumor, surgery may be warranted to remove the tumor. Nurses should help prepare patients for surgery and provide care after surgery. This may include wound care, as well as pain management.
Coordinate with occupational therapist.	Some patients with MG may benefit by learning how to use appliances, such as electrical toothbrushes and electric can openers, to conserve their body's energy by reducing the use of voluntary muscles. Coordinate with the occupational therapist as needed.

TABLE 17.10 Nursing Interventions for Patients with MG

Evaluation of Nursing Care for the Patient with Myasthenia Gravis

For patients with MG who struggle to breathe, the desired outcome is maintaining the optimal quality of breathing, and abatement of the medical emergency caused by the patient's breathing difficulties. Because MG is incurable, the desired outcome for all patients with MG is symptom management that helps patients manage the disease and have a better quality of life. An example includes, after consultation with a mental health professional does the patient appear they can cope with MG prognosis. Another evaluation includes if the bed is positioned to help the patient breathe easier, do they appear in respiratory distress after repositioning.

Medical Therapies and Related Care

The medical therapies used for patients with MG may include those in Table 17.11.

Medical Therapy	Explanation of Care
MG exacerbations that cause breathing difficulties should be treated with medications and possibly ventilation	Medications may include inhaled bronchodilators and/or inhaled steroids. Ventilators may use either endotracheal intubation or a BiPAP.
Medication for ongoing symptoms	Medications to manage ongoing MG symptoms may include corticosteroids, immunosuppressants, and cholinesterase inhibitors.
Intravenous therapy	For some patients with MG, intravenous therapies such as plasmapheresis, intravenous immunoglobulin (IVIG), and monoclonal antibodies given by vein may be useful.
Surgery	For patients with MG who have a thymus gland tumor, surgery may be an option to remove the tumor.
Occupational therapy	Patients with MG may need to be taught to use appliances, such as electrical toothbrushes and electric can openers, to use their voluntary muscles less and conserve energy.
Mental health support	Support may include counseling, as well as medication, to treat issues such as anxiety and depression for patients who need mental health support to manage MG.

TABLE 17.11 Medical Therapies for Patients with MG

INTERDISCIPLINARY PLAN OF CARE

Interdisciplinary Care for Patients with MG

Patients with MG require an interdisciplinary approach to provide care that addresses all of their needs. For example, in addition to treatment from a primary provider, patients with MG typically need occupational therapy to learn how to use tools, such as electric toothbrushes, that can help patients with MG expend less energy to perform everyday tasks. Physical therapists can teach patients with MG about stretching and other exercises that can help them build and conserve physical energy. Mental health professionals can counsel patients with MG about mental health issues they may experience, such as anxiety and depression, and help them learn coping techniques. If needed, mental health professionals can prescribe medication to help patients with MG control issues such as anxiety. Nurses can help patients with MG by acting as the liaison among their care team and helping patients with MG coordinate with each member of their team to get the best possible treatment.

17.4 Major Neurocognitive Disorder and Neurodegenerative Diseases

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations for MNDs, Alzheimer disease, amyotrophic lateral sclerosis (ALS), and Parkinson disease
- Describe the diagnostics and laboratory values in MNDs, Alzheimer disease, ALS, and Parkinson disease
- Apply nursing concepts and plan associated nursing care for the patient with MND, Alzheimer disease, ALS, and Parkinson disease
- Evaluate the efficacy of nursing care for the patient with MND, Alzheimer disease, ALS, and Parkinson disease
- Describe the medical therapies that apply to the care of MND, ALS, Alzheimer disease, and Parkinson disease

The decline in cognitive abilities, such as memory and reasoning, in a manner that disrupts patients' daily lives is known as **major neurocognitive disorder (MND)**. MND refers to a group of disorders characterized by neurological changes that make it more challenging for patients to continue routine activities.

LINK TO LEARNING

It is important to note that in *DSM-5* criteria, the definition of dementia (https://openstax.org/r/77DementiaDef) has been updated. The term *major neurocognitive disorder* is now the correct terminology for *dementia*.

MND varies in severity and may worsen over time. For some patients, MND is mild enough that they can still function reasonably well, whereas other patients experience MND so severely that they are unable to care for themselves. MND is a general term that refers to several neurological disorders. The most common form of MND is Alzheimer disease, which is also a **neurodegenerative disease**, a chronic condition that damages the brain and central nervous system, causing problems with cognitive abilities as well as physical movement. In addition to Alzheimer disease, amyotrophic lateral sclerosis (ALS) and Parkinson disease are other neurodegenerative diseases. Neurodegenerative diseases are incurable, but they can be treated and managed. This section will provide an overview of MND, Alzheimer disease, ALS, and Parkinson disease, including symptoms and how nurses can assess, plan, and care for patients with these diseases.

MND Pathophysiology

MND occurs when the brain's neurons, or nerve cells, die after they become inactive and lose their connections to other brain cells. This is a normal process that every person experiences, particularly as individuals age. But for patients who develop MND, this process is more active, and they lose a larger number of neurons. Although MND is associated with aging, not everyone develops MND as they get older. The National Institute on Aging estimates that about one-third of people over age 85 may have some type of MND (Figure 17.8). In addition to Alzheimer disease, other common forms of MND include the following (National Institute on Aging [NIA], 2022b):

- Abnormal deposits of protein in the brain lead to **Lewy body dementia**. The condition progresses slowly and changes patients' ability to think and concentrate.
- Damage to the brain's frontal and temporal lobe neurons leads to a **frontotemporal disorder**. The condition progressively gets worse and causes personality and behavior changes.
- Insufficient blood and oxygen to the brain leading to damage to the brain's blood vessels causes **vascular dementia**. The condition may affect all aspects of a patient's cognitive abilities, including behavior, memory, and reasoning.

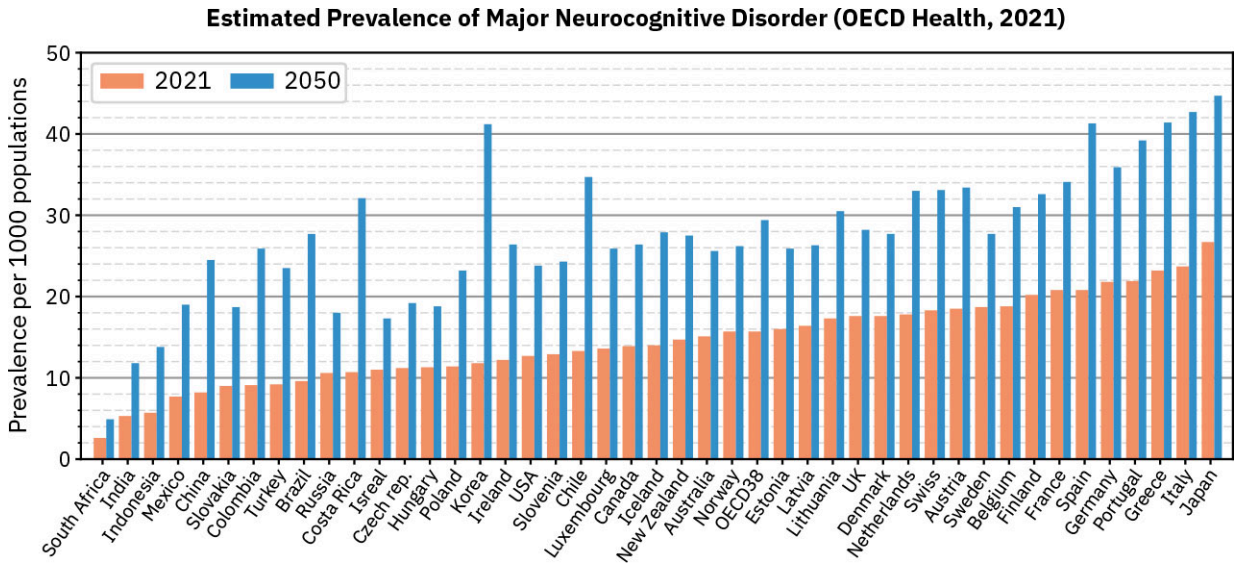

FIGURE 17.8 This graph compares the global prevalence of MND in 2021 to the estimated prevalence in 2050. (credit: modification of "Dementia Prevalence in OECD" by "Yuasan"/Wikimedia Commons, CC0 1.0)

Clinical Manifestations

The symptoms of MND include cognitive problems such as memory loss, disorientation, and confusion; difficulty reasoning and using abstract thinking, logic, and judgment to think and solve problems; decreased ability to organize and plan; communication difficulties, including forgetting simple words; spatial awareness issues, which may include getting lost; and needing more time than usual to complete routine tasks. Patients may lose things or put them in the wrong place for safekeeping. MND symptoms may also include psychological issues, such as changes in personality, which may include losing interest in favorite activities and/or no longer caring about others; feelings of paranoia; being irrational and/or impulsive; hallucinations; anxiety; and depression.

Assessment and Diagnostics

Health-care professionals assess and diagnose MND with a physical examination that includes a review of the patient's symptoms, as well as diagnostic tests. Patients should be asked about their medical background and history, including whether their family has a history of MND and whether they are taking any medications, such as anticholinergic drugs and opioids, which can cause symptoms of MND. The patient's general health needs to be assessed, because patients with MND may have other health problems, such as traumatic brain injury, cardiovascular disease, Parkinson disease, and immune disorders. Patients with MND may also lead unhealthy lifestyles, which may include poor nutrition and lack of exercise, particularly if they are forgetful and don't remember to eat or get exercise.

Diagnostics and Laboratory Values

The diagnostic tests that can help diagnose MND include brain scans, such as a CT or MRI, lumbar puncture, positron emission tomography (PET) scans, and cognitive and neurological tests. Brain scans may show tumors and stroke, and lumbar punctures may show a high level of protein in CSF. PET scans may show abnormal brain activity and may also reveal deposits of protein in the brain. Cognitive and neurological tests will show decline and problems in the patient's mental abilities. Each of these problems can contribute to MND.

LINK TO LEARNING

The Alzheimer's Association (AA) provides a guide to help patients understand the medical tests available (https://openstax.org/r/77AlzheimerTests) to determine if someone has Alzheimer disease or another form of MND. AA's website also includes a link to an interactive tour that helps patients understand what to expect when they are evaluated for cognitive issues.

Nursing Care of the Patient with MND

MND cannot be cured. Patients who have mild MND may be able to continue functioning reasonably well with minimal assistance, but as MND progresses, patients may need more in-depth and routine care. Patients with MND should be in a safe, secure environment that provides the resources they need to function as well as possible, such as health-care facilities that provide memory care or assistance with ADLs.

Recognizing Cues and Analyzing Cues

To recognize and analyze the cues of MND, nurses should review the findings of the patient's physical examination. This includes noting whether the patient seems confused, struggles to communicate, or has paranoid tendencies. Patients with MND may do things such as repeat questions, have trouble writing, or lack interest in a conversation. To gather additional cues, nurses can talk with the patient's family members and ask them about problems they have noticed in the patient. Other cues will come from diagnostic test results. If the results of brain scans, lumbar punctures, PET scans, and/or cognitive and neurological tests show abnormal results, these may be cues that indicate the patient has MND.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

The symptoms of patients with MND should be prioritized based on their severity. For example, if a patient's symptoms are so severe that they do not remember others and do things such as wander from home and get lost, this is more urgent than symptoms that cause a patient to do things such as misplace their keys. Keeping patients safe is paramount, and symptoms that put patients in danger must be prioritized. Solutions should focus on ensuring patients' safety while helping them live as independently as possible. The nursing interventions appropriate for patients with MND may include those in Table 17.12.

Nursing Care	Rationale
Complete focused neurological assessments.	The patient's cognitive status, including confusion, memory issues, communication difficulties, and problem-solving skills may indicate MND. This includes whether the patient acts impulsively, wanders away and gets lost, seems disinterested in others, and repeats questions.
Monitor vital signs.	Changes in the patient's vital signs, such as heart rate and blood pressure, as well as balance issues may indicate health problems.
Administer medications.	Patients with MND may need medications, such as cholinesterase inhibitors and memantine, to help with MND symptoms.
Coordinate with occupational therapist.	Some patients with MND may benefit from occupational therapy, which can teach coping behaviors, particularly how to keep patients with MND safe from threats such as losing their balance and falling. Nurses may refer patients to occupational therapy.

TABLE 17.12 Nursing Interventions for Patients with MND

Nursing Care	Rationale
Help with exercise.	Patients with MND may benefit from exercise and should be encouraged to develop an exercise regimen. Although results are not definitive, research suggests that exercise such as walking and swimming may improve brain functioning. Nurses can help patients identify exercise opportunities and formulate a plan to make exercise part of their daily routine.
Coordinate mental health support.	Patients with MND and their families may need consultation with a mental health professional to help them cope with the challenges of living with MND. Some patients may need prescription medications to help with issues such as anxiety and depression.

TABLE 17.12 Nursing Interventions for Patients with MND

LINK TO LEARNING

Read this article to learn more about how exercise can decrease the risk for cognitive decline (https://openstax.org/r/77BrainExercise) from the Alzheimer's Association.

Evaluation of Nursing Care for the Patient with MND

The desired outcome for patients with MND is alleviation of symptoms if possible. If a patient's symptoms of MND cannot be alleviated, or at least improved, the desired outcome is to help patients and their families learn how to cope with MND. Patients with MND should be kept safe and provided the support needed to enhance their quality of life as much as possible. Goals for patients with MND include helping them live at home if possible, maintaining a routine of physical activity, engaging in activities that provide mental stimulation, and avoiding hospitalization.

REAL RN STORIES

Nurse: Jen
Years in Practice: Five
Clinical Setting: Memory care/Alzheimer unit
Geographic Location: Las Vegas, Nevada

As part of my nursing shift, I struggled with both anger and empathy when caring for Mrs. Sutherland, an older patient experiencing advanced Alzheimer disease. My challenge lay not in an absence of commitment or medical interventions but in Alzheimer disease itself being incurable. Mrs. Sutherland's memory loss and confusion were emotionally taxing, which highlighted medical limitations, as it left Mrs. Sutherland emotionally distraught and confused. It was profoundly humbling. Normally, people with Alzheimer disease can become mean, but she was so sweet and childlike. She seemed to have reverted to the mental capacity of a 3-year-old who was sweet and trusting. As I carefully attended to her needs by providing comfort, reassurance, and steady presence, I struggled with the inherent frustration associated with treating a condition that demands not just clinical competence but an inexhaustible reservoir of compassion. My focus remained on compassionate care rather than finding solace in small victories such as fleeting smiles or moments of clarity. I saw pictures her family brought in when she used to be a fancy nightclub singer, and now she was a wheelchair-bound older woman who took no care for her physical appearance anymore. It was such a contrast and humbling to see what life can reduce a person to. Gentle redirection was essential, creating an environment that minimized confusion and anxiety for Mrs. Sutherland. I met her where she was instead of where she was previously. I acknowledged the fragmented elements of her reality while managing the fluctuations of her emotional landscape. Disgust turned to profound admiration of human

resilience, leading me to pledge my advocacy on behalf of those dealing with Alzheimer disease. By providing care that transcended medical interventions alone, I witnessed firsthand the profoundly powerful effect that compassionate nursing care could have in dealing with an incurable condition. Her family was deeply grateful for the compassionate care I showed to her, which was also rewarding.

Medical Therapies and Related Care

The medical therapies used for patients with MND may include medications, such as cholinesterase inhibitors, which can decrease acetylcholine breakdown, enabling nerve cells to communicate; and memantine, which can decrease neurotoxicity (damage to nerve cells) and protect nerve cells from damage. Other treatments include occupational therapy and regular exercise. Some patients may also need mental health support.

Amyotrophic Lateral Sclerosis (ALS)

A disease of the central nervous system, **amyotrophic lateral sclerosis (ALS)** affects the motor neurons of the brain and spinal cord, causing patients to lose control of their muscles. The disease, which is incurable and ultimately fatal, is sometimes called Lou Gehrig disease for the baseball player who had the disease. The cause of ALS is unknown, but a small percentage of cases, perhaps 5 to 10 percent, are inherited. In all cases of ALS, as motor neurons die and the disease progresses, patients may lose the ability to walk, eat, speak, and breathe (ALS Association, n.d.).

Pathophysiology

ALS occurs when motor neurons degenerate and die, causing the muscles they control to also weaken and degenerate. Except for the small percentage of ALS cases caused by an inherited gene, medical experts do not know why patients contract ALS. A few environmental factors, such as smoking and exposure to toxins, have been linked with an increased risk for ALS. Age is also a factor, because the disease usually affects patients over age 60 (Mayo Clinic, 2023c).

Clinical Manifestations

ALS typically begins with stiffness and weakness in the muscles that control the limbs, including the legs and arms. As the disease progresses, it typically spreads to muscles in the trunk and eventually to muscles that control vital functions, such as breathing. As the muscles get weaker, patients lose the ability to do things, such as walk, chew, swallow, speak, and breathe. The muscle weakness may be accompanied by muscle cramps, as well as twitching in the shoulders and arms. In some patients, the tongue may also twitch. The disease also affects cognitive abilities, changing a patient's behavior and affecting their ability to think. Some patients with ALS also develop frontotemporal MND.

The progression of the disease varies by patient, and some patients even have periods when the disease stops progressing for a few months or longer. On average, patients who develop ALS live about three years once the disease is diagnosed. Some patients do live longer, with about 20 percent surviving at least five years, about 10 percent living for ten years, and 5 percent surviving for more than twenty years after they are diagnosed (ALS Association, n.d.).

Assessment and Diagnostics

Typically, ALS is diagnosed by ruling out other conditions and diseases with similar symptoms, such as multiple sclerosis and myasthenia gravis. The tests that can be useful to help identify whether the patient has a disease or condition other than ALS include blood and urine tests, lumbar punctures, nerve conduction studies, electromyogram (EMG), imaging such as MRI, nerve biopsy, and muscle biopsy. A physical examination can also determine if a patient has symptoms typical of ALS.

Diagnostics and Laboratory Values

The diagnostics and laboratory values that may help diagnose ALS may include the following:

- Blood and urine tests may show higher-than-normal levels of serum **neurofilament light chain (NfL)**, a protein that increases when neurons are damaged.
- Nerve conduction studies may show that the patient has nerve damage, which is an indicator of ALS.
- EMGs document the muscles' electrical activity at rest as well as when contracting. In patients with ALS, this

test, which should be performed in tandem with a nerve conduction study, will show muscle and/or nerve damage.
- MRI imaging with high resolution will show changes in nerves and muscles, such as cortex iron deposition, which indicates ALS. MRIs may also show problems such as herniated disks and spinal cord tumors, which can be used to rule out ALS.
- A nerve biopsy will not show if a patient has ALS but may be used to rule out ALS by diagnosing another condition or disease. For example, a nerve biopsy may show inflammation of the nerves or a **demyelinating disease**, which is a condition that damages the protective covering of the brain's nerve fibers.
- A muscle biopsy will not show if a patient has ALS but may be used to rule out ALS by diagnosing another condition or disease. For example, a muscle biopsy may show infections in the muscles or a disorder such as muscular dystrophy.

Nursing Care of the Patient with Amyotrophic Lateral Sclerosis (ALS)

Nursing care for patients with ALS should focus on controlling symptoms and helping patients and their families learn to manage the disease. Because ALS is a fatal disease, nursing care should include mental health support. As patients with ALS near the end of life, they may need palliative care.

Recognizing Cues and Analyzing Cues

The cues of ALS will be found in the patient's physical examination and test results and may include muscle weakness that affects the patient's ability to speak, swallow, and walk. Some patients may struggle to concentrate and may exhibit unusual behavior, such as untimely laughing or crying. A discussion with the patient may reveal that the patient is struggling to carry out routine activities because of muscle weakness. Nerve conduction studies may show that the patient's lumbar punctures will not reveal findings that indicate ALS, but they may indicate that the patient has a condition with similar symptoms, such as MS.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

ALS symptoms should be prioritized based on severity, with symptoms that affect patients' ability to do life-sustaining activities, such as breathing and eating, given priority over symptoms that do not create life-threatening situations. Solutions should focus on sustaining lives of patients with ALS and enabling them to live as independently as possible. The nursing interventions appropriate for patients with ALS may include those in Table 17.13.

Nursing Care	Rationale
Complete focused neurological assessments.	Patients with ALS may have a limited ability to do things, such as speak, eat, and use their hands. They may also have twitching and/or exhibit unusual behavior, such as untimely laughing.
Monitor vital signs.	Changes in the vital signs of patients with ALS, such as heart rate, blood pressure, and ability to breathe, may indicate severity of ALS symptoms. This is particularly true for patients in more advanced stages of ALS.
Administer medications specifically for ALS.	ALS can be treated with riluzole, edaravone, and/or sodium phenylbutyrate-taurursodiol. Patients with ALS should receive prescribed drugs as appropriate and side effects should be monitored. For example, riluzole may cause gastrointestinal problems and dizziness, whereas edaravone may cause headaches and bruising.

TABLE 17.13 Nursing Interventions for Patients with ALS

Nursing Care	Rationale
Administer other medications.	Patients with ALS may need medications to control other problems that may occur as a result of ALS. For example, patients who experience constipation may need a laxative, patients who have trouble sleeping may benefit by taking a sedative, and patients in pain may get relief with acetaminophen.
Give breathing support.	Patients with ALS who struggle to breathe may need mechanical ventilation assistance.
Coordinate with speech therapist.	Patients with ALS who struggle to speak may benefit by working with a speech therapist to learn how to speak with weakened muscles.
Coordinate with physical therapist.	Physical therapy can help patients with ALS learn exercises and techniques to strengthen their muscles, maintain a greater range of motion, and improve their cardiovascular fitness.
Coordinate with occupational therapist.	Occupational therapy can help patients with ALS learn how to use assistive devices, such as an electric toothbrush, to overcome muscle weakness and continue doing routine activities, such as brushing their teeth.
Coordinate mental health support.	Patients with ALS and their families may need consultation with a mental health professional to help them cope with the challenges of living with ALS. Some patients may need prescription medications to help with issues such as anxiety and depression.

TABLE 17.13 **Nursing Interventions for Patients with ALS**

Evaluation of Nursing Care for the Patient with Amyotrophic Lateral Sclerosis (ALS)

The desired outcome for patients with ALS is control and management of their symptoms to improve their quality of life and help them live longer. This may include enabling them to maintain their independence with activities such as feeding themselves.

Medical Therapies and Related Care

The medical therapies used for patients with ALS may include medications, such as riluzole, which blocks glutamatergic neurotransmission in a patient's central nervous system; edaravone, which captures molecules that can damage cells and thereby protects neurons; and/or sodium phenylbutyrate-taurursodiol, which can help prevent nerve cells from breaking down and dying. Other medications needed to treat problems caused by ALS may include laxatives for constipation and sedatives for insomnia. In the early stages of ALS, some patients may benefit from speech, physical, and/or occupational therapy. Therapy may enable patients with ALS to retain mobility for a longer period. Therapy may also help patients with ALS avoid, or at least postpone, issues such as **contracture**s, which can cause deformity and rigidity in joints if muscles, tendons, and tissues are shortened and/or hardened. As ALS progresses, some patients may need mechanical ventilators for breathing support. Mental health support should be provided as needed. As conditions deteriorate for a patient with ALS, nurses should also strive to help them and their families make end-of-life preparations.

Alzheimer Disease

Alzheimer disease is a disorder in the brain that gradually destroys patients' memory and thinking abilities, eventually making it challenging for patients to handle basic tasks and live independently. As noted previously,

Alzheimer disease is the most common form of MND, accounting for at least 60 percent of MND cases. Generally, Alzheimer disease affects people over age 65 and gradually worsens as patients age. The disease, which has no cure, affects memory and causes patients to be disoriented and confused. Patients with Alzheimer disease struggle to remain independent and continue their daily routines (Alzheimer's Association, 2024).

LIFE-STAGE CONTEXT

Early-Onset Alzheimer Disease

Whereas Alzheimer disease may be regarded as a disease that primarily affects individuals over age 65, early-onset Alzheimer disease affects people in their 40s and 50s. Cases for this age group may be overlooked because providers generally do not expect younger patients to have Alzheimer disease. But occasionally, younger patients with memory problems are experiencing Alzheimer disease, particularly if they have a family history of the disease.

Pathophysiology

Medical experts have not identified the specific cause(s) of Alzheimer disease, but it appears to be linked to factors such as a family history of Alzheimer disease; poor lifestyle, such as lack of exercise and excessive alcohol consumption; head trauma; and environmental factors, such as excessive exposure to air pollution. Alzheimer disease may result when the brain's neurons become damaged, losing their connections and eventually dying.

In addition, patients with Alzheimer disease tend to have issues with beta-amyloid and tau proteins, which provide support to the brain's neurons. When the beta-amyloid proteins malfunction, they may clump together in **amyloid plaque** deposits, which disrupt cell functioning, and the tau proteins may transform into structures called **neurofibrillary tangle**s, which occur when proteins inside neurons accumulate abnormally. These conditions contribute to Alzheimer disease by disrupting brain functioning.

Clinical Manifestations

Typically, Alzheimer disease affects memory first before spreading to affect other brain functioning. Initially, patients with Alzheimer disease may do things such as forget appointments, misplace items, and have trouble remembering the right words to describe things. As problems with memory progress, patients with Alzheimer disease may repeat themselves, sometimes over and over, and do other things such as get lost in familiar surroundings and even forget people they know well.

As the disease progresses, it affects other brain functioning, making it challenging for patients with Alzheimer disease to do things such as reason, make decisions, organize, and make plans. Patients with Alzheimer disease also typically experience personality changes, which may include disinterest in activities they once enjoyed, social withdrawal, moodiness, and aggressive behavior that may include anger. They may also have delusions, change their sleeping habits, and become depressed. As the disease progresses into late-stage Alzheimer disease, patients experience additional symptoms, including the inability to participate in a conversation and difficulty responding to their environment. Eventually, they tend to lose the ability to control their movements, and additional personality changes may occur. At this stage, patients typically need round-the-clock care, and they may become more susceptible to infections, such as pneumonia.

Assessment and Diagnostics

Alzheimer disease is diagnosed by conducting a physical examination that reviews the patient's overall health to gather details about any recent changes in memory, personality, and daily habits. This examination should include a family member who can provide additional details about any recent changes in the patient's behavior and thinking abilities. One goal of the physical examination is to rule out other conditions and diseases that may be causing symptoms similar to Alzheimer disease, such as brain tumors, stroke, and Parkinson disease. As part of this process, the physical examination should review the patient's overall physical health, including eye movements, coordination, speaking patterns, and reflexes.

Diagnostics and Laboratory Values

Diagnostic tests of the patient's memory and skills, such as cognitive/thinking, language, and mathematical abilities, can provide additional evidence of Alzheimer disease. Other tests that may provide helpful data include blood tests, lumbar puncture, and imaging with brain scans. For patients with Alzheimer disease, the diagnostics and laboratory

values that indicate the patient has Alzheimer disease include the following:

- Blood tests cannot confirm an Alzheimer disease diagnosis but can be used to rule out other causes of memory loss, such as vitamin deficiencies and thyroid disorders.
- Lumbar punctures will show increased levels of beta-amyloid and tau proteins, which are indicative of Alzheimer disease and other forms of MND.
- MRI imaging may show shrinkage of areas of the brain that are associated with Alzheimer disease. In addition, MRIs provide evidence to rule out other conditions and diseases that have symptoms similar to Alzheimer disease, such as brain tumors and strokes.
- PET scans can show areas of the brain that have poor metabolism, which is an indicator of Alzheimer disease.
- CT scans will not help diagnose Alzheimer disease, but their findings can help rule out other conditions and diseases, such as head injuries, strokes, and brain tumors.

Nursing Care of the Patient with Alzheimer Disease

Nursing care for patients with Alzheimer disease should focus on controlling symptoms, as well as helping patients and their families learn to manage and live with the disease. This includes helping patients recognize when they are no longer able to care for themselves. Nurses should educate patients and their families about Alzheimer disease and help them establish routines that can help patients live more independently. For example, caregivers should be educated to gently remind patients with Alzheimer disease when it is time for meals and other tasks, such as taking medications. Nurses should also help patients and their caregivers create a safe environment that protects patients from risks, such as wandering away from home and forgetting where they are.

LINK TO LEARNING

Visit the Alzheimer's Association (https://openstax.org/r/77AlzheimAssoc) for more information and resources about MND.

Recognizing Cues and Analyzing Cues

The cues of Alzheimer disease may include memory loss, struggles to think clearly, language difficulties, personality changes, despondency, and aggression. The cues from the diagnostic tests may include increased levels of beta-amyloid and tau proteins and shrinkage of the areas of the brain that control memory and related functioning.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Care for patients with Alzheimer disease should be prioritized based on the severity of their symptoms. Symptoms that threaten patient safety should be prioritized over less severe symptoms, such as mild forgetfulness. Solutions should be generated based on recommendations from the patient's care team to address each patient's needs. The nursing interventions appropriate for patients with Alzheimer disease may include assisting with daily routines and providing healthy meals.

Evaluation of Nursing Care for the Patient with Alzheimer Disease

The desired outcome for patients with Alzheimer disease is control and management of their symptoms to improve their quality of life and help them live as independently as possible. This includes enabling them to cope with the challenges of Alzheimer disease and maintaining a safe environment. For example, helping them develop a daily schedule that includes healthy meals and an exercise regimen can help them establish a routine that promotes independence and safety, while also helping them learn to live with Alzheimer disease.

Medical Therapies and Related Care

The medical therapies used to treat Alzheimer disease may include medications such as antiamyloid treatments, which remove beta-amyloid proteins from the brain, preventing the formation of plaques and promoting healthy brain cells. Some patients with Alzheimer disease may benefit from taking cholinesterase inhibitors, which increase the amount of acetylcholine in the nervous system, promoting healthy nerve cells that can sustain memory and learning processes. Some patients with Alzheimer disease may need other medications, such as sedatives and pain relievers to treat additional health problems such as insomnia and pain. If necessary, patients and their families struggling to cope with the challenges of Alzheimer disease should receive mental health support.

Parkinson Disease

Parkinson disease is an incurable brain disorder that affects the nervous system, causing body parts, such as the hands, to have movements that are unintended and uncontrollable. This includes stiffness and shakiness, as well as balance and coordination issues. Parkinson disease affects multiple parts of the body, including the face, arms, and legs.

Pathophysiology

Parkinson disease occurs when neurons in the brain's basal ganglia are damaged and/or die. The **basal ganglia** are the areas of the brain where movement is controlled. The basal ganglia's neurons produce **dopamine**, a chemical neurotransmitter involved in movement, as well as disposition and memory. When the basal ganglia's neurons are damaged or die, the body does not have sufficient dopamine to control movement. In patients with Parkinson disease, the nerve endings that generate norepinephrine are also damaged and die. The primary chemical messenger for the sympathetic nervous system, **norepinephrine**, controls bodily functions such as blood pressure and heart rate.

Parkinson disease appears to be caused by genetics in a few cases and may be hereditary for some patients. But in most cases, Parkinson disease is not inherited and may be caused by other factors, such as exposure to toxic substances. The brains of patients with Parkinson disease also tend to have clumps of Lewy bodies, which are abnormal protein clumps, and these contain clumps of alpha-synuclein protein that cells cannot break down. This creates chemical changes in the brain, affecting patients' moods and their abilities to think and remember (NIA, 2022a).

Clinical Manifestations

The symptoms of Parkinson disease typically begin subtly and progress gradually. The primary symptoms include the following:

- tremors in head, jaw, arms, hands, and legs
- stiffness and contractions in muscles
- slowed movement, called **bradykinesia**, as patients attempt to do things such as walk or write
- loss of balance and coordination
- difficulty speaking, chewing, and swallowing
- loss of automatic movements, such as blinking or swinging the arms while walking
- constipation and urination issues
- blood pressure irregularities, including **orthostatic hypotension**, a sudden drop in blood pressure when standing up or sitting down
- sleep disorders
- fatigue
- pain
- cognitive issues, such as thinking difficulties, dementia, and MND
- depression and other mental health issues

Assessment and Diagnostics

Parkinson disease is assessed and diagnosed through a physical examination and by conducting tests to rule out other conditions and diseases, such as a brain tumor, which may be causing symptoms similar to those experienced by patients with Parkinson disease. A physical examination may show symptoms of Parkinson disease such as tremors, stiff muscles, coordination and balance difficulties, loss of automatic movements, constipation and urination issues, and cognitive issues.

Diagnostics and Laboratory Values

Tests that can be helpful to confirm a Parkinson disease diagnosis include a dopamine transporter (DAT) scan and imaging tests, such as MRI and PET scans. A DAT scan may reveal that the patient has an unhealthy dopamine system. This does not provide a definitive diagnosis of Parkinson disease, but it is an indicator of Parkinson disease. MRI and PET scans will not diagnose Parkinson disease but may help rule out other disorders, such as a brain tumor, which may be causing the patient to have symptoms similar to those of patients with Parkinson disease.

Nursing Care of the Patient with Parkinson Disease

Because Parkinson disease is incurable, nursing care for patients with Parkinson disease should focus on controlling symptoms, which can be done with medication as well as techniques such as exercise. Nursing care should also strive to teach patients and their families how to live with the disease.

Recognizing Cues and Analyzing Cues

The cues of Parkinson disease will primarily be found in the physical examination. Nurses should analyze these cues, which may include tremors, stiff muscles, coordination and balance difficulties, loss of automatic movements, constipation and urination issues, and cognitive issues. In addition, if the DAT scan finds that the patient has an unhealthy dopamine system, this is a cue that the patient has Parkinson disease.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Parkinson disease should be prioritized based on the severity of symptoms, with more severe symptoms a higher priority than less severe symptoms. Symptoms that affect a patient's ability to function and live independently, such as severe tremors and pain, are more urgent than milder symptoms, such as muscle tension. Solutions should be generated with input from the patient's care team. The nursing interventions appropriate for patients with Parkinson disease may be those in Table 17.14.

Nursing Care	Rationale
Complete focused neurological assessments.	Patients may struggle to do things such as speak, eat, and use their hands.
Monitor vital signs.	The vital signs of the patient with Parkinson disease, particularly blood pressure, can be adversely affected by Parkinson disease.
Administer medications as ordered specifically for Parkinson disease.	The medications that may be ordered for Parkinson disease include the following, which should be administered as prescribed: • Carbidopa-levodopa converts to dopamine inside the brain. • Dopamine agonists mimic dopamine. • Monoamine oxidase B inhibitors prevent the breakdown of dopamine. • Catechol-O-methyltransferase inhibitors block enzymes that break down dopamine. • Anticholinergics control tremors. • Amantadine controls involuntary movements in early stages of Parkinson disease. • Adenosine receptor antagonists allow the release of more dopamine. • Nuplazid treats hallucinations and delusions.
Prepare for surgery and provide aftercare.	Some patients with Parkinson disease may benefit from deep brain stimulation, which is the process of implanting electrodes into the brain that are connected to a generator implanted in the patient's chest. Electrical pulses from the generator to the brain may help with symptoms. For surgery patients, nurses should help them prepare for surgery and then provide surgery aftercare, such as dressing their surgical wounds.

TABLE 17.14 Nursing Interventions for Patients with Parkinson disease

Nursing Care	Rationale
Coordinate with speech therapist.	Speech therapy can help patients with Parkinson disease learn how to control their voices and speak despite muscle difficulties.
Coordinate with physical therapist.	Physical therapy can help patients with Parkinson disease learn exercises and techniques to strengthen their muscles, improve balance and coordination, and gain greater flexibility.
Coordinate with massage therapist.	Massage therapy can help patients with Parkinson disease reduce tension in their muscles.
Coordinate with occupational therapist.	Occupational therapy can help patients with Parkinson disease learn how to use assistive devices, such as electric toothbrushes, which can help them maintain more independence.
Assist with mental health support.	Patients with Parkinson disease and their families may need consultation with a mental health professional to help them cope with the challenges of living with Parkinson disease. Some patients may need prescription medications to help with issues such as anxiety and depression.

TABLE 17.14 Nursing Interventions for Patients with Parkinson disease

Evaluation of Nursing Care for the Patient with Parkinson Disease

The desired outcome for patients with Parkinson disease is control and management of their symptoms to improve their quality of life. This includes educating patients and their families about Parkinson disease and helping them cope with their symptoms to function as normally as possible. If a patient's Parkinson disease is well-managed, they should be reasonably independent, with the ability to feed and dress themselves. They should also have the ability to manage their medications. Their home and other environments where they spend a lot of time should promote safety and provide surroundings that help them avoid falls and other hazards.

Medical Therapies and Related Care

The medical therapies used to treat Parkinson disease may include medications such as dopamine agonists, which activate dopamine receptors to make the brain think that it is receiving dopamine, the neurotransmitter needed for learning and motivation. Some patients with Parkinson disease benefit by taking anticholinergics, which treat tremors by blocking dopamine uptake. In addition to medications, some patients may benefit from speech, physical, massage, and/or occupational therapy.

Surgery may be an option for some patients. The surgical procedures that benefit some patients with Parkinson disease include **deep brain stimulation**, which implants a device in the brain to produce electrical impulses and disrupt the brain signals causing Parkinson disease. Another surgical procedure, **ablative surgery** destroys the brain tissues that produce abnormal chemical or electrical impulses responsible for a Parkinson disease patient's tremors. With transplantation, the brains of patients with Parkinson disease are implanted with cells that produce dopamine.

17.5 Seizures

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations for seizures
- Describe the diagnostics and laboratory values in seizures
- Apply nursing concepts and plan associated nursing care for the patient with seizures
- Evaluate the efficacy of nursing care for the patient with seizures
- Describe the medical therapies that apply to the care of seizures

A **seizure** occurs when some of the brain's neurons experience sudden and uncontrolled electrical activity, sending incorrect messages between brain cells. Electrical bursts may cause changes in consciousness or may cause the body to react with involuntary movements and behavior.

Seizures come in several types and have various causes. Some patients experience seizures because they have **epilepsy**, an incurable neurological disease that causes recurring seizures. This section provides an overview of seizures, including epilepsy, and explains the nursing care that is needed to help patients with seizures.

Pathophysiology

When the brain's neurons function normally, they produce chemical and electrical signals that interact with other neurons, as well as the body's muscles and organs, to create each person's feelings, thoughts, and behaviors. During a seizure, the neurons send signals at a much greater speed, and multiple neurons may send signals at the same time, creating overlapping neuron communication that is too rapid. The body responds with seizures.

Seizures can be triggered by a variety of factors, including high fever, brain tumors, strokes, head trauma, heart attacks, and infections such as encephalitis and meningitis. Patients who have diabetic hypoglycemia may experience a seizure if their glucose level drops too low. Diseases, such as Alzheimer disease, can cause seizures, and seizures have been linked to alcoholism. Any condition or disease that deprives the brain of oxygen or causes the brain to become inflamed has the potential to cause a seizure. In addition, seizures can be triggered by physical problems such as stress, sleep deprivation, hormonal changes, and dehydration. Certain medications, such as atypical antipsychotic drugs and opioids, may lower a patient's **seizure threshold**, which is the likelihood that a patient will have a seizure.

Some patients have seizures because of epilepsy, which is a neurological disorder that causes surges of electrical activity in the brain, resulting in recurring seizures. Epileptic seizures are unprovoked, and doctors typically diagnose epilepsy in patients with seizures when they have two unprovoked seizures.

Types of Seizures

Seizures are categorized as either focal or generalized, and each category includes several different subtypes of seizures:

- **focal seizure**—As the name implies, a focal seizure begins in one area of the brain. Focal seizures include the following types:
  - **onset awareness**—The patient is awake and aware throughout the seizure, which may begin with twitching or stiffness in a specific part of the body, such as the hand; as the twitching and/or stiffness spreads, the patient may experience a range of emotions including happiness, fear, or depression, and they may have déjà vu accompanied by nausea; they may also have hallucinations and see flashing lights.
  - **onset impaired awareness**—The patient is confused and not fully aware during the seizure; they may lose consciousness and have uncontrolled movements such as lip smacking and bicycling legs.
- **generalized seizure**—A generalized seizure affects both sides of the brain at the same time. Generalized seizures include the following types:
  - **absence generalized seizure**—The patient stares into space and may have slight twitching.
  - **atonic generalized seizure** —The patient loses normal muscle tone, which may cause them to involuntary drop their head or fall down.
  - **clonic generalized seizure** —The patient has repetitious jerking movements on both sides of their body
  - **myoclonic generalized seizure** —The patient has twitches and/or jerks in the arms, upper body, or legs.

- **tonic generalized seizure** —The patient's muscles stiffen, typically in the arms, legs, and/or back.
- **tonic-clonic generalized seizure** —The patient has a combination of reactions that may include repetitious jerking, stiffening, and/or a loss of consciousness.

Each type of seizure may have three phases. The **prodrome** phase occurs before the seizure actually begins and includes warning signals—such as a headache, dizziness, racing thoughts, or disorientation—that indicate a seizure is going to happen. Prodrome may occur hours, or even days, before a seizure ensues. The **ictal** phase begins with the first symptom of the seizure and lasts until the seizure ends. The **postictal** phase is the recovery period after a seizure ends. During the postictal phase, which may last minutes or hours, patients may be confused, scared, frustrated, and anxious. They may have memory lapses and may struggle to do things such as walk or write. They may also experience physical symptoms, such as a headache, muscle weakness, and loss of bladder control.

Clinical Manifestations

The symptoms of seizures vary and can be mild or severe. Common symptoms include confusion, staring, uncontrollable twitching or jerking of the arms and legs, sudden falls, body spasms, tense and/or stiffened muscles, weakened muscles, loss of awareness or consciousness, anxiety and fear, and a feeling of déjà vu. Patients may also experience strange sensations and emotions and feel that they have an aura when a seizure begins. An **aura** may include a sense of déjà vu and/or a sudden feeling of intense emotion such as fear or happiness.

If seizures are caused by factors such as hypoglycemia, infection, or head trauma that can be treated and resolved, treating the cause should also stop the patient's seizures. If seizures are caused by factors that cannot be cured, including epilepsy, the patient will need health care focused on minimizing and managing the seizures.

Assessment and Diagnostics

Seizures are assessed and diagnosed with a physical examination and tests. The physical examination should assess the patient's cognitive functioning, behavior, and motor abilities, as well as gather the patient's medical history. This should include information about illnesses and medications that could be a factor in the patient's seizures, and details about a family history of seizures.

Diagnostics and Laboratory Values

Tests for patients with seizures may include blood tests, lumbar puncture electroencephalogram (EEG), stereoelectroencephalography (SEEG), MRI, CT, PET, and single-photon emission computed tomography (SPECT).

Blood tests will show if the patient has genetic conditions or infections that can cause seizures. Lumbar punctures also show infections that can cause seizures. An EEG shows the brain's electrical activity and can reveal abnormal patterns that cause seizures. A SEEG involves surgically implanting electrodes in the brain to track brain activity and determine where seizures originate. MRIs and CTs show abnormal changes in the brain, such as brain tumors and cysts, which may be the cause of seizures. PET scans track abnormal chemical changes in the brain that may cause seizures. PET scans also show areas of the brain that have abnormal metabolism, which indicates the area of the brain that is the focus of a seizure after it is over. SPECT tracks the brain's blood flow during a seizure. SPECT blood flow tracers should be injected during periods of seizure and compared to periods when the patient is not having a seizure. During a seizure, the seizure onset area will show a higher blood flow, identifying where the seizure originates.

Nursing Care of the Patient with Seizures

Nursing care for patients with seizures should focus on keeping patients safe while controlling symptoms. Hazards, such as footstools and other things that could cause patients to fall if they have a seizure, should be removed. If patients are in bed, they should have guard rails, and during a seizure, their head should be supported with a pillow. Tight clothing should be removed, and some patients may need oxygen to support breathing. Nurses should provide education to help patients and their families learn to live with and manage seizures. This may include eating a healthier diet and avoiding triggers for seizures, such as bright lights and sleep deprivation.

LINK TO LEARNING

Every seizure causes neurological dysfunction, making the treatment of seizures critical for patient well-being. Patients with seizures need early therapy and preventative measures (https://openstax.org/r/77SeizureTrtmt) to minimize the possibility of recurring seizures.

Recognizing Cues and Analyzing Cues

The cues of seizures will be found in the patient's physical examination and test results. Patients and their family members should be able to tell the nurse if the patient has had seizures. Even if the patient does not have a seizure during the examination, the physical examination may still yield cues of seizures if the patient exhibits symptoms such as confusion, weakened muscles, and anxiety. If the patient is under observation and has a seizure, the cues may include uncontrollable twitching or jerking of the arms and legs, body spasms, tense muscles, and loss of awareness or consciousness. Other cues, which the provider will use for diagnosis, will come from the patient's test results. Blood tests and lumbar punctures may show infections that are causing the seizures. Imaging may show cues such as brain tumors and cysts that can cause seizures. Results of EEGs, SEEGs, PETs, and SPECTs will show additional cues by providing information about the brain's blood flow, electrical activity, and chemical activity.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Seizures should be prioritized based on the severity of symptoms. Severe symptoms, particularly for frequent seizures, should be a higher priority than infrequent seizures and/or seizures with mild symptoms. In particular, severe seizures that jeopardize patients' safety, and possibly even put them at risk of death, must be prioritized over mild seizures that cause more minor issues, such as mild twitching and muscle weakness. Nurses should work with patients' health-care team members to generate solutions. The nursing interventions appropriate for patients with seizures may include those in Table 17.15.

Nursing Care	Rationale
Complete focused neurological assessments.	Twitching, muscle weakness, staring, confusion, anxiety, and other related symptoms are cues of seizures.
Care during seizures.	During a seizure, remove hazards, particularly sharp objects, and allow the patient's body to move freely. Place a pillow under their head and turn the patient on their side to keep their tongue from blocking the airway. If the patient is wearing eyeglasses and/or necklaces or other items around their neck, remove these if possible. Never attempt to place your fingers into a mouth of a patient who is seizing, and do not attempt to put a barrier between the teeth of a patient having a seizure. After the seizure, provide emotional support and check the patient's vital signs, including awareness levels. Apply supplemental oxygen and provide suction to prevent the patient from aspirating. Ask the patient questions, such as, What is your name? Where are you? Documentation of a seizure includes time of onset, duration of the active seizure, and the length of the postal state. It also includes assessing if the patient experienced an aura before the seizure onset. If the seizure lasts more than five minutes, it is an emergency, and the provider should be called.
Monitor vital signs.	Changes in the patient's vital signs such as heart rate and blood pressure may indicate health problems.

TABLE 17.15 Nursing Interventions for Patients with Seizures

Nursing Care	Rationale
Administer medications specifically for seizures.	The appropriate medicine for each patient depends on the type of seizure and frequency, patient's lifestyle and age, and other factors such as other medications the patient is taking and whether the patient is pregnant. Medications that may be considered include brivaracetam, cannabidiol oral solution, cenobamate, clonazepam, and divalproex sodium.
Administer other medications.	Patients with seizures may need medications to control other problems that may occur as a result of their seizures. For example, patients who develop a headache following a seizure may need pain medication, and patients who have trouble sleeping may benefit by taking a sedative.
Prepare for surgery and aftercare.	Some patients may need surgery to stop seizures. Nurses should help prepare patients for surgery and should provide surgery aftercare, such as dressing the patient's surgical wound(s). Options for surgical procedures that can help patients with seizures include the following: • Corpus callosotomy cuts the connections between the neurons in the brain's right and left halves to stop seizures that begin on one side and travel to the brain's other side. • Hemispherotomy disconnects the side of the brain that has seizures from the rest of the brain and body. • Lobectomy removes the area of the brain where seizures originate. • Multiple subpial transection makes several cuts in the brain that are designed to prevent seizures. • Thermal ablation uses highly concentrated energy to destroy brain cells causing seizures.
Assist with electrical stimulation.	Nurses may assist providers as they conduct electrical stimulation, which includes the options of vagus nerve stimulation, responsive neurostimulation, and deep brain stimulation to implant devices that send signals to the brain to stop seizures.
Consult with a dietician for nutrition issues.	Some patients with seizures, particularly those with epilepsy, may need to change their diet to eat foods that are high in protein and fat, while low in carbohydrates.
Assist with mental health support.	Patients with seizures, particularly those with epilepsy, and their families may need consultation with a mental health professional to help them cope with the challenges of living with seizures. Some patients may need prescription medications to help with issues such as anxiety and depression.

TABLE 17.15 Nursing Interventions for Patients with Seizures

Evaluation of Nursing Care for Patients with Seizures

The desired outcome for patients with seizures is a cure if their seizures are caused by a factor that can be cured, such as infection. If patients with seizures cannot be cured, their condition should be controlled, and they should

experience few or no seizures even if they still have an incurable condition, such as epilepsy, that triggers seizures. Patients with seizures should also understand the risks associated with seizures, and they should exercise safety protocols to minimize the dangers posed by seizures. They should also understand the importance of medications in treating seizures and should be committed to taking the appropriate medications as needed.

Medical Therapies and Related Care

The medical therapies used to treat patients with seizures typically include antiepileptic drugs (AEDs), which are categorized as either broad-spectrum or narrow-spectrum. Broad-spectrum AEDs treat various seizure types and are often used initially, particularly if the patient's diagnosis has not determined seizure type. Broad-spectrum AEDs include clobazam, clonazepam, lamotrigine, levetiracetam, perampanel, rufinamide, topiramate, valproic acid, and zonisamide. Narrow-spectrum AEDs generally are used to treat focal seizures and include carbamazepine, ezogabine, gabapentin, lacosamide, oxcarbazepine, phenytoin, pregabalin, and vigabatrin.

Some patients with seizures may benefit from surgery, such as corpus callosotomy, a procedure that involves cutting the connection between the right and left sides of the brain to slow electrical activity between the hemispheres. Laser interstitial thermal therapy uses computer navigation to find and destroy lesions in a patient's brain that cause seizures. Stereotactic radiosurgery relies on 3D imaging to locate and destroy misfiring nerve cells.

Electrical stimulation benefits some patients with seizures. In this procedure, a neurostimulator is placed inside the patient's skull and connected to electrodes that continuously monitor the patient's brain activity. When a seizure is detected, the electrodes emit an electrical signal that attempts to stop the seizure.

Nutrition can also be a vital part of helping patients with seizures. Patients with seizures need a balanced diet that includes proteins, fats, and carbohydrates along with sufficient fluid intake to prevent dehydration.

17.6 Polyneuropathy

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations for polyneuropathy
- Describe the diagnostics and laboratory values of polyneuropathy
- Apply nursing concepts and plan associated nursing care for the patient with polyneuropathy
- Evaluate the efficacy of nursing care for the patient with polyneuropathy
- Describe the medical therapies that apply to the care of polyneuropathy

A peripheral nerve disorder called **polyneuropathy** occurs when multiple peripheral nerves all over the body are damaged and malfunction simultaneously. As noted previously, the **peripheral nervous system** is the division of the nervous system containing the nerves that travel from the brain and spinal cord to carry signals to the rest of the body. The peripheral nervous system enables somatic functions and autonomic functions. A **somatic function** is a conscious movement that an individual controls, such as moving the arms and legs. An **autonomic function** is an automatic movement, such as heart beating, that individuals do not control.

Polyneuropathy can disrupt nerve communication in several ways. For example, lost nerve signals should occur but do not, whereas other nerve signals occur at inappropriate times. And, still other signals occur when they should but deliver an error message. Although the symptoms of polyneuropathy can be severe, even disabling some patients, the condition is rarely life-threatening.

Pathophysiology

Polyneuropathy may be caused by health conditions, such as infections, tumors, bone marrow disorders, kidney failure, cancer, autoimmune diseases such as lupus or rheumatoid arthritis, and other diseases such as hypothyroidism or liver disease. Other causes include alcoholism, vitamin deficiencies, exposure to toxins, and injuries that damage the peripheral nerves. Some medications, particularly those used in chemotherapy, may cause polyneuropathy. Finally, the most common cause is diabetes, with more than 50 percent of people who have diabetes also developing a type of neuropathy, including polyneuropathy (Mayo Clinic, 2023g).

Clinical Manifestations

Polyneuropathy develops slowly in some patients, becoming a chronic case, whereas other patients have an acute case, with a sudden appearance of polyneuropathy. The symptoms vary depending on which type of nerves are damaged. Polyneuropathy can affect the following nerves:

- A **motor nerve** controls muscles that require voluntary control, such as those used to talk and walk. Symptoms include muscle weakness and/or shrinking, cramps, inability to move body parts under voluntary control such as the hands and feet, and **fasciculation**, which is an uncontrolled twitching in the muscles.
- A **sensory nerve** transmits messages about pain, temperature, feelings, and other information gathered by the senses. Symptoms include loss of reflexes; lack of coordination and/or balance; numbness, particularly in the hands and feet; feelings of sensitivity and pain from things that should not hurt, such as clothing; feeling like pins and needles are sticking in the skin; and burning sensations.
- An **autonomic nerve** controls muscles and organs regulating bodily functions that patients cannot control consciously, such as the heart, lungs, and digestive system. Symptoms include heat intolerance, gastrointestinal issues, loss of bowel and/or bladder control, sweating excessively, lack of expansion and contraction in the small blood vessels, dizziness from drops in blood pressure, and breathing difficulties if the muscles that control the lungs are affected.

Assessment and Diagnostics

To assess a patient for polyneuropathy, nurses should conduct a physical examination focused on patients' movements, sense of touch, and pain. Patients may exhibit difficulty moving their hands, arms, legs, and/or feet. This may affect their ability to stand and walk, as well as the ability to do routine tasks such as writing or buttoning a shirt. Patients with polyneuropathy may also experience a loss of their sense of touch and no longer be able to feel cold or heat. They may also have numbness or a sensation that feels like they have pins and needles in their skin. Nurses should also be alert for pain, which patients with polyneuropathy may describe as throbbing and/or sharp, and the pain may occur in any part of the body.

Other ways to assess and diagnose polyneuropathy include blood and urine tests, lumbar puncture, imaging tests, spirometry, EMG, and nerve conduction studies. In some cases, skin and/or nerve biopsies may be useful. Often, polyneuropathy can be diagnosed based on the symptoms noted previously that can affect a patient's motor, sensory, and/or autonomic nerves. Testing confirms the diagnosis and helps to identify the cause.

Diagnostics and Laboratory Values

An examination of patients with polyneuropathy may reveal the following diagnostics and laboratory results:

- Blood and urine tests may identify problems such as diabetes, kidney dysfunction, liver issues, vitamin deficiencies, and infections that can cause polyneuropathy.
- Lumbar punctures may find high protein levels in CSF and/or a low white blood cell count. These findings indicate that the patient may have a condition or disease, such as an autoimmune disorder, that can cause polyneuropathy.
- Imaging such as an MRI or CT scan may find that the patient has pinched nerves, a herniated disk, growths, or other problems that affect the nerves, causing polyneuropathy.
- EMG records the muscles' electrical activity when contracted as well as during rest. This identifies abnormal muscular activity and helps determine if the patient's problem is a muscle or nerve disorder. For patients with polyneuropathy, the EMG will find a nerve disorder.
- Nerve conduction studies measure the speed and strength of signals in the motor and sensory nerves and whether the myelin sheath or axons have been damaged. This information helps determine the severity of nerve damage experienced by patients with polyneuropathy.
- Spirometry can determine if the muscles involved in breathing have been affected. Spirometry is a pulmonary function test that measures the amount of air a patient can inhale and exhale, including how quickly the patient can exhale. During the test, the patient's nostrils are closed with a clip, and their mouth is covered with a breathing mask. The patient is asked to breathe in deeply and hold the breath for a few seconds. Then they exhale, pushing the breath into the mask with as much force as possible.
- Nerve biopsies provide details about the nerve cells that are damaged and causing polyneuropathy. Nerve biopsies have the risk of further damaging nerve cells, however, so they typically are used in more severe

cases when additional information is needed to understand the patient's polyneuropathy.

- Skin biopsies provide information about the number of nerve endings patients have in their skin. For some patients with polyneuropathy, their condition is caused by damage to the nerve endings in the skin rather than damage in the nerves. A skin biopsy can determine this.

Nursing Care of the Patient with Polyneuropathy

When a patient's polyneuropathy is caused by a health issue that can be treated and cured, nursing care should focus on helping the patient overcome the condition. For example, if a curable infection is the cause of a patient's polyneuropathy, nurses should provide patients with the medications needed to eradicate the infection. If the patient's polyneuropathy is caused by a vitamin deficiency, nursing care should focus on helping the patient develop a healthy diet, which may include appropriate dietary supplements, to overcome the vitamin deficiency.

If the patient's polyneuropathy is caused by a condition or disease that cannot be cured, such as type I diabetes, nursing care should focus on education. Nurses should help patients with incurable polyneuropathy understand the disease and learn how to manage the symptoms. This may include medications, as well as teaching patients with polyneuropathy about lifestyle changes that can help them deal with the symptoms. For example, patients may need guidance to help them develop an exercise regimen and understand the need to make changes such as wearing loose-fitting clothes.

Recognizing Cues and Analyzing Cues

The cues of polyneuropathy will be found in the patient's physical examination and test results. The cues from the physical examination may include a family history of neurological issues, as well as problems experienced by the patient, such as diabetes and alcoholism. The patient will also exhibit symptoms of polyneuropathy, which may include muscle weakness, loss of reflexes, coordination and balance issues, numbness, and low blood pressure.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Polyneuropathy should be prioritized based on the severity of symptoms, with priority given to more severe symptoms. For example, symptoms such as pain and the loss of bladder control should be prioritized over mild numbness. Nurses should work with other members of the patient's health-care team to generate solutions. For example, a physical therapist can help a patient with polyneuropathy develop an exercise regimen to address problems such as muscle control. The nursing interventions appropriate for patients with polyneuropathy may include those in Table 17.16.

Nursing Care	Rationale
Complete focused neurological assessments.	The patient's ability to move different body parts, and issues such as muscle weakness, twitching, loss of reflexes, loss of bowel or bladder control, excessive sweating, heat intolerance, balance or coordination issues, numbness, burning sensations, and feelings of pins and needles may indicate polyneuropathy.
Monitor vital signs.	Changes in the patient's vital signs, particularly blood pressure and breathing, may indicate health issues.

TABLE 17.16 Care for Patients with Polyneuropathy

Nursing Care	Rationale
Administer medications.	Patients who have a condition that is causing polyneuropathy, such as an infection, should be treated with medications that can cure the condition and thereby relieve the polyneuropathy. For other patients, such as patients with diabetes, medications that can provide better control of diabetes or other conditions causing polyneuropathy can also improve the polyneuropathy. Patients with chronic polyneuropathy can be given medications that relieve the symptoms, such as pain relievers and topical treatments such as lidocaine cream. Some patients may benefit by taking antiseizure medicines, such as gabapentin and pregabalin, which can also relieve pain. Drugs used to treat depression, such as nortriptyline and duloxetine hydrochloride, can also treat pain by making the brain more capable of inhibiting pain signals. Particularly for patients with polyneuropathy who have a chronic condition and also experience depression, these drugs may be an effective treatment.
Provide breathing support.	Provide mechanical ventilation assistance to patients with polyneuropathy who struggle to breathe.
Coordinate with physical therapist.	Physical therapy can help patients with polyneuropathy learn exercises and techniques to strengthen their muscles and maintain a greater range of motion. For patients who have a disability as a result of polyneuropathy, physical therapy can help them learn to use assistive devices, such as a brace for their hand and/or foot, as well as a walker, cane, or wheelchair if needed.

TABLE 17.16 Care for Patients with Polyneuropathy

Evaluation of Nursing Care for the Patient with Polyneuropathy

The desired outcome for patients with polyneuropathy is relief from their symptoms. Nurses can evaluate whether symptoms of a patient with polyneuropathy have improved by checking their reflexes, lightly touching them and gauging their reaction, and monitoring their level of sensation to a pinprick. The steadiness of a patient's gait can also indicate if they still have symptoms. If patients with polyneuropathy cannot be cured, their symptoms should be managed to improve quality of life.

Medical Therapies and Related Care

In some cases, polyneuropathy can be cured, and even if it isn't curable, medical treatment can usually help patients with polyneuropathy. The medical therapies used to treat patients with polyneuropathy may include those in Table 17.17.

Medical Therapy	Explanation of Care
Medications	May include medications that • treat underlying conditions, such as an infection, that cause polyneuropathy and can be cured.; • treat underlying conditions, such as type 1 diabetes, that cannot be cured but may be better managed with changes in medication; and • treat polyneuropathy symptoms, particularly pain.
Provide breathing support	May include mechanical ventilation assistance.
Physical therapy	May include exercises and techniques to accomplish goals such as strengthen patients' muscles and maintain a greater range of motion. For patients with polyneuropathy who have a disability, physical therapy can help them learn to use assistive devices, such as braces, walkers, canes, or wheelchairs.
Surgery	May include surgical procedures to remove tumors and treat other conditions that can be relieved with surgery. For patients who have surgery, help them prepare for surgery. After surgery, provide wound care, suture incisions, empty drains, change dressings and bandages, and apply heat/cold packs to assist with any swelling.
Scrambler therapy	This procedure uses electrodes to administer electrical stimulation through the patient's skin to block the nerve endings from sending pain signals to the brain.
Spinal cord stimulation	This procedure implants neurostimulators into the patient's body to emit low levels of electricity into the patient's spinal cord, blocking pain signals to the brain.
Plasma exchange	This procedure purifies blood to help with conditions such as inflammation or an autoimmune condition.
Intravenous immune globulin	This therapy can strengthen the immune system.
Mental health support	Support can help patients who have a chronic, ongoing condition cope with the challenges of living with polyneuropathy. It may include medications to help with issues such as anxiety and depression.

TABLE 17.17 Medical Therapies for Polyneuropathy

17.7 Chronic Pain Disorders

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations for migraines and fibromyalgia
- Describe the diagnostics and laboratory values for migraines and fibromyalgia
- Apply nursing concepts and plan associated nursing care for the patient with migraines and fibromyalgia
- Evaluate the efficacy of nursing care for the patient with migraines and fibromyalgia
- Describe the medical therapies that apply to the care of migraines and fibromyalgia

Any type of pain, such as a headache or lower back pain, that is ongoing and continues for longer than three months

is known as chronic pain. This section reviews migraines, which include severe headaches, and fibromyalgia, which causes musculoskeletal pain that is widespread throughout the body.

Migraines

Migraines are typically thought of as severe headaches. But a **migraine** is actually a serious neurological disease characterized by a severe, throbbing pain or pulsing sensation that may affect one or both sides of the head. The pain from a migraine is so severe that it disrupts routine activities. If untreated, a migraine attack can last for several days. According to the American Migraine Foundation (2021), migraines affect at least 39 million Americans.

Pathophysiology

The causes of migraines are not fully determined, but genetics may be a factor for some patients because migraines sometimes run in families. Migraines also tend to be triggered by factors such as stress, anxiety, tobacco, alcohol, certain foods such as cheese, food additives such as monosodium glutamate (MSG), low blood sugar, weather changes, bright flashing lights, loud sounds, and irregular sleep patterns. Concussions, hormonal changes, and chemical imbalances in the brain also cause migraines in some patients.

Clinical Manifestations

For some patients, migraines progress through four stages—prodrome, aura, attack, and postdrome. Other patients may only experience some of the stages (Mayo Clinic, 2023e; NIH, 2023). Generally, the symptoms of the four stages include the following:

- prodrome—This stage occurs twenty-four to forty-eight hours before a migraine. During this stage, premonitory symptoms occur, which may include the following:
  - mood changes with euphoria or depression
  - cravings for certain foods
  - uncontrollable yawning
  - increased need to urinate
  - fluid retention
  - constipation
  - stiff neck
- aura—This stage occurs in the minutes immediately before the migraine begins. Symptoms during this stage include the following:
  - muscle weakness and/or numbness
  - visions with flashing lights
  - loss of eyesight
  - speaking difficulties
  - sensations of pins and needles in the arm or leg
- **attack**—In this stage, the headache begins and gradually worsens. Symptoms during this stage include the following:
  - throbbing or pulsating pain on one or both sides of the head
  - sensitivity to sound, light, touch, and/or smell
  - nausea, which may lead to vomiting
- **postdrome**—This stage, which may last up to twenty-four hours, occurs after the headache is over. The symptoms during this stage include the following:
  - exhaustion
  - confusion
  - elation

Generally, migraines are incurable unless caused by an underlying condition, such as head trauma that can be cured. But migraines can be treated, and nursing care can help patients learn to live with migraines.

Assessment and Diagnostics

To assess and diagnose migraines, patients must undergo a physical examination that includes a review of their family background, medical history, and symptoms.

For patients with migraines, a physical examination may reveal a family history of migraines. It may also reveal

factors, such as tobacco and alcohol use, irregular sleep patterns, and stress that are risk factors for migraines. The physical examination should provide details about patients' headaches, including frequency, duration, and severity, that can help identify if the headaches are migraines. Other details, such as going through prodrome, aura, and/or postdrome in addition to having a headache, can help determine if a patient has migraines.

Diagnostics and Laboratory Values

Tests, such as blood tests, cannot confirm a migraine diagnosis. However, blood tests and imaging, such as MRI and CT scans, can help rule out conditions, such as low blood sugar, infections, brain tumors, and strokes, which may be causing migraines. MRI and CT scans may find problems such as brain tumors and strokes that can cause migraines.

If test results do not reveal health problems that cause migraines, providers may diagnose migraines based on patients' symptoms, including the frequency, location, and duration of headaches. A family history of migraines as well as known triggers, such as certain foods and bright lights, can help confirm a migraine diagnosis.

Nursing Care of the Patient with Migraines

If a patient's migraines cannot be relieved by addressing an underlying cause, the patient should receive nursing care that helps them learn techniques to prevent migraines and manage them when they do occur. This includes identifying migraine triggers, such as sleep deprivation and loud noises, and teaching patients to avoid those triggers. This also includes teaching patients how to deal with the symptoms of migraines, such as pain and nausea.

Nursing care for patients with migraines should focus on treating underlying causes to eliminate migraines if possible. For example, if a patient has an infection or a brain tumor that is causing migraines, nursing care should focus on resolving this problem. If other factors, such as smoking or irregular sleep patterns, are causing migraines, patients should receive help to overcome these problems.

Recognizing Cues and Analyzing Cues

The cues for migraines will be found in the patient's physical examination. Nurses should be alert for cues such as a family history of migraines and risk factors such as stress, tobacco and alcohol use, and irregular sleep patterns. Primary cues will come from information patients provide verbally about their experiences with migraines, including the frequency, duration, and intensity of headaches, as well as whether patients experience the symptoms found in prodrome, aura, and/or postdrome stages of migraines. Additional cues may be found in test results. Although these tests cannot diagnose migraines, they can reveal if patients have problems such as infections and brain tumors that can cause migraines.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Migraine symptoms should be prioritized on the basis of their severity. Severe migraine pain that disables patients and leaves them unable to function should be prioritized over milder migraine pain. Although migraines generally are not life-threatening, they can severely disrupt patients' lives, making it challenging for them to handle their daily routines. Solutions should include eradicating underlying causes of migraines if possible. If migraines cannot be relieved, solutions should focus on helping patients learn to manage and cope with migraines. The nursing interventions appropriate for patients with migraines may include those in Table 17.18.

Nursing Care	Rationale
Complete focused neurological assessments.	Patients may have headaches and other issues such as mood changes, food cravings, muscle weakness, speaking difficulties, and other symptoms that might indicate a migraine is forthcoming.
Monitor vital signs.	Changes in the patient's vital signs such as heart rate and blood pressure may indicate health issues.
Provide a peaceful environment.	Patients with migraines need a quiet room with dim lights. They may also need a cool cloth or ice pack to help with pain.

TABLE 17.18 **Nursing Interventions for Patients with Migraines**

Nursing Care	Rationale
Administer medications for immediate relief.	Patients with migraines may need medications such as the following during a headache: • pain relievers such as aspirin or acetaminophen • opioids • lasmiditan • dihydroergotamine • triptans such as sumatriptan or rizatriptan • zavegepant nasal spray • gepants
Administer medications to prevent migraines, as ordered.	Patients with migraines may need medications such as the following to prevent a migraine: • antiseizure drugs • antidepressants • beta blockers to lower blood pressure • monoclonal antibodies • gepants Some patients also benefit from routine Botox injections.
Assist with mental health support.	Patients with migraines who are unable to get relief may need consultation with a mental health professional to help them cope with the challenges of living with migraines. Some patients may need prescription medications to help with issues such as anxiety and depression.

TABLE 17.18 Nursing Interventions for Patients with Migraines

Evaluation of Nursing Care for the Patient with Migraines

The desired outcome for patients with migraines is to stop migraine headaches and their symptoms, as well as prevent attacks in the future. For patients whose migraines cannot be stopped, nursing care should help them learn to manage the factors that trigger migraines, limiting the frequency and severity of migraines. To evaluate patients with migraines, nurses should consider vital signs, such as the patient's temperature and heart rate. They should also examine the patient's neck and head, noting if the patient has areas of tenderness or swelling. The patient's behavior should also be evaluated, focused on whether the patient appears to be restless, grimaces in pain, or moves into certain positions in an effort to alleviate pain.

Medical Therapies and Related Care

The medical therapies for patients with migraines may include medications to prevent migraines, as well as medications to provide relief after a migraine occurs. For example, some patients may benefit by taking triptans, which change the way the brain circulates blood and processes pain signals. Other patients with migraines, especially those who experience nausea, may get relief by taking antiemetics, which interfere with the neurotransmitter receptors that trigger nausea and vomiting. For many patients with migraines, the most effective medications are simply anti-inflammatories, such as aspirin and ibuprofen. Some patients with migraines also find alternative medical treatments helpful, such as yoga and massage therapy.

Fibromyalgia

A chronic condition that affects soft tissues and muscles throughout the body, causing musculoskeletal pain and tenderness, is called **fibromyalgia**. The condition has no cure and affects at least one in twenty-five people in the United States. Most patients with fibromyalgia are middle-aged females, although anyone can experience it, including children. The condition often runs in families, although it also occurs in patients without a family history of the condition (Johns Hopkins Medicine, 2024b; NIAMSD, 2021).

Pathophysiology

The cause of fibromyalgia is unknown, although medical experts suspect the condition is linked to stress and sleep disorders. Other causes may include endocrine, biochemical, and immune disorders. Patients who have conditions and diseases such as migraines, lupus, rheumatoid arthritis, osteoarthritis, chronic back pain, irritable bowel syndrome, anxiety, and/or depression also tend to be more likely to develop fibromyalgia. In some cases, the condition appears to be triggered by an infection, such as HIV, Lyme disease, and both hepatitis B and C (National Institute of Arthritis and Musculoskeletal and Skin Diseases, 2021). Although fibromyalgia is a chronic condition without a cure and the pain can be severe enough to disrupt patients' daily routines, it does not damage the body's muscles or bones.

Clinical Manifestations

Fibromyalgia affects patients in varied ways, and pain can affect any part of the body. Often, the pain is worse in tendons and ligaments, where the muscles attach to the body's bones. For some patients with fibromyalgia, the pain is mild, whereas others experience more severe pain. The pain may present as stiffness, soreness, aching, or a burning sensation. Other common symptoms of fibromyalgia include the following:

- fatigue
- headaches, including migraines
- restless legs
- stiff joints
- numbness and/or tingling in the legs and arms
- sensitivity to touch
- sensitivity to noise, light, and temperature
- lack of exercise endurance
- cognitive difficulties referred to as **fibro fog**. Fibro fog may include the following issues (Arthritis Foundation, n.d.):
  - difficulty concentrating
  - lack of alertness
  - forgetfulness
  - reduction in thinking skills, including inefficient and slow thinking abilities
  - difficulty retrieving information stored in the brain
- sleep disorders
- anxiety and depression
- constipation and/or bladder disorders, such as interstitial cystitis
- excessive pain during menstrual periods

Assessment and Diagnostics

Typically, fibromyalgia is diagnosed by ruling out other conditions and diseases that cause similar pain, such as rheumatoid arthritis. Patients undergo a physical examination and generally must experience ongoing pain for at least three months in at least four body areas before their condition is considered to be fibromyalgia. The body areas include the jaw, neck, shoulders, arms, legs, back, chest, and buttocks. To rule out other conditions that cause similar pain, doctors usually order blood tests. Other symptoms experienced by patients may include sleep disorders, fatigue, restless legs, headaches, stiff joints, cognitive difficulties, and issues such as constipation or bladder dysfunctions. Patients may also have anxiety and/or depression.

Diagnostics and Laboratory Values

If blood tests show results such as rheumatoid factor, thyroid dysfunction, vitamin D deficiency, a high erythrocyte sedimentation rate, or antinuclear antibodies, doctors may determine that the patient has another condition, such as lupus or rheumatoid arthritis, rather than fibromyalgia. If blood tests have normal results and offer no explanation for the patient's pain, fibromyalgia is a likely diagnosis.

Nursing Care of the Patient with Fibromyalgia

Nursing care for patients with fibromyalgia should focus on controlling symptoms and helping patients learn how to manage their condition. For some patients, this may require lifestyle changes as well as treatment for conditions such as anxiety and depression that contribute to fibromyalgia.

Recognizing Cues and Analyzing Cues

The cues of fibromyalgia will be found in the patient's physical examination, particularly the locations and duration of the pain. Nurses will find other cues in patient symptoms such as fatigue, stiff joints, restless legs, and sensitivity to touch. By talking to the patient, nurses can learn about other cues, such as sleep disorders, anxiety, and depression. Finally, cues will be found in the patient's blood test results. If tests do not identify another cause for the patient's pain, such as rheumatoid arthritis, it is reasonable to make a fibromyalgia diagnosis.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Fibromyalgia should be prioritized based on the severity of symptoms. For example, symptoms that cause severe, widespread pain and sleep deprivation should be prioritized over milder symptoms that cause fewer disruptions to a patient's daily routine. Solutions should be generated that help patients learn to manage the pain and discomfort caused by fibromyalgia, while also learning to cope and function. The nursing interventions appropriate for patients with fibromyalgia may include those in Table 17.19.

Nursing Care	Rationale
Complete focused physical examination.	Patients with fibromyalgia will experience pain and likely other symptoms, such as headaches, restless legs, stiff joints, anxiety, and depression. They may also have difficulty sleeping and may experience fibro fog or other problems, such as constipation and/or bladder issues.
Monitor vital signs.	Changes in the patient's vital signs such as heart rate and blood pressure may indicate health issues.
Administer medications for pain.	Although fibromyalgia cannot be cured, patients can be helped with medications. Pain relievers such as acetaminophen and ibuprofen may be beneficial, and patients who need stronger medications may find pain relief by taking antiseizure drugs, such as pregabalin and gabapentin. Some patients may be helped with antidepressants, such as milnacipran and duloxetine, which can treat patients' pain, as well as anxiety and depression.
Administer medications for other symptoms.	Other medication may include laxatives, sedatives, and other drugs appropriate to treat issues such as constipation and sleep disorders.
Coordinate with physical therapist.	Physical therapy can help patients with fibromyalgia learn exercises and techniques to strengthen their muscles, improving their flexibility and strength.
Coordinate with occupational therapist.	Occupational therapy can help patients with fibromyalgia learn how to organize their home and work areas to make it easier to accomplish tasks without stressing the body.
Assist with mental health support.	Patients with fibromyalgia and their families may need consultation with a mental health professional to help them cope with the challenges of living with fibromyalgia. Some patients may need prescription medications to help with issues such as anxiety and depression, which may also help with pain.

TABLE 17.19 Nursing Interventions for Patients with Fibromyalgia

Evaluation of Nursing Care for the Patient with Fibromyalgia

The desired outcome for patients with fibromyalgia is symptom relief, including relief from pain as well as other problems such as restless legs, stiff joints, and anxiety. If patients' symptoms cannot be completely relieved, nursing care should help them learn to control and manage their symptoms, improving their quality of life. This goal is met if patients are able to function despite their pain and do so without experiencing problems such as anxiety and depression. This can be evaluated with tools such as serial assessments of patients' pain levels, screening for depression, and assessment of patients' ability to perform activities of daily living (ADLs) and instrumental activities of daily living (IADLs).

Medical Therapies and Related Care

The medical therapies used to treat fibromyalgia may include medications for pain, as well as medications for other symptoms such as constipation and insomnia. For example, as noted previously, some patients may benefit by taking triptans or antiemetics, whereas others may do well with anti-inflammatories such as aspirin and ibuprofen. Some patients may find relief from antiseizure drugs, such as pregabalin and gabapentin, which can also be used to fight pain. For constipation and insomnia, medications such as laxatives and sedatives may be beneficial. Physical and/or occupational therapy may also be helpful.

17.8 Spinal Disorders

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations for low back pain and spinal tumors
- Describe the diagnostics and laboratory values for low back pain and spinal tumors
- Apply nursing concepts and plan associated nursing care for the patient with low back pain and spinal tumors
- Evaluate the efficacy of nursing care for the patient with low back pain and spinal tumors
- Describe the medical therapies that apply to the care of low back pain and spinal tumors

Diseases or injuries that affect the spinal cord and back are known as **spinal disorder**s. Spinal disorders include a variety of conditions that cause problems for patients, including pain. This section will cover two spinal disorders, low back pain and spinal tumors. One reason spinal issues are so serious is that every part of the body except the face is innervated by spinal nerves that travel through the spinal cord. The area innervated by a single spinal nerve is called a **dermatome**. So, when the spinal cord experiences disorder, it can affect almost all of the body (Figure 17.9).

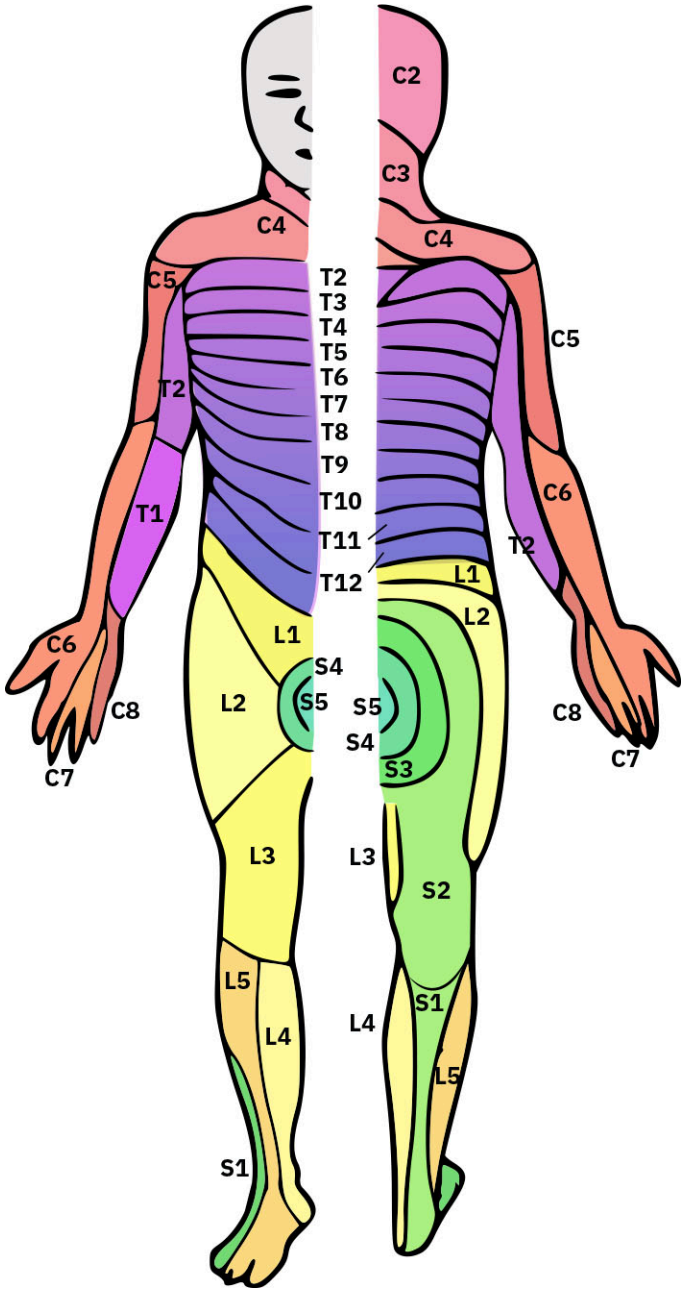

FIGURE 17.9 Dermatomes are connected to each section of the spine, including the cervical, thoracic, lumbar, sacral, and coccyx spine. They affect every part of the body except the face. (credit: "Dermatoms alt" by Ralf Stephan/Wikimedia Commons, Public Domain)

Low Back Pain

Any feeling of aching, burning, or stabbing in the muscles of the lower back is referred to as **low back pain**. It may include sensations of shooting pains, and the pain may travel down the leg. Low back pain affects the **lumbar spine**, the five vertebrae that comprise the lower section of the spine found between the body's ribs and pelvis (Figure 17.10).

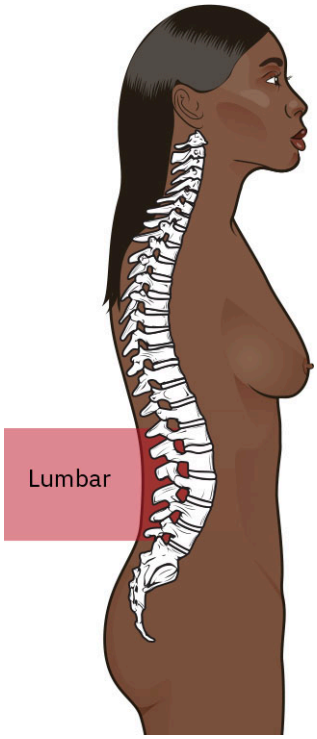

FIGURE 17.10 The lumbar spine represents the portion of the spine located between the ribs and pelvis, between the thoracic and sacral spine. (modification of work from Maternal Newborn Nursing. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Low back pain is a common disorder experienced by an estimated 75 to 80 percent of Americans at least once during their lifetimes. In about 90 percent of cases, low back pain is a temporary problem that can be treated without surgery (AANS, 2024). But for about 50 percent of these patients, low back pain recurs. When low back pain lasts longer than twelve weeks, it is considered a chronic condition (AANS, 2024).

Pathophysiology

Low back pain is caused by a variety of factors that vary among patients. Common causes include injuries, strains, and sprains. Other causes include the following:

- **herniated disk**—A disk in the spine is compressed, irritating nearby nerves.
- **lumbar spinal stenosis**—The spinal cord narrows in the lower back, putting pressure on the nerves.
- **osteoarthritis**—Inflammation in the joints that can occur in the spine.
- **osteoporosis**—Skeletal disorder that causes bones to lose mass and become at greater risk for fracture.
- **axial spondyloarthritis**—Inflammatory disease that affects the spine.
- **sciatica**—The sciatic nerve in the lower back is compressed by a bone spur or herniated disk.
- **scoliosis**—Condition that causes the spine to curve sideways.
- **spondylolisthesis**—A vertebra slips out of place in the spine.

Low back pain has three classifications: **acute back pain**, which occurs suddenly and typically lasts for a few days to a few weeks; **subacute back pain**, which may occur suddenly, but can also appear gradually, and usually lasts for at least four but no longer than twelve weeks; and **chronic back pain**, which can appear suddenly or gradually, occurs daily, and lasts more than twelve weeks (National Institute of Arthritis and Musculoskeletal and Skin Diseases, 2023).

Some patients are at greater risk for low back pain. Risk factors include obesity, lack of exercise, and using improper techniques for lifting. Age can be a factor, with older people generally experiencing more low back pain compared to younger people. Smoking and psychological conditions, such as anxiety and depression, have been linked to low back pain. Some diseases, such as arthritis, may cause low back pain (Mayo Clinic, 2023d).

LINK TO LEARNING

Nurses are at risk of developing low back pain due to lifting patients as part of nursing care. To avoid developing lower back problems, nurses must learn proper lifting techniques (https://openstax.org/r/77SafeLifting) of their patients.

Clinical Manifestations

Low back pain symptoms can vary by patient. Some patients experience localized pain in a certain area, whereas other patients have a more generalized pain that spreads across the back. The pain may also radiate to other parts of the body, including the legs or abdomen. Some patients experience mild low back pain whereas for others, the pain can be intense. Symptoms typical of low back pain include the following:

- pain that comes and goes, becoming worse with activities such as sitting too long, bending, and lifting
- decreased range of motion and/or flexibility, which may include difficulty with standing straight
- weakness, numbness, and/or tingling in legs and/or feet
- bowel and/or bladder issues
- fever
- unexplained weight loss

Assessment and Diagnostics

To assess and diagnose low back pain, patients should undergo a physical examination that includes a review of their medical history and gathers information about the nature of their pain. This includes details about when the pain started, the nature of the pain, and the area(s) of the body affected with pain. The physical examination should check the patient's muscle strength and reflexes, and the spine should be examined to check for issues such as bone structure changes.

Diagnostics and Laboratory Values

Testing options include x-rays, imaging such as MRIs and CTs, electrophysiological tests, bone scans, discography, nerve conduction studies, and blood tests.

- X-rays may show fractures or breaks in the spine or spinal alignment issues.
- Imaging, such as MRIs and CTs, may show issues such as herniated disks or issues in the spine, nerves, muscles, tendons, tissues, ligaments, and blood vessels that can cause low back pain.
- Electrophysiological tests may show poor electrical activity in the muscles and nerves.
- Bone scans may show fractures and/or infections that have affected the spine.
- Discography may identify disks that are the source of the low back pain.
- Nerve conduction studies measure the nerves' electrical impulses and show muscle responses. If the nerves are not functioning appropriately, this may indicate the nerves are affected by a problem such as a herniated disk.
- Blood tests identify issues, such as infections, that may contribute to low back pain.

Nursing Care of the Patient with Low Back Pain

Nursing care for patients with low back pain should focus on finding the cause of the pain and treating that cause with the goal of relieving the back pain. For patients who have chronic back pain that cannot be relieved by treating the cause, nursing care should focus on helping patients control and manage the pain.

Recognizing Cues and Analyzing Cues

The cues of low back pain will be found in the patient's physical examination and test results. Information provided by patients with details about the nature and duration of the pain, as well as findings during the physical examination, such as muscle weakness and reflex issues, will provide additional cues.

Test results should provide cues to confirm the diagnosis. If applicable, cues such as herniated disks, fractures, poor nerve functioning, and infections should be revealed in x-rays and other test results.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Low back pain should be prioritized based on the severity of symptoms. The nursing interventions appropriate for

patients with low back pain may be those in Table 17.20.

Nursing Care	Rationale
Complete focused neurological assessments.	Patients may experience varying levels of pain, decreased range of motion, numbness and/or tingling in their hands and/or feet, and bowel and/or bladder issues.
Monitor vital signs.	Changes in the patient's vital signs, such as heart rate and blood pressure, and fever may indicate health issues.
Administer medications.	Low back pain may be treated with medications including pain relievers such as naproxen sodium and anti-inflammatory drugs, topical pain relievers, muscle relaxants, and antidepressants such as amitriptyline and duloxetine. For patients with more severe pain, narcotics such as opioids may be helpful if their use is limited.
Provide care before and after surgery.	Some patients may require surgery to relieve their low back pain. Surgical options may include procedures to repair herniated disks and create more space in the spine. Some patients may benefit by having nerve stimulators implanted under the skin to deliver electrical impulses to nerves, blocking pain signals. Nurses help patients prepare for surgery and provide surgical aftercare, such as dressing a patient's wound(s).
Assist with other procedures.	In addition to medication and surgery, some patients may benefit from cortisone injections, which can relieve inflammation and provide pain relief for a few weeks. Other patients may benefit from radiofrequency ablation, which involves using a needle to damage the nerves that are sending pain signals and stop these signals from reaching the brain. Nurses can assist with these procedures by providing care such as giving injections and ensuring that patients are positioned properly for treatment.
Coordinate with physical therapist.	Physical therapy can help patients with low back pain learn exercises and techniques to strengthen their muscles, maintain a greater range of motion, and improve their posture, which can help with low back pain. Physical therapists can also teach patients with low back pain how to modify their movements to put less strain and motion on the lower back.
Coordinate to arrange mental health support.	Patients who have chronic low back pain may need help coordinating a consultation with a mental health professional to help them cope with the challenges of living with pain. Some patients may need prescription medications to help with issues such as anxiety and depression.

TABLE 17.20 Nursing Interventions for Patients with Low Back Pain

Evaluation of Nursing Care for the Patient with Low Back Pain

The desired outcome for patients with low back pain is to identify the cause of their symptoms and relieve their pain. If their low back pain is chronic, the desired outcome is to help them control and manage their symptoms.

Medical Therapies and Related Care

The medical therapies used to treat low back pain may be those in Table 17.21.

Medical Therapy	Explanation of Care
Medications	May include pain relievers such as naproxen sodium and anti-inflammatory drugs, topical pain relievers, muscle relaxants, and antidepressants such as amitriptyline and duloxetine. In some cases, narcotics such as opioids may be helpful if use is limited.
Surgery	Surgical options may include procedures to • repair herniated disks, • create more space in the spine, and • implant nerve stimulators under the skin to deliver electrical impulses and block pain signals
Other procedures	May include cortisone injections and radiofrequency ablation.
Physical therapy	May focus on exercises and techniques to strengthen muscles, maintain a greater range of motion, improve posture, and modify movements to put less strain and motion on the lower back. Coordinate with the physical therapist as needed.
Mental health support	May focus on helping patients cope with the challenges of living with pain. May include prescription medications to help issues such as anxiety and depression.

TABLE 17.21 Medical Therapies for Low Back Pain

LINK TO LEARNING

Some patients with low back pain caused by growths may benefit from radiofrequency ablation (RFA). A minimally invasive procedure called RFA (https://openstax.org/r/77RFA) relies on radiofrequency waves to shrink growths, such as tumors or nodules, that cause chronic pain.

Spinal Tumors

A growth of abnormal tissue inside or encompassing the spinal column or the spinal cord is called a **spinal tumor**. Like other tumors, spinal tumors can be benign (noncancerous) as well as malignant (cancerous). When a spinal tumor originates in the spine or spinal cord, it is considered a **primary spinal tumor**. When it originates elsewhere in the body and spreads to the spine, it is considered a secondary spinal tumor, or a **metastatic spinal tumor**.

Pathophysiology

The cause of spinal tumors is unknown. Some of the factors that may create a risk for spinal tumors include defective genes, exposure to toxins, and a compromised immune system. Spinal tumors are also linked to Von Hippel-Lindau disease and neurofibromatosis 2, genetic disorders that can cause tumors throughout the body, including the spine.

Spinal tumors are classified according to the area of the spine where they are located—cervical, thoracic, lumbar, and sacrum—as well as their position within the spinal column (Figure 17.11). These positions include the following:

- **intradural-extramedullary—**Tumors are located on the inside of the **dura**, which is the spinal cord's thin covering, but remain outside the actual spinal cord.
- **intramedullary—**Tumors are located on the inside of the spinal cord.

- **extradural—**Tumors are located outside both the dura and the spinal cord.

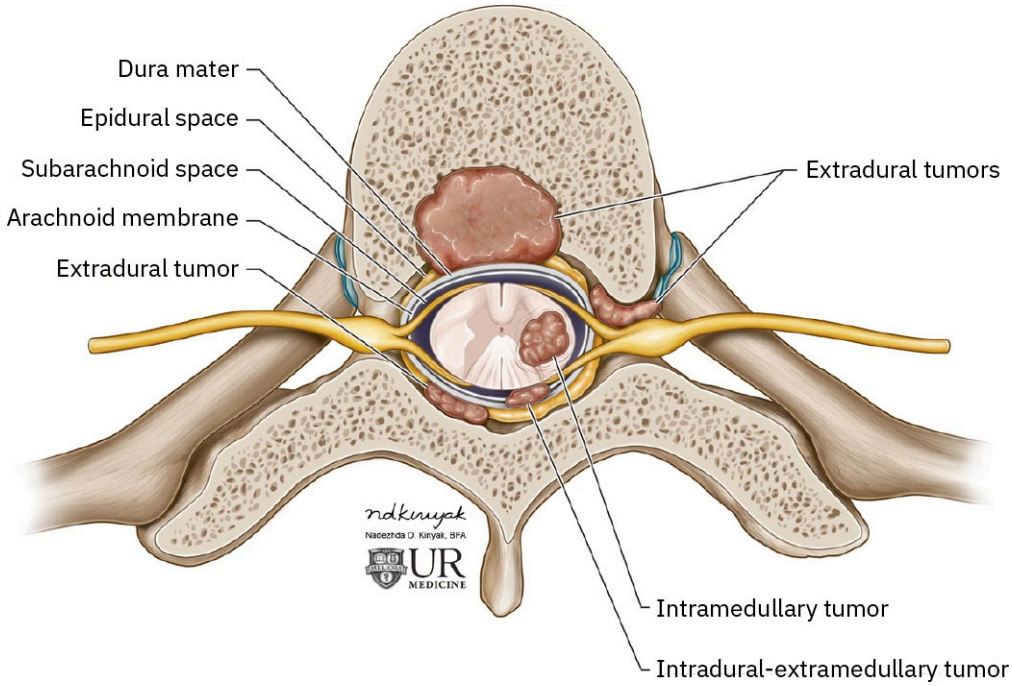

FIGURE 17.11 Spinal tumors are classified according to the area of the spine where they are located. This includes intradural-extramedullary, intramedullary, and extradural tumors. (credit: "Classification of spinal tumors by location" by Nadezdha D. Kiriyak/ Wikimedia Commons, CC BY 4.0)

Clinical Manifestations

The symptoms of spinal tumors vary by patient and by the tumor's progression. Typical symptoms include the following:

- localized pain at the site of the tumor
- low back pain that may radiate to other areas of the body
- muscle weakness that may spread throughout the body
- stiff back or neck
- difficulty walking
- paralysis in any part of the body as a result of compressed nerves
- loss of sensitivity to pain, cold, and heat
- loss of bladder and/or bowel functioning

Assessment and Diagnostics

Spinal tumors are uncommon, comprising about 15 to 20 percent of central nervous system tumors. Of 100,000 people, 0.5 to 2.5 are predicted to develop a spinal tumor, which makes the lifetime risk less than one percent for developing a malignant spinal tumor (Yale Medicine, n.d.). The symptoms of spinal tumors may resemble symptoms of other diseases and conditions, such as low back pain. To assess and diagnose a spinal tumor, patients should undergo a physical examination that gathers information such as the nature and location of the pain, as well as details of other symptoms, such as difficulty walking and loss of sensitivity to pain, cold, and heat.

Diagnostics and Laboratory Values

X-rays, CT scans, and MRIs may show images of the tumor. If a tumor is found, a biopsy will test a sample of the tissue where the tumor is located and determine if the tumor is cancerous.

Nursing Care of the Patient with Spinal Tumors

Health care for patients with spinal tumors should focus on nursing care before and after the provider removes the tumor and curing the patient if possible. Postoperative nursing care for patients should focus on prevention of infections, as well as ensuring the patient stays immobile without bending, lifting, or twisting the spine. To examine patients and move them as necessary, nurses should rely on the log roll maneuver, rolling the patient in 90-degree

steps. Nurses should also note any changes in the patient's sensations.

If the tumor cannot be removed but it is benign, nursing care should focus on helping the patient learn to cope with the condition. If the tumor cannot be removed and it is malignant, nursing care should focus on treating the cancer as well as possible and, if necessary, helping the patient prepare for the end of life.

Recognizing Cues and Analyzing Cues

The cues of spinal tumors will be observed in the patient's physical examination, which will show symptoms such as low back pain, mobility difficulty, and bowel and bladder issues. Other objective cues will be found in the patient's test results, which will show if the patient has a tumor and if so, whether that tumor is benign or malignant.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Spinal tumor interventions should be prioritized based on the severity of symptoms and whether the tumor is benign or malignant. The nursing interventions appropriate for patients with spinal tumors may include those in Table 17.22.

Nursing Care	Rationale
Complete focused neurological assessments.	The patient's pain levels, range of motion, symptoms such as difficulty walking, and loss of sensitivity may indicate a spinal tumor.
Monitor vital signs.	Changes in the patient's vital signs such as heart rate and blood pressure may indicate health issues.
Provide care before and after surgery.	Some patients with a spinal tumor can be helped with surgery. Nurses should prepare patients for surgery and provide care after surgery, such as dressing patients' wound(s).
Assist with radiation therapy.	Patients may need radiation therapy, which may include side effects such as nausea. Nurses should help patients prepare for radiation therapy and provide care afterward, such as administering medications to deal with side effects such as nausea.
Assist with chemotherapy.	Patients may need chemotherapy, which may include side effects, such as nausea and fatigue.
Administer medications.	Patients may need medication to help with pain relief, as well as other problems, such as inflammation.

TABLE 17.22 **Nursing Interventions for Patients with Spinal Tumors**

Evaluation of Nursing Care for the Patient with Spinal Tumors

The desired outcome for patients with a spinal tumor is removal of the tumor. If their tumor cannot be removed, the desired outcome and goal of nursing is to help patients learn to live with the tumor, controlling the symptoms and problems caused by the tumor as much as possible. This includes helping patients learn to control the pain and improve their quality of life with interventions such as better nutrition and exercise. To evaluate the effectiveness of these interventions, nurses can assess patients' functioning with ADLs. For patients whose tumor causes a terminal condition, end-of-life preparation and care may be needed.

Medical Therapies and Related Care

The medical therapies used to treat patients with spinal tumors may include surgery, radiation therapy, chemotherapy, and medications, such as corticosteroids, which can help reduce inflammation.

17.9 Neurological Injuries

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations for traumatic brain injuries and spinal cord injuries
- Describe the diagnostics and laboratory values in traumatic brain injuries and spinal cord injuries
- Describe the medical therapies that apply to the care of traumatic brain injuries and spinal cord injuries
- Apply nursing concepts and plan associated nursing care for the patient with traumatic brain injuries and spinal cord injuries
- Evaluate the efficacy of nursing care for the patient with traumatic brain injuries and spinal cord injuries

Traumatic brain and spinal cord injuries occur when the brain and/or spinal cord are damaged by trauma. Such trauma may include a forceful blow to the head and/or body that happens when an individual falls, or trauma may result when an object slams into the head and/or body. Although some patients may be able to recover from brain or spinal cord injuries, in some cases, these injuries cause permanent disability and even death.

Traumatic Brain Injury

Damage that results when the brain experiences a sudden assault from an external source is called **traumatic brain injury (TBI)**. The external source can be a variety of things, including a powerful blow to the head from falling, as well as something like a bullet that shatters the skull and pierces the brain. Incidents that may lead to traumatic brain injuries include automobile accidents, blunt force trauma, and being struck by a flying object.

Pathophysiology

TBI may cause temporary or long-term problems, depending on the nature and severity of the injury. TBIs may be **penetrating**, which occurs when the skull is pieced by a sharp object that enters brain tissue. Other TBIs are **nonpenetrating**, which occurs when the assault is strong enough to move the brain around inside the skull, but the skull is not broken.

The problems caused by TBIs may include cognitive difficulties, such as the inability to think, communication issues, and/or struggling to move body parts. A **primary injury** occurs immediately, whereas a **secondary injury** occurs gradually in response to reactive processes in the brain that are caused by the trauma. Secondary injuries may take days, or even weeks, to appear.

LINK TO LEARNING

Read this article for more information about TBI (https://openstax.org/r/77TBIinfo) from Mayfield Brain & Spine.

Clinical Manifestations

TBIs have symptoms in three areas: physical, cognitive and behavioral, and perception and sensation. Physical symptoms may include headaches, double or blurred vision, seizures, convulsions, tremors, nausea and vomiting, slurred speech and/or difficulty swallowing, muscle weakness, paralysis, balance and coordination issues, drainage in the ears or nose, and bowel and/or bladder control issues. Cognitive and behavioral symptoms may include lack of consciousness, coma, disorientation and confusion, concentration issues, loss of memory, difficulty thinking, short attention span, mood changes, irritability, frustration, loss of inhibitions, and sleep disorders. Perception and sensation symptoms may include ringing in the ears, sensitivity to sound and/or light, vertigo and dizziness, fatigue and lack of energy, anxiety, depression, foul tastes in the mouth, and decreased understanding of time and/or space. Typically, symptoms, such as headache and confusion, tend to occur immediately following a TBI, whereas symptoms that involve moods and emotions may take longer to develop.

Assessment and Diagnostics

To assess and diagnose a TBI, patients should undergo a physical examination that gathers information about the type of injury the patient has, including whether the injury is penetrating or nonpenetrating. The examination should also review the patient's symptoms, which may include physical, cognitive and behavioral, and/or perception and sensation symptoms. If a TBI diagnosis cannot be confirmed through a physical examination, patients should

undergo MRIs, CTs, and/or other neuropsychological tests.

Diagnostics and Laboratory Values

To confirm a TBI diagnosis, patients may need to be tested. Options for testing include MRIs, CTs, and neuropsychological tests. The Glasgow Coma Scale (GCS) can be used to assess the patient's consciousness level. MRIs and CTs will show evidence of injury, such as skull fractures and swelling, bruising, and/or bleeding on the brain. Neuropsychological tests will reveal problems the patient may be having with concentration, memory, problem-solving, and other cognitive skills. As noted previously, a GCS score lower than eight indicates problems with a patient's consciousness level. The highest possible score on the GCS is 15. Patients with higher scores have less severe injuries.

Nursing Care of the Patient with Traumatic Brain Injury

Nursing care for a patient with TBI should focus on helping the patient recover if possible. If the patient has permanent health issues as a result of the injury, nursing care should focus on helping the patient adjust and learn to manage the new health issues, which may include problems such as nerve damage and seizures. Patients may also experience issues such as memory loss, a decline in cognitive thinking abilities, double vision, and headaches. If needed, the patient and their family should be provided with mental health support.

Recognizing Cues and Analyzing Cues

The cues of TBI will be found in the patient's physical examination and test results. The findings should reveal whether the patient has TBI, and if so, the nature and severity of the injury.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

TBI treatment should be prioritized based on the severity of the symptoms. The nursing interventions appropriate for patients with TBI may include those in Table 17.23.

Nursing Care	Rationale
Complete focused neurological assessments.	The patient's pain levels, cognitive abilities, and other symptoms may indicate TBI.
Monitor vital signs.	Changes in the patient's vital signs such as heart rate and blood pressure may indicate health issues. Patient may also show signs of infection.
Provide care before and after surgery.	Some patients with TBI may need surgery. Nurses should help patients prepare for surgery and provide care after surgery, such as dressing patients' wound(s), maintaining oxygenation, positioning the patient, monitoring ICP, and assessing with GCS.
Administer medications.	Patients may need medication to help with pain relief. Other medications that can help limit additional damage to the brain following an injury include antiseizure and coma-inducing drugs. Some patients may need diuretics to help with fluid retention.
Help prevent seizures and provide seizure care.	In some patients, traumatic brain injuries can cause seizures. Nurses should take actions to help prevent seizures, such as low lighting, and provide care to help patients during a seizure, such as safe bedding and pillows.
Coordinate with therapists.	As they recover, some patients need therapy to regain skills and overcome problems incurred by traumatic brain injury. This may include speech, physical, and/or occupational therapists.

TABLE 17.23 Nursing Interventions for Patients with TBI

Evaluation of Nursing Care for the Patient with Traumatic Brain Injury

The desired outcome for patients with TBI is recovery from the injury and relief of their symptoms. If their symptoms cannot be relieved, the desired outcome is to help them control and manage their symptoms, overcoming any losses in skills and functioning.

Medical Therapies and Related Care

The medical therapies used to help patients with TBI may include surgery, medications, and therapy. Depending on the severity of their injury and symptoms, some patients may need rehabilitation and long-term care to recover.

Spinal Cord Injuries

A **spinal cord injury** is damage to any area of the spinal cord, including the nerves and nerve fibers that transmit signals from the brain. Spinal cord injuries may involve the spinal cord and/or the bones and tissues that surround the spinal cord. As with TBIs, spinal cord injuries can be caused by various events, including automobile accidents, falls, sports injuries, and violence. Infections that cause abscesses on the spinal cord can also result in spinal cord injuries.

Pathophysiology

Like TBIs, spinal cord injuries may cause temporary or permanent damage to the body. Depending on the nature of a spinal cord injury, the patient may experience issues with strength, movement, feeling, and functioning in areas of the body below the injured area.

Spinal cord injuries fall into two categories—incomplete and complete. With incomplete injuries, the spinal cord retains some capability to communicate with the brain, enabling patients to maintain some functioning, muscle control, and feeling below the injured area. In complete injuries, patients lose all nerve communication below the injured area, leading to a total loss of functioning, muscle control, and feeling below the injured area.

Spinal cord injuries may also lead to paralysis. A form of paralysis from a spinal cord injury known as **paraplegia** affects some or all of the truck, pelvic organs, and legs. But with paraplegia, patients can still move their arms. A form of paralysis from a spinal cord injury that is known as **tetraplegia**, or **quadriplegia**, affects patients' arms and hands, as well as their trunk, pelvic organs, and legs.

Clinical Manifestations

Typically, the symptoms of a spinal cord injury include the inability to move, pain and/or stinging sensations, muscle weakness, numbness and tingling, balance and coordination difficulties, spasms and/or exaggerated reflexes, loss of bladder and/or bowel control, decreased or lost sensations, and sexual dysfunction. Some patients also experience difficulty breathing.

Assessment and Diagnostics

To assess and diagnose a spinal cord injury, patients should undergo a physical examination that gathers information about the incident that led to the injury and the symptoms the patient is experiencing. This includes impairments, such as the patient's range of motion, muscle weakness, and level of sensations. This also includes the patient's sensory functions as determined by pinpricks and touching. Patients may also need tests such as x-rays, MRIs, and CTs to reveal fractures and other damage to the spine.

Nursing Care of the Patient with Spinal Cord Injury

As with patients who have TBIs, nursing care for the patient with a spinal cord injury should focus on helping the patient recover if possible. If the patient has permanent health issues as a result of the injury, nursing care should focus on helping the patient adjust and learn to manage the new health issues. If needed, the patient and their family should be provided with mental health support.

Recognizing Cues and Analyzing Cues

The cues of a spinal cord injury will be found in the patient's physical examination and test results. In addition to the patient's symptoms, such as pain and inability to move, the findings may include results such as bone fractures and swelling that reveal whether the patient has a spinal cord injury, and if so, the nature and severity of the injury.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Spinal cord injuries should be prioritized based on the severity of the symptoms. The nursing interventions

appropriate for patients may include those in Table 17.24.

Nursing Care	Rationale
Complete focused neurological assessments.	The patient's pain levels and other symptoms, such as ability to move, indicate if a spinal cord injury is present and its severity.
Monitor vital signs.	Changes in the patient's vital signs such as heart rate and blood pressure may indicate health issues. In particular, patients may exhibit signs of shock.
Provide care before and after surgery.	Some patients with spinal cord injury may need surgery. Nurses should help patients prepare for surgery and provide care after surgery, such as dressing patients' wound(s).
Administer medications.	Patients may need medication to help with pain relief.
Assist with traction.	Some patients may need to be placed in traction to keep them immobile and help realign their spine.
Coordinate with therapists.	As they recover, some patients need therapy to regain skills and overcome problems incurred by spinal cord injury. This may include physical and/or occupational therapists.

TABLE 17.24 Nursing Interventions for Patients with a Spinal Cord Injury

Evaluation of Nursing Care for the Patient with Spinal Cord Injuries

The desired outcome for patients with spinal cord injuries is relief of their symptoms. If their symptoms cannot be relieved, the desired outcome is to help them control and manage their symptoms.

Medical Therapies and Related Care

The medical therapies used to help patients with spinal cord injuries may include surgery, medications, and therapy. The medications that may be useful include steroid injections to reduce swelling, as well as nonsteroidal anti-inflammatory drugs, which can also relieve pain and swelling. Some patients may benefit by taking corticosteroids for swelling, and for short-term pain relief, opioids may benefit some patients. For muscle pains and spasms, patients may benefit from drugs such as tizanidine and diazepam. To deal with pain, as well as depression, some patients may find serotonin-norepinephrine reuptake inhibitors helpful. Depending on the severity of their injury and symptoms, some patients may need rehabilitation and long-term care to recover.

Summary

17.1 Intracranial Pressure Changes

- In neurology and neurosurgery, the Monro-Kellie doctrine establishes relationships among brain, blood, and cerebrospinal fluid (CSF) volumes within a skull's rigid confines. Any increase or decrease in one of these components must be counterbalanced with an increase or decrease in one or both other components to maintain a stable intracranial pressure (ICP) in the brain.
- Increased intracranial pressure (IICP) is a serious clinical issue that requires rapid assessment and intervention.
- IICP may be caused by cerebral edema, displacement of brain tissue, impaired blood flow, trauma, or tumors.
- Decreased ICP, a less serious clinical issue (but still in need of treatment), may be due to dehydration, CSF leak, hemorrhage, or brain atrophy.
- Nursing interventions for both increased and decreased ICP include monitoring neurological status and vital sign changes, providing a quiet and calm environment, monitoring and maintaining fluid and electrolyte balance, managing headache pain, oxygenation and ventilation support, recognizing and notifying the provider of any worsening trends, and providing education and support to the patient and their family.
- Nursing care for patients with either increased or decreased ICP must be evaluated to determine efficacy. This is accomplished by using clinical judgment and reviewing nursing interventions to determine if they addressed the patient's concerns.
- Medical therapies to address increased ICP focus on treating the underlying cause of ICP and may include medications, surgical interventions, and shunt systems.
- Medical therapies to address decreased ICP may include interventions, such as epidural blood patches, to stop fluid leaks in the brain as well as therapies, such as salt tablets, to address dehydration.

17.2 Acute Disorders of the Nervous System

- Brain tumors, Guillain-Barré syndrome (GBS), and meningitis are serious threats to neurological well-being that require prompt medical attention.
- Brain tumors, which are the uncontrolled proliferation of abnormal cells within the brain, may produce symptoms such as headaches, seizures, and neurological deficits.
- Brain tumors are typically diagnosed through imaging studies and tissue biopsies and can be benign or malignant. Treatments for brain tumors include surgery, radiation, and chemotherapy.
- Guillain-Barré syndrome is an autoimmune disorder that causes peripheral nerve inflammation and muscle weakness. Commonly caused by infections, GBS may present with ascending paralysis that can progress rapidly.
- GBS can be diagnosed with lumbar punctures, nerve conduction studies, and EMG. Treatment for GBS may include plasma exchange and immunoglobulin therapy. Nursing care goals are to alleviate symptoms, such as fatigue, numbness, or weakness, and help the patient return to normal peripheral nervous system function.
- Meningitis, which is inflammation of the meninges surrounding the brain and spinal cord, may produce symptoms, such as sudden-onset fever, severe headaches, neck stiffness, skin rashes, and petechiae.
- Meningitis can be diagnosed with blood tests, cerebrospinal fluid lumbar punctures, and CT or MRI imaging. Treatments for meningitis may include antibiotics, skin care, and anti-inflammatory medications. Adequate nursing care can alleviate symptoms and prevent long-term effects.

17.3 Chronic Disorders of the Nervous System

- Multiple sclerosis and myasthenia gravis are both chronic autoimmune neurological disorders.
- MS is caused by inflammation, demyelination, and neurodegeneration of the nerve cells.
- MG is caused by the body's production of hyperreactive antibodies that block acetylcholine receptors on muscle fibers, prohibiting communication to the nerves.
- MS manifestations include muscle weakness, lack of coordination, vertigo, eyesight and hearing issues, balance issues, bladder and bowel dysfunction, and cognitive issues.
- MG manifestations include difficulty breathing, vision problems, difficulties with swallowing and speaking, facial movement difficulties, and weakness in voluntary muscles.
- MS treatments may include corticosteroids, plasmapheresis, injections, infusions, and oral treatments. Muscle

relaxants, pain relievers, and physical therapy may also be useful.
- MG treatments may include corticosteroids and intravenous therapy. Surgery may be needed for patients with MG who have a thymus gland tumor.
- Patients with MG may face a life-threatening situation if their disease causes breathing difficulties. In these circumstances, patients will need immediate medical attention, which may include treatments such as inhaled bronchodilators and/or inhaled steroids, as well as a ventilator.
- Neither MS nor MG is curable, and patients must learn to cope with the disease. Some patients may need mental health support to do this.

17.4 Major Neurocognitive Disorder and Neurodegenerative Diseases

- MND is the decline in cognitive abilities, such as memory and reasoning, in a manner that disrupts patients' daily lives.
- MND refers to a group of disorders characterized by neurological changes that make it more challenging for patients to continue routine activities.
- MND occurs when the brain's neurons, or nerve cells, die after they become inactive and lose their connections to other brain cells.
- The symptoms of MND include cognitive problems, such as memory loss and confusion, as well as psychological issues, such as personality changes and feelings of paranoia.
- MND is diagnosed with a physical examination and diagnostic tests, such as lumbar punctures and PET scans. Cognitive and neurological tests that evaluate problem-solving skills, sensory responses, reflexes, and other cognitive abilities provide further evidence of MND.
- MND cannot be cured. But the condition can be managed with medications, such as cholinesterase inhibitors and memantine, as well as treatments, such as occupational therapy and mental health support.
- A neurodegenerative disease is an incurable chronic condition that damages the brain and central nervous system, causing problems with cognitive abilities as well as physical movement. Alzheimer disease, ALS, and Parkinson disease are some of the more common neurodegenerative diseases.
- Amyotrophic lateral sclerosis (ALS) is a disease of the central nervous system that affects the brain and spinal cord's motor neurons, causing patients to lose control of their muscles.
- ALS typically begins with stiffness and weakness in the muscles that control the limbs, including the legs and arms, before spreading to muscles that control vital functions, such as breathing. The disease also affects cognitive abilities, changing a patient's behavior and their ability to think.
- Alzheimer disease is a disorder in the brain that gradually destroys patients' memory and thinking abilities. In addition to being a neurodegenerative disease, Alzheimer disease is the most common form of MND, accounting for at least 60 percent of MND cases.
- Typically, Alzheimer disease affects memory first before spreading to affect other brain functioning. The symptoms often experienced by patients with Alzheimer disease include personality changes, social withdrawal, moodiness, aggressive behavior, delusions, and depression.
- Parkinson disease is an incurable brain disorder that affects the nervous system, causing body parts controlled by nerves to have movements that are unintended and uncontrollable.
- Symptoms of Parkinson may include tremors, stiffness and contractions in muscles, bradykinesia, loss of balance and coordination, difficulty speaking and swallowing, loss of automatic movements such as blinking, constipation and urination issues, blood pressure irregularities, sleep disorders, fatigue, MND, and depression.
- For all patients who have Alzheimer disease, ALS, and Parkinson disease, the overall goal of nursing care is to help the patients manage the disease and improve their quality of life as much as possible.

17.5 Seizures

- A seizure occurs when some of the brain's neurons experience sudden and uncontrolled electrical activity, sending incorrect messages between brain cells, causing the body to react with involuntary movements and behavior, as well as changes in consciousness and feelings.
- Seizures come in several types and have various causes. Some patients experience seizures because they have epilepsy, an incurable neurological disease that causes recurring seizures.
- Seizures can be triggered by a variety of factors, including high fever, brain tumors, strokes, head trauma, heart attacks, infections, diseases, alcoholism, stress, sleep deprivation, hormonal changes, dehydration, and

certain medications.

- Seizures are categorized as either focal, which begin in one area of the brain, or generalized, which affect both sides of the brain at the same time.
- Focal seizures include onset awareness and onset impaired awareness.
- Generalized seizures include absence, atonic, clonic, myoclonic, tonic, and tonic-clonic.
- Seizures may have three phases, including prodrome, which occurs before the seizure actually begins and includes warning signals; ictal, which is the actual seizure; and postictal, which is the recovery period after a seizure ends.
- The symptoms of seizures vary and can be mild or severe. Common symptoms include confusion, staring, uncontrollable twitching or jerking of the arms and legs, body spasms, stiffened and/or weakened muscles, loss of awareness or consciousness, anxiety and fear, and a feeling of déjà vu.
- Nursing care for patients with seizures should focus on identifying the cause of the seizures and curing that cause, if possible, to stop the seizures. If the cause is a condition or disease that cannot be cured, such as epilepsy, nursing care should focus on controlling symptoms and helping patients and their families learn to live with and manage seizures.

17.6 Polyneuropathy

- Polyneuropathy is a peripheral nerve disorder that occurs when multiple peripheral nerves all over the body are damaged and malfunction simultaneously.
- Polyneuropathy can disrupt nerve communication in several ways. For example, lost nerve signals should occur but do not, whereas other nerve signals occur at inappropriate times, and still other signals occur when they should but deliver an error message.
- Polyneuropathy is a serious condition that can disrupt life and cause unpleasant symptoms, such as pain. But generally, polyneuropathy is not life-threatening.
- Polyneuropathy may be caused by health conditions such as infections or tumors, or by alcoholism, vitamin deficiencies, exposure to toxins, and peripheral nerve injuries. The most common cause is diabetes.
- Symptoms vary depending on whether polyneuropathy affects the motor, sensory, or autonomic nerves. Common symptoms include muscle weakness, uncontrolled twitching, loss of reflexes, numbness, feeling of pins and needles, burning sensations, heat intolerance, and gastrointestinal issues. Some patients also experience dizziness from drops in blood pressure and breathing difficulties if the muscles that control the lungs are affected.
- Polyneuropathy is assessed and diagnosed with a physical examination as well as tests, such as blood and urine tests, lumbar puncture, imaging tests, spirometry, EMG, and nerve conduction studies.
- Nursing care for patients with polyneuropathy focuses on identifying the cause of the patient's condition. If patients cannot be cured of polyneuropathy, nursing care should focus on helping the patient understand polyneuropathy and learn how to control and manage the symptoms.

17.7 Chronic Pain Disorders

- Chronic pain refers to any type of pain, such as a headache or lower back pain, that is ongoing and continues for longer than three months.
- Migraines are a serious neurological disease with headache pain so severe that it disrupts routine activities.
- Migraines may be caused by factors including family genetics, stress, anxiety, tobacco, alcohol, foods such as cheese, low blood sugar, irregular sleep patterns, concussions, hormonal changes, and chemical imbalances in the brain.
- Migraines may progress through four stages—prodrome, aura, attack, and postdrome.
- Prodrome symptoms may include mood changes, food cravings, and uncontrollable yawning. Aura symptoms may include muscle weakness, loss of eyesight, and speaking difficulties. During the attack, the migraine headache may be accompanied by sensitivity to sound, light, touch, and/or smell, as well as nausea. In the postdrome stage, patients may experience exhaustion, confusion, and/or elation.
- Generally, migraines are incurable, but migraines can be treated, and nursing care can help patients learn techniques to prevent migraines and manage them when they do occur.
- Fibromyalgia is a chronic, incurable condition that affects soft tissues and muscles throughout the body, causing musculoskeletal pain and tenderness. It does not damage the body's muscles or bones, but the pain

can disrupt daily routines.

- The cause of fibromyalgia is unknown, but it has been linked to factors such as stress, sleep disorders, migraines, lupus, rheumatoid arthritis, osteoarthritis, chronic back pain, irritable bowel syndrome, anxiety, and depression, as well as endocrine, biochemical, and immune disorders.
- In addition to pain throughout the body, common symptoms of fibromyalgia include fatigue, headaches, restless legs, stiff joints, numbness, tingling, sensitivity to things such as touch and light, fibro fog, constipation, bladder disorders, and painful menstrual periods.
- Fibromyalgia generally is diagnosed with a physical examination and blood tests focused on ruling out other conditions and diseases that cause similar pain, such as rheumatoid arthritis.
- To have a fibromyalgia diagnosis, patients must experience ongoing pain for at least three months in at least four body areas, such as the jaw, neck, shoulders, arms, legs, back, chest, and buttocks.
- Nursing care for patients with fibromyalgia should focus on controlling symptoms and helping patients learn how to manage their condition.

17.8 Spinal Disorders

- Spinal disorders refer to diseases or injuries that affect the spinal cord and back.
- Low back pain refers to any feeling of aching, burning, or stabbing in the muscles of the lower back. When low back pain lasts longer than twelve weeks, it is considered a chronic condition.
- Common causes of low back pain include injuries, strains, and sprains, herniated disks, lumbar spinal stenosis, osteoarthritis, osteoporosis, axial spondyloarthritis, sciatica, scoliosis, and spondylolisthesis.
- Low back pain can be classified as acute, subacute, or chronic.
- Risk factors for low back pain include obesity, lack of exercise, using improper techniques for lifting, age, smoking, anxiety, depression, and arthritis.
- Symptoms of low back pain may include pain that comes and goes, decreased range of motion, difficulty standing straight, weakness in legs and/or feet, bowel and/or bladder issues, fever, and unexplained weight loss.
- Nursing care for patients with low back pain should focus on finding the cause of the pain and treating that cause with the goal of relieving the back pain. For patients with chronic back pain, nursing care should focus on helping patients control and manage the pain.
- Spinal tumors are growths of abnormal tissue inside or encompassing the spinal column or the spinal cord. Spinal tumors can be benign (noncancerous) as well as malignant (cancerous).
- When spinal tumors originate in the spine or the spinal cord, they are considered primary tumors. If they originate elsewhere in the body and spread to the spine, they are considered secondary, or metastatic, tumors.
- Factors that may create a risk for spinal tumors include defective genes, exposure to toxins, a compromised immune system, Von Hippel-Lindau disease, and neurofibromatosis 2.
- Symptoms of spinal tumors may include localized pain at the tumor site, low back pain, muscle weakness, stiff back or neck, difficulty walking, paralysis, loss of sensitivity, and loss of bladder and/or bowel functioning.
- Nursing care for patients with spinal tumors should focus on support when removing the tumor and curing the patient if possible. For benign tumors that cannot be removed, nursing care should focus on helping the patient learn to cope with the condition. For malignant tumors, nursing care should focus on treating the cancer and, if necessary, help the patient prepare for the end of life.

17.9 Neurological Injuries

- Traumatic brain and spinal cord injuries occur when the brain and/or spinal cord are damaged by trauma, typically in an accident.
- Traumatic brain and spinal cord injuries may cause temporary or long-term problems, depending on the nature and severity of the injury.
- Traumatic brain injuries may be penetrating, when the skull is pieced by a sharp object that enters brain tissue, or nonpenetrating, when the skull is not broken.
- The problems caused by traumatic brain injuries may include the inability to think, communicate, and/or struggle to move body parts.
- Primary traumatic brain injuries occur immediately, whereas secondary injuries occur gradually in response to

reactive processes in the brain caused by the trauma. Secondary injuries may take days, or even weeks, to appear.
- Traumatic brain injuries can have physical, cognitive and behavioral, and/or perception and sensation symptoms. Typically, symptoms such as headache and confusion tend to occur immediately following a traumatic brain injury, whereas symptoms that involve moods and emotions may take longer to develop.
- Spinal cord injuries may be incomplete, with the spinal cord retaining some capability to communicate with the brain, or complete, with patients losing all functioning, muscle control, and feeling below the injured area.
- Symptoms of a spinal cord injury include the inability to move, pain and/or stinging sensations, muscle weakness, numbness and tingling, balance and coordination difficulties, spasms and/or exaggerated reflexes, loss of bladder and/or bowel control, decreased or lost sensations, and sexual dysfunction.
- Nursing care for traumatic brain and spinal cord injuries should focus on helping the patient recover, if possible. For patients with permanent health issues, nursing care should focus on helping the patient adjust and learn to manage the condition.

Key Terms

ablative surgery procedure that destroys the brain tissues that produce abnormal chemical or electrical impulses responsible for the tremors in a patient with Parkinson disease
absence generalized seizure seizure during which the patient stares into space and may have slight twitching
acetylcholine key neurotransmitter essential in muscle contraction
acute back pain sudden pain in the back that typically lasts for a few days to a few weeks
Alzheimer disease disorder in the brain that destroys memory and thinking abilities
amyloid plaque deposits that occur when the brain's beta-amyloid proteins malfunction
amyotrophic lateral sclerosis (ALS) disease of the central nervous system that affects the brain and spinal cord's motor neurons, causing patients to lose control of their muscles
angiogenesis formation of new blood vessels
apoptosis normal, controlled process of cell death
astrocyte star-shaped glial cell that forms part of the brain's supportive tissue
astrocytoma malignant tumor originating in astrocytes
atonic generalized seizure seizure during which the patient loses normal muscle tone, which may cause them to involuntarily drop their head or fall down
attack migraine stage when the headache begins; symptoms during this stage include throbbing or pulsating pain, nausea, and sensitivity to sound, light, touch, and/or smell
aura occurrence that may take place at the beginning of a seizure and may include a sense of déjà vu and/or a sudden feeling of intense emotion such as fear or happiness
autonomic function automatic movements, such as the heart beating, that individuals do not control
autonomic nerve nerve that controls muscles and organs regulating bodily functions that patients cannot control consciously, such as the heart, lungs, and digestive system
axial spondyloarthritis inflammatory disease that affects the spine
basal ganglia areas of the brain where movement is controlled
benign noncancerous
bradykinesia slowed movement as patients attempt to do things such as walk or write
brain atrophy loss of neurons and synapses sometimes caused by disorders such as MND, infections, and cerebral palsy
brain sagging disorder that causes cognitive dysfunction and other issues typically associated with MND. Imaging shows the brain in a sagging position
brain tumor abnormal growth of cells found within the brain or near it
Brudzinski's sign condition characterized by rigidity and passive flexion of the neck with flexion of both legs and thighs
bulbar nerve nerve that holds the jaw in place and controls swallowing, chewing, and speaking processes
cerebral angiography type of x-ray that creates digital images of the anatomy of the brain with a focus on the blood vessels within and around the brain
cerebral perfusion pressure (CPP) net pressure gradient required to ensure sufficient oxygen delivery to the brain and allow optimal pressure levels for proper brain health

cerebral spinal fluid (CSF) colorless fluid found within the subarachnoid space of the meninges of the brain, which surrounds both brain and spinal cord, acting to maintain health and functioning of the brain
chordoma rare, slow-growing benign tumor found at the base of the skull or in the lower spine
chronic back pain back pain that appears suddenly or gradually, occurs daily, and lasts more than twelve weeks
clonic generalized seizure seizure during which the patient has repetitious jerking movements on both sides of their body
contracture shortening and/or hardening of muscles, tendons, and tissues that causes deformity and rigidity in joints
craniopharyngioma benign tumor that typically arises from the pituitary gland and becomes embedded deep in the brain near critical structures
Cushing's triad changes in a patient's vital signs, including widened pulse pressure in systolic blood pressure, bradycardia (low pulse rate), and irregular breathing patterns
decerebrate posturing neurological reflex movement of muscles causing the limbs to extend and hold rigidly at the sides of the body
decorticate posturing neurological reflex movement of muscles causing the limbs to flex and hold rigidly across the chest
deep brain stimulation surgical procedure that implants a device in the brain to produce electrical impulses and disrupt the brain signals causing Parkinson disease
demyelinating disease condition that damages the protective covering of the brain's nerve fibers
dermatome section of the body's skin that depends on nerves connected to the spinal cord
dopamine chemical neurotransmitter in the brain's basal ganglia that is involved in movement, as well as disposition and memory
dura spinal cord's thin covering
ependymoma less common malignant brain tumor that occurs when the ependymal cells that line the ventricular system experience a neoplastic transformation
epidural blood patch process of injecting a small amount of autologous blood into a patient's epidural space to plug the leak
epilepsy neurological disease that causes recurring seizures
exacerbation time period when symptoms are manifested and/or worsened in patients with MS
extradural relating to spinal tumors located outside both the dura and the spinal cord
fasciculation uncontrolled twitching in the muscles
fibro fog cognitive difficulties caused by fibromyalgia that may include difficulty concentrating, lack of alertness, forgetfulness, reduction in thinking skills, and difficulty retrieving information stored in the brain
fibromyalgia chronic condition that affects soft tissues and muscles throughout the body, causing musculoskeletal pain and tenderness
flaccid posturing abnormal body posturing that occurs when muscles lack tension and go limp
focal seizure seizure that begins in one area of the brain
frontotemporal disorder condition that occurs when the brain's frontal and temporal lobe neurons are damaged; condition progressively gets worse and causes personality and behavior changes
gangliocytoma rare benign tumor that involves the neoplastic nerve cells and typically occurs in young adults
generalized seizure seizure that affects both sides of the brain at the same time
glial cell brain's supporting cell that provides nourishment to neurons
glioblastoma multiforme (GBM) most invasive of the malignant glial tumors
glioma malignant brain tumor produced from the brain's glial cells
glomus tumor rare benign tumor that occurs in the head and neck, often near the jugular vein
Guillain-Barré syndrome (GBS) rare autoimmune disease in which the immune system attacks the peripheral nervous system, affecting motor function
herniated disk compression in the disk in the spine, irritating nearby nerves
herniation protrusion of tissue that can displace the brain
ictal relating to the phase of a seizure that begins with the first symptom and lasts until the seizure ends
increased intracranial pressure (IICP) increase in intracranial pressure that occurs as a result of factors such as changes to blood volume, changes in the rates of CSF production and absorption, fluctuations in brain tissue volume, and obstruction of CSF flow

intracranial pressure (ICP) pressure within the rigid confines of a skull in which brain tissue, blood, and CSF exist together
intradural-extramedullary relating to spinal tumors located on the inside of the dura but outside the actual spinal cord
intramedullary relating to spinal tumors located on the inside of the spinal cord
Kernig's sign condition characterized by the inability to fully extend the knee when the hip is flexed at a 90-degree angle while the patient is supine
Lewy body dementia condition that occurs when the brain has abnormal deposits of protein; condition progresses slowly and changes a patient's ability to think and concentrate
low back pain feeling of aching, burning, stabbing, or shooting pains in the muscles of the lower back
lumbar spinal stenosis narrowing of the spinal cord in the lower back, putting pressure on the nerves
lumbar spine five vertebrae that comprise the lower section of the spine found between the body's ribs and pelvis
major neurocognitive disorder (MND) group of disorders characterized by neurological changes that make it more challenging for patients to continue routine activities
malignant describing a cancerous growth that harms normal tissue by invading and spreading
medulloblastoma malignant, high-grade brain tumor that typically occurs in children, affecting the cerebellum
meningioma the most common type of benign intracranial tumor that begins growing in the meninges around the brain and spinal cord
meningitis (also: *meningoencephalitis*) an inflammation of the meninges, which are the membranes covering both brain and spinal cord
metastatic brain tumor secondary tumor that originates outside the brain, such as in the lung or breast tissue, and spreads into brain tissue
metastatic spinal tumor tumor that originates elsewhere in the body and spreads to the spine
migraine serious neurological disease characterized by a severe, throbbing pain or pulsing sensation that affects one side of the head
Monro-Kellie doctrine principle that intracranial volume remains constant while within rigid skull constraints
motor nerve nerve that controls muscles that patients voluntarily control, such as those used to talk and walk
multiple sclerosis (MS) autoimmune condition of the central nervous system characterized by inflammation, demyelination, and neurodegeneration
myasthenia gravis (MG) autoimmune neuromuscular condition caused by the body's production of hyperreactive antibodies that block acetylcholine receptors on muscle fibers, prohibiting communication to the nerves and affecting voluntary muscles
myoclonic generalized seizure seizure during which the patient has twitches and/or jerks in the arms, upper body, or legs
neoplastic transformation when oncogenes are activated while tumor suppressor genes are inactivated
neurodegenerative disease chronic condition that damages the brain and central nervous system, causing problems with cognitive abilities and physical movement
neurofibrillary tangle disorganized structure that results when the brain's tau proteins malfunction
neurofilament light chain (NfL) protein that increases when neurons are damaged; patients with ALS typically have a high serum level of NfL
neuromuscular junction point where nerve impulses meet muscles to create movement
nonpenetrating relating to brain injuries that occur when the assault is strong enough to move the brain around inside the skull, but the skull is not broken
norepinephrine primary chemical messenger for the sympathetic nervous system, which controls bodily functions such as blood pressure and heart rate
oligodendroglioma malignant brain tumor occurring in the cells that produce the brain's myelin, which insulates the brain's wiring
oncogene mutated proto-oncogene that can cause cancer
onset awareness focal seizure in which the patient is awake and aware
onset impaired awareness focal seizure in which the patient is confused and not fully aware
orthostatic hypotension sudden drop in blood pressure when standing up or sitting down
osteoarthritis inflammation in the joints that can occur in the spine
osteoporosis skeletal disorder that causes bones to lose mass and possibly fracture; when this occurs in the

spine, the fractures cause low back pain

papilledema swelling in the eye's optic disks

paraplegia form of paralysis from a spinal cord injury that affects some or all of the trunk, pelvic organs, and legs, but patients can still move their arms

paresthesia abnormal sensations of burning, prickling, and tingling

Parkinson disease brain disorder that affects the nervous system, causing body parts controlled by nerves to have movements that are unintended and uncontrollable

penetrating relating to brain injuries that occur when the skull is pieced by a sharp object that enters brain tissue

peripheral nervous system division of the nervous system that contains the nerves that travel from the brain and spinal cord to carry signals to the rest of the body

petechiae round spots on the skin caused by bleeding in the skin

phonophobia aversion to loud noises

photophobia increased sensitivity to light

pituitary adenoma common type of benign tumor that begins in the pituitary gland

polyneuropathy peripheral nerve disorder that occurs when multiple peripheral nerves all over the body are damaged and malfunction simultaneously

postdrome migraine stage that may last up to twenty-four hours after the headache is over; postdrome symptoms include exhaustion, confusion, and elation

postictal relating to the recovery period after a seizure ends when patients may experience issues such as confusion, anxiety, memory lapses, headache, muscle weakness, and loss of bladder control

primary brain tumor tumor that originates within the brain or the area surrounding the brain; may be benign or malignant

primary injury injury that occurs immediately after a traumatic brain injury happens

primary spinal tumor tumor that originates in the spine or the spinal cord

prodrome phase before a seizure actually begins; includes warning signals that indicate a seizure is going to happen

proto-oncogene gene that enables cells to stay alive by growing and dividing properly

ptosis vision problem that includes double vision and drooping eyelids

quadriplegia (also: **tetraplegia**) paralysis from a spinal cord injury that affects patients' arms and hands, as well as their trunk, pelvic organs, and legs

remission time period when symptoms disappear or minimize for patients with MS

schwannoma common type of benign brain tumor found in adults near nerves

sciatica compression of the sciatic nerve in the lower back by a bone spur or herniated disk

scoliosis condition that causes the spine to curve sideways

secondary injury injury that occurs gradually in response to reactive processes in the brain that are caused by the trauma

seizure sudden and uncontrolled electrical activity in of the brain's neurons, sending incorrect messages between brain cells

seizure threshold likelihood that a patient will have a seizure

sensory nerve nerve that transmits messages about pain, temperature, feelings, and other information gathered by the senses

somatic function conscious movement that individuals control

spinal cord injury damage to any area of the spinal cord, including the nerves and nerve fibers that transmit signals from the brain

spinal disorder disease or injury that affects the spinal cord and back

spinal tumor growth of abnormal tissue inside or encompassing the spinal column or the spinal cord

spondylolisthesis condition in which a vertebra slips out of place in the spine

subacute back pain back pain that may occur suddenly or gradually and usually lasts four to twelve weeks

tetraplegia (also: **quadriplegia**) paralysis from a spinal cord injury that affects patients' arms and hands, as well as their trunk, pelvic organs, and legs

thymus gland gland that can produce antibodies that block acetylcholine; if the gland has a tumor and malfunctions, it may contribute to MG

tonic generalized seizure seizure during which the patient's muscles stiffen, typically in the arms, legs, and/or

back

tonic-clonic generalized seizure seizure during which the patient has a combination of reactions that may include repetitious jerking, stiffening, and/or a loss of consciousness

traumatic brain injury (TBI) damage that results when the brain experiences a sudden assault from an external source

vascular dementia condition that occurs when the brain does not have sufficient blood and oxygen, resulting in damage to the brain's blood vessels; condition may affect all aspects of a patient's cognitive abilities, including behavior, memory, and reasoning

vertigo sensation that causes patients to feel dizzy, sometimes as if they are spinning or in motion while still

Assessments

Review Questions

1. What is Cushing's triad?
   a. changes in body posture that occur when muscles lack tension and go limp
   b. changes in vital signs including widened pulse pressure, bradycardia, and irregular breathing.
   c. changes in body posture that occur when patients hold their arms and legs out straight
   d. changes in vital signs including decreased pulse pressure, bradycardia, and vertigo

2. When a patient is upright, what is considered normal ICP?
   a. no more than 7 mm Hg
   b. between 7 and 15 mm Hg
   c. no more than 15 mm Hg
   d. no less than 15 mm Hg

3. Why should patients with decreased ICP be placed in flat HOB position?
   a. to control headaches and dizzy spells
   b. to increase ICP
   c. to provide more accurate ICP readings for comparison to baseline levels
   d. to maintain the patient's airway and support oxygenation

4. What are metastatic brain tumors?
   a. tumors that originate elsewhere in the body and spread into brain tissue
   b. tumors that originate in brain tissue
   c. tumors that are cancerous and spread aggressively through the brain's tissue layers
   d. tumors that are noncancerous and rarely spread

5. Why should some patients avoid Valsalva maneuvers?
   a. to decrease the likelihood of causing temporary paralysis
   b. to decrease blood pressure and heart rate
   c. to decrease pressure in the skull caused by coughing, bowel straining, etc.
   d. to decrease experiences of photophobia and phonophobia

6. Why does blocking acetylcholine receptors cause myasthenia gravis?
   a. Communication between nerves and muscle is inhibited, leading to damage in the myelin sheath's protective covering.
   b. Communication with antibodies is inhibited, leading to weakness in the thymus gland.
   c. Communication between nerves and muscle is inhibited, leading to muscle fatigue and weakness.
   d. Communication with antibodies is inhibited, leading to the creation of sclerosis scar tissue.

7. What is plasmapheresis?
   a. process of removing a patient's plasma and replacing it with antibodies
   b. process of removing a patient's plasma, mixing it with saline, and putting it back in the patient's body

c. process of removing a patient's plasma and replacing it with white blood cells
d. process of removing a patient's plasma, mixing it with a protein solution, and putting it back in the patient's body

8. What causes vascular dementia?
a. damage to the brain's blood vessels caused by insufficient blood and oxygen
b. damage to the brain's blood vessels caused by abnormal deposits of protein
c. damage to the brain's blood vessels caused by growths in the frontal and temporal lobe neurons
d. damage to the brain's blood vessels caused by an increase in antibodies

9. When treating patients with ALS, what unusual behavior should nurses watch for?
a. delusions
b. untimely laughing or crying
c. forgetting people they know well
d. getting lost in familiar surroundings

10. How can antiamyloid treatments help patients with Alzheimer disease?
a. by removing beta-amyloid, antibodies that block nerve communication
b. by stopping the inhibition of beta-amyloid, a protein that is vital for nerve communication
c. by removing beta-amyloid, a protein that can develop into plaques
d. by stopping the inhibition of beta-amyloid, antibodies necessary to develop plaques

11. When a patient has a tonic seizure, what happens?
a. The patient's body has repetitious jerking movements.
b. The patient's muscles have twitches and/or jerks.
c. The patient's body has a combination of jerking and stiffening.
d. The patient's muscles stiffen.

12. What is the difference between focal and generalized seizures?
a. Focal seizures affect the entire body, whereas generalized seizures are restricted to one body part.
b. Focal seizures begin in one area of the brain, whereas generalized seizures affect both sides of the brain at the same time.
c. Focal seizures have more obvious symptoms, whereas generalized seizures are milder.
d. Focal seizures are life-threatening, whereas generalized seizures are less risky.

13. What surgical treatment for seizures disconnects the side of the brain that has seizures from the rest of the brain and body?
a. lobectomy
b. corpus callosotomy
c. hemispherotomy
d. thermal ablation

14. What type of patients are likely to develop polyneuropathy?
a. patients with cancer
b. patients with Alzheimer disease
c. patients with multiple sclerosis
d. patients with diabetes

15. How can scrambler therapy help patients with polyneuropathy?
a. by blocking nerve endings from sending pain signals to the brain
b. by removing inflammation that causes polyneuropathy
c. by shrinking tumors that cause polyneuropathy
d. by blocking neurostimulators from sending pain signals to the brain

16. How can antiseizure drugs help patients with fibromyalgia if they are not having seizures?
   a. Antiseizure drugs can also treat restless legs.
   b. Antiseizure drugs can help with constipation and/or bladder issues.
   c. Antiseizure drugs can also treat pain.
   d. Antiseizure drugs can help with fibro fog.

17. What criteria must patients meet before their condition can be diagnosed as fibromyalgia?
   a. ongoing pain for at least six months in at least three body areas
   b. ongoing pain for at least three months in at least three body areas
   c. ongoing pain for at least three months in at least four body areas
   d. ongoing pain for at least six months in at least four body areas

18. What stage of a migraine may be characterized by uncontrollable yawning and cravings for certain foods?
   a. prodrome
   b. aura
   c. attack
   d. postdrome

19. What stage of a migraine may be characterized by both confusion and elation?
   a. prodrome
   b. aura
   c. attack
   d. postdrome

20. If a patient's low back pain is caused by a herniated disk, how is this diagnosed?
   a. electrophysiological test
   b. imaging, such as an MRI or CT scan
   c. nerve conduction study
   d. blood test

21. What type of spinal tumor is located on the inside of the spinal cord?
   a. intramedullary
   b. extradural
   c. dura
   d. intradural-extramedullary

22. How can traction help patients with spinal cord injuries?
   a. help them recover from shock
   b. keep them from developing inflammation after surgery
   c. help them regain skills affected by the injury
   d. keep them immobile and help realign their spine

23. What type of traumatic brain injuries occur gradually in response to reactive processes in the brain that result from trauma?
   a. penetrating
   b. primary
   c. nonpenetrating
   d. secondary

24. For patients with traumatic brain injury, what does the Glasgow Coma Scale assess?
   a. patient's cognitive thinking abilities
   b. patient's swelling and bleeding on the brain
   c. patient's consciousness level

d. patient's pain levels

Check Your Understanding Questions

1. Between increased intracranial pressure and decreased intracranial pressure, which one is an acute medical condition that needs immediate attention and why?
2. Typically, how is ALS diagnosed?
3. What is neurofilament light chain, how is it detected, and why is it important to patients with ALS?
4. What is the prodrome phase of a seizure, and what happens during this phase?
5. What causes a seizure?
6. What is a migraine?
7. What other health conditions can cause symptoms similar to fibromyalgia, and how are these conditions ruled out as a cause for the patient's symptoms?
8. What is the difference between paraplegia and tetraplegia?

Reflection Questions

1. What is the basic principle of the Monro-Kellie doctrine and why is it important?
2. A multiple sclerosis patient is thrilled because their symptoms have disappeared, and they declare themselves cured. But MS cannot be cured. How would you explain to the patient what they are experiencing?
3. A patient appears anxious, confused, and scared, and they have lost control of their bladder and bowel. They also have a headache and muscle weakness, but they cannot remember anything from earlier in the day. What is likely going on with this patient?
4. A patient is frustrated because they cannot function normally and are confident that they have fibromyalgia. They want to begin treatment. But their doctor will not diagnose their condition as fibromyalgia because the symptoms have been ongoing for six weeks and affect only the patient's neck and shoulders. Why is the doctor unwilling to diagnose the patient's condition as fibromyalgia?

What Should the Nurse Do?

1. A patient is being treated for a brain tumor and is at risk for a seizure. What steps should the nurse take to implement seizure precautions?
   a. Keep the head of the bed elevated 90 degrees, provide bedside padding, and have a ventilator nearby.
   b. Keep the bed in the lowest position with the side rails up, provide bedside padding, and have suction equipment set up nearby.
   c. Keep the head of the bed elevated 45 degrees, provide bedside padding, and have suction equipment set up nearby.
   d. Keep the bed in a high position with the side rails up, provide bedside padding, and have a ventilator nearby.

2. An older adult patient is wandering the hallways and seems confused. The patient is unable to state their name, and they also do not know where they are. While trying to answer questions, the patient becomes agitated. What is the nurse's first priority with this patient?
   a. Find the patient's family so they can take the patient home.
   b. Conduct a physical examination of the patient.
   c. Get the patient to a safe, secure location.
   d. Give the patient medicine to help them feel calmer.

3. A patient is being treated for a spinal tumor and has just learned that the tumor is benign and cannot be removed. What should the nurse do?

a. Coordinate with the patient's primary care physician and help them make end-of-life preparations.
b. Provide the patient with educational materials and help them learn how to live with the tumor.
c. Provide the patient with educational materials and help them make end-of-life preparations.
d. Recommend that the patient seek a second opinion.

Competency-Based Assessments

1. Explain each grade—1, 2, 3, and 4—of brain tumors. Be creative and prepare a handout for your patients that helps them understand each grade.
2. Develop a concept map to compare and contrast the types of nerves affected by polyneuropathy, and specify what each set of nerves does.
3. Create several slides describing and explaining the concept of fibro fog and how it affects patients.
4. What are the three classifications of low back pain? Briefly explain each.

CHAPTER 18
Sensory Organs

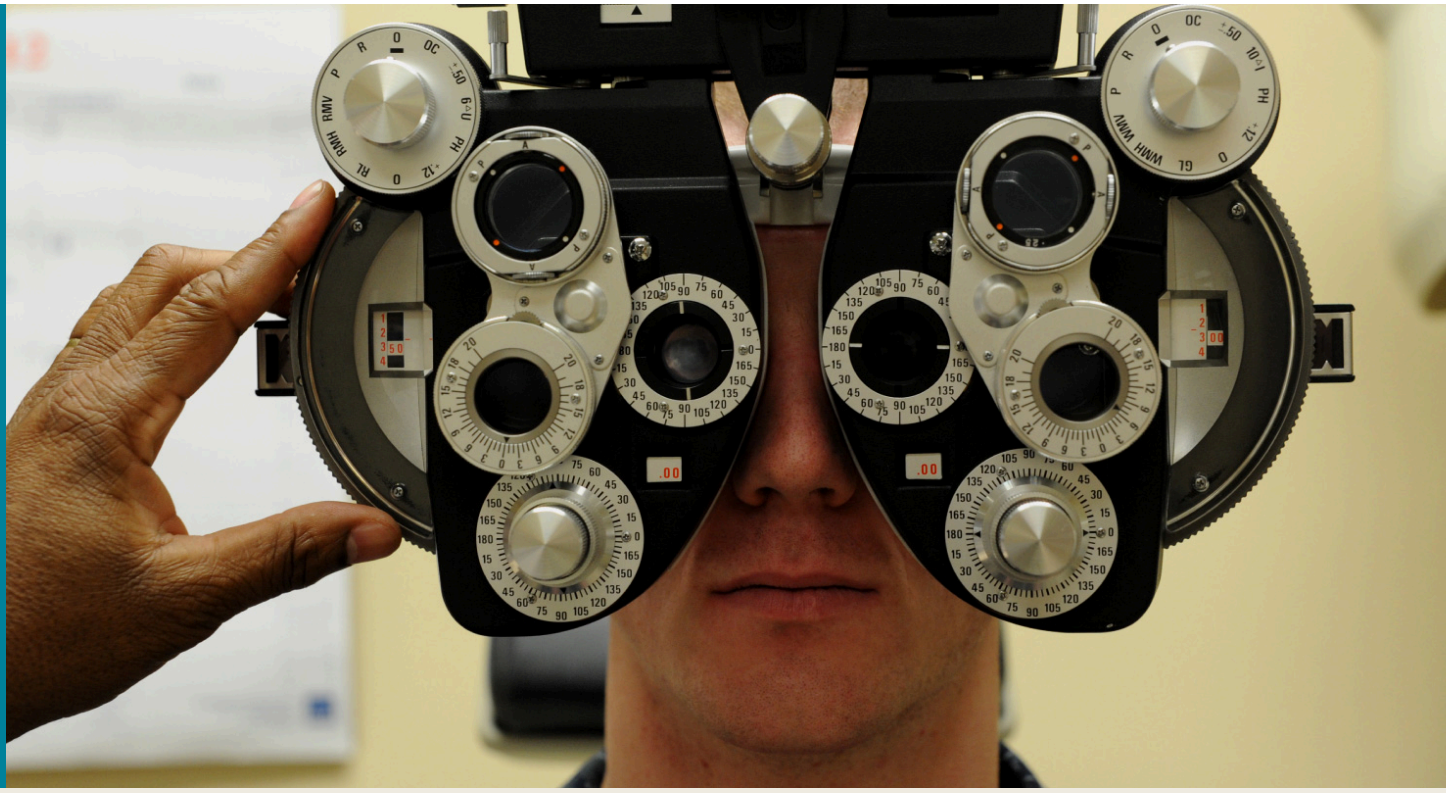

FIGURE 18.1 Eye health is important because early detection and treatment of eye disorders can prevent progression or even loss of vision. (credit: "Optometrists help clear JB Charleston's vision" by Senior Airman Anthony J. Hyatt 628th Air Base Wing Public Affairs/ Joint Base Charleston, Public Domain)

CHAPTER OUTLINE

INTRODUCTION We receive most of the information about the world around us from our vision and hearing. Eye health is directly linked to brain health; in fact, 80 percent of what we perceive comes from our sense of sight (Assi et al., 2021). Without the key senses of sight and sound, our human experience can change drastically. Impaired vision or hearing often impairs quality of life. As primary caregivers, nurses play a crucial role in identifying, assessing, and managing these disorders. Understanding eye and ear disorders is essential for nurses to provide holistic care, optimize patient outcomes, and ensure patient safety.

18.1 Disorders of the Eye

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss pathophysiology, risk factors, and clinical manifestations for ocular diseases and disorders
- Describe the diagnostics and laboratory values for ocular diseases and disorders
- Apply nursing concepts and plan associated nursing care for patients with ocular diseases and disorders
- Evaluate the efficacy of nursing care for patients with ocular diseases and disorders
- Describe the medical therapies that apply to the care of ocular diseases and disorders

Nurses need to possess knowledge about ocular disorders such as cataracts, glaucoma, and macular degeneration, as these conditions can significantly impair visual acuity and affect a patient's quality of life. By recognizing the signs

and symptoms, nurses can promptly refer patients for specialized ophthalmic evaluation and treatment, promoting early intervention and preventing irreversible vision loss. Moreover, nurses must be well-versed in the administration of eye medications, understanding proper dosing, potential side effects, and appropriate patient education. With this knowledge, nurses can collaborate effectively with ophthalmologists and optometrists to provide optimal care and support to patients with ocular disorders, facilitating their recovery and adaptation to visual impairments.

Assessment of the Eye

The eye is a vital sensory organ, playing a fundamental role in a person's daily activities, independence, and overall quality of life. By conducting a comprehensive eye assessment, nurses can identify any abnormalities, changes, or potential disorders of the eye. Early detection of such disorders is critical in preventing or minimizing irreversible damage to the patient's vision. Deteriorating vision can also suggest underlying conditions. For example, both diabetes and hypertension can cause disease of the retina, or **retinopathy**. Certain medications, such as corticosteroids, can increase the risk of developing conditions like glaucoma or cataracts. By regularly assessing the eye, nurses can help to address such issues.

Anatomy and Physiology of the Eye

The eye consists of three layers: the outer fibrous layer, the middle vascular layer, and the inner neural layer (Ball et al., 2020) (Figure 18.2).

- The outermost layer consists of the cornea and sclera. The cornea is a transparent, dome-shaped structure that refracts, or bends, and focuses light onto the retina. The sclera, or white of the eye, provides protection and maintains the shape of the eyeball.
- The middle layer includes the iris, which—a bit like an onion—consists of multiple pigmented layers; each layer contributes to eye color. The muscles of the iris regulate the amount of light entering the eye through the pupil.
- The innermost layer consists of the retina. The retina's photoreceptor cells convert light into electrical impulses, which are then transmitted to the brain for visual interpretation.

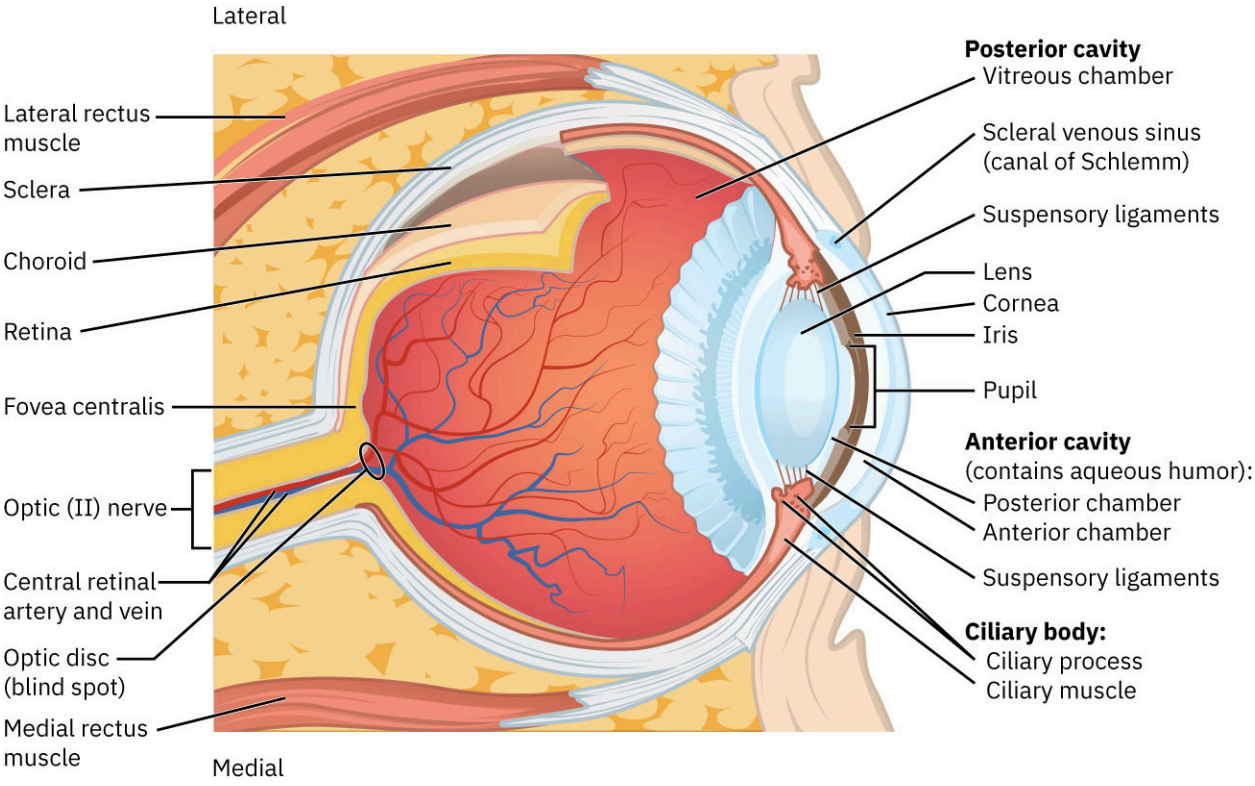

FIGURE 18.2 This cross-section of a human eye reveals the key ocular structures and their various connections. (credit: modification of work from *Anatomy and Physiology*, 2e. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

When light enters the eye, it passes through the cornea, which refracts the light rays to focus them on the retina at the back of the eyeball. The lens, controlled by the ciliary muscles, adjusts its shape to further focus the light onto the retina. The retina has two types of photoreceptor cells: rods and cones. Rods are responsible for vision in low-light conditions, as well as peripheral vision. Cones are responsible for color vision and visual acuity. The rods and cones generate electrical impulses that travel through the neural layers of the retina to the optic nerve. The optic nerve then carries these electrical signals to the brain's visual cortex, which interprets the visual stimuli.

Nurses need to know and understand basic eye anatomy and physiology to perform an effective physical assessment. For example, knowing the sclera should generally be white helps a nurse identify redness, swelling, or streaks as abnormal. When using a penlight, a nurse will recognize whether both pupils are equally sized or whether the patient has **anisocoria**. When using an ophthalmoscope, a nurse will recognize a normal retina and be able to compare it to an abnormal one.

Physical Assessment

A comprehensive eye examination is important for early detection, assessment, and management of ocular disorders. The first step in an eye examination is to obtain a thorough patient history. This history should gather information about the patient's chief complaint, previous eye conditions or surgeries, family history of vision disorders, current medications, and any systemic conditions that may affect ocular health. It is also important to collect information on the patient's occupation, hobbies, and exposure to environmental hazards, all of which may contribute to ocular disorders. For example, a **pterygium**—a raised thickening of the **conjunctiva**: the thin, clear membrane that covers and protects the eye—may be caused by the eye's efforts to protect itself from environmental irritants such as wind, UV light, or dust (Figure 18.3).

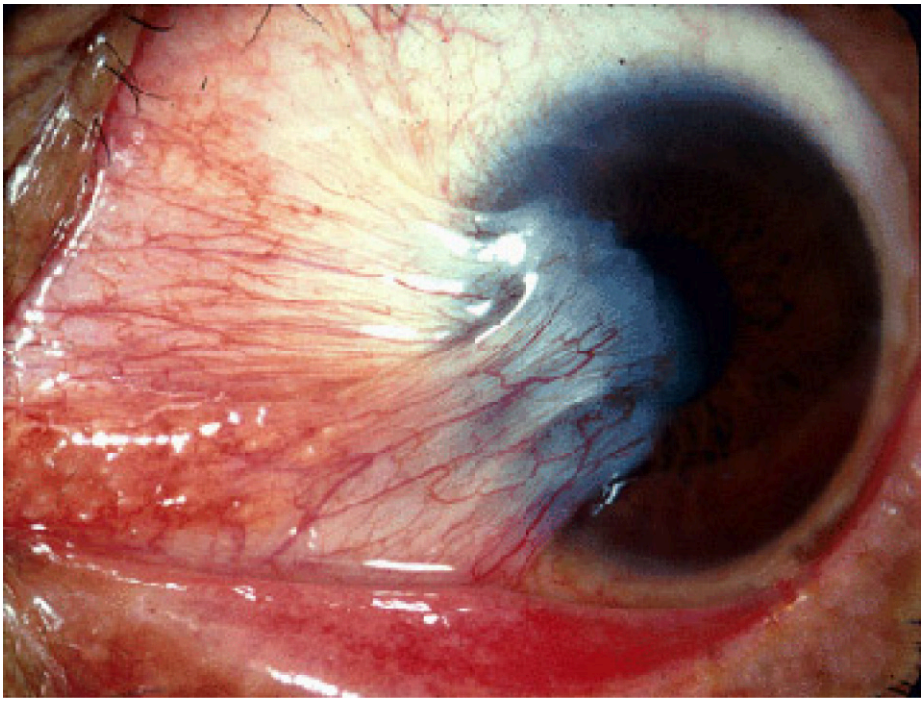

FIGURE 18.3 This pterygium of the right eye shows thickened tissue extending from the lateral side across the iris. (credit: "Pterygium" by Jonathan Trobe, M.D., University of Michigan Kellogg Eye Center/ Wikimedia Commons, CCBY 3.0)

When you think of an exam examination, you may imagine a Snellen chart, which shows the patient rows of letters of varying sizes. However, a complete eye examination has multiple components (Table 18.1).

Component	Nursing Action	Tools	Disorders to Identify
Visual acuity	Measure vision at different distances for each eye.	Snellen chart	Hyperopia myopia
External eye exam	Palpate structures surrounding the eye. Inspect eyelids, eyelashes, conjunctiva, sclera, lacrimal glands, movement of eyelids, tear production, and presence of discharge.	Visual inspection penlight	Infection nerve disorders affecting the eyes eye damage or trauma
Pupil assessment	Assess size, shape, equality, and reaction to light. Assess accommodation, or the eye's ability to focus.	Visual inspection penlight	Abnormalities such as anisocoria, sluggish or nonreactive pupils, or abnormal constriction or dilation may indicate underlying neurological or ophthalmic conditions.
Ocular motility	Evaluate movements of both eyes.	Penlight	Nystagmus or muscle weakness may indicate underlying neurological or ocular abnormalities.
Intraocular pressure (IOP)	Evaluate pressure behind the eyes.	Tonometer	Elevated IOP may warrant further evaluation by an ophthalmologist or optometrist.
Fundoscopic exam	Dilate the eyes to view the fundus.	Ophthalmoscope	Disorders of the retina, optic disc, blood vessels, and macula

TABLE 18.1 Components of an Eye Assessment

Impaired Vision

Vision impairment encompasses a range of conditions that can significantly affect an individual's quality of life and independence. Although an ophthalmologist must make a detailed assessment of a patient's vision, the nurse plays a crucial role in understanding and managing vision impairment. Nurses should understand the common causes of blindness, including cataracts, glaucoma, macular degeneration, diabetic retinopathy, and retinal detachment. They should also be aware of congenital conditions such as congenital cataracts or retinopathy of prematurity.

REAL RN STORIES

Nurse: Julietta
Years in Practice: 7
Clinical Setting: Primary care office
Geographic Location: Kansas City, KS

Julietta, a registered nurse, worked with Mr. Johnson, who was diagnosed with age-related macular degeneration (AMD), a progressive eye condition that can cause severe vision loss. Mr. Johnson was devastated and felt helpless as his visual impairment affected his independence and quality of life.

Julietta took the initiative to provide compassionate support. She engaged in therapeutic communication with Mr. Johnson, allowing him to express his fears and concerns about living with visual impairment. She provided information on low vision aids, such as magnifiers, large-print materials, and adaptive technologies that could

enhance his remaining vision and promote independence. She connected Mr. Johnson with a local support group for individuals with visual impairments. She also arranged for a vision rehabilitation specialist to visit Mr. Johnson at home and assist with environmental modifications to enhance safety and navigation. Julietta collaborated closely with the interdisciplinary health-care team. She invited Mr. Johnson's wife and children to participate in education sessions, teaching them how to provide appropriate support and understanding for someone with visual impairment.

Through the nurse's holistic approach, Mr. Johnson's quality of life improved significantly. Despite his visual impairment, he regained a sense of independence and purpose.

Refractive Errors

Refractive disorders are common visual conditions that result from abnormalities in the eye's ability to refract light properly. Common ocular disorders include **myopia** (commonly called nearsightedness); **hyperopia** (commonly called farsightedness); **astigmatism**, or blurred vision; and age-related macular degeneration (AMD) (Table 18.2).

Disorder	Definition	Causes	Diagnosis	Treatment
Myopia (nearsightedness)	Difficulty seeing distant objects clearly	Genetics Environmental factors Eye strain Anatomical changes	Visual acuity test Retinoscopy Autorefraction	Corrective contact lenses (orthokeratology) Refractive surgery (LASIK)
Hyperopia (farsightedness)	Difficulty seeing close objects clearly	Insufficiently curved cornea Aging Damage to the lens	Visual acuity test Retinoscopy Autorefraction	Reading glasses Surgery
Astigmatism	Blurred vision	Irregularly shaped cornea or lens	Visual acuity test Retinoscopy Autorefraction	Corrective lenses
Age-related macular degeneration (AMD)	Degenerative eye disease affecting the macula	Unknown causes but attributed to aging, smoking, hypertension, or atherosclerosis	Amsler grid test	Treat the causative factor with, for example, antihypertensives, antihyperlipidemic, surgery, or intravitreal injections of anti-vascular endothelial growth factor (VEGF) medications to inhibit abnormal blood vessel growth.
Cataracts	Clouding of the lens	Aging Congenital	Visual inspection	Surgery to remove and replace lens

TABLE 18.2 Common Ocular Disorders

Disorder	Definition	Causes	Diagnosis	Treatment
Glaucoma	Blurred vision from high intraocular pressure	Hypertension Smoking Aging	Tonometry	Medicated eye drops
Diabetic retinopathy	Blindness caused by overgrowth of vessels in the retina	Chronic hyperglycemia Hypertension	Retina scan	Blood glucose control Antihypertensive medications

TABLE 18.2 Common Ocular Disorders

Glaucoma

Glaucoma is a leading cause of irreversible blindness worldwide. This progressive eye disease is typically characterized by increased intraocular pressure (IOP), which can damage the optic nerve and lead to irreversible vision loss if left untreated. Lifelong management is necessary to preserve vision (Kanski & Bowling, 2020).

There are several causes of glaucoma. Some individuals develop glaucoma as they progress past the age of 60. Other individuals—particularly those with a family medical history of glaucoma—may be diagnosed before the age of 60. Pre-existing medical conditions such as diabetes and hypertension can trigger glaucoma development. Glaucoma can also be caused by chronic steroid use or previous eye injuries or surgeries. Understanding the pathophysiology of glaucoma is crucial for nursing professionals as it helps in recognizing early signs and symptoms; treating the condition as soon as possible minimizes vision loss.

Normal IOP is between 11 and 21 mm Hg and shifts throughout the day, with the lowest measurement being in the morning (Assi et al., 2021). It also commonly increases with aging but still should not measure greater than 21 mm Hg. Elevated IOP results when the balance is disrupted between the production and drainage of **aqueous humor**, a clear fluid inside the eye. This leads to an accumulation of fluid and increased pressure within the eye, which damages the optic nerve. Over time, this damage leads to the gradual loss of peripheral and central vision; if left untreated, it can lead to total blindness. It is important to note that whereas increased IOP is a significant risk factor, there are cases of glaucoma where optic nerve damage can occur even with normal IOP. Glaucoma can easily go untreated because early stages of peripheral vision loss can go unnoticed. It is often only when the central vision is affected that patients take steps to treat the illness. At that point, the lost vision can no longer be regained.

There are two general types of glaucoma: open-angle and closed-angle. In the most common type, **open-angle glaucoma**, the drainage angle between the cornea and the iris remains open, but the fluid outflow is impeded. In **closed-angle glaucoma**, the drainage angle suddenly becomes blocked, leading to a rapid increase in IOP and severe symptoms. Elevated IOP can lead to compression of and damage to the optic nerve fibers.

Clinical manifestations of glaucoma can vary depending on the type and stage of the disease. Common clinical manifestations of glaucoma include

- blurred vision,
- gradual loss of peripheral vision,
- halos and glares around lights,
- headaches around the temples or brow region,
- optical nerve changes,
- redness and discomfort in the eye(s), and
- nausea, vomiting, and in some cases abdominal pain.

Assessment and Diagnostics

Assessment and diagnostics play a crucial role in identifying and managing glaucoma. The scope of nurses is

supportive, as the optometrist or ophthalmologist makes the formal diagnosis. Nurses may administer medications, educate patients, collect a patient's health history, and assess their symptoms, and even help with visual acuity testing.

Diagnostics and Laboratory Values

Glaucoma diagnosis primarily relies on clinical assessment and specialized eye examinations. There are no specific laboratory tests to diagnose glaucoma. However, certain diagnostic procedures and tests can provide valuable information to aid in the diagnosis and management of glaucoma. Testing includes **tonometry**, or the measuring intraocular pressure (IOP) (Figure 18.4), as well as visual field testing, optic nerve imaging, and measurements of the corneal thickness and blood flow.

FIGURE 18.4 Tonometry is a test used to check for glaucoma. (credit: "Glaucoma Awareness" by Staff Sgt. Liliana Moreno/ U.S. Air Force, Public Domain)

Nursing Care of the Patient with Glaucoma

Treatment and management of glaucoma focus on reducing IOP to slow down or halt the progression of the disease. Early detection and proactive management can help prevent or delay vision loss. Treatment options include eye drops that lower IOP and prevent optic nerve damage, oral medications that lower IOP, laser therapy, and surgery. Regular monitoring of vision, adherence to treatment, and lifestyle modifications such as avoiding activities that increase IOP (like straining or exercising with a lowered head) are essential components of glaucoma management.

Regardless of the treatment plan, nurses should provide support and education, address concerns, and promote medication compliance to prevent disease progression and vision loss. Nurses should also be aware of complications that result from some treatment options. For example, a major category of medication for glaucoma is a beta blocker, which helps open the eye canals to decrease pressure. A side effect of beta blockers is a decrease in blood pressure if the medication is absorbed systemically. Consequently, it is important for nurses to regularly monitor the blood pressure of glaucoma patients treated with beta blockers.

CLINICAL SAFETY AND PROCEDURES (QSEN)

Quality Improvement Strategies to Guide Patient Care

The Quality and Safety Education for Nurses (QSEN) competencies are essential in guiding nursing practice and ensuring the provision of safe, quality care to patients. When working with patients with ocular disorders, nurses can apply the following QSEN competencies:

- Patient-Centered Care: Nurses prioritize patient-centered care by considering the unique needs, preferences, and goals of patients with ocular disorders. They involve patients in the decision-making process, actively listen to their concerns, and provide education and support tailored to their specific condition.
- Evidence-Based Practice: Nurses use evidence-based practice to inform their interventions and decision-making when caring for patients with ocular disorders. They stay updated with current research, guidelines, and best practices in the field of ophthalmology to provide the most effective and appropriate care.
- Safety: Ensuring patient safety is of utmost importance when working with individuals with ocular disorders. Nurses assess environmental factors that may contribute to falls or accidents related to visual impairment.
- Informatics: Nurses utilize informatics to manage and communicate patient information effectively when caring for patients with ocular disorders. They utilize electronic health records (EHRs) to document and retrieve patient data, including ophthalmic assessments, treatment plans, and medication administration records.
- Teamwork and Collaboration: Collaboration is essential when caring for patients with ocular disorders, as it involves an interdisciplinary approach. Nurses work closely with ophthalmologists, optometrists, ophthalmic technicians, and other health-care professionals to provide comprehensive care.
- Quality Improvement: Nurses embrace the competency of quality improvement to identify areas for improvement and implement changes in the care of patients with ocular disorders.

Medical Therapies and Related Care

Collaborative care and interprofessional communication are essential components of providing comprehensive treatment for patients with glaucoma. Given the multifaceted nature of glaucoma management, involving various health-care professionals in a collaborative, coordinated approach ensures optimal patient outcomes. Collaborative care involves the active participation of different health-care professionals working together to provide comprehensive and holistic care for patients with glaucoma.

INTERDISCIPLINARY PLAN OF CARE

Taking on Glaucoma Care as an Interdisciplinary Team

The interdisciplinary plan of care for a patient with glaucoma includes a variety of health-care professionals who work together to coordinate care. Their goal is to provide continued care management and preventive measures to reduce progression of the disease and improve the patient's quality of life. The interdisciplinary team includes the following members:

- a pharmacist to manage medications and verify compatibility;
- a social worker to coordinate post-discharge resources and referrals;
- an occupational therapist to provide interventions as part of the vision rehabilitation team;
- an ophthalmologist to manage and oversee the patient's plan of care;
- an optometrist to monitor and correct changes to the patient's vision; and
- a nurse educator to provide best practices for preventing disease progression and improving quality of life at home.

Nurses are pivotal members of the glaucoma care team. They assess patients, educate them about the disease, provide information on medication administration and side effects, and reinforce and promote adherence to treatment plans. Nurses also monitor IOP, administer eye drops, and provide guidance on proper technique. They play a vital role in patient education, emphasizing the importance of regular follow-up appointments, lifestyle

modifications, and eye health maintenance. Nurses act as advocates, ensuring patients receive appropriate referrals, support, and access to resources.

CLINICAL JUDGMENT MEASUREMENT MODEL

Recognize and Analyze Cues

Before a nurse can analyze cues to form a hypothesis, they must first make sure they have enough information about a patient's situation to correctly interpret the information and develop a plan of care. Suppose you are educating a patient with diabetes on the need to get a yearly eye examination for early detection of glaucoma. You explain that eye examinations are a preventive measure that can reduce the risk of undiagnosed glaucoma. The patient is hesitant, due to lack of eye care insurance, and claims that yearly eye exams are unnecessary and a waste of money. You explain to the patient that any medical diagnosis that results in eye disease covers one yearly exam. You also explain that although glaucoma cannot be cured, medications can stop the progression and deterioration of vision if caught in the early stages.

In this situation the nurse recognized the patient did not oppose an eye exam but was instead concerned about their lack of vision insurance. Having obtained sufficient information, the nurse is able to address the patient's concerns and develop the most appropriate plan of care.

Cataracts

A **cataract**—the clouding of the lens within the eye—is another common vision disorder and a leading cause of impaired vision (Figure 18.5). Cataracts occur when the balance between water and proteins in the lens is disrupted. When this happens, the proteins undergo structural changes that cause them to clump together and aggregate. This aggregation clouds the lens, making it more difficult for light to pass through it. Consequently, the affected lens becomes increasingly opaque, leading to visual impairment.

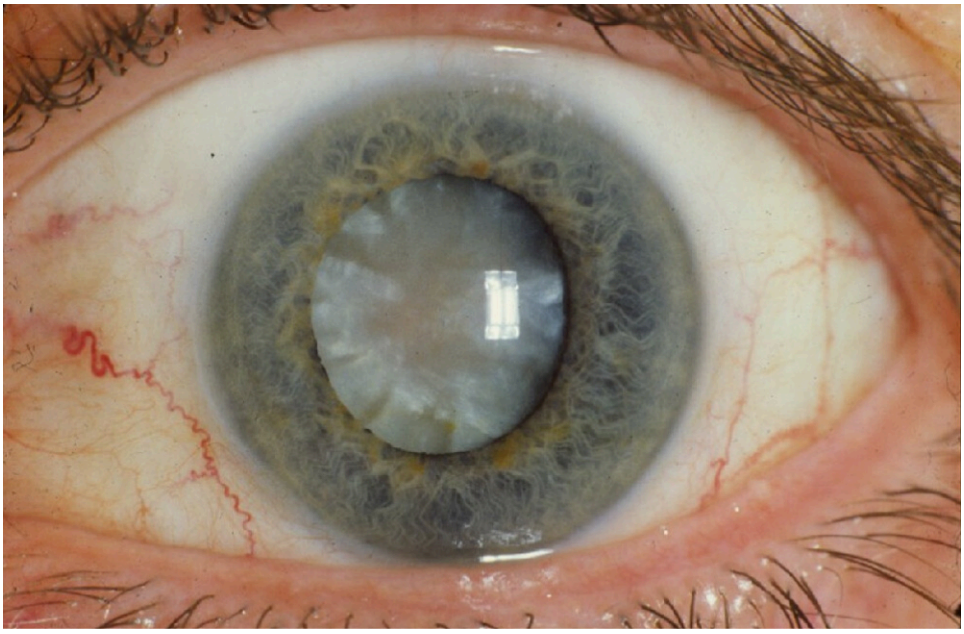

FIGURE 18.5 A cataract looks like an opaque circle in the center of the eye. (credit: "Cataract" by NIH Image Gallery/ Flickr, Public Domain)

The development of cataracts is often age-related, caused by factors such as long-term exposure to ultraviolet light, oxidative stress (periods of reduced oxygenation to the eye), or metabolic changes within the lens. However, younger people can also develop cataracts due to factors such as genetic predisposition, trauma, certain medications, or underlying medical conditions such as metabolic disorders. It is essential to note that the progression and impact of cataracts on vision can vary among individuals. Some may experience gradual deterioration over years, whereas others may notice more rapid changes. Common clinical symptoms associated with cataracts include

- blurred vision,
- increased sensitivity to glare,
- difficulty perceiving colors and contrasts,
- reduced night vision, and
- altered depth perception.

Assessment and Diagnostics

The assessment and diagnostic process for cataracts involves a comprehensive evaluation of the patient's visual symptoms, a medical history, and a thorough eye examination (Table 18.3). Nurses play a vital role in assisting with this process by gathering relevant information, performing initial screenings, and collaborating with other health-care professionals.

Nursing Action	Includes . . .
Take patient history	• Medical history • Onset and duration of symptoms • Health conditions • Smoking history • Trauma • Medications
Assess symptoms	• Vision changes • Sensitivity to light • Difficulty with night vision or depth perception
Test visual acuity	• Use of Snellen chart and penlight • Test for accommodation and confrontation (visual field) • Test for cranial nerves 2, 3, and 6

TABLE 18.3 **Cataract Assessment** (Ball et al., 2020)

Diagnostics and Laboratory Values

The diagnosis of cataracts is primarily based on the patient's reported symptoms and a comprehensive eye examination by an optometrist or ophthalmologist. Lab tests are not typically used as primary diagnostic tools for cataracts.

Nursing Care of the Patient with Cataracts

Nurses play a role in coordinating care and ensuring optimal outcomes for individuals with cataracts. They do this by providing education about the condition, assisting with visual aids (e.g., glasses, magnifiers), and supporting patients through the surgical process if indicated. Collaborative care with ophthalmologists is vital to determine the appropriate treatment approach, which may involve cataract extraction surgery to replace the clouded lens with an artificial intraocular lens (IOL).

Nurses also help to develop a care plan, which involves reviewing and understanding the patient's medical history, visual assessment findings, and reported symptoms. The next step is to identify interventions and strategies to address the diagnosis. These may include helping the patient to adapt to visual changes, recommending regular eye examinations, promoting compliance with prescribed medications or eye drops, collaborating with the health-care team to arrange for surgical interventions, helping the patient to access necessary visual aids or devices, and educating the patient on lifestyle modifications to prevent further cataract progression. Once the plan of action has been established, the nurse should continue to evaluate outcomes and communicate regularly with the patient to determine if modifications are necessary. As always, nurses should aim to involve the patient in the decision-making process to promote patient-centered care.

Medical Therapies and Related Care

Medical therapies and collaborative care for cataracts involve a combination of conservative management strategies, patient education, and coordination with health-care professionals. Although cataract surgery remains the definitive treatment, medical therapies and collaborative care play a crucial role in managing the condition and optimizing visual function. Conservative management involves offering visual aids such as corrective glasses. Collaborative care includes involving the specialist who may plan for and perform any needed surgery.

Corneal Disorders

Common corneal disorders encompass a range of conditions that affect the transparent outermost layer of the eye, the cornea. These include corneal abrasion, corneal ulcer, keratoconus, and corneal dystrophies, all of which may cause vision distortions (National Eye Institute, 2024).

Corneal Abrasion

A **corneal abrasion** is the loss or disruption of the corneal epithelium, the outermost layer of the cornea. It can occur due to trauma, foreign bodies in the eye, or misused contact lenses. A corneal abrasion can produce eye pain, foreign body sensation, excessive tearing, redness, blurred vision, increased sensitivity to light, and conjunctival injection.

Corneal Ulcer

A **corneal ulcer** is an area of tissue breakdown in the cornea. It is usually caused by a bacterial, viral, or fungal infection. When the infection breaches the corneal epithelial barrier, it leads to inflammation and tissue damage. A corneal ulcer can produce severe eye pain, redness, sensitivity to light, blurred vision, foreign body sensation, and excessive tearing. Additionally, a corneal ulcer may present with a visible white or yellowish opacity on the cornea, along with surrounding corneal edema, or swelling.

Keratoconus

A progressive corneal disorder, **keratoconus** is characterized by the thinning and distortion of the cornea, resulting in a conical shape. The weakened corneal structure leads to corneal irregularities and astigmatism. The exact cause is unclear, but genetic factors and chronic eye rubbing may contribute. Patients with keratoconus often experience progressive myopia and astigmatism. Corneal scarring, corneal hydrops (sudden corneal swelling), and contact lens intolerance may develop as the condition advances.

Corneal Dystrophies

The **corneal dystrophies** are a group of inherited disorders characterized by abnormal deposits or changes in corneal structure. Patients with these conditions may experience gradual vision loss, corneal clouding, recurrent corneal erosions, sensitivity to light, and decreased visual acuity. In some cases, corneal dystrophies may lead to corneal opacities, irregular astigmatism, and visual distortion.

Assessment and Diagnostics

Like most other ocular disorders, the assessment and diagnostic process for corneal disorders involves a comprehensive evaluation of the patient's symptoms and medical history and a thorough ophthalmic examination. Testing for corneal disorders should include a visual acuity test and an external eye examination looking for signs of inflammation, swelling, discharge, or eyelid abnormalities. Patients may also require a slit lamp examination to assess the corneal surface for irregularities, opacities, infiltrates, lesions, ulcers, dystrophic changes, or signs of infection. Other necessary tests may include corneal topography imaging to map the corneal surface and tests to identify infections and guide appropriate antimicrobial treatment.

Nursing Care of the Patient with Corneal Disorders

Recognizing and analyzing cues of corneal disorders requires keen observation and assessment skills on the part of the nurse. Nurses can identify potential corneal disorders by listening to patient reports of eye pain, blurred vision, sensitivity to light, grittiness in the eye, or decreased visual acuity. With a physical assessment, nurses can observe the appearance of the conjunctiva and sclera, the transparency of the cornea, localized or diffuse redness, the presence of excessive tearing (epiphora) or ocular discharge, and irregularities or changes in corneal curvature. Patients may demonstrate eye rubbing or shielding their eyes from light. It is important to note that the assessment and analysis of cues should happen in conjunction with a comprehensive eye examination conducted by an eye care professional.

Medical Therapies and Related Care

Medical therapies for corneal disorders vary depending on the specific condition and its underlying cause. Table 18.4 lists some common medical therapies used in the management of corneal disorders.

Type of Management	Examples	Uses
Topical medications	Antibiotics	• Treat bacterial corneal infections • Prevent secondary infections in corneal ulcers
	Antivirals	• Treat viral corneal infections such as herpes simplex keratitis
	Antifungals	• Treat fungal infections
	Anti-inflammatory agents (corticosteroids or NSAIDs)	• Reduce inflammation and associated symptoms in certain corneal disorders
Lubricants and tear substitutes	Artificial tears	• Alleviate dryness • Soothe discomfort • Protect the cornea from further damage
	Tear substitutes	• Provide long-lasting lubrication to treat severe dry eye or inadequate tear production
More-complex treatments	Bandage contact lenses	• Protect the cornea • Promote healing • Improve patient comfort in conditions such as corneal erosions, recurrent corneal erosions, or persistent epithelial defects
	Amniotic membrane transplantation (placement of a thin layer of dehydrated amniotic membrane onto the cornea)	• Promote healing • Reduce inflammation • Improve corneal surface integrity in conditions like corneal ulcers or severe ocular surface diseases
	Collagen cross-linking (application of riboflavin eye drops followed by ultraviolet light exposure)	• Used primarily for the treatment of progressive keratoconus to strengthen the cornea and slow down the progression of the disease
	Corneal transplantation (replacing the damaged cornea with a healthy donor cornea)	• Used to treat advanced corneal disorders • Improve vision and restore corneal integrity when conservative measures fail

TABLE 18.4 Management of Corneal Disorders

Ocular and Orbital Trauma

Nurses should be familiar with common ocular and orbital trauma conditions to provide prompt and effective care. Table 18.5 lists some of the conditions that nurses should be knowledgeable about.

Condition	Clinical Symptoms	Nursing Actions
Chemical eye burn	• Severe eye pain • Redness • Tearing • Blurred vision • Tissue damage	• Eye irrigation with sterile saline or water
Orbital fracture	• Periorbital swelling • Ecchymosis • Diplopia • Limited eye movement	• Pain management • Application of cold compress to reduce swelling • Eye protection • Immediate referral for ophthalmic evaluation
Hyphemia	• Blood in the anterior chamber of the eye • Eye pain • Decreased vision • Photophobia	• Strict bed rest • Elevation of head of bed (HOB) • Administration of prescribed medications (topical corticosteroids)
Globe rupture	• Severe eye pain • Decreased vision • Blood in eye	• Application of rigid eye shield • Elevation of HOB • Administration of IV antibiotics • Consultation with ophthalmic specialist
Blowout fracture	• Periorbital edema • Ecchymosis • Restricted eye movement • Infraorbital numbness • Pain	• Pain management • Application of cold compress • Eye protection

TABLE 18.5 Common Ocular and Orbital Trauma Conditions (Yanoff & Duker, 2018)

Assessment and Diagnostics

Following the collection of a patient history and physical exam of the eyes and orbits of the eyes, nurses should obtain a detailed history of the trauma, time of occurrence, and any associated symptoms. The physical examination should include inspection for signs of injury such as swelling, ecchymosis, deformities, lacerations, and symptoms like pain, as well as changes in visual acuity, signs of orbital or globe penetration, and **diplopia** (or "double vision"). Nurses should also evaluate eye movements, visual acuity, pupillary reactions, and extraocular muscle function. It is also important to conduct a visual acuity test and examine the anterior and posterior segments of the eye.

Diagnostic tests that may be necessary for ocular and orbital traumas include x-rays to identify fractures or foreign bodies in the orbit or eye socket, computed tomography (CT) scans to check for hemorrhage and globe ruptures, and magnetic resonance imaging (MRI) to assess for soft tissue injuries and nerve involvement or to rule out associated intracranial pathology. Other tests include measuring IOP and using ultrasonography to check for globe rupture, intraocular hemorrhage, or retinal detachment. In some cases, providers order blood tests, such as a complete blood count (CBC) or coagulation profile, to assess for bleeding disorders or evaluate the extent of systemic involvement in traumatic injuries.

Nursing Care of the Patient with Ocular and Orbital Trauma

When providing care for patients with ocular and orbital trauma, nurses play a crucial role in implementing appropriate nursing interventions. Throughout the period of assessment and treatment, nurses listen carefully to the patient's self-reported symptoms, concerns, and observations. They should pay attention to nonverbal cues, such as facial expressions, body language, and signs of distress. It is important to also document all assessment findings, including objective data, subjective complaints, and changes in the patient's condition over time. Any significant cues or changes should be promptly and accurately reported to the health-care team. Vigilant and attentive assessment of cues can assist nurses in ensuring timely interventions, preventing complications, and optimizing outcomes for patients with ocular or orbital trauma.

After the nurse has collected and analyzed data, the nurse will move to prioritize possible diagnoses and plan appropriate interventions. The specific interventions may vary depending on the severity and nature of the injury. Table 18.6 lists some general nursing interventions for ocular and orbital trauma.

Nursing Action	Notes
Assess and monitor	• Document vital signs.
Manage pain	• Use pain assessment tools. • Apply cold compresses to reduce swelling.
Protect eye	• Use eye patch, shield, or cup to protect from further trauma.
Maintain proper positioning	• Keep HOB above 30 degrees to minimize edema. • Support with pillows.
Promote eye care and hygiene	• Use eye irrigation and cleaning as needed.
Administer medication	• Properly apply eye drops or ointments.
Educate patient	• Teach patient to avoid rubbing the eye.
Assist with ADLs	• Help patient with grooming, dressing, and eating to promote independence and comfort.
Offer emotional support	• Offer support for impaired vision. • Include family members in the recovery process.
Collaborate with health-care team	• Collaborate with ophthalmologists, ophthalmic specialists, and other health-care professionals to ensure coordinated care and timely interventions.

TABLE 18.6 Nursing Interventions for Ocular and Orbital Trauma (Yanoff & Duker, 2018)

Evaluation of Nursing Care for the Patient with Ocular and Orbital Trauma

Part of evaluating outcomes requires the continuous collection of data from the patient. This means measuring the response of the patient to the nursing interventions—for example, with visual acuity testing, ophthalmic examinations, pain assessments, and observations of the healing process. All data—including any changes from the baseline assessment—should be carefully documented, allowing the nurse to compare the collected data to the

established expected outcomes. Based on the evaluation of outcomes and collaboration with the health-care team, nurses can assist in modifying the care plan, as necessary.

Medical Therapies and Related Care

Medical therapies and collaborative care for ocular and orbital trauma involve an interdisciplinary approach to address the specific needs of the patient. Table 18.7 lists some common medical therapies and collaborative care strategies for ocular and orbital trauma.

Therapy or Strategy	Description
Ophthalmologic consultation	• For diagnosis and treatment
Pharmacological interventions	• Topical antibiotics or ointments • Analgesics • NSAIDs
Surgical interventions	• To repair lacerations, ruptures, or orbital trauma
Wound management	• To ensure proper healing
Pain management	• Cold compresses • Elevation of head • Relaxation techniques
Visual rehabilitation	• Visual aids • Adaptive techniques
Patient education and support	• Eye care • Eye hygiene • Safety measures

TABLE 18.7 Medical Therapies and Collaborative Care Strategies for Ocular and Orbital Trauma (Yanoff & Duker, 2018)

Other Common Ocular Disorders

In addition to refractive or trauma disorders, other common ocular disorders include conjunctivitis, retinal vascular disorders, dry eye, retinitis, trauma, and diabetic retinopathy.

Conjunctivitis

Commonly known as “pink eye,” **conjunctivitis** is the inflammation of the conjunctiva. Conjunctivitis can have various causes, including viral, bacterial, or allergic reactions. Viral conjunctivitis is commonly caused by adenovirus, whereas bacterial conjunctivitis is often caused by *Staphylococcus aureus*, *Streptococcus pneumoniae*, or *Haemophilus influenzae*. Allergic conjunctivitis occurs due to an immune response triggered by allergens such as pollen, dust mites, or pet dander. Patients with conjunctivitis often experience redness in the eye, eye discharge, itching and irritation, tearing, swelling, and sensitivity to light.

The diagnosis of conjunctivitis is primarily based on a thorough patient history and clinical examination. Specific diagnostic tests may include visually inspecting the eye, obtaining and analyzing microbiological cultures, and testing for allergies. The choice of medical treatment for conjunctivitis depends on the underlying cause. Viral conjunctivitis, for example, is self-limiting and resolves without specific treatment. To alleviate symptoms, patients can use cold compresses, artificial tears, and good hygiene practices, such as washing their face and eyes daily. For bacterial conjunctivitis, patients typically are administered topical antibiotic eye drops or ointments. Allergic

conjunctivitis is usually treated with antihistamine eye drops, mast cell stabilizers, or corticosteroid eye drops. Nurses play an important role in the care of patients with conjunctivitis by educating patients on the condition and the importance of good hygiene practices and compliance with medication regimens.

Retinal Vascular Disorders

A **retinal vascular disorder** is any condition that affects the blood vessels supplying the retina. These disorders comprise two main types: occlusive and proliferative. Occlusive disorders involve the obstruction or narrowing of retinal blood vessels, whereas proliferative disorders are characterized by the abnormal growth of new blood vessels in the retina. Common consequences of retinal vascular disorders include blurred vision, floaters (spots or lines in the field of vision), or sudden vision loss. These symptoms may have a variety of causes.

- Retinal hemorrhages happen when damaged blood vessels bleed in the retina.
- Retinal ischemia, or inadequate blood flow to the retina, results in altered metabolic function due to the lack of oxygen flow. Examples of damage include reduced visual acuity, visual field defects, or even complete vision loss.
- Neovascularization is the growth of abnormal blood vessels on the retina's surface.

The diagnosis of retinal vascular disorders involves a comprehensive evaluation and may include visual acuity testing, ophthalmoscopy, optical coherence tomography (OTC), and fluorescein angiography (a test that uses a camera and dye to assess blood vessels in the eye). Depending on the specific condition, retinal vascular disorders may be treated with a variety of procedures including laser photocoagulation, intravitreal injections, and retinal detachment repair.

To manage retinal vascular disorders, it is important to address any underlying conditions, such as controlling blood pressure, blood glucose levels, or cholesterol levels. Nurses can help by providing patient education and visual and emotional support and by facilitating collaboration within the health-care team.

Dry Eye

Dry eye, also known as **keratoconjunctivitis sicca**, is a common ocular disorder characterized by insufficient tear production or poor tear quality, leading to dryness and discomfort of the eyes. Dry eye results from an imbalance between tear production and tear evaporation. In dry eye, there may be decreased tear production from the lacrimal glands or increased evaporation of tears due to factors such as reduced lipid layer integrity. This results in an unstable tear film, leading to dryness, inflammation, and irritation of the ocular surface. Signs and symptoms of dry eye include:

- blurred vision,
- burning,
- dryness,
- excessive tearing,
- foreign body sensation,
- redness,
- scratchiness, and
- sensitivity to light.

The diagnosis of dry eye is typically based on clinical evaluation and patient history. Specific diagnostic tests may include tests that measure the amount of tear production and irregularities on the ocular surface.

The medical treatment of dry eye aims to alleviate symptoms, improve tear film stability, and promote ocular surface health. This can be done with artificial tears to lubricate the eyes, topical medications to reduce inflammation, plugs to reduce tear drainage, moisture chamber glasses to reduce evaporation. Nurses can support patients with dry eye by educating patients on proper eye hygiene and the importance of consistently using prescribed artificial tears or medications.

Ocular Tumors

Ocular tumors refer to abnormal growths that occur within the structures of the eye. These tumors can develop in various parts of the eye, including the retina, iris, choroid, or conjunctiva. Ocular tumors result from the uncontrolled proliferation of cells within the eye. These tumors can be either benign or malignant. Malignant tumors have the potential to invade surrounding tissues and spread to other parts of the body, known as metastasis. The specific

type and location of the tumor determines its effects on ocular function and the overall prognosis. Common signs and symptoms of the presence of ocular tumors include blurred vision or vision loss, eye pain and discomfort, redness and swelling, abnormal eye movements, and the presence of a visible mass on the eye. To diagnose the presence of ocular tumors, health-care specialists use visual acuity testing, ophthalmoscopy to examine the structure of the eye, biopsies to analyze the tumor itself, and different types of imaging, such as CT and MRI, to identify and evaluate the extent of the tumor.

The treatment of ocular tumors depends on various factors, including the type, location, size, and stage of the tumor. Treatment options may include

- surgically removing the tumor with the assistance of advanced technologies, such as laser or cryotherapy;
- using high-energy radiation to target and destroy cancer cells in the eye;
- using chemotherapy to kill cancer cells or inhibit their growth; and
- using specialized medications designed to specifically target cancer cells while minimizing damage to healthy cells.

Nursing interventions for patients with ocular tumors focus on providing comprehensive care and support throughout the treatment process. Nurses should assist in providing patients and their families with information about the diagnosis, treatment options, and potential side effects.

Cytomegalovirus Retinitis

The ocular infection caused by the cytomegalovirus (CMV) that primarily affects the retina is **CMV retinitis**. It occurs most commonly in individuals with weakened immune systems, such as those with advanced human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS), organ transplant recipients, or individuals receiving immunosuppressive therapy. The virus can spread to the retina through the bloodstream, leading to inflammation and damage to the retinal cells. If left untreated, CMV retinitis can progress to cause retinal detachment and vision loss. Patients with CMV retinitis may experience blurred vision, floaters, dark spots or flashes of light, and vision loss.

The diagnosis of CMV retinitis involves a combination of clinical evaluation and specialized tests.

- Ophthalmoscopy is the examination of the retina using an ophthalmoscope to visualize characteristic signs of CMV retinitis, such as areas of retinal inflammation, hemorrhages, or retinal detachment.
- Fluorescein angiography is the injection of a fluorescent dye into the bloodstream, followed by the capturing of sequential images of the retina. This test helps identify abnormal blood vessel growth, leakage, and areas of compromised blood flow.
- Polymerase chain reaction (PCR) is a laboratory test that detects and amplifies the genetic material of the CMV virus to confirm the presence of active infection.

The medical treatment of CMV retinitis aims to control viral replication, manage inflammation, and preserve vision. The condition can be treated with antiviral medications such as ganciclovir, valganciclovir, or foscarnet to inhibit CMV replication and reduce the progression of retinal damage. Nurses can assist in the treatment process by supporting patients in managing their symptoms and educating patients on treatment options and the value of proper medical adherence and follow-up visits.

Diabetic Retinopathy

Diabetic retinopathy is a progressive eye disease that affects individuals with diabetes. It results from long-standing high blood sugar levels and is a leading cause of visual impairment and blindness. Prolonged exposure to high blood sugar levels causes blood vessel abnormalities, including weakened vessel walls, leakage, and the formation of new, fragile blood vessels. These changes disrupt the normal blood supply to the retina, leading to ischemia (decreased tissue perfusion) and subsequent tissue damage. Patients with diabetic retinopathy can experience blurred vision, floaters, blind spots, or vision loss and have difficulty perceiving colors accurately.

The diagnosis and monitoring of diabetic retinopathy involve several specialized tests, including a dilated eye examination, a visual acuity test, fundus photography to monitor changes in the blood vessels, a fluorescein angiography to identify areas of abnormal blood vessel growth, and optical coherence tomography (OCT) to observe the retinal thickness and the presence of fluid or swelling.

The medical treatment of diabetic retinopathy aims to manage the underlying diabetes and prevent or slow down the progression of retinal damage. This can be accomplished by managing the patient's blood sugar, blood pressure, and cholesterol through lifestyle changes and medications. Here are some other treatments.

- Medications such as anti-vascular endothelial growth factor (anti-VEGF) agents or corticosteroids are injected into the vitreous gel of the eye to reduce retinal swelling, prevent abnormal blood vessel growth, and improve visual outcomes.
- Laser photocoagulation is a procedure that uses a laser to treat areas of leaking blood vessels or create small burns on the retina to promote the regression of abnormal blood vessels and the reduction of edema.
- Surgery to remove the vitreous gel (vitrectomy) or repair the retina may be necessary in advanced cases with significant vitreous hemorrhage or retinal detachment.

Visual Changes Due to Hypertension

Chronic hypertension can lead to vascular changes, including arteriosclerosis and endothelial dysfunction, which can affect the small blood vessels in the retina and optic nerve. These changes disrupt the normal blood flow and oxygen supply to the eye structures, leading to various visual problems, such as blurred vision, visual field defects, retinopathy, diplopia, and optic neuropathy in severe cases.

Assessing visual changes related to hypertension often involves a comprehensive eye examination by an ophthalmologist or optometrist, a fundoscopy to examine the retina and blood vessels, an optical coherence tomography to view cross-sectional images of the retina and optic nerve, and regular blood pressure monitoring to evaluate the severity and control of hypertension. Treating visual changes related to hypertension involves managing blood pressure with lifestyle changes around diet and exercise as well as using antihypertensive medications such as angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor blockers (ARBs), beta-blockers, diuretics, or calcium channel blockers.

LIFE-STAGE CONTEXT

Age-Related Considerations in Ocular Disorders

Age-related ocular disorders, such as cataracts, macular degeneration, and glaucoma, are more prevalent among older adults. Nurses should be aware of the unique challenges and physiological changes that occur with aging, such as decreased visual acuity, reduced contrast sensitivity, and increased susceptibility to eye conditions. Providing additional support, patient education, and appropriate visual aids can improve communication and ensure patient safety.

Pediatric patients with ocular disorders require special attention. Nurses must adapt their communication techniques and provide age-appropriate explanations to children and their caregivers. Collaboration with pediatric ophthalmologists and child life specialists can help alleviate anxiety and facilitate child-friendly interventions.

18.2 Disorders of the Ear

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations for disorders of the ear
- Describe the diagnostics and laboratory values for disorders of the ear
- Apply nursing concepts and plan associated nursing care for patients with disorders of the ear
- Evaluate the efficacy of nursing care for patients with disorders of the ear
- Describe the medical therapies that apply to the care of disorders of the ear

Hearing is an integral source of information about the world around us. Understanding ear disorders that result in hearing loss is crucial for nurses, as these conditions can significantly affect communication, social interactions, and overall well-being. Nurses need to be able to recognize the signs and symptoms of ear disorders and assess their impact on patients' daily activities. The nurse who identifies a hearing impairment can facilitate a timely referral to an **audiologist**, a specialist in hearing testing and treatment, for further evaluation and potential interventions. Nurses must also educate patients on preventive measures, such as proper ear hygiene and noise protection, to

reduce the risk of developing ear disorders. By having a solid understanding of ear disorders, nurses can provide comprehensive care, promote patient advocacy, and enhance the quality of life for individuals affected.

Anatomy and Physiology of the Ear

The ear consists of three main parts: the outer ear, the middle ear, and the inner ear (Figure 18.6).

- The outer ear comprises the pinna (auricle) and the ear canal. The pinna is the visible part of the ear that collects sound waves and directs them into the ear canal. The ear canal, also known as the external auditory canal, is a tube-like structure that channels sound waves from the pinna to the middle ear.
- The middle ear consists of the tympanic membrane, or eardrum, and the tympanic cavity: a space spanned by three small bones called the ossicles. The three ossicles are the malleus, incus, and stapes, which are Latin names that roughly translate to hammer, anvil, and stirrup. The malleus attaches to the tympanic membrane and articulates with the incus. The incus, in turn, articulates with the stapes. The stapes attaches to the inner ear, where the sound waves are transduced into a neural signal. The middle ear also connects to the pharynx via the Eustachian tube, which helps equilibrate air pressure across the tympanic membrane.
- The inner ear is like a bony labyrinth: it consists of a series of canals embedded within the temporal bone. It has two separate regions, the cochlea and the vestibular system. The cochlea is involved in hearing and contains thousands of tiny hair cells that convert sound vibrations into electrical signals. The vestibular system is responsible for maintaining our sense of balance and spatial orientation by detecting the position and movement of our head. It includes three semicircular canals and the vestibule.

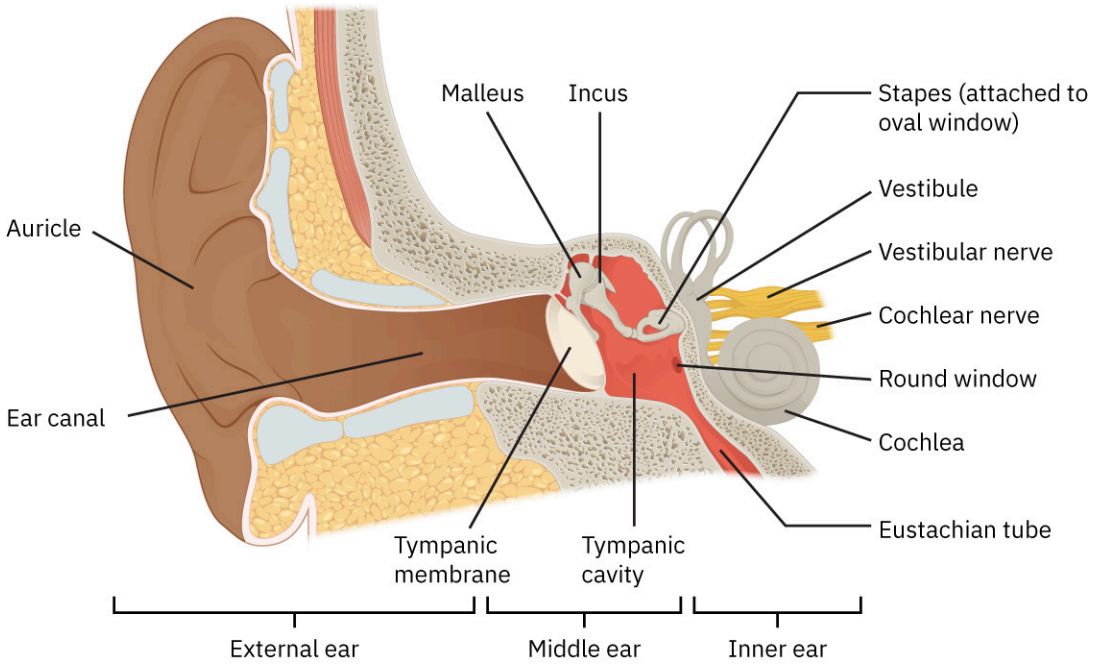

FIGURE 18.6 The main three parts of the ear are the outer ear, middle ear, and inner ear. (credit: modification of work from *Anatomy and Physiology*, 2e. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

The various parts of the ear function together to allow for sound transmission and interpretation. When sound waves reach the outer ear, the pinna directs them into the ear canal. The sound waves then travel through the ear canal, causing the eardrum to vibrate. These vibrations are amplified by the ossicles in the middle ear and then transmitted to the cochlea in the inner ear. Within the cochlea, the vibrations cause the hair cells to bend, stimulating the auditory nerve fibers. These nerve fibers convert the mechanical energy of the sound vibrations into electrical signals, which are then transmitted to the brain for interpretation. The brain processes these electrical signals, allowing us to perceive and interpret various sounds.

Conditions of the External Ear

Common disorders and conditions of the external ear include cerumen impaction, external otitis, and various tumors and masses.

Cerumen Impaction

Cerumen impaction is an accumulation of **cerumen**, or earwax, in the ear canal. Cerumen is a natural substance produced by the ceruminous glands in the ear canal. It serves as a protective barrier, lubricating the ear canal and trapping dust, debris, and microorganisms to prevent them from reaching the eardrum. Over time, however, an excess of earwax can build up and become impacted, creating a blockage in the ear canal. This can lead to hearing loss, an uncomfortable sensation of fullness in the ear, ear pain, **tinnitus** (ringing in the ear), and in rare cases dizziness or imbalance. Cerumen impaction is a common condition that can affect individuals of all ages, but it is more prevalent in older adults due to changes in the consistency and composition of earwax. It can occur in one or both ears.

Diagnosing cerumen impaction is primarily done through physical examination. The nurse or health-care provider will use an otoscope to visualize the ear canal and identify the presence of impacted earwax. In some cases, a hearing test may be conducted to assess the extent of hearing loss caused by the impaction.

Nursing Care of the Patient with Cerumen Impaction

Assessing and analyzing cues is an essential aspect of nursing care when dealing with patients with cerumen impaction. Nurses can identify the presence of cerumen impaction and develop an appropriate care plan by obtaining a patient history, completing a physical exam, and observing how the patient communicates and hears. Nursing interventions may also involve softening the impaction with cerumenolytic agents, medications that break down cerumen; other options include irrigation of the ear canal and manual removal of the earwax by a health-care professional. It is important to approach cerumen impaction with caution to avoid injury to the ear canal or eardrum.

Medical Therapies and Related Care

Cerumen impaction can often be managed by softening the earwax to facilitate its removal. Over-the-counter cerumenolytic agents are available for this purpose; they should be used according to the manufacturer's instructions and health-care provider's recommendations. The nurse typically administers several drops into the ear canal and places a cotton ball at the ear’s opening to keep the drops in place. The patient should then lie on their opposite side for 15–20 minutes to ensure the drops remain in the ear and are fully absorbed. Once the cerumen is softened, the ear can then be irrigated by washing out the loosened wax from the ear. This involves gently flushing the ear canal with warm water using a syringe or specialized irrigation kit. A trained health-care professional should perform ear irrigation to avoid injuring the ear canal or eardrum. Water should be tepid or warm—neither too hot nor too cold, as any extreme temperature can cause dizziness or even pain for the patient.

In cases where cerumen impaction is particularly severe or resistant to other treatment methods, manual removal may be necessary. This procedure is usually performed by an otolaryngologist, or a speech and ear specialist, using specialized instruments to carefully extract the impacted earwax. Medical management also includes teaching patients about prevention. Patients should know never to push cotton swabs directly into the ear; rather, they should be swirled gently around the external canal.

Nurses should monitor the patient's response to the nursing interventions. Evaluate if the patient's symptoms have improved: whether hearing has improved, pain or discomfort have been alleviated, and tinnitus or dizziness have resolved. Gather data using assessment techniques such as **otoscopy**, a visual examination of the ear using an otoscope. Compare the actual outcomes with expected outcomes and refer to the goals established in the nursing care plan. If the patient's response aligns with the expected outcomes and goals, the intervention can be considered effective. If not, reassess the intervention and consider alternative strategies. As always, nurses should accurately document the evaluation findings, including the patient's response to the interventions, any modifications made to the care plan, and the ongoing management plan.

External Otitis

Commonly known as swimmer's ear, **external otitis** is an inflammatory condition affecting the external auditory canal (Medina-Blasini & Sharman, 2023) (Figure 18.7). This condition is often caused by exposure to persistent moisture, which can disrupt the protective barrier of the ear canal, leading to bacterial or fungal infections. External otitis can develop because of prolonged exposure to water, such as from swimming or bathing. Additionally, excessive cleaning of the ear canal with cotton swabs or other objects may cause trauma, making the ear more susceptible to infection. Also, hot and humid climates, dermatological conditions like eczema, and the use of hearing aids or earplugs can contribute to the development of external otitis.

FIGURE 18.7 When the ear canal becomes infected, inflammation can disrupt one's hearing. (credit: "Otitis externa" by Klaus D. Peter, Wiehl, Germany/ Wikimedia Commons, CC BY 3.0)

External otitis involves the disruption of the ear canal's natural defense mechanisms. Normally, the ear canal maintains an acidic pH, which inhibits bacterial and fungal growth. However, when the protective barrier is compromised, microorganisms can invade the skin lining the canal. This invasion triggers an inflammatory response, leading to swelling, pain, and pruritus. In some cases, the infection may extend beyond the ear canal, causing cellulitis or abscess formation on the external helix; this is sometimes known as "cauliflower ear."

Symptoms from external otitis may vary in severity and can include

- decreased hearing,
- pruritus,
- tenderness,
- edema,
- **erythema** (redness),
- **otalgia** (ear pain), and
- **otorrhea** (ear discharge).

Assessment and Diagnostics

Nurses gather relevant information to guide appropriate care and interventions. Begin by obtaining a detailed history, including the patient's chief complaint, previous ear infections, dermatological conditions like eczema, immune system disorders, onset and duration of symptoms, and any precipitating factors (such as recent swimming or water exposure). Assess risk factors, such as the use of hearing aids or earplugs, recent trauma or injury to the ear, or a history of recurrent external otitis.

The physical examination includes the inspection of the external ear and auditory canal for erythema, swelling, discharge, or any visible debris. Palpate the area around the external ear to assess for tenderness or localized swelling. Evaluate the patient's hearing by performing a simple whisper test or using a tuning fork to assess air conduction. Check for regional lymphadenopathy, especially in cases where the infection has spread beyond the ear canal. To rule out other conditions, such as middle ear infections or foreign bodies, an otoscopy may be necessary. In certain cases, you may need to obtain a swab of the ear canal for culture and sensitivity testing to guide antimicrobial therapy. Additional procedures may include a gram stain of the ear canal discharge to evaluate the presence of bacteria or a fungal stain to identify fungal elements such as hyphae or spores.

It is appropriate to include a psychosocial assessment, as a decrease in hearing and pain can affect quality of life.

Explore the patient's understanding of the condition, treatment expectations, and any concerns or fears they may have. This should also include evaluating the patient's support system, including family or caregivers who may assist with treatment adherence and home care.

Nursing Care of the Patient with External Otitis

The primary focus should be on alleviating symptoms, promoting healing, and preventing complications. Nurses assist with pain management by administering analgesics as prescribed, applying warm compresses, and educating the patient about pain management strategies, as well as assisting the patient in the proper use of prescribed medications. Nurses should also educate the patient on how to keep the ear dry and why to avoid cotton swabs, which may further irritate the ear canal.

Observe for any signs of complications, such as cellulitis (skin infection) spreading beyond the ear canal or the infection not responding to treatment. Monitor for worsening symptoms, increased pain, swelling, or fever. If any concerning signs arise, notify the health-care provider promptly. Schedule a follow-up appointment with the health-care provider to monitor the progress of the infection, assess healing, and adjust the care plan if needed. Regularly reassess the patient's condition and modify the care plan accordingly, while maintaining open communication with the health-care provider to ensure optimal care and recovery.

Medical Therapies and Related Care

Medical treatment for external otitis aims to eradicate the infection and alleviate symptoms. It typically involves a combination of antimicrobial or antifungal agents and supportive measures. The specific treatment plan may vary based on the causative organism, severity of infection, and patient factors. Common medical interventions include the following.

- Topical medications such as antibiotic or antifungal eardrops are commonly prescribed to combat the infection. These medications are usually administered several times a day for a specified duration. It is essential to ensure accurate administration and educate the patient about proper techniques for instilling eardrops and applying topical cream.
- Systemic therapy involving oral antibiotics or antifungal agents may be necessary in severe cases or when the infection spreads beyond the ear canal. Systemic therapy is particularly beneficial for individuals with compromised immune systems or widespread infection.
- Nonsteroidal anti-inflammatory drugs (NSAIDs) or analgesics may be used to control pain.

Foreign Bodies and Masses

Foreign bodies and masses in the ears can have a variety of causes, including obstructions, inflammation and infection, injury, and trauma, and can disrupt hearing in numerous ways. A foreign object can introduce bacteria, increasing the risk of infection, the formation of an abscess, and damage to the surrounding structures. Some foreign bodies, particularly sharp objects, can cause physical injury to the delicate structures of the ear canal, such as the tympanic membrane or the skin lining the canal.

Masses or growths within the ear can be benign or malignant tumors, cysts, or abnormal tissue growth. In the case of tumors or abnormal tissue growths, there is an uncontrolled proliferation of cells within the ear that results in a mass that can grow and interfere with normal ear function. As the mass expands, it can compress surrounding structures, such as the ear canal, tympanic membrane, or ossicles. This compression can lead to hearing loss, pain, or changes in the perception of sound. Malignant tumors may also invade nearby tissues and metastasize, spreading to other parts of the body, causing further complications, and potentially affecting overall health.

Assessment and Diagnostics

Signs of a foreign body or mass growth in the ear include hearing loss, ear pain and irritation, tinnitus, discharge and odor, vertigo, and in some cases facial weakness or numbness if the mass affects the facial nerve. Beyond these symptoms, nurses can assess the problem by performing a physical examination of the external ear, ear canal, and surrounding structures using an otoscope or other specialized instruments. This should include looking for signs of inflammation, injury, or the presence of a visible foreign body or mass. Imaging studies can provide detailed information about the foreign body or mass, including its size, location, and impact on surrounding structures.

Different types of imaging may also be required. These include x-ray imaging to view the foreign body or bony erosion, a CT scan to produce a cross-sectional image of the surrounding structures, and an MRI to assess soft

tissue masses, tumors, or any involvement of nerves and blood vessels. To determine the degree of hearing loss, the patient may require audiological tests. Although laboratory tests are not typical for diagnosing foreign bodies or masses, some tests may be requested: for example, a complete blood count (CBC) can detect signs of infection, like an elevated white blood cell count; C-reactive protein and erythrocyte sedimentation rate tests can diagnose inflammation.

Medical Therapies and Related Care

The primary medical therapy for foreign bodies in the ear involves their safe and gentle removal. A health-care professional can do this using specialized tools like forceps, suction devices, or irrigation techniques. For more complex or deeply lodged objects, a referral to an ear, nose, and throat (ENT) specialist may be necessary. If the foreign body is an insect, small debris, or non-irritating material, ear irrigation with warm water or saline solution may help to dislodge and remove it. In certain situations, ear drops may be prescribed to soften earwax or provide lubrication, facilitating the natural expulsion of the foreign body.

For masses in the ear, surgical removal is the common treatment. This may involve procedures such as excision, biopsy, or tumor resection. An ENT specialist will typically perform these surgeries. In cases of malignant tumors or cancerous masses, radiation therapy may be part of the treatment plan. This involves the use of targeted radiation to destroy cancer cells and reduce tumor size. For certain types of malignant tumors, chemotherapy drugs may be prescribed to help shrink or control the growth of the mass. This may involve pain management, supportive care, and efforts to address the patient's emotional and psychological needs. Depending on the size of the tumor removed, the patient may experience deafness and require a cochlear implant to resume the ability to hear.

LINK TO LEARNING

Cochlear implants are interventions to assist deaf patients resume a quality life with little to no disruption in the auditory senses. Read more about cochlear implants (https://openstax.org/r/77CochImplants) in this article by the National Institute on Deafness and Other Communication Disorders.

Nursing Care of the Patient with Foreign Bodies and Masses

As a nurse, recognizing and analyzing cues for a foreign body or mass in the ear require careful assessment and observation of the patient's symptoms and physical findings. This includes gathering a patient history about recent incidents, such as foreign body insertion, trauma, or exposure to potential irritants, as well as inquiring about symptoms such as ear pain, hearing loss, tinnitus, discharge, itching, dizziness, or facial weakness and numbness. During the physical examination, nurses should use an otoscope to inspect the external ear for signs of trauma, redness, swelling, discharge, or abnormal growths within the ear canal or behind the tympanic membrane. Causes include foreign bodies, masses, infections, or other ear-related conditions.

Conditions of the Middle Ear

Recall that the middle ear is where sound waves are amplified by the tympanic membrane and ossicles. Disorders of the middle ear include acute otitis media, chronic otitis media, and tympanic membrane perforation.

Acute Otitis Media

Commonly called a middle ear infection, **otitis media** is primarily caused by the invasion of microorganisms into the middle ear, often preceded by an upper-respiratory tract infection. These microorganisms gain entry to the middle ear through the Eustachian tube, which connects the middle ear to the nasopharynx. The tube's dysfunction, often associated with inflammation or obstruction, disrupts the normal ventilation and drainage of the middle ear, creating an environment conducive to infection.

The development of acute, or short-term, otitis media is common in infants and young children. They are particularly susceptible to the condition because of their shorter, more horizontal Eustachian tubes, which can easily become blocked. Infants who are bottle fed in the supine position are at risk of such an infection because of the possibility of backflow of nasopharyngeal secretions into the Eustachian tube. Additionally, children attending daycare or school also have an increased risk of exposure to upper-respiratory tract infections transmitted from their peers. Other common risk factors include exposure to secondhand smoke, allergies that cause infection, and physical

abnormalities that affect the Eustachian tube, such as cleft palate.

Otitis media typically begins with a viral upper-respiratory tract infection that causes inflammation in the nasopharynx. This leads to edema and increased mucus production. The inflammation and excess mucus can obstruct the Eustachian tube, resulting in impaired ventilation and decreased clearance of middle ear secretions. The stagnant fluid within the middle ear creates an ideal environment for bacterial growth, leading to infection and subsequent inflammation of the middle ear mucosa, which causes pain, erythema, and swelling of the tympanic membrane.

Understanding the typical signs and symptoms associated with acute otitis media is crucial for early detection and intervention. Common signs and symptoms include

- fever,
- hearing loss,
- otalgia,
- tympanic membrane changes,
- tinnitus, and
- balance issues.

Assessment and Diagnostics

Accurate and thorough nursing assessment is vital for identifying and understanding the manifestations of acute otitis media. Nurses collect a detailed health history, including information about symptoms like ear pain, hearing difficulties, tinnitus, fever, and past medical issues like previous episodes of otitis media, chronic ear conditions, craniofacial abnormalities, or recurrent upper-respiratory tract infections. Nurses gather information about allergies and exposure to secondhand smoke.

During the physical examination, nurses must pay particular attention to ear abnormalities, discharge, or inflammation. They should check the tympanic membrane with an otoscope for signs of infection, such as erythema, bulging, or fluid behind the membrane. Nurses should also check for hearing loss and changes in the patient's vital signs that may indicate systemic infection. Accurate documentation of assessment findings is important for ongoing monitoring, evaluating treatment effectiveness, and facilitating continuity of care. Nurses should listen attentively to the patient's description of pain. For very young children, this means watching for signs of pain like touching or pulling their ears and exhibiting irritability or fussiness. Nurses should ask about any changes in hearing acuity. Patients may report muffled sounds or difficulty understanding conversations, particularly in noisy environments. Children may exhibit delayed language development or reduced responsiveness to auditory stimuli. Ask about additional symptoms, such as tinnitus, dizziness, or a sense of imbalance. These cues may indicate involvement of the vestibular system. Assess for signs of systemic infection, including fever, malaise, or decreased appetite. Although fever is not always present, its presence, along with other symptoms, may suggest bacterial otitis media.

To confirm a diagnosis of acute otitis media, health-care providers may employ several diagnostic techniques, such as using an otoscope or testing with audiometry and tympanometry.

Nursing Care of the Patient with Acute Otitis Media

Nurses must critically analyze the data collected during the assessment phase to prioritize hypotheses related to acute otitis media. This involves considering the patient's symptoms, history, and objective findings. Solutions focus on addressing the underlying cause, alleviating symptoms, and preventing complications—often by administering pharmacological or nonpharmacological interventions. Collaboration with the health-care team to initiate appropriate pharmacological interventions is important.

Provide patient and caregiver education about acute otitis media, including the nature of the condition, the importance of medication adherence, the proper method for administering eardrops (if prescribed), and strategies for preventing recurrent infections. Counsel patients on the importance of follow-up appointments and recommended immunizations, such as pneumococcal and influenza vaccines.

Actions to take may include administering medications, monitoring continually, collaborating with other members of the health-care team, making referrals as needed, and documenting nursing actions. Nurses educate patients and caregivers on the importance of completing the full course of antibiotics if prescribed. Regularly assess the patient's vital signs, pain level, and response to interventions. Monitor for any signs of complications, such as worsening

symptoms or the development of complications like mastoiditis or meningitis. Collaborate with the health-care team, including physicians, audiologists, and other specialists, as needed. Facilitate referrals for audiological evaluations, surgical interventions (if necessary), or management of complications. Document all nursing actions, patient responses, and interventions in a timely and accurate manner. This ensures continuity of care, facilitates communication among health-care providers, and provides a record of the patient's condition and progress.

Medical Therapies and Related Care

The management of acute otitis media involves medical therapies aimed at treating infection, alleviating symptoms, and preventing complications. These therapies include certain pharmacological interventions, such as the use of antibiotics to treat the infection, as well as analgesics and decongestants. The choice of antibiotic depends on the causative pathogen and may include amoxicillin, amoxicillin-clavulanate, cefuroxime, or ceftriaxone. Analgesics, such as ibuprofen or acetaminophen, are used to alleviate pain and reduce fever associated with infection. Decongestants, both oral and topical, can relieve nasal congestion and improve middle ear ventilation. However, their use is controversial, and caution should be exercised due to potential side effects and limited evidence of efficacy.

In some cases, surgical interventions may be required for acute otitis media. Otolaryngologists (ENT specialists) typically perform these interventions, which may include **myringotomy** and the use of a **tympanostomy tube**. Myringotomy involves creating a small incision in the tympanic membrane to drain fluid or release pressure. Tympanostomy tubes, also known as ventilation tubes or grommets, may be inserted to maintain middle ear ventilation and facilitate fluid drainage.

Evaluation of Nursing Care for the Patient with Acute Otitis Media

In the case of acute otitis media, evaluating outcomes involves assessing the patient's response to treatment, monitoring symptom resolution, and identifying any complications or persistent issues. Nurses monitor the patient's symptoms and evaluate their resolution over time. This includes assessing for ear pain, hearing acuity, and systematic symptoms such as fever.

Chronic Otitis Media

Chronic otitis media is a long-standing inflammatory condition of the middle ear characterized by persistent or recurrent infection and inflammation. It is typically diagnosed when symptoms and signs of middle ear inflammation and dysfunction last for at least three months or recur multiple times over a prolonged period. This condition can result from unresolved acute otitis media or ongoing inflammation in the middle ear. Clinical manifestations, causes, diagnosis, nursing care, and management are like those for acute otitis media.

Chronic otitis media is often associated with several characteristic features, including otorrhea, hearing loss, and tympanic membrane perforation. The condition may also lead to complications such as **cholesteatoma** (a growth of abnormal skin in the middle ear), **mastoiditis** (infection of the mastoid bone behind the ear), or damage to various middle ear structures.

Patients with chronic otitis media may experience symptoms such as chronic ear pain or discomfort, recurrent ear infections, hearing difficulties or impairment, tinnitus, and occasionally dizziness or imbalance. The severity and presentation of symptoms can vary among individuals.

Management of chronic otitis media typically involves a combination of medical and surgical interventions. Medical therapies may include antibiotic treatment to control infection, ear drops to alleviate inflammation or manage discharge, and medications for symptomatic relief. In cases where medical management is ineffective or complications arise, surgical interventions such as **tympanoplasty** (surgical reconstruction of the eardrum) or **mastoidectomy** (removal of infected cells from the mastoid bone) may be necessary.

Pathophysiology

The pathophysiology of chronic otitis media involves a complex interplay of factors that contribute to persistent inflammation and infection in the middle ear. Causes may include Eustachian tube dysfunction and microbial infection, Risk factors are like those for acute otitis media; they include genetics, anatomical abnormalities, children with smaller Eustachian tubes, secondhand smoke, and recurrent ear infections.

Assessment and Diagnostics

The clinical manifestation of chronic otitis media may resemble those of acute otitis media, but the duration is longer. Ear discharge, perforated tympanic membrane, hearing loss, ear pain, tinnitus, and balance problems may result due to chronic middle ear infections. A comprehensive nursing assessment includes a focused symptom assessment, ear exam, hearing exam, and balance exam.

Diagnostics and Laboratory Values

To confirm the diagnosis of chronic otitis media, health-care providers may order specific diagnostic tests including audiometric testing, tympanometry, imaging studies, culture, sensitivity, and allergy testing.

Nursing Care of the Patient with Chronic Otitis Media

Like nursing management of acute otitis media, chronic otitis media requires nursing care that focuses on medication administration, patient education, and evaluation of outcomes to monitor improvement. The primary focus should be on alleviating symptoms, promoting healing, and preventing complications. Nurses assist with pain management by administering analgesics as prescribed, applying warm compresses, and educating the patient about pain management strategies, as well as assisting the patient in the proper use of prescribed medications such as antimicrobial and antifungal medications. Nurses should also educate the patient on how to keep the ear dry and why to avoid the use of cotton swabs that may further irritate the ear canal.

Monitor for worsening symptoms, increased pain, swelling, or fever. If any concerning signs arise, notify the health-care provider promptly. Schedule a follow-up appointment with the health-care provider to monitor the progress of the infection, assess healing, and adjust the care plan if needed. Regularly reassess the patient's condition and modify the care plan accordingly, maintaining open communication with the health-care provider to ensure optimal care and recovery.

Medical Therapies and Related Care

Nurses should collaborate with the interdisciplinary team, which typically includes otolaryngologists, audiologists, pharmacists, and speech pathologists who provide specialized expertise in diagnosing, treating, and managing ear conditions. Additionally, regular communication and coordination with the otolaryngologist ensure a comprehensive and integrated approach to care over time.

To help prevent chronic otitis media, immunizations may be available. Promote and educate patients about routine immunizations, including the pneumococcal conjugate vaccine and annual influenza vaccine. If allergies are identified as a contributing factor to chronic otitis media, collaborate with an allergist for proper evaluation and management. Encourage smoking cessation for patients and their family members. Teach techniques for equalizing ear pressure during altitude changes, such as swallowing, yawning, or using decongestants if appropriate.

CLINICAL JUDGMENT MEASUREMENT MODEL

Prioritize Cues for a Patient Experiencing Chronic Otitis Media

The treatment plan for chronic otitis media involves a combination of therapeutic interventions, collaborative care, and preventive measures. Managing this condition aims to control symptoms, prevent complications, and improve the patient's quality of life. To provide the patient with optimal quality of care, it is often necessary to prioritize interventions to address the most urgent cues first. For example:

1. Fighting the infection: Antibiotics are commonly prescribed to manage chronic otitis media, particularly if there is evidence of infection. Antibiotic or steroid ear drops may be recommended to directly target the infected or inflamed ear.
2. Alleviating the Pain: Ear drops can help reduce inflammation, control pain, and promote healing. Proper administration techniques should be taught to the patient or their caregiver.
3. Educating the Patient: Patients and their families should be taught how to prevent recurrent infections and limit exposure to triggers.

Tympanic Membrane Perforation

A **tympanic membrane perforation**, also known as a ruptured eardrum, refers to a hole or tear in the thin

membrane that separates the external ear canal from the middle ear. The tympanic membrane (eardrum) plays a vital role in transmitting sound waves from the external environment to the middle ear and facilitating proper hearing.

Tympanic membrane perforations can occur due to various reasons. Direct trauma to the ear—such as a blow to the ear or the insertion of a foreign object—can cause the eardrum to rupture. Severe or recurrent middle ear infections (otitis media) can also lead to eardrum rupture because of the accumulation of fluid and pressure. Other factors that can increase pressure to the point of rupture include exposure to loud noises and sudden changes in air pressure (**barotrauma**), such as during air travel or scuba diving.

Patients with a tympanic membrane perforation may experience sudden pain in the affected ear, which may subside after the rupture occurs. Some may experience drainage from the ear in the form of a clear, bloody, or pus-like substance. Hearing loss, a decrease in hearing acuity, tinnitus, and vertigo are also common.

Assessment and Diagnostics

Diagnosis of a tympanic membrane perforation is typically confirmed through visual examination of the eardrum using an otoscope. Using this tool, providers can observe the perforation, note its location and size, and search for signs of infection or inflammation. Additional tests, such as **tympanometry**, may be performed to assess middle ear function and evaluate the extent of hearing loss. Tympanometry measures the movement of the tympanic membrane in response to changes in air pressure. It involves inserting a probe into the ear canal and creating variations in air pressure while measuring the resulting acoustic energy reflected from the eardrum. Other procedures include **audiometry** (to measure the patient's ability to hear sounds of different frequencies and volumes) and cultures and sensitivity testing (to identify microorganisms causing infection).

Medical Therapies and Related Care

Treatment for tympanic membrane perforation depends on various factors, including the size and location of the perforation, the underlying cause, and associated symptoms. In many cases, small perforations heal spontaneously within a few weeks. However, medical interventions may be required, such as prescribing antibiotic eardrops to prevent infection, placing a temporary patch over the ear, or even surgically repairing the tympanic membrane (tympanoplasty) for larger or non-healing perforations. Tympanoplasty involves the placement of a graft—typically taken from the patient's own tissues or produced from synthetic materials—to close the perforation and promote healing. For cases of recurrent ear infections and chronic middle ear fluid, a tympanostomy tube may be required. This involves inserting a tiny tube through the tympanic membrane to facilitate drainage and equalize pressure in the middle ear. This procedure can help prevent future perforations and improve middle ear ventilation. In cases where the tympanic membrane perforation results in significant hearing loss, the use of hearing aids or other assistive devices may be recommended.

Regular follow-up appointments will be scheduled to monitor the perforation's healing progress. It is also important to manage the underlying conditions contributing to the perforation. If a tympanic membrane perforation is associated with an active infection, such as otitis media, antibiotic therapy may be prescribed. The choice of antibiotic ordered by the provider will depend on the suspected or identified causative organisms. To prevent infection, the patient may be advised to keep water from entering the ear during bathing or swimming.

Nursing Care of the Patient with Tympanic Membrane Perforation

The nursing care of a patient with a tympanic membrane perforation focuses on promoting healing, preventing complications, managing symptoms, and providing education and support.

Nursing care involves completing a physical assessment, assessing for signs of infection, evaluating the patient's hearing, offering patient education, and administering medications as ordered by the provider.

The comprehensive assessment of the patient's condition should include a thorough history of symptoms, previous ear infections, trauma, or exposure to loud noises. The nurse assesses for signs of infection, such as fever, increased pain, redness, or discharge from the ear. The assessment should also test for hearing acuity deterioration and other associated symptoms like tinnitus or vertigo. Nurses should pay attention to the patient's facial expressions and body language for signs of discomfort or pain.

Nurses also play a role in educating the patient and their family about the condition, including the causes, risk factors, and importance of following the prescribed treatment plan. This should include emphasis on the importance

of follow-up appointments and the proper use of prescription medications.

Finally, nurses may offer emotional support and reassurance to the patient and their family, as hearing loss or changes in hearing acuity can be distressing. Encourage the patient to express their concerns or fears and provide information to address their questions and alleviate anxiety. If necessary, collaborate with other health-care professionals, such as audiologists or psychologists, to provide additional support and counseling.

Evaluation of Nursing Care for the Patient with Tympanic Membrane Perforation

Evaluating interventions for a tympanic membrane perforation is important in determining the effectiveness of the care provided and making necessary adjustments to optimize patient outcomes. As a nurse, it is essential to systematically assess the patient's progress and response to interventions. This includes monitoring the patient's reported symptoms and observing for any signs of infection, assessing the patient's response to prescribed medications, and documenting any adverse reactions.

Nurses compare current findings with baseline assessments to determine improvement or worsening of the perforation. This may require repeated audiometry or other hearing tests to assess any changes in the patient's hearing acuity. Encourage the patient to share any concerns, questions, or changes they have noticed. Ongoing communication and collaboration with otolaryngologists, audiologists, or other health-care professionals involved in the patient's care is valuable.

Common Conditions of the Inner Ear

Common disorders of the inner ear may cause hearing loss as well as imbalance. The inner ear changes soundwaves into electrical impulses, which nerves transmit to the brain. The brain then interprets these messages into sound. The inner ear also influences the sense of balance; when fluids within the semicircular membrane are disrupted, so is a normal sense of balance, which often results in vertigo.

Motion Sickness and Vertigo

Two common conditions of the inner ear are motion sickness and vertigo. Motion sickness occurs when there is a conflict between the sensory input received from the inner ear and the eyes or other body receptors. This discordance between visual input and signals from the inner ear disrupts the brain's ability to process and integrate these signals, resulting in symptoms such as nausea, vomiting, dizziness, sweating, and pallor. Common triggers include travel by car, boat, or airplane, as well as amusement park rides. Medications commonly used to alleviate motion sickness symptoms include antihistamines (e.g., dimenhydrinate, meclizine) and scopolamine patches. These medications help to suppress the signals from the inner ear and reduce symptoms.

Vertigo is a sensation of the loss of balance. It results from dysfunction or disturbances in the vestibular system of the inner ear. The inner ear's vestibular organs, along with the brain stem and cerebellum, maintain balance and coordinate eye movements. Any disruption in these structures or their communication pathways can cause a false perception of movement, leading to vertigo symptoms. The medical treatment for vertigo depends on the underlying cause and may include head repositioning techniques such as the **Epley maneuver** for benign paroxysmal positional vertigo (BPPV), as well as medications such as antihistamines (e.g., meclizine) or benzodiazepines (e.g., diazepam) to control symptoms, diuretics or dietary modifications for Meniere's disease, and antiviral medications and corticosteroids for viral-related causes.

Nurses help educate patients about triggers and prevention strategies, such as focusing on a stable object, sitting in the front seat of a vehicle, or avoiding excessive head movements. They can also provide comfort measures during episodes, such as cool cloths, fresh air, or guided relaxation. Nurses should assist with medication administration as prescribed, ensuring proper dosage and monitoring for side effects like drowsiness or dry mouth. They may also encourage patients to keep a journal to identify specific triggers and patterns, aiding in the development of personalized coping strategies.

LINK TO LEARNING

Vertigo or dizziness is often caused by the displacement of small crystals within the inner ear canal. The Epley maneuver is a positioning method to remove these crystals trapped in the inner ear's canal. Learn how to perform

the Epley Maneuver (https://openstax.org/r/77EpleyManeuver) by watching this video.

Tinnitus

Tinnitus is a common condition of the inner ear characterized by the perception of ringing, buzzing, hissing, or other sounds in the absence of external auditory stimuli. Scientists do not understand the exact mechanism of tinnitus, but they think it involves abnormal neural activity in the auditory pathway. It can arise from damage or dysfunction in the inner ear structures, such as the cochlea, auditory nerve, or auditory pathways in the brain. This leads to the perception of sound without any external source. Changes in the neural circuits, neurotransmitter imbalances, and alterations in the processing of sound signals contribute to the development and persistence of tinnitus (Medina-Blasini & Sharman, 2023). Tinnitus can have numerous causes, such as hearing loss, blockage, ear infections, Meniere's disease, joint disorders, temporomandibular joint (TMJ) disorders, head or neck injuries, stress, and certain medication toxicities.

Treating tinnitus commonly involves identifying a specific underlying cause and treating it. There is no specific medication to cure tinnitus, but certain prescriptions may help manage associated symptoms or underlying conditions. For example, antidepressants, antianxiety medications, and anticonvulsants can help reduce the perceived intensity of tinnitus or alleviate related anxiety or depression. Types of sound therapy may help to mask or distract from the perception of tinnitus by introducing soothing external sounds via white noise machines, hearing aids, or wearable sound generators.

Ototoxicity

Certain medications or chemicals are characterized by **ototoxicity**: they have toxic effects on the structures of the inner ear, leading to hearing loss, balance problems, or other auditory-related symptoms. The exact mechanisms of ototoxicity vary depending on the specific medication or chemical involved. However, the common pathway involves damage to the sensory cells (hair cells) of the cochlea or vestibular system in the inner ear. This damage disrupts the normal transmission of sound signals or balance information to the brain, resulting in hearing loss, tinnitus, dizziness, or imbalance. Several medications can have ototoxic effects, including certain antibiotics (e.g., aminoglycosides like gentamicin), chemotherapy drugs (e.g., cisplatin), nonsteroidal anti-inflammatory drugs (NSAIDs), loop diuretics (e.g., furosemide), and some antimalarial drugs. Exposure to certain chemicals, such as solvents (e.g., toluene) or heavy metals (e.g., lead or mercury), can also cause ototoxicity.

In some cases, stopping or adjusting the dosage of the ototoxic medication may help prevent further damage or minimize the symptoms. If possible, alternative medications that are less ototoxic may be considered under the guidance of a health-care provider. Depending on the severity of symptoms, various interventions may be employed, such as hearing aids, assistive listening devices, or balance rehabilitation therapy.

Acoustic Neuroma

Also known as a vestibular schwannoma, an **acoustic neuroma** is a benign tumor that develops on the vestibular nerve between the inner ear and the brain. Acoustic neuromas arise from the Schwann cells that normally wrap around and support the vestibular nerve. The overgrowth of these cells leads to the formation of a tumor. As the tumor enlarges, it can compress nearby structures, including the vestibulocochlear nerve (responsible for hearing and balance), cranial nerves, and brain stem. This compression disrupts the normal functioning of these structures, leading to symptoms such as hearing loss, tinnitus, dizziness, imbalance, and facial weakness or numbness. Although most cases are sporadic, a small percentage may be associated with a genetic condition called neurofibromatosis type 2 (NF2).

For small tumors that are not causing significant symptoms, providers may recommend close monitoring with regular imaging to observe tumor growth and assess any changes in symptoms. For larger tumors, surgical removal is a common treatment option. Another treatment is radiosurgery, which is the delivery of highly focused radiation to the tumor, aiming to halt its growth. Radiosurgery is typically used for smaller tumors or in cases where surgical removal poses a higher risk. After treatment, patients may require rehabilitation therapy to address any residual deficits in hearing, balance, or facial function. This may involve working with audiologists, physical therapists, and occupational therapists.

Nurses play a role in the treatment and recovery of patients with acoustic neuroma by providing education and emotional support to patients and their families before surgery. They should monitor the patient closely after

surgery, assessing vital signs, neurological status, and wound healing. This includes assisting with pain management, wound care, and medication administration. Finally, nurses can support and educate the patient on rehabilitation exercises, assistive devices, and coping strategies to optimize recovery.

REAL RN STORIES

Nurse: Kevin, RN
Years in Practice: Six
Clinical Setting: Acute care hospital
Geographic Location: Oregon

In a busy hospital setting, Kevin was assigned to care for a patient with documented hearing impairment. The patient had difficulty hearing and relied heavily on lip reading and written communication. Kevin recognized the importance of effective communication and took several steps to ensure the patient receives high-quality nursing care.

Kevin began by thoroughly assessing the patient's hearing impairment, including the degree and type of hearing loss, preferred communication methods, and any assistive devices or strategies the patient uses. Kevin also reviewed the patient's medical history, including any related conditions or concerns that may affect communication.

Prepared with this information, Kevin adopted appropriate strategies to facilitate effective communication with the patient. These included facing the patient directly, speaking clearly and at a moderate pace, and avoiding covering the mouth or speaking with food or objects in hand. Kevin ensured that the patient's vision was unobstructed, allowing for lip-reading cues. Recognizing the patient's reliance on written communication, Kevin provided written instructions, explanations, and important information—using a whiteboard, notepad, or electronic device—whenever possible. Kevin verified the patient understood the information and encouraged them to ask questions or seek clarification as needed. Kevin also explored available assistive listening devices, amplification systems, and other resources to enhance communication. This involved collaborating with the hospital's audiology department.

Kevin took the time to educate the patient and their family about strategies for communicating effectively and optimizing the patient's environment. Kevin also provided information on available resources, such as support groups and organizations for individuals with hearing impairments, to promote patient empowerment and self-advocacy. Kevin collaborated with other health-care team members, including speech-language pathologists and sign language interpreters, to ensure comprehensive care and effective communication across disciplines. Kevin facilitated open communication among the team to ensure everyone was aware of the patient's hearing impairment and communication needs.

Throughout the care process, Kevin demonstrated respect, empathy, and patience. He ensured that the patient's privacy and confidentiality were maintained during all interactions.

By providing these interventions and creating a supportive environment, Kevin demonstrated high-quality nursing care for the patient with hearing impairment.

Summary

18.1 Disorders of the Eye

Ocular disorders encompass a wide range of conditions that affect the eyes and visual system. Clinical symptoms of ocular problems include blurred vision, eye pain, redness, tearing, and vision changes.

Ocular disorders require collaborative care with ophthalmologists and optometrists. Medical treatments include protecting the eyes, administering medication, and educating the patient about eye hygiene, protection, and safety. Nursing duties include collecting a patient's medical history and conducting a baseline-focused exam of the eyes. Health promotion includes advocating for regular eye exams and promoting preventive measures such as UV protection, eye safety goggles, smoking cessation, and controlled blood pressure.

18.2 Disorders of the Ear

The pathophysiology of ear disorders includes obtaining a detailed history, including the patient's chief complaint, previous ear infections, dermatological conditions like eczema, immune system disorders, onset and duration of symptoms, and any precipitating factors (such as recent swimming or water exposure). Risk factors include recent upper-respiratory tract infections, exposure to secondhand smoke, allergies that cause sinus infections, and physical abnormalities that affect the Eustachian tube, such as cleft palate. Other risk factors include the use of hearing aids or earplugs, recent trauma or injury to the ear, and a history of recurrent external otitis.

Clinical manifestations of ear disorders may include otorrhea, hearing loss, and tympanic membrane perforation. Severe ear conditions may lead to complications such as loss of hearing, abnormal growths, infection, or damage to various ear structures. Diagnostics and labs associated with ear disorders include audiometric testing, tympanometry, imaging studies, and culture, sensitivity, and allergy testing. Medical therapies for disorders of the ear include antibiotic or antifungal eardrops. In severe cases or when the infection spreads beyond the ear canal, oral antibiotics or antifungal agents may be necessary. Nonsteroidal anti-inflammatory drugs (NSAIDs) or analgesics may be used to control pain.

As primary caregivers, nurses must possess a thorough understanding of ear disorders to provide holistic care, facilitate early interventions, and optimize patient outcomes. By recognizing the signs and symptoms, collaborating with health-care professionals, and educating patients, nurses can play a vital role in preventing and managing ear disorders, ensuring the well-being and satisfaction of their patients. Evaluating the efficiency of nursing care includes monitoring the patient's response to nursing interventions and determining if symptoms have improved: for example, has there been a reduction in hearing loss, alleviation of discomfort, or resolution of associated symptoms like tinnitus or dizziness? Compare the patient's actual response to the desired outcomes. If the patient's response aligns with the expected outcomes, the intervention can be considered effective.

Key Terms

acoustic neuroma benign tumor of the vestibular nerve
anisocoria unequally sized pupils
aqueous humor one of the clear fluids inside the eyeball
astigmatism blurred vision caused by irregularities in the cornea or lens
audiologist specialist in hearing testing and treatment
audiometry comprehensive hearing test that measures a person's response to frequencies and volumes of sound
barotrauma rapid or extreme changes in air pressure that cause the eardrum to rupture
cataract clouding of the lens within the eye
cerumen earwax
cholesteatoma growth of abnormal skin in the middle ear
closed-angle glaucoma type of glaucoma in which the drainage angle between the cornea and iris suddenly becomes blocked, leading to a rapid increase in intraocular pressure and other severe symptoms
CMV retinitis ocular infection caused by the cytomegalovirus (CMV) that primarily affects the retina
conjunctiva thin, clear membrane that covers and protects the eye
conjunctivitis inflammation of the conjunctiva
corneal abrasion loss or disruption of the corneal epithelium, the outermost layer of the cornea

corneal dystrophies group of inherited disorders characterized by abnormal deposits or changes in corneal structure
corneal ulcer area of tissue breakdown in the cornea
diplopia double vision
Epley maneuver repositioning of the head through physical therapy to treat vertigo
erythema redness of the skin or mucus membranes
external otitis inflammation of the external ear
hyperopia (also: *farsightedness*) the condition of seeing distant objects more clearly than closer objects
keratoconjunctivitis sicca (also: *dry eye*) common ocular disorder characterized by insufficient tear production or poor tear quality, leading to dryness and discomfort of the eyes
keratoconus progressive corneal disorder characterized by the thinning and distortion of the cornea, resulting in a conical shape
mastoidectomy removal of infected cells from the mastoid bone
mastoiditis infection of the mastoid bone behind the ear
myopia (also: *nearsightedness*) the condition of seeing closer objects more clearly than distant objects
myringotomy surgical incision in the tympanic membrane
open-angle glaucoma type of glaucoma in which the drainage angle between the cornea and iris remains open but the fluid outflow is impeded
otalgia ear pain
otitis media (also: *middle ear infection*) prevalent condition caused by the invasion of microorganisms into the middle ear via the Eustachian tube
otorrhea ear discharge
otoscopy visual examination of the ear using an otoscope
ototoxicity toxic effects of certain medications or chemicals on the structures of the inner ear, leading to hearing loss, balance problems, or other auditory-related symptoms
pterygium raised thickening of the conjunctiva which extends into the cornea
retinal vascular disorder condition that affects the blood vessels supplying the retina
retinopathy disease of the retina
tinnitus ringing or buzzing in the ear
tonometry measurement of the pressure within the eyes
tympanic membrane perforation ruptured eardrum
tympanometry physical test to measure the function of the tympanic membrane
tympanoplasty surgical reconstruction of the eardrum
tympanostomy tube small tube placed within the tympanic membrane to prevent fluid buildup behind the ear

Assessments

Review Questions

1. What condition is characterized by clouding of the lens of the eye?
   a. cataracts
   b. glaucoma
   c. diabetic retinopathy
   d. ocular trauma

2. What ocular disorder is associated with increased intraocular pressure and optic nerve damage?
   a. cataracts
   b. glaucoma
   c. diabetic retinopathy
   d. ocular trauma

3. What ocular disorder is commonly seen in individuals with diabetes and is caused by damage to the blood vessels in the retina?
   a. cataracts

b. glaucoma
c. diabetic retinopathy
d. ocular trauma

4. What is normal intraocular pressure (IOP) of the eye?
a. 15–25 mm Hg
b. 10–20 mm Hg
c. 12–24 mm Hg
d. 11–21 mm Hg

5. What ocular disorder is characterized by the gradual loss of central vision and is a leading cause of visual impairment in older adults?
a. cataracts
b. glaucoma
c. diabetic retinopathy
d. macular degeneration

6. You are the nurse caring for a patient with cataracts. You anticipate what medical treatment?
a. Remove the cataracts.
b. Treat for increased intraocular pressure.
c. Manage blood glucose control.
d. Prescribe corrective lenses.

7. What tool tests the patient's visual acuity?
a. otoscope
b. Snellen chart
c. FACES pain scale
d. Glascow coma scale

8. The nurse is preparing to assess the ears of a patient who has complained of hearing loss. What instrument will the nurse use to assess the ear during a physical examination?
a. stethoscope
b. ophthalmoscope
c. otoscope
d. sphygmomanometer

9. The nurse is caring for a 4-year-old child with suspected acute otitis media. What is a common symptom of acute otitis media?
a. tinnitus
b. vertigo
c. hearing loss
d. cerumen impaction

10. What would indicate the interventions applied to the plan of care for a child with acute otitis media have been effective?
a. reduced pulling at the ear lobe
b. crankiness or inability to be comforted
c. reduced feedings throughout the day
d. completion of prescribed antibiotic

11. What are examples of medical therapies for disorders of the ear? Select all that apply.
a. antibiotic drops
b. antifungal eardrops

c. nonsteroidal cream
d. nonsteroidal anti-inflammatory drugs (NSAIDs)

Check Your Understanding Questions

1. Explain the difference between open-angle and closed-angle glaucoma.
2. What should be included in the treatment plan for a patient diagnosed with keratoconjunctivitis sicca?
3. How is the diagnosis of a tympanic membrane perforation confirmed?
4. Often the provider orders ear drops for a patient with an ear infection or build-up of earwax. Describe how to administer ear drops.

Reflection Questions

1. Describe nursing interventions you might implement for a patient diagnosed with age-related macular degeneration. What impact might they have on the patient's well-being and overall experience?
2. Reflecting on your response to the previous question, consider any areas where you could have further enhanced your care delivery or patient education. How will you apply this experience to future encounters with patients with ocular disorders?
3. What special accommodations and resources would you need to best serve a patient who is hearing impaired?

What Should the Nurse Do?

1. You are a nurse working with a 65-year-old patient recently diagnosed with glaucoma. The patient appears worried and mentions experiencing increasing difficulty with her peripheral vision. What should the nurse do?
2. What treatments should the nurse anticipate for a patient suspected of closed-angle glaucoma? What should the nurse do in an emergency like this?

Competency-Based Assessments

1. Imagine you are caring for a patient diagnosed with an ocular disorder. How will your knowledge and understanding of the specific ocular disorder influence your approach to patient care? Develop a pamphlet outlining the specific ocular disorder and identifying three cues you would recognize and analyze before developing a hypothesis for care.
2. Develop a brief presentation to share with your peers outlining the medical management a of patient diagnosed with a retinal vascular disorder.
3. Develop a table that outlines the differences between acute otitis media and chronic otitis media.
4. Develop a pamphlet explaining how nurses should educate the parents of an infant who has been diagnosed with acoustic neuroma.

CHAPTER 19

Gastrointestinal System and Disorders

FIGURE 19.1 Gastrointestinal disorders can cause discomfort when left untreated. (credit: "Home remedies to get relief from stomach aches – 1" by News Fibers/Flickr, Public Domain)

CHAPTER OUTLINE

INTRODUCTION The gastrointestinal (GI) system (also referred to as the digestive system) is responsible for several functions, including digestion, absorption, elimination, and immune response. It breaks down food and then absorbs nutrients into the bloodstream via the small intestine and large intestine. Because good health depends on good nutrition, any disorder affecting the functioning of the digestive system can significantly affect overall health and well-being and increase the risk of chronic health conditions. Nutrients from food and fluids are used by the body for growth, energy, and bodily processes. Essential nutrients must come from dietary intake. The carbohydrates, lipids, and proteins in foods are used for energy to power molecular, cellular, and organ system activities.

19.1 Nutritional Disorders

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology of, risk factors for, and clinical manifestations of obesity, anorexia nervosa, and malabsorption
- Describe the diagnostics for and laboratory values monitored in the management of obesity, anorexia nervosa, and malabsorption
- Apply nursing concepts and plan associated nursing care for the patient with obesity, anorexia nervosa, or malabsorption
- Evaluate the efficacy of nursing care for patients with obesity, anorexia nervosa, or malabsorption
- Describe the medical therapies that apply to the care of obesity, anorexia nervosa, and malabsorption

Diet—what you eat and how much you eat—has a dramatic impact on your health. Eating too much or too little food can lead to serious medical issues, including cardiovascular disease, cancer, anorexia, and diabetes, among others. Combine an unhealthy diet with unhealthy environmental conditions, such as smoking, and the potential medical complications increase significantly. This module examines the common nutritional disorders of obesity, anorexia, and malabsorption. Because each disorder creates unique patient care needs, the nurse must be familiar with the appropriate medical care to develop effective care plans.

Obesity

The term **obesity** is defined as abnormal or excess fat accumulation (World Health Organization, n.d.) and a state of malnutrition by excess (Khanna et al., 2022). It is the result of having a chronic positive energy balance from consuming more calories than are being used by the body. This chronic excess of calories is stored as glycogen in the liver, muscle, and fat cells. Understanding the hormonal control of the digestive system is an important area of ongoing research. Scientists are exploring the role of each hormone in the digestive process and developing ways to target these hormones. Advances could lead to knowledge that may help battle the obesity epidemic.

Pathophysiology

Fatty foods are **calorie-dense**, meaning that they have more calories than carbohydrates or proteins per unit mass. One gram of carbohydrates has four calories, 1 gram of protein has four calories, and 1 gram of fat has nine calories. The signals of hunger (time to eat) and satiety (time to stop eating) are controlled in the hypothalamus region of the brain. Foods that are rich in fatty acids tend to promote satiety more than foods that are rich only in carbohydrates.

Excess carbohydrate and adenosine triphosphate (ATP) are used by the liver to synthesize glycogen. The pyruvate produced during glycolysis is used to synthesize fatty acids. When there is more glucose in the body than required, the resulting excess pyruvate is converted into molecules that eventually result in the synthesis of fatty acids within the body. These fatty acids are stored in adipose cells—the fat cells in the mammalian body whose primary role is to store fat for later use.

Risk Factors

There are several behavioral, genetic, and social determinants of health that can contribute to obesity. The more risk factors a person has, the greater chance for obesity.

Poor eating patterns or food choices, inadequate sleep, and insufficient activity are all behavioral risk factors for obesity. Eating large portions and consuming large amounts of calorie-dense foods creates an excess of calories needed by the body to survive. An inactive or sedentary lifestyle also makes it easy to consume more calories than needed to remain healthy. Insufficient sleep causes an imbalance of **leptin** (the hormone that makes you feel full) and **ghrelin** (the hormone that makes you feel hungry), causing you to overeat.

Genetic risk factors for obesity are still being researched. Some variants in certain genes can cause increasing hunger and increased food intake. In rare instances, a mutation of a single gene can cause inherited obesity within a family (CDC, 2024).

The environment and conditions we live in are called social determinants of health. People who have limited access to healthy food choices or safe access to physical activity are more likely to have obesty. Affordability, social supports, marketing and advertising, and policy are all other community factors that can contribute to obesity.

Other factors that can contribute to obesity are certain illnesses and medications. Microbiome and chemical exposures are also being researched to determine a connection to obesity (CDC, 2024).

Clinical Manifestations

Obesity is defined as having a **body mass index (BMI)** of 30 or greater (Table 19.1). An individual's BMI is calculated by dividing their weight (in kilograms) by the square of their height (in meters): kg/m^2. BMI classifications range from severely underweight to obese, with three classifications of obesity. BMI should be used alongside other measurements, because it doesn't account for differences based on a person's ethnicity, body type/shape, or age. For example, the traditional BMI chart underestimated the Asian population risk, so their classification has slight alterations. Genetically, Asian and South Asian people have 3 to 5 percent more body fat, which alters the range (Weir & Jan, 2023).

Weight Status	BMI (kg/m^2)
Severely underweight	<16.5
Underweight	<18.5
Normal range	18.5–24.9
Overweight	25.0–29.9
Obese	≥30.0
Obesity class I	30–34.9
Obesity class II	35–39.9
Obesity class III	≥40 (also known as severe, massive, or extreme obesity)
Asian and South Asian Population	
Overweight	23–24.9
Obesity	≥25

TABLE 19.1 **Classification of Weight Status by BMI** (Weir & Jan, 2023)

A large waist circumference is an indicator of high levels of **visceral fat**, or abdominal fat. This type of body fat is found deep in the abdominal wall and surrounds the organs. High levels of visceral fat can lead to heart disease, diabetes, and stroke. Patients can have a normal BMI and still have a large waist circumference, so many practitioners also measure a person's waist circumference to help guide treatment decisions. Weight-related health problems are more common in males with a waist circumference of greater than 40 inches and in females with a waist measurement of greater than 35 inches (NIH, n.d.).

Assessment and Diagnostics

A thorough nutritional assessment provides information about an individual's nutritional status, as well as risk factors for nutritional imbalances, including obesity. Diagnostics can be used to evaluate for comorbid conditions that can occur with obesity.

Diagnostics and Laboratory Values

Diagnostics and laboratory studies will generally focus on ruling out other comorbidities or health conditions, according to the subjective and objective assessment data found. Laboratory studies that may be performed include a basic metabolic panel, liver function study, kidney function study, lipid profile, thyroid-stimulating hormone and other hormone-level studies, vitamin D levels, urinalysis, hemoglobin A_{1c}, and C-reactive protein. An

electrocardiogram may be ordered to evaluate cardiac rhythm and function. A sleep study can evaluate for sleep apnea, if warranted (Panuganti et al., 2023). Other potential diagnostic studies include

- computed tomography (CT) scan to evaluate internal organ structure
- dual x-ray absorptiometry (DEXA) scan to measure bone density
- hydrostatic weighing (weight while submerged in water) to more accurately measure body fat
- skinfold thickness evaluation to measure subcutaneous body fat

Nursing Care of the Patient with Obesity

Care for patients with obesity is individualized, according to any underlying causes of obesity and any comorbid conditions. Treatment includes behavioral interventions, nutritional modification, medications, and surgical intervention, if appropriate (Panuganti et al., 2023). Nursing management focuses on reinforcement of treatment, patient support, and health teaching and education.

REAL RN STORIES

Nurse: Tommy
Years in Practice: Eight
Clinical Setting: Hospice
Geographic Location: Texas

I had been caring for Ms. C, 55 years old, who had a massive decubitus ulcer to her upper legs and buttocks, for a week. Ms. C weighed 600 pounds. She was a super sweet lady, and she had coronary artery disease, diabetes, and hypertension. Turning Ms. C required the assistance of three other nursing staff members. I spent a large amount of time with Ms. C because of her extensive wound care. She was also cheerful and talkative, so I really didn't mind. One day, Ms. C shared with me that she hadn't been able to get out of bed for a long time, so her son helped her with meals and personal care. Her son, Dominic, was in the room and said he wanted his mom to lose weight, but he was unsure of how to accomplish that while she was bedridden. I asked Dominic what types of foods he prepared for his mom. When he began to list the foods, it became apparent that they often ordered takeout, and when Dominic did cook, he cooked processed, calorie-dense foods that weren't very healthy. After he finished, I asked them both if they'd be willing to have a conversation with me and a nutritional counselor to come up with a realistic diet for Ms. C that Dominic would be able to cook. They both said yes, very enthusiastically. So after I was finished, I set up the meeting. I realized then that one of the reasons Ms. C and Dominic struggled with her weight was because they lacked the knowledge to make healthy changes.

Recognizing Cues and Analyzing Cues

Targeted subjective information focuses on screening for any underlying causes contributing to obesity, such as childhood weight history, family history, sleep patterns, prior weight loss efforts and results, physical activity, surgical history, social history of alcohol and tobacco use, and medications that can cause weight gain. An associated past medical history may reveal thyroid disease, diabetes, cardiovascular disease, or psychosocial disorders such as mood disorders (Panuganti et al., 2023).

Objective assessment data are obtained through inspection, auscultation, and palpation. The nurse begins the physical examination by making general observations about the patient's status. Height, weight, BMI, and waist circumference should be accurately measured and documented. Focused findings may include a crowded oropharynx, abdominal pannus, pedal and/or tibial edema, abdominal striae, distant breath and cardiac sounds, gynecomastia, signs of venous insufficiency, and gait abnormalities (Panuganti et al., 2023).

Prioritizing Hypotheses, Generating Solutions, and Taking Action

The patient's psychosocial well-being and motivation to comply with treatment are important factors in weight reduction. Ways the nurse can reinforce treatment include encouraging healthy eating, reinforcing the importance of positive self-esteem and self-care, developing a food diary for the patient to use, and being realistic about weight-loss goals. Promote increased physical activity through participation in exercise programs, including group exercise programs, to provide the patient with feelings of support. Allow the patient to express their feelings about their weight, appearance, and food, and positively reinforce the patient's efforts to promote weight loss. Educating the

patient, family, and caregivers about the importance of healthy sleep habits, eating schedules, portion control, and a healthy diet can help positive reinforcement and adherence continue after discharge.

Evaluation of Nursing Care for the Patient with Obesity

The process of evaluating nursing care requires the nurse to evaluate each intervention, how the patient responded to it, whether goals were met. It entails a reflection of what could have been done differently to improve the patient's state. Goals of nursing care for a patient with obesity may include

- The patient will have 30 minutes of activity three times a week.
- The patient will have a reduction in depression symptoms within 2 months.
- The patient will have a reduction in snoring within 6 months.
- The patient will have an increased tolerance to activity in 1 month.
- The patient will lose 10% of their body weight in 4 months.

Each goal should have a timeline, and goals can be short term or long term. As the patient reaches goals, a new goal should be made with the patient to direct the next portion of care.

Evaluating Outcomes

The primary patient outcome related to obesity is management of weight loss. The nurse evaluates the patient's meal choices, level of activity, and engagement of care. If the patient is struggling with an exercise regimen, for example, the nurse should evaluate if the patient is not engaged enough to participate or if the exercise is too complicated for the patient to do.

Medical Therapies and Related Care

The goal of obesity treatment is to assist the patient to reach and maintain an ideal weight for their height, body build, and their health. This can improve the overall health and lower the risk of developing complications related to obesity. Medical therapy includes dietary modification, behavior intervention, medications, and possible surgical intervention. The collaborative, interdisciplinary health team may include a dietitian or nutritionist, endocrinologist, bariatric nurse, and behavioral counselor to help the patient understand and make changes in their eating and activity habits. The goal is to create a permanent lifestyle change for the patient, not just something temporary.

The initial treatment goal is incorporation of a low-calorie diet, with frequent emphasis on patient adherence. Maintaining realistic weight loss goals increases patient success. Cognitive therapy, motivational interviewing, and interpersonal psychotherapy may also be used to increase patient compliance.

Behavioral Interventions

The provider may encourage the patient to participate in behavioral modification therapy (BMT) with a therapist who has experience in bariatrics. Through BMT, the patient will learn structured ways to improve lifestyle habits, such as diet choices, exercise, and other behavior choices (Olateju et al., 2021). BMT will also teach the patient about self-monitoring, goal setting, stimulus control, stress management, cognitive restructuring, and problem solving. Patients who participate in BMT are more likely to succeed in long-term weight loss (Olateju et al., 2021).

Medications

Anti-obesity medications may be prescribed for patients with a BMI of 30 or higher or those with a BMI of 27 or higher who have comorbidities. The most common first-choice medication prescribed is orlistat, because of its limited absorption and lack of systemic effects (Panuganti et al, 2023). Other commonly prescribed, U.S. Food and Drug Administration (FDA)-approved medications are listed in (Table 19.2).

FDA-Approved Weight Loss Medication	Mechanism of Action	Contraindications
Orlistat (Alli, Xenical)	Blocks absorption of fat during digestion	Digestive problems, cholestasis, hypothyroidism, kidney stones, seizures
Phentermine-topiramate (Qsymia)	Lessens hunger; makes patients feel full sooner	Glaucoma, hyperthyroidism, mood disorders, cardiac disease, kidney disease Do not use if pregnant or breastfeeding.
Naltrexone-bupropion (Contrave)	Lessens hunger; makes patients feel full sooner	Hypertension, seizures, opioid-use disorder, history of eating disorders May increase suicidal ideation
Liraglutide (Saxenda, Victoza)	Mimics glucagon-like peptide-1 (GLP-1), which regulates appetite in the brain	May increase risk of pancreatitis
Semaglutide (Ozembic, Rybelsus Wegovy)	Mimics GLP-1, which regulates appetite in the brain	Not for use in combination with other GLP-1 agonists or weight loss products; may increase risk of pancreatitis
Setmelanotide (Imcivree)	May reduce appetite and increase resting metabolism	Only for use by patients with proopiomelanocortin deficiency, proprotein convertase subtilisin/kexin type 1 deficiency, or leptin receptor deficiency

TABLE 19.2 **Commonly Prescribed, FDA-Approved Weight Loss Medications** (National Institute of Diabetes and Digestive and Kidney Disease [NIDDK], 2024)

Surgery

The branch of medicine that researches and treats obesity is called **bariatrics**. Bariatric surgery is a consideration for patients with a BMI of 40 kg/m^2 or patients with a BMI of 35 kg/m^2 with significant health issues that would be expected to improve with weight loss. Before preoperative consideration, the patient must show efforts to lose weight for a period of 12 months or more. A dietitian will collaborate with the patient in these efforts and start preoperative teaching for bariatric surgery at the appropriate time. Two common procedures performed are a vertical sleeve gastrectomy and Roux-en-Y gastric bypass.

A **vertical sleeve gastrectomy** is a surgical procedure in which a portion of the stomach is removed, and the size of the stomach is reduced to 3 to 4 ounces (Figure 19.2). This can be done laparoscopically or as an open surgical procedure. A vertical sleeve gastrectomy also reduces the production of ghrelin, resulting in the patient feeling full quickly after consuming a small amount of food. Complications patients may experience from this type of surgery include gastroesophageal reflux, strictures, and gastric ulcers from nonsteroidal anti-inflammatory drug (NSAID) use or smoking.

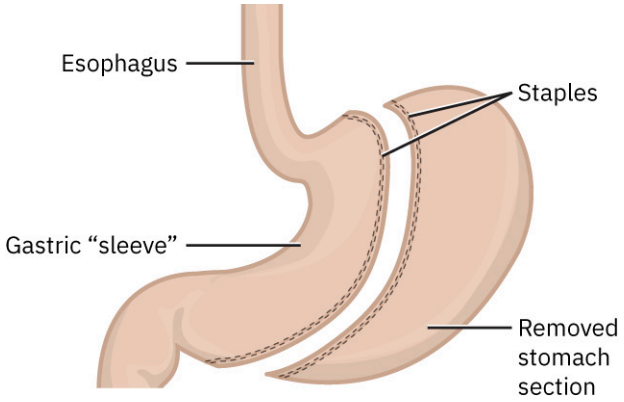

FIGURE 19.2 A gastric sleeve drastically reduces the size of the stomach, to promote weight loss. (credit: modification of work from Anatomy and Physiology 2e. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

A **Roux-en-Y gastric bypass** is the most common type of malabsorption bypass surgery performed in the United States. The procedure involves creating a small, 1-ounce gastric pouch at the gastroesophageal junction, separating the rest of the stomach and bypassing the duodenum to connect the gastric pouch to the lower segment of the small intestine (Figure 19.3). Bypassing part of the small intestine causes malabsorption of vitamins, macronutrients, and minerals. The combination of restrictive stomach size and malabsorption causes rapid weight loss. Complications of gastric bypass include gastric ulcers from NSAID use or smoking, dumping syndrome, steatorrhea, stricture, reactive hypoglycemia, and vitamin and mineral deficiencies.

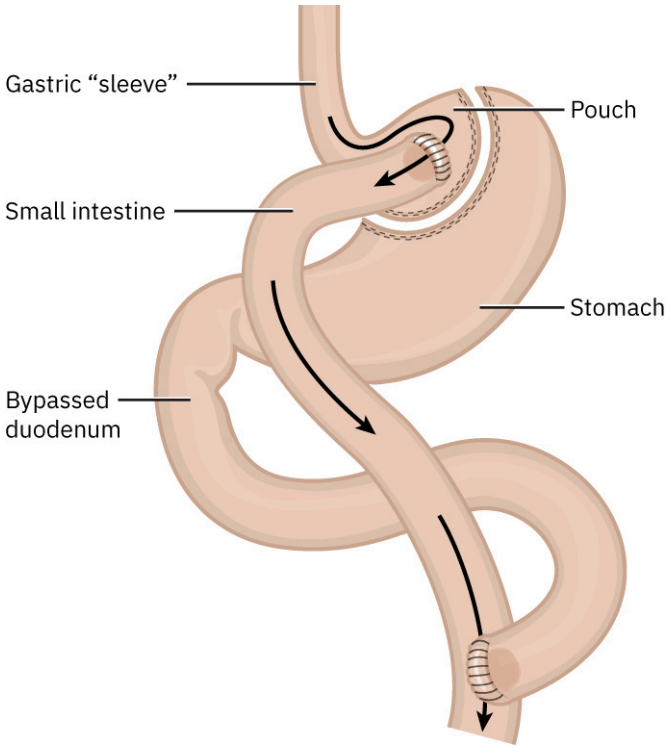

FIGURE 19.3 A gastric bypass significantly reduces food intake and absorption, resulting in rapid weight loss. (credit: modification of work from Anatomy and Physiology 2e. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

LINK TO LEARNING

Dumping syndrome (https://openstax.org/r/77dumpsyndrome) is a common complication of bariatric surgery.

Anorexia Nervosa

The eating disorder **anorexia nervosa** is characterized by the maintenance of a body weight well below average

through severe dietary restriction and/or excessive exercise. Individuals with anorexia nervosa often view themselves as overweight even though they are not. This distorted body image is considered a type of **body dysmorphia**, which is a mental illness characterized by constant worrying over a perceived or slight defect in appearance. Estimates of the prevalence of anorexia nervosa vary from study to study but generally range from just under 1 percent to just over 4 percent in females. Generally, prevalence is considerably lower among men.

Although anorexia nervosa occurs in people from many cultures, White girls and women from Western societies tend to be the most at-risk population. Recent research indicates that girls between the ages of 15 and 19 years are most at risk, and it has long been suspected that eating disorders are culture-bound phenomena that are related to messages of a thin ideal often portrayed in popular media and the fashion world. Although social factors play an important role in the development of eating disorders, there is also evidence that genetic factors may predispose people to this disorder.

Pathophysiology

Anorexia nervosa deprives the body of the basic nutrition necessary to properly function. Studies have evaluated the role of biological and environmental factors that contribute to the development of anorexia nervosa. Patients with anorexia nervosa have deficits in dopamine and serotonin neurotransmitters, which are responsible for eating behavior, reward, impulse control, and neuroticism (Moore & Bokor, 2023). Endocrine abnormalities can include decreased production of thyroid hormones from lack of iodine, increased production of cortisol in response to stress on body from lack of nutrition, and decreased levels of gonadal hormones, such as estrogen and testosterone. Patients often have comorbid psychiatric disorders, such as generalized anxiety disorder and major depressive disorder (Moore & Bokor, 2023).

Clinical Manifestations

Patients with anorexia nervosa usually report symptoms of endocrine dysfunction, such as **amenorrhea** (cessation of the menstrual period), cold intolerance, fatigue, loss of libido, irritability, and extremity edema. Many will also exercise compulsively for extended periods of time and have restrictive behaviors related to food intake, such as calorie counting and portion control (Moore & Bokor, 2023).

Assessment, Diagnostics, and Laboratory Values

Anorexia nervosa is associated with several important negative health outcomes, namely, bone loss, heart failure, kidney failure, reduced function of the gonads, and, in extreme cases, death. Furthermore, there is an increased risk for several psychological problems, including anxiety disorders, mood disorders, and substance misuse. Assessment and treatment of anorexia nervosa focus on understanding the patient's experience and concerns, as well as determining potentially reversible causes. Psychiatric evaluation and diagnosis of anorexia nervosa are based on criteria provided by the American Psychiatric Association. These criteria include the patient having a distorted view of themselves and their condition, intense fear of gaining weight, and a significantly low body weight resulting from severe conscious restriction of calories.

Initial laboratory tests will focus on disease complications based on signs and symptoms gathered from assessment data. Basic laboratory work will include complete blood cell count (CBC), complete metabolic profile, 25-hydroxyvitamin D concentration, testosterone (male patients), and thyroid-stimulating hormone. Urine testing will evaluate beta-hCG in females, as well as a drug screen (illicit and prescription).

An echocardiogram will be completed for patients with cardiopulmonary symptoms, such as dyspnea, syncope, or heart murmur, to assess for arrhythmias. A CT scan of the abdomen may also be done for patients with prolonged amenorrhea or to rule out superior mesenteric artery conditions that could affect the duodenum.

Nursing Care of the Patient with Anorexia

Although anorexia nervosa is a treatable disease, patients have a high risk for relapse. Close monitoring, constant positive reinforcement, and patient education are important interventions to optimize outcomes.

Recognizing Cues and Analyzing Cues

The nurse providing care to a patient with anorexia nervosa uses subjective and objective data to optimize care. Subjective data may include body image disturbances, GI complaints, dizziness, feeling cold, sleep problems, menstrual problems, and muscle weakness. Objective data may include general body emaciation, dry skin, cold extremities, poor wound healing, lower extremity edema, and abnormal laboratory values. Vital signs should focus

on blood pressure and apical heart rate.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Patients being treated for anorexia nervosa in the hospital setting are usually medically unstable due to potential electrolyte imbalances; they may have an increased risk of self-harm due to existing psychiatric disorders. Safety measures the nurse should take to ensure patient safety include following facility protocol for suicide precautions to ensure the patient environment is safe, supervising feedings, and frequent collaboration with the interdisciplinary team.

Evaluation of Nursing Care and Outcomes for the Patient with Anorexia

The nurse will evaluate each nursing action and determine how the patient responded. In addition, the nurse determines if the goals are met using patient input. Among possible goal examples are that the patient will eat 75 percent of their meals every day; the patient will gain 1 pound a week; and the patient will state three things they like about their body every day.

The primary patient outcome for anorexia nervosa management is an increase in caloric intake to sustain healthy bodily function. Collaboration with psychiatry is important in understanding and overcoming the patient's negative thoughts about food and body image.

Medical Therapies and Related Care

Nutritional rehabilitation and psychotherapy are the primary components of treatment for anorexia nervosa. In addition to the nurse and provider, the interdisciplinary team can include a dietitian, psychologist, social worker, and gastroenterologist. In some instances, pharmacotherapy may help. Antipsychotics, such as olanzapine, may help with weight restoration. Patients with comorbid psychiatric conditions may be prescribed serotonin reuptake inhibitors along with psychotherapy.

Malabsorption

The term **malabsorption** refers to the condition whereby the GI tract is unable to properly absorb nutrients, such as proteins, carbohydrates, fats, vitamins, minerals, or trace elements. This can occur with one vitamin or macronutrient, several, or all.

Pathophysiology

Malabsorption occurs when an abnormality in the GI tract impedes the body from absorbing nutrients correctly. Most absorption occurs in the large intestine, but some occurs in the small intestine and stomach. Malabsorption can occur at any phase of the digestion: luminal, mucosal, or postabsorptive (Table 19.3).

Phase of Digestion	Process
Luminal	Carbohydrates, dietary fats, and proteins are hydrolyzed and solubilized by secreted digestive enzymes and bile.
Mucosal	Intestinal epithelial cells transport digested products from the lumen into the cells.
Postabsorptive	Reassembled lipids and other nutrients are transported from intestinal epithelial cells to other parts of the body.

TABLE 19.3 **Phases of Digestion** (Hammami, 2019)

Clinical Manifestations

The most common clinical manifestations of malabsorption are diarrhea, **steatorrhea** (fatty stool), fatigue, abdominal bloating and cramping, increased flatulence, and unintentional weight loss. If the malabsorption is of a vitamin, the patient will have symptoms of that vitamin deficiency (Table 19.4). If the malabsorption is of a macronutrient, the patient will have symptoms resulting from a lack of fat, carbohydrate, or protein.

Vitamin/Mineral Deficiency	Symptoms
Iron	Anemia
Vitamin A	Night blindness
Vitamin B_{12}	Anemia, poor balance
Vitamin K	Abnormal bleeding, ecchymosis
Vitamin D	Osteopenia, osteomalacia, bone pain, motor weakness
Calcium	Secondary hyperparathyroidism, tetany
Magnesium	Tetany
Vitamin B_1 (thiamine)	Peripheral neuropathy
Vitamin B_5	Motor weakness
Vitamin B_7 (biotin)	Seizures

TABLE 19.4 Symptoms Associated with Vitamin and Mineral Deficiencies

Assessment, Diagnostics, and Laboratory Values

The nurse will obtain a history including health history and a general physical assessment, including the course of symptoms. Medical history may reveal a disorder that causes malabsorption, such as celiac disease, lactose intolerance, pancreatic insufficiency, ulcerative colitis, parasite infection, inflammatory bowel disease, or Whipple disease.

When malabsorption is suspected, general testing is done to try to narrow down areas that need more specific testing. Blood tests will include a comprehensive metabolic panel to check liver and kidney function and evaluate for electrolyte imbalances; a CBC count will evaluate for anemia, zinc, phosphorous, albumin, and magnesium; and vitamin levels will be evaluated.

Fecal testing may be done to evaluate for fat malabsorption. Jejunal aspirate samples will be cultured to check for bacterial overgrowth in the small intestine. A breath test can evaluate for carbohydrate malabsorption. Some examples of studies for specific conditions include

- colonoscopy and biopsy to diagnose ulcerative colitis
- CT scan to diagnose pancreatitis
- endoscopic retrograde cholangiopancreatography (ERCP) to diagnose pancreatic insufficiency in patients with a history of pancreatitis or alcohol use disorder
- endoscopy to diagnose Crohn disease or jejunoileitis
- magnetic resonance elastography to diagnose liver fibrosis or stiffness
- magnetic resonance cholangiopancreatography to diagnose exocrine pancreatic insufficiency

Nursing Care of the Patient with Malabsorption

The care of the patient with malabsorption focuses on ongoing assessments and patient and family education. If the cause of malabsorption is determined, then more focused care can be provided. A general measure that may be helpful to the patient is food journaling, logging symptoms and the time symptoms occur.

Recognizing Cues and Analyzing Cues

Patients with malabsorption may present with common GI symptoms, along with symptoms of vitamin or mineral deficiencies. Objective data may include signs of muscle wasting, distended abdomen, ascites, ecchymosis, peripheral neuropathy, oral mucus membrane ulcers, peripheral edema, a positive Chvostek or Trousseau sign, and

pale skin. Evaluate vital signs with a focus on blood pressure. The nurse may note orthostatic hypotension. It is important to ask the patient about their medical and surgical history and the history of their symptoms, including when they began and how they have progressed. A history of GI surgery, especially weight loss surgery, also increases a patient's risk for malabsorption.

LINK TO LEARNING

Watch this video to learn more about the signs and symptoms of malabsorption (https://openstax.org/r/77malabsorption) along with causes and treatment of the condition.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

The patient's GI symptoms may be the primary condition or a symptom of a disease. The nurse will assist with diagnostic testing and educate the patient about any diagnostic procedures performed. The nurse will provide emotional support to the patient (Zuvarox & Belletieri, 2020).

Evaluation of Nursing Care and Outcomes for the Patient with Malabsorption

Evaluation of care centers around improvement of symptoms and diet modifications. Accurately understanding the cause of malabsorption can improve the nurse's ability to evaluate outcomes. The nurse evaluates if the patient is receiving adequate nutrition. The nurse monitors vital signs and completes a physical assessment to evaluate symptom improvement. Laboratory blood values can reveal improvements in vitamin, mineral, and electrolyte balance.

Medical Therapies and Related Care

Medical treatment is focused on finding and treating the underlying cause of malabsorption, avoiding any food triggers, and symptom management. Treatment can vary from dietary changes and supplementation to surgical intervention, if necessary. Consider referral to a gastroenterologist.

19.2 Disorders of the Oral Cavity

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss pathophysiology, risk factors, and clinical manifestations for oral cavity disorders
- Describe the diagnostics for and laboratory values monitored in the management of oral cavity disorders
- Apply nursing concepts and plan associated nursing care for the patient with oral cavity disorders
- Evaluate the efficacy of nursing care for patients with oral cavity disorders
- Describe the medical therapies that apply to the care of oral cavity disorders

Digestion begins in the upper gastrointestinal tract at the mouth, where individuals chew food—a process called **mastication**. Mastication results in mechanical digestion when food is broken down into small chunks and swallowed. Masticated food is formed into a bolus as it moves toward the pharynx in the back of the throat and then into the esophagus (Figure 19.4). Dental caries, periapical abscesses, oral cancer, salivary calculus, or temporomandibular joint (TMJ) disorders can prevent a patient from this first step of digestion. This section will look at common oral cavity disorders, as well as how the nurse can effectively care for these patients.

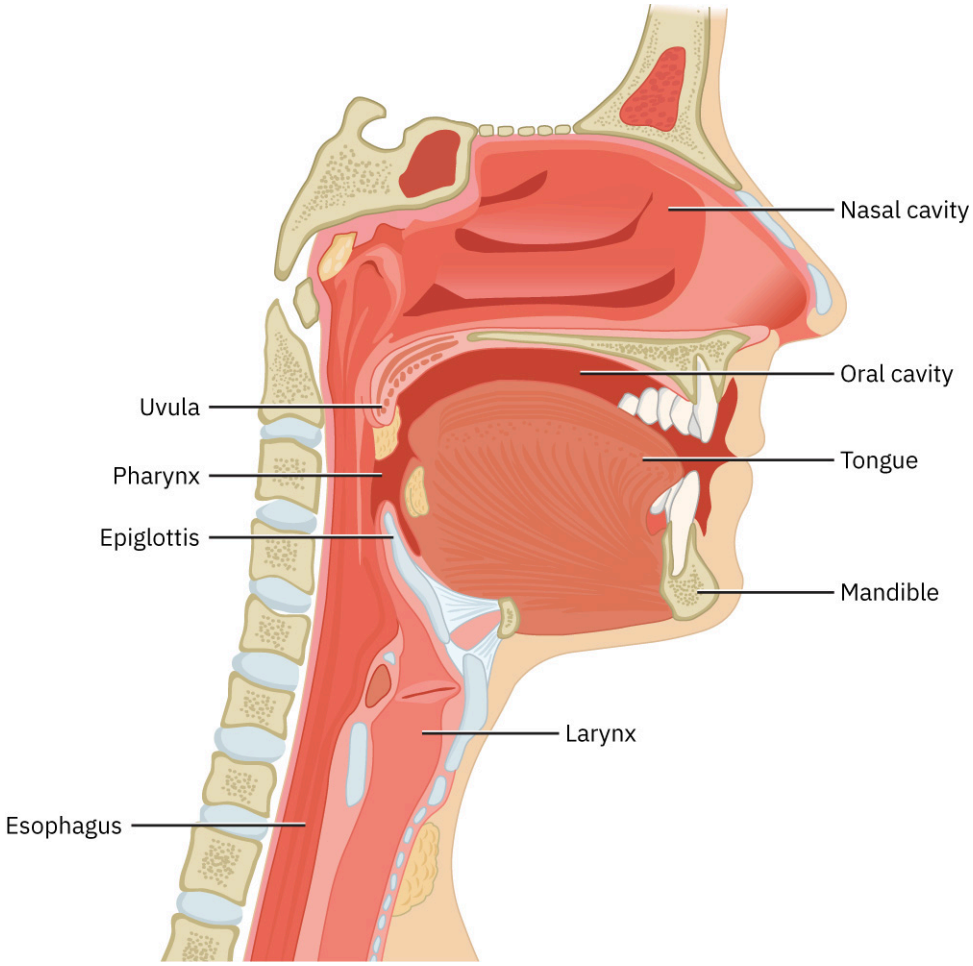

FIGURE 19.4 This illustration shows the anatomy of the mouth and throat, where digestion begins. (credit: modification of work from *Anatomy and Physiology* 2e. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Dental Caries and Plaque

The term **plaque** refers to a sticky film on the teeth made up of leftover food particles and bacteria. Poor dental hygiene allows plaque to break down or demineralize tooth enamel, causing **dental caries** or cavities. Dental caries (Figure 19.5) are one of the most common chronic oral cavity diseases, even though they are easily preventable with good oral hygiene (CDC, 2022b). Caries may cause pain, make it difficult to chew foods and drink liquids, and can also affect an individual's self-esteem when the caries are easily visible.

FIGURE 19.5 This image shows a patient with multiple dental caries. (credit: Centers for Disease Control and Prevention/Public Health Image Library, Public Domain)

Pathophysiology

Dental caries are caused by **cariogenic bacteria**, bacteria that cause tooth decay, in the mouth. These bacteria live in plaque and biofilm on the teeth and convert carbohydrates, such as starches and sugars, into acids (Rathee & Sapara, 2023). This acidic environment causes the calcium on enamel to be slowly dissolved or demineralized, resulting in caries. The caries will continue to expand until appropriately treated. Factors that contribute to an increased chance of dental caries include tobacco use, diabetes, high carbohydrate intake (including high amounts of sugar), advanced age, and dry mouth.

Clinical Manifestations

Initially, dental caries can be asymptomatic. A patient may complain of tooth pain or sensitivity when eating foods that are hot, cold, or sweet. Physical signs ultimately include brown, black, or white discoloration or staining of the tooth. With more advanced disease, a small hole or cavity may appear.

Prevention

Prevention of dental caries starts with brushing teeth two times a day with a fluoride toothpaste and flossing daily. The recommendation is for individuals to see a dentist every 6 months to get a professional teeth cleaning, identify and treat troublesome areas early, and apply a fluoride treatment. Toothbrushes should be replaced every 3 to 4 months. Smoking cessation can also reduce the incidence of dental caries. Other interventions, such as drinking fluorinated water and eating a well-balanced diet, also prevent caries.

In the inpatient setting, it is important for nurses to provide mouth care for patients who are unable to perform self-care. This includes brushing the teeth with a soft-bristled toothbrush or oral sponge and placing water soluble ointment or gel on the lips to prevent drying.

LIFE-STAGE CONTEXT

Older Adult Oral Health

Caries and tooth loss can increase with age because of decreased saliva production, receding gums, chronic disease, and vision, cognitive, and physical limitations. Because older adults often have receding gums, cavities are more likely to develop at the root of the tooth. Dry mouth also causes bacteria to build up in the mouth more easily, leading to tooth decay (NIDCR, 2021). Loss of dental benefits upon retirement can contribute to difficulty accessing appropriate dental care (CDC, 2020).

Cancer of the Oral Cavity or Pharynx

Cancer of the oral cavity or pharynx can develop on the tissue of the mouth and gums, on or under the tongue, and at the back of the mouth or throat. It is diagnosed most often in people over the age of 40 years, and accounts for about 3 percent of the yearly diagnosed cancers in the United States (NIDCR, 2023). The 5-year relative survival rate for these types of cancers is 68% in the United States.

Pathophysiology

Oral cancer is caused by DNA mutations in the cells of the mouth, causing a growth of mutated cells to occur. Although the immune system usually detects and eliminates mutated cells in the body, these cells can multiply unnoticed. Although it is unknown what exactly causes the DNA mutations, factors that have been shown to increase the risk of oral cancer include tobacco use, heavy alcohol use, exposure to human papillomavirus, excessive sun exposure to the lips, and a weak immune system.

Clinical Manifestations

Oral cancer is suspected when an oral lesion will not heal and is in place for 2 weeks or longer. The lesion may be an unusual color compared with the surrounding tissues. The cancer may grow or cause bleeding. Generally, the patient is otherwise asymptomatic (Figure 19.6), which delays diagnosis and treatment.

FIGURE 19.6 Oral cancer is seen on the tongue of the patient. (credit: Welleschik/Wikimedia Commons, CC BY 4.0)

Assessment, Diagnostics, and Laboratory Values

When assessing a patient for oral cancer, signs and symptoms to seek include loose teeth, lip or mouth sores that do not heal, white or red patches inside the mouth, lumps (visible in the mouth or palpated around the jaw or neck), pain in the ears or mouth, hoarseness, and difficulty swallowing, chewing, or moving the jaw. Be sure to accurately document and report findings appropriately.

When a patient is suspected to have oral cancer, the selection of diagnostic testing is dependent on the area of the lesion or tumor. Diagnostic tests that may be used to diagnose oral cancer include endoscopy, biopsy, oral brush biopsy, human papillomavirus testing, x-ray, CT scan, barium swallow study, magnetic resonance imaging (MRI), ultrasound, and positron emission tomography (PET) scan. If metastasis is suspected, other areas of the body may be evaluated.

Nursing Care of the Patient with Cancer of the Oral Cavity

Nursing care of the patient with oral cancer focuses on patient support during therapy and treatment, nutrition promotion, pain control, and providing emotional support. Patient teaching is done, with a focus on smoking and alcohol cessation, a healthy diet, and sun safety, and regular exercise should be emphasized. The nursing plan of care should be evaluated and updated as the patient progresses through treatment.

Recognizing Cues and Analyzing Cues

Follow-up is important when discovering lesions or growths in the oral cavity or neck. Asking focused and specific questions, such as when the patient noticed the growth or lesion, if it is painful, and if it has changed at all, will give the nurse cues to further evaluate. Assess the patient for any breathing, chewing, or swallowing difficulties, and report findings to the provider.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

The priorities of care during treatment are maintaining a patent airway and healthy nutritional status, and providing emotional support, pain relief, and patient education. Frequent airway assessments may be necessary. The patient may require enteral (i.e., through the GI tract) or parenteral (i.e., through an intravenous [IV] access) nutrition during treatment. The nurse should ensure the patient has access to a pen and paper so they can communicate postoperatively. Developing an appropriate care plan based on nursing diagnoses and developing SMART goals will aid the nurse in patient care.

Evaluation of Nursing Care and Outcomes for the Patient with Cancer of the Oral Cavity

To evaluate the effectiveness of nursing actions, review the goal and see if it was achieved by the set deadline. If the goal is not met, goals and interventions will need to be modified. The ideal outcome of care related to oral or oropharangeal cancer is to cure the disease. The nurse maintains an active role in administering and monitoring therapies, including noting the patient's response. The nurse also evaluates how well symptoms are being managed and collaborates with the provider frequently.

Medical Therapies and Related Care

Medical therapy for the treatment of oral and oropharyngeal cancer depends on the type or nature of the lesion and the preference of the physician and patient. Smaller lesions on the lip may be surgically excised; larger lesions may need radiation therapy. Tongue lesions may be treated with radiation, chemotherapy, surgery, or a combination of therapies. Some cases necessitate removal of part or all of the tongue. For larger neck or mouth dissections, reconstructive surgery may be required using a skin flap from the arm or chest. Depending on the progression of disease and care, the patient may require a temporary or permanent tracheostomy and feeding tube for management. Multiple people make up the interdisciplinary team and can include an oncologist, surgical oncologist, radiation oncologist, plastic surgeon, oncologic dentist, physical therapist, speech language pathologist, psychologist, audiologist, and nutritionist.

Temporomandibular Disorders

The TMJ is a sliding hinge (Figure 19.7) that connects the mandible to the skull. This sliding joint, located on each side of the jaw, allows for the range of motion needed during mastication. Temporomandibular disorder (TMD) is a collection of more than 30 disorders that cause pain and dysfunction of jaw movement. TMD is twice as common in women, especially those between 35 and 44 years old (NIDCR, 2023).

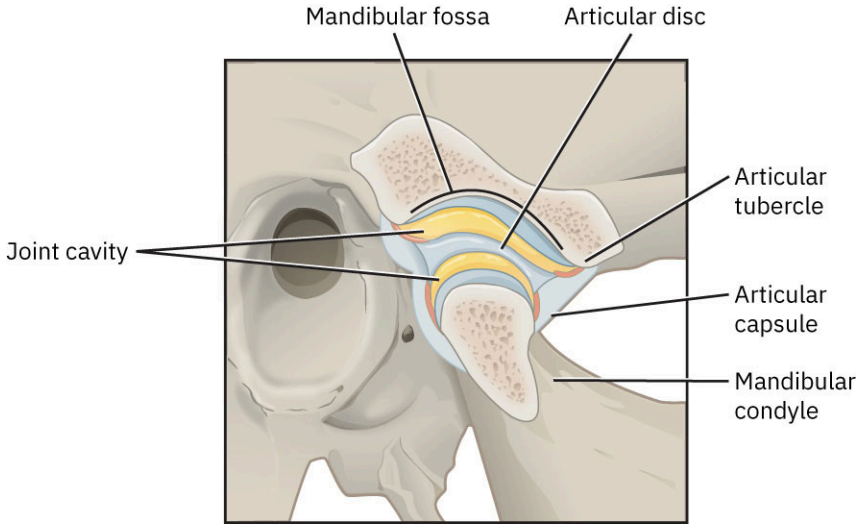

FIGURE 19.7 The temporomandibular joint is a sliding hinge between the temporal bone and the mandible. (credit: modification of work from *Anatomy and Physiology* 2e. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Pathophysiology

The pathophysiology of TMD is unclear. Research suggests it is caused by a combination of psychological stressors, life stressors, genes, jaw trauma, grinding the teeth, and arthritis or other inflammatory conditions.

Clinical Manifestations

The patient may present with pain in the jaw area that may radiate to the face, neck, or ears; limited movement or locking of the jaw; clicking or popping when opening or closing the mouth; and a change in bite alignment.

Assessment and Diagnostics

To assess for TMD, perform a focused assessment of the jaw. Inquire when the symptoms started, what makes them worse or better, and their frequency. Assess the range of movement of the jaw and ask the patient to identify any aggravating factors. Ask if there are any accompanying symptoms, such as headaches or back pain.

LINK TO LEARNING

This animation shows a healthy TMJ (https://openstax.org/r/77healthyTMJ) in motion.

The three main classes of TMD (Figure 19.8) are disorders of the joints, disorders of the muscles, and headaches associated with TMD (NIDCR, 2023).

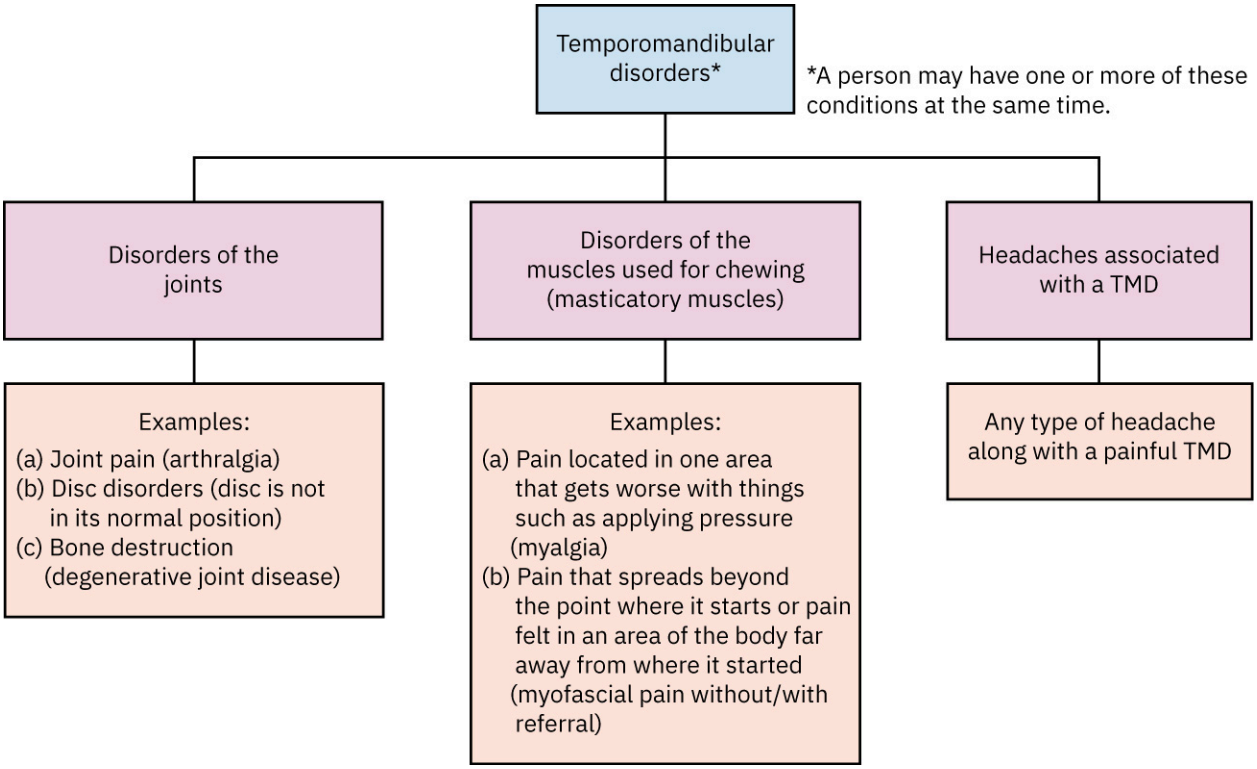

FIGURE 19.8 TMD is classified into three categories. (credit: "Classification of Temporomandibular Disorders (TMDs) with Examples" by National Institute of Dental and Craniofacial Research, Public Domain)

Generally, diagnosis is based on symptoms, physical assessment, and medical history. An x-ray, CT scan, or MRI may be performed for further evaluation and to rule out other conditions.

Nursing Care of the Patient with Temporomandibular Disorders

Nursing care should focus on pain relief and education about prevention. Prevention education should include self-management strategies, such as stress management to prevent grinding teeth and jaw clenching, that the patient can use in conjunction with other treatments.

Recognizing Cues and Analyzing Cues

A patient who presents with a complaint of jaw pain and also has a history of jaw clenching when experiencing stress, may have TMD. After collecting and recording assessment data, the nurse presents the findings to the provider for further evaluation.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

The priority of care would be symptom improvement along with pain management and patient teaching. Teaching should include avoiding eating hard foods, reducing the habit of jaw clenching or gum chewing, application of heat or cold to area, taking NSAIDs, and gently performing stretching exercises of the jaw.

Evaluation of Nursing Care and Outcomes for the Patient with TMD

The nurse will evaluate the care provided to see if symptoms of jaw pain have improved. It is important to note that symptom improvement may happen over time and the patient will have to be educated on the importance of therapy compliance. The primary patient outcome for TMD is improvement of symptoms. The nurse evaluates how often the patient is experiencing pain, including if or how often it is preventing the patient from performing normal tasks, such as eating. It is also important for the nurse to assess if there is improvement to any underlying factors, such as stress management or healthy coping mechanisms the patient has developed.

Medical Therapies and Related Care

TMD is usually a temporary disorder that resolves without aggressive treatment. Physical therapy may be helpful by stretching the soft tissues and muscles supporting the joint to increase range of motion and reduce pain. Medications, such as NSAIDs, muscle relaxants, opioids, or antidepressants, may be prescribed as pain management measures. An intraoral orthotic, or bite guard, may protect the jaw at night from nocturnal teeth grinding (Figure 19.9). Psychological and behavioral therapy can also help the patient with stress management and grinding prevention.

FIGURE 19.9 A bite guard provides a cushion for the teeth in patients who grind their teeth when they sleep, helping to protect the TMJ. (credit: Linkhiei/Wikimedia Commons, CC BY 1.0)

19.3 Parenteral and Enteral Nutrition

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Describe the indications for parenteral and enteral nutrition
- Identify the nurse's role in administering parenteral and enteral nutrition

Nutrients from food and fluids are used by the body for growth, energy, and bodily processes. When the patient is unable to eat, they need to receive nutrition in a different way. This section discusses the different ways nutrition can be administered, and the role of the nurse in managing and evaluating their effectiveness.

Parenteral Nutrition

The term **parenteral nutrition** refers to a concentrated solution containing glucose, amino acids, minerals, electrolytes, and vitamins that is administered to a patient intravenously. An IV fat emulsion solution is typically administered as a separate infusion one to three times a week. Parenteral nutrition is administered via a large central IV catheter (also known as a "line"), typically in the subclavian or internal jugular vein, because the high dextrose concentration is irritating to small blood vessels and can cause chemical phlebitis.

Parenteral nutrition is typically used when the patient's intestines or stomach are not working properly and must be bypassed, such as during paralytic ileus, in which peristalsis has completely stopped, or after postoperative bowel surgeries, such as bowel resection. It may also be prescribed for conditions such as severe malnutrition, severe burns, metastatic cancer, liver failure, or hyperemesis with pregnancy.

Total Parental Nutrition

Parenteral nutrition that includes an **intravenous fat emulsion** (IV administration of fat) provides complete nutritional support and so is called **total parental nutrition (TPN)**. The provider orders the TPN daily for the patient

(Figure 19.10), based on the patient's electrolytes laboratory values. TPN rates should be strictly followed. If administered too fast, the patient can go into fluid overload (hypervolemia) and become hyperglycemic; if administered too slowly, the patient can become hypoglycemic.

FIGURE 19.10 This is an example of a total parenteral nutrition bag in which the glucose, amino acids, and fats are kept separate to enable room temperature storage. Before use, they are all mixed together. (credit: "Tpn 3bag.jpg" by Tristanb/Wikimedia, CC BY SA 3.0)

TPN may be administered through a central or peripheral IV site. The decision is made based on the formula prescribed by the provider and a discussion with the patient. Whichever is chosen, the purpose is to provide needed nutrients. The central line is the most likely route for TPN. The central line is inserted by the provider, then a chest x-ray is ordered and read prior to using the site. The chest x-ray ensures proper placement of the line and that placement did not cause a **pneumothorax**, or collapsed lung. If the chest x-ray shows a pneumothorax, the patient may require a chest tube to reinflate the lung (for more discussion, see Chapter 11 Gas Exchange, Airway Management, and Respiratory System Disorders). If the chest x-ray shows the central line is in position and there is no pneumothorax, the TPN will be started. Commonly, the central line may have a double or triple lumen so the patient can receive fluids and medications without disruption of the TPN.

Peripheral TPN, also called peripheral parenteral nutrition, is typically used for shorter-term nutritional support or for a patient who cannot tolerate a central line. If the peripheral line infiltrates, the line must be restarted promptly. A delay in restarting the IV line is a safety concern because it places the patient at risk for hypoglycemia.

Nursing Management

Administering parenteral medications, as with other injectable medications, is considered an invasive procedure. It is imperative to take additional measures when administering parenteral medications to prevent health care–associated infections. These measures include hand hygiene, prevention of needle or syringe contamination, preparation of the access site, prevention of contamination of the solution, and use of new, sterile tubing for each bag of nutrition.

Nursing management of the patient receiving parenteral nutrition includes

- verifying the appropriateness of the parenteral nutrition
- assessing the patient's response to the infusion
- monitoring for complications, such as electrolyte imbalances or central line–associated bloodstream infection
- monitoring the patient's glucose levels regularly and managing hypoglycemia or hyperglycemia promptly
- if administering peripheral parenteral nutrition, ensuring the site is monitored frequently and per facility protocol for signs of complications such as infiltration

Enteral Nutrition

Nutrition provided directly into the GI tract through an enteral tube that bypasses the oral cavity is called **enteral nutrition (EN)**, or tube feeding. EN is used widely in rehabilitation, long-term care, and home settings. EN requires an interdisciplinary team approach, including a registered dietitian, health care provider, pharmacist, and bedside nurses. The registered dietitian performs a nutrition assessment and determines what type of EN is appropriate to promote improved patient outcomes. The health care provider writes the order for the EN. Prescriptions for EN should be reviewed by the nurse for the following components: type of EN formula, amount and frequency of free water flushes, and administration route, method, and rate. Any concerns about the components of the prescription should be verified with the provider before tube feeding is administered.

Clinical Indications

Enteral feeding is indicated for patients who cannot maintain adequate oral intake to meet nutritional demands. Indications for EN include

- comatose patients with a traumatic brain injury or receiving mechanical ventilatory support
- conditions associated with higher nutritional demands, such as burns, critical illness, and cystic fibrosis
- mental illness such as dementia
- neuromuscular disorders, such as advanced Parkinson's disease
- severe anorexia from human immunodeficiency virus (HIV), chemotherapy, or sepsis
- Upper GI obstruction, stricture, or tumor

Types of Enteral Feeding Tubes

There are several different types of EN tubes; they differ in their location in the GI system as well as their function. Three commonly used enteral tubes are the nasogastric (NG) tube, the percutaneous endoscopic gastrostomy (PEG) tube, and the percutaneous endoscopic jejunostomy (PEJ) tube (Figure 19.11).

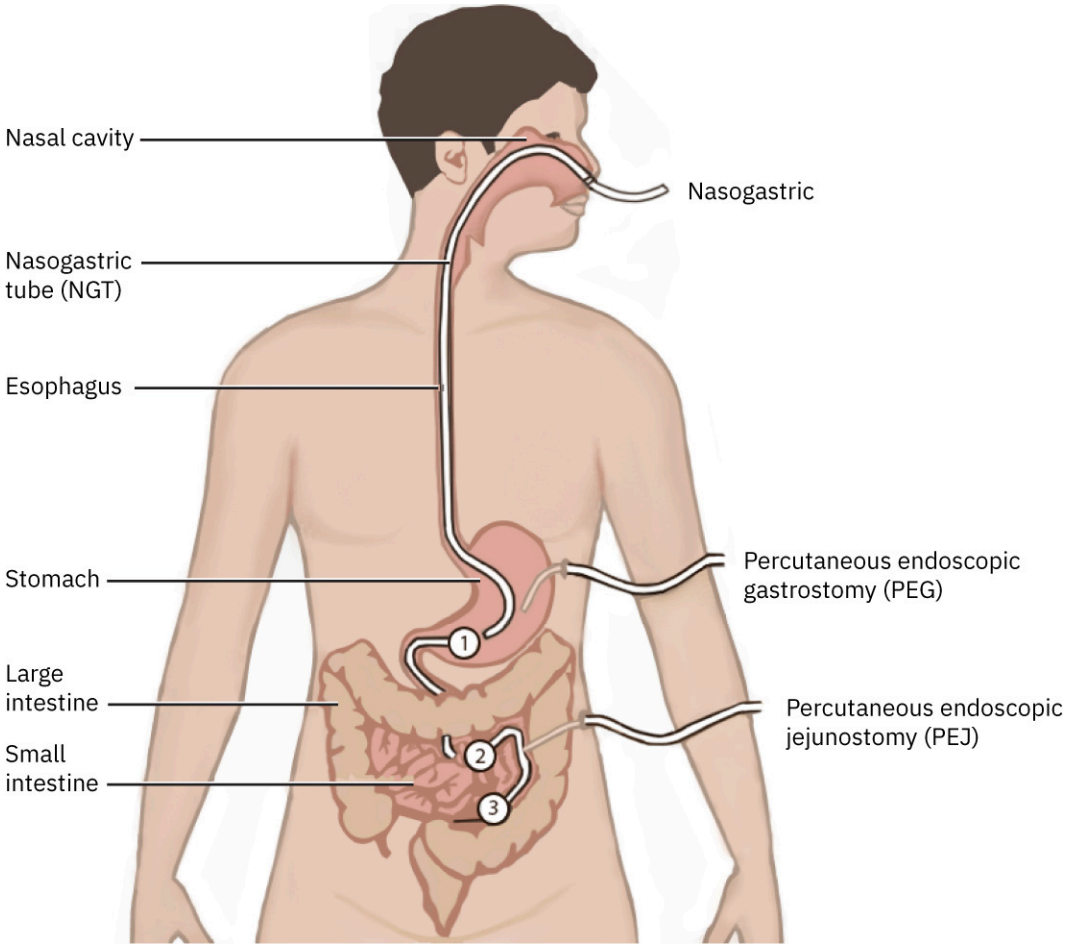

FIGURE 19.11 Enteral feeding tubes can be placed through the nose or through the skin and reach several places in the digestive system. (credit: "Types and Placement of Enteral Tubes" by OpenRN/*Nursing Skills*, 2e, CC BY 4.0)

An NG tube is a single- or double-lumen tube that is inserted into the nasopharynx, then down through the esophagus, and into the stomach. NG tubes can be used for feeding, medication administration, and suctioning. NG tubes used for feeding and medication administration are small and flexible, whereas NG tubes used for suctioning are larger and more rigid. NG tubes are secured externally to the patient's nose or cheek by adhesive tape or a fixation device, so this area should be assessed daily for signs of pressure damage.

Other types of tubes are placed through the patient's abdominal wall and are used for long-term enteral feeding. A PEG tube is placed into the stomach via an endoscopic procedure. Alternatively, a PEJ tube is placed in the jejunum of the small intestine for patients who cannot tolerate the administration of enteral formula or medications into the stomach, due to medical conditions such as delayed gastric emptying.

Nursing Management

The most serious complication of enteral feeding is inadvertent respiratory aspiration of gastric contents, which can cause life-threatening aspiration pneumonia. Other complications include tube clogging, tubing misconnections, and patient intolerance of enteral feeding. To prevent tubing misconnections, the nurse should take the following precautions:

- Make tubing connections under proper lighting.
- Do not modify or adapt IV or feeding devices, because doing so may compromise the safety features incorporated into their design.
- When making a reconnection, routinely trace lines back to their origins and then ensure they are secure.
- As part of a hand-off process, recheck connections and trace all tubes back to their origins.
- Clearly label all tubing at both the proximal and distal ends (Boullata et al., 2017).

Nurses perform interventions to prevent aspiration. The American Association of Critical-Care Nurses recommends

the following guidelines to reduce the risk for aspiration:

- Assess feeding tube placement at 4-hour intervals.
- Assess for GI intolerance at 4-hour intervals (Boullata et al., 2017).
- Maintain the head of the bed at 30° to 45° unless contraindicated.
- Monitor the nare for skin integrity. Adhere to facility protocol for adhesive and medical device pressure injury prevention strategies.
- Observe for change in the amount of external length of the tube. The centimeter mark at the nare should be documented and verified with at each assessment.
- Use sedatives as sparingly as possible.

Feeding tubes are prone to clogging for a variety of reasons, including size or location of the tube, insufficient water flushes, aspiration for **gastric residual volume** (GRV; the volume of stomach contents), contaminated formula, and incorrect medication preparation and administration. Research supports water as the best choice for initial declogging efforts (Boullata et al., 2017). If water does not work, a pancreatic enzyme solution, an enzymatic declogging kit, or mechanical devices for clearing feeding tubes are the best second-line options. To prevent EN tube clogging, the nurse should:

- Flush feeding tubes at a minimum of once a shift.
- Flush feeding tubes immediately before and after intermittent feedings. During continuous feedings, flush at standardized, scheduled intervals.
- Flush feeding tubes before and after medication administration and follow appropriate medication administration practices.
- Limit GRV checks because the acidic gastric contents may cause protein in enteral formulas to precipitate within the lumen of the tube.

REAL RN STORIES

Nurse: Tommy
Years in Practice: Fifteen
Clinical Setting: Emergency department and intensive care unit (ICU)
Geographic Location: Northwest Texas

I was working in the ICU and received an order to insert a weighted feeding tube with a wire guide for Mr. R, who was sedated and on a ventilator. I was able to insert the tube without difficulty, and a chest x-ray was ordered. The x-ray showed the tube was inserted into the trachea and into the lung. I paged the critical care provider to come and together we were able to reposition the tube into the correct position. A second x-ray confirmed proper placement.

At first, I have to admit it bothered me that I didn't get it on the first try, but I then realized that sometimes these things happen. The hospital had a process for nurses to be credentialed to insert the weighted feeding tubes with a wire guide, and I followed the whole procedure. I was so sure I had the tube in the correct spot; thank goodness we're required to confirm placement by x-ray, or I would've been infusing feedings into Mr. R's lungs.

19.4 Disorders of the Upper GI System

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations of upper GI disorders
- Describe the diagnostics for and laboratory values monitored in the management of upper GI disorders
- Apply nursing concepts and plan associated nursing care for the patient with upper GI disorders
- Evaluate the efficacy of nursing care for a patient with upper GI disorders
- Describe the medical therapies that apply to the care of upper GI disorders

This section focuses on common disorders of the esophagus and stomach that can prevent proper digestion and absorption of nutrients, and how the nurse can effectively plan and implement care. Recall that masticated food from the mouth is formed into a bolus as it moves toward the pharynx in the back of the throat and then into the

esophagus. Coordinated muscle movements in the esophagus, called **peristalsis**, move the food bolus into the stomach, where it is mixed with acidic gastric juices and further broken down into **chyme** through a chemical digestion process. As chyme is moved out of the stomach and into the duodenum of the small intestine, it is mixed with bile from the gallbladder and pancreatic enzymes from the pancreas for further digestion.

Barrett's Esophagus

A condition called **Barrett's esophagus** entails the cells lining the esophagus change, becoming more like intestinal cells. It is more common in men and usually is diagnosed around age 55 years (Spechler, 2022). The cells that develop on the esophagus can be precancerous and increase the patient's chance of developing esophageal adenocarcinoma (Souza & Spechler, 2022).

Pathophysiology

Although the exact pathophysiology is unknown, researchers believe that damage to the squamous esophageal cells resulting from gastroesophageal reflux disease (GERD) causes the cells to undergo constant repair and wound healing. The continuous damage and wound healing causes progenitor cells (cells that can differentiate into a specific cell type) from the esophagogastric junction to travel to the esophagus to aid in wound healing and replace the squamous epithelial cells. Along with GERD, other risk factors for developing Barrett's esophagus include central obesity, smoking, and family history.

Clinical Manifestations

Barrett's esophagus is frequently asymptomatic, but patients tend to have other symptoms of GI conditions, such as frequent heartburn and acid regurgitation or reflux. In some cases, Barrett's esophagus can cause ulceration and stricture, and patients may have the symptoms of dysphagia or **odynophagia** (painful swallowing).

Assessment, Diagnostics, and Laboratory Values

Assessment is primarily based on focused subjective data gathered by the nurse and provider. Although often there are no signs or symptoms of Barrett's esophagus, it is often discovered when completing diagnostic testing for other more common GI issues, such as heartburn or reflux.

An upper endoscopy will confirm visual changes to the tissues in the esophagus. A biopsy of the tissues will ultimately confirm Barrett's esophagus. Tissue changes that are 3 cm or longer are termed long-segment Barrett's, and tissue changes that are 1 cm or shorter are termed short-segment Barrett's (Spechler, 2022).

Nursing Care of the Patient with Barrett's Esophagus

Patients in the hospital setting with Barrett's esophagus have often had surgical intervention to remove parts of the esophagus. Nursing care consists of administration of prescribed medications such as antireflux agents to control reflux and monitoring for symptom improvement.

Recognizing Cues and Analyzing Cues

When providing care to a patient with Barrett's esophagus, the nurse relies heavily on a focused subjective assessment, because there are often no physical signs or symptoms of disease. Subjective data may include a history of frequent GERD, heartburn, dysphagia, or odynophagia. The nurse inquires about the frequency, severity, and duration of symptoms, and if symptoms interrupt the patient's sleep.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Foods that are spicy, fatty, acidic, or contain caffeine, carbonation, or alcohol can exacerbate symptoms of reflux and heartburn and trigger episodes of odynophagia or dysphagia. The nurse may ensure the patient receives prescribed proton pump inhibitors as ordered. A **proton pump inhibitor (PPI)** is a medication that binds to the hydrogen-potassium ATPase enzyme system of the parietal cell, thereby pumping hydrogen ions into the stomach. The nurse should provide patient education about food choices that help prevent acid reflux, such as whole grains, root vegetables, and green vegetables.

Evaluation of Nursing Care and Outcomes for the Patient with Barrett's Esophagus

Symptom improvement and patient understanding of the importance of diet modification and medication adherence are the goals of treatment for Barrett's esophagus. Reassessment of symptoms reported and monitoring of the patient's food choices can determine areas that need further intervention. A patient who is still having symptoms, or not experiencing symptom improvement, may need additional medical or dietary intervention. It is important to

collaborate with the interdisciplinary team when evaluating outcomes so treatment therapies can be modified to be more effective.

Medical Therapies and Related Care

Patients diagnosed with Barrett's esophagus are prescribed a PPI, such as omeprazole or pantoprazole, to eliminate GERD symptoms and prevent further esophageal irritation. When reflux symptoms are not controlled by PPI therapy, antireflux surgery (fundoplication) may be performed. Diet modification is also important, and patients are encouraged to eat a low-acid, GERD-friendly diet.

Gastritis

Inflammation and redness of the lining of the stomach is called **gastritis**. The incidence of gastritis in the United States is 8 out of 1,000 people (Cleveland Clinic, 2023b). It may be acute or chronic, and erosive or nonerosive; once the underlying cause is treated, it usually resolves. A common complication of gastritis, **peptic ulcer disease (PUD)** is a defect in the lining of the stomach or duodenum and can occur when gastritis is left untreated. Approximately 10% of the U.S. population has had PUD at some time (Malik et al., 2023).

Pathophysiology

Acute gastritis is usually caused by an irritant, such as aspirin or NSAID use, heavy alcohol use, smoking, and certain infections. It can also be stress induced, caused by a decrease in bicarbonate concentration in the mucosal lining of the stomach. Chronic gastritis most commonly is caused by *Helicobacter pylori* infection (Figure 19.12) but can also be caused by autoimmune disease, Crohn's disease, gastric surgery, and other infections, such as HIV. There is an increased risk for complications, including gastric cancer, peptic ulcers, and gastric bleeding or perforation, when gastritis is untreated (Azer et al., 2023).

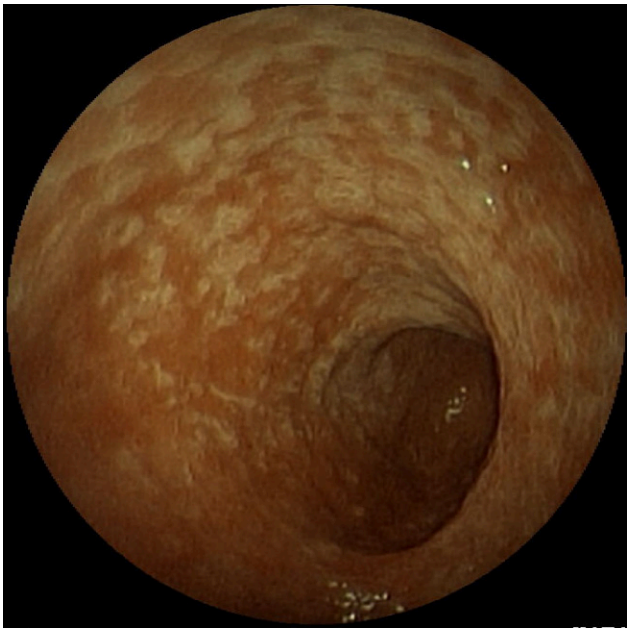

FIGURE 19.12 This image shows chronic gastritis caused by *H.* pylori infection. (credit: "Helicobacter gastritis 2.jpg" by Med_Chaos/ Wikimedia Commons, Public Domain)

Clinical Manifestations

Patients with acute gastritis may present with epigastric pain, nausea, vomiting, or a feeling of fullness in the upper abdomen after eating. In chronic gastritis, patients are usually asymptomatic.

Patients with PUD will most commonly present with epigastric pain after meals, with pain being more immediate in gastric ulcers, and 2 to 3 hours after eating in patients with duodenal ulcers. Other symptoms include heartburn, dyspepsia, chest discomfort, hematemesis (vomiting of blood), melena (black tarry stools), fatigue, and dyspnea

Assessment, Diagnostics, and Laboratory Values

Gastritis is difficult to diagnose based on symptoms alone. It is important to take a detailed medical and social history so proper diagnostic testing can be performed. Endoscopy with biopsy is the gold standard for diagnosing

gastritis (Azer et al., 2023). *H. pylori* infection can be diagnosed through endoscopy and biopsy, or through a urease breath test. Other testing is focused on finding the underlying cause of the gastritis.

LINK TO LEARNING

Watch this video for an explanation and demonstration of the urea breath test (https://openstax.org/r/77ureabrtest) for *H. pylori* infection.

An upper GI series, or barium swallow, can check for GERD, dysphagia, hiatal hernia, ulcers, tumors, or achalasia. Serological tests will evaluate for the presence of autoantibodies. Bloodwork will check for the presence of *H. pylori* infection and will also check for iron deficiency anemia that can be caused by blood loss in the GI tract. A stool sample may be evaluated to check for bacteria or the presence of blood.

Nursing Care of the Patient with Gastritis

Nursing care of the patient with gastritis focuses on symptom improvement and patient education. It is important to teach the patient the importance of avoiding any foods, drinks, or medications that irritate their stomach. Smoking cessation education is also important.

Recognizing Cues and Analyzing Cues

Subjective data for a patient with gastritis can include the patient's report of presence of gastric pain, belching or hiccups, nausea or vomiting, blood in vomit or stool, or loss of appetite. Inquire about any history of smoking, alcohol use, regular NSAID or aspirin use, or high stress levels.

For PUD, life-threatening, or alarm symptoms that warrant immediate action are

- bleeding or anemia
- early satiety
- family history of GI cancers
- progressive dysphagia or odynophagia
- recurrent vomiting
- unexplained weight loss

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Signs of GI bleeding are a high priority to be addressed. Monitor the patient's stool for the presence of blood in the stool; bloody stool may present as a fresh, bright red color (frank) or dark and tarry. Be sure to notify the provider immediately.

Evaluation of Nursing Care and Outcomes for the Patient with Gastritis

While providing care, the nurse will evaluate outcomes to see if goals have been achieved. Goal priorities are improvement of symptoms and patient education. Treatment of the underlying cause and prevention therapy ensure an excellent prognosis. The nurse will examine every intervention taken and the patient's response. The nurse evaluates how often the patient experiences symptoms, including timing, severity, and what could have triggered them. When comparing the patient's history of symptoms before care, the nurse can evaluate if the interventions provided are adequate or if modifications are needed.

Medical Therapies and Related Care

Treatment can be singular or a combination of antibiotics, PPIs, vitamin supplementation, **immunomodulatory therapy** (medications that change the body's immune response), and dietary modifications (Azer et al, 2023). PPIs bind to the hydrogen-potassium ATPase enzyme system of the parietal cell, also referred to as the proton pump, because it pumps hydrogen ions into the stomach. PPIs inhibit the secretion of hydrochloric acid, and the antisecretory effect lasts longer than 24 hours (Table 19.5). Treatment is dependent on the underlying cause. Other treatments for gastritis include smoking and alcohol cessation, stress management, and discontinuation of anti-inflammatory medications.

Medication	Indication	Nursing Considerations
Pantoprazole	GERD Zollinger-Ellison syndrome *H. pylori* infection	Can interfere with the liver metabolism of other drugs IV pantoprazole can potentially exacerbate zinc deficiency. Long-term therapy can cause hypomagnesemia.
Raberprazole	GERD Peptic and esophageal ulcers Erosive esophagitis *H. pylori* infection Zollinger-Ellison syndrome	May cause kidney damage Can interfere with the liver metabolism of other drugs Long-term therapy can cause hypomagnesemia. May cause vitamin B_{12} deficiency
Dexlanosoprazole	GERD Esophageal erosion (treatment and prevention)	Can interfere with the liver metabolism of other drugs Long-term therapy can cause hypomagnesemia.
Esomeprazole	GERD Stomach and peptic ulcers Esophageal erosion Zollinger-Ellison syndrome	May cause kidney damage May cause vitamin B_{12} deficiency Can interfere with the liver metabolism of other drugs Long-term therapy can cause hypomagnesemia.
Lansoprazole	GERD Esophageal erosion Zollinger-Ellison syndrome Duodenal and gastric ulcers (treatment and prevention) *H. pylori* infection (in combination with antibiotics)	Can interfere with the liver metabolism of other drugs Long-term therapy can cause hypomagnesemia (Gillson, 2023).

TABLE 19.5 **Comparison of Proton Pump Inhibitors**

Gastric Cancer

Stomach cancer, or **gastric cancer**, is the fifth most frequently diagnosed cancer and the third leading cause of cancer deaths worldwide (Mukkamalla et al., 2023). Stomach cancers tend to develop slowly and often do not have symptoms until disease has progressed. Ethnicity variations are noted, with highest incidence in Hispanic Americans, Black Americans, and American Indians. Risk factors linked to stomach cancer include *H. pylori* infection; obesity; a diet high in salted foods or grilled or charcoaled meats; heavy alcohol use; and smoking (American Cancer Society, 2021).

Pathophysiology

Most stomach cancers begin at the cells that line the stomach and produce mucus. These cancers are called adenocarcinomas. There are two main types of adenocarcinomas: intestinal and diffuse. Intestinal cells are more clustered, more likely to have cell mutations, and more receptive to targeted therapy. Diffuse cells are more scattered and harder to see on the surface.

Clinical Manifestations

Because stomach cancer is slow growing, cancer in most patients who present with symptoms is usually at an

advanced stage (Mukkamalla et al., 2023). Symptoms include nonspecific weight loss, dysphagia, persistent abdominal pain, anorexia, nausea, hematemesis, early satiety (fullness when eating), and indigestion.

Assessment and Diagnostics

Most patients with symptoms will present with advanced disease. A palpable abdominal mass may be found, indicating advanced disease. An upper endoscopy with biopsy is the most common way stomach cancer is diagnosed. A barium swallow study may also be done in certain circumstances. Other studies to rule out **metastasis**, or secondary malignant growths in other parts of the body, may include abdominal CT scans, x-ray, endoscopic ultrasound, and serum studies.

Interdisciplinary Management

The provider will give the patient treatment options. Potential treatments for stomach cancer may include surgery, chemotherapy, radiation therapy, targeted drug therapy, and immunotherapy. The nurse will coordinate care, complete ongoing assessments, provide patient education, and plan and evaluate nursing care.

Medical Therapies and Related Care

Surgery is the primary treatment for stomach cancer. Surgery may be performed via endoscopy, laparoscopy, or open surgery, depending on the stage and location of the cancer. The goal is to remove the tumor and all affected tissues and leave a surgical margin that is negative for cancer cells. Common surgical procedures performed in patients with stomach cancer are total gastrectomy, partial gastrectomy, esophagogastrectomy, lymph node dissection, gastrojejunostomy, gastrostomy tube insertion, and jejunostomy tube insertion. Systemic therapy, such as chemotherapy, chemoradiation, immunotherapy, or targeted therapy, may be initiated to kill any remaining cancer cells after surgical resection.

19.5 Disorders of the Lower GI System

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations of lower GI disorders
- Describe the diagnostics for and laboratory values monitored in the management of lower GI disorders
- Apply nursing concepts and plan associated nursing care for the patient with lower GI disorders
- Evaluate the efficacy of nursing care for patient with lower GI disorders
- Describe the medical therapies that apply to the care of the patient with lower GI disorders

This section focuses on common alterations in function of the large intestines. These alterations result in common symptoms of several diseases and conditions of the GI system that can impede proper absorption of nutrients and elimination of stool. After upper GI digestion, the muscles of the small intestine push the contents onward for further digestion in the lower GI tract. Bacteria in the GI tract, called normal flora make up part of the **microbiome**, which is all of the microorganisms in the GI tract. These normal flora assist with digestion. As peristalsis continues, the waste products of the digestive process move into the large intestine. The large intestine absorbs water and changes the waste from liquid into stool. The rectum, at the lower end of the large intestine, stores stool until it is pushed out of the anus during a bowel movement.

Constipation

Constipation is difficult or infrequent passage of stools associated with hard, dry feces. Typically, a patient is diagnosed with constipation if they have fewer than three bowel movements per week.

Pathophysiology

Constipation can be caused by slowed peristalsis due to decreased activity, dehydration, lack of fiber, medications like opioids, depression, or surgical procedures in the abdominal area. As the stool moves slowly through the large intestine, additional water is reabsorbed, resulting in the stool becoming hard, dry, and difficult to move through the lower intestines.

Clinical Manifestations

The patient may experience associated symptoms, such as rectal pressure, abdominal cramps, bloating, distension, and straining. In more serious cases, constipation can be a sign of fecal impaction, intestinal obstruction, or paralytic ileus. A **fecal impaction** is a blockage that occurs when stool accumulates in the rectum, usually due to the

patient not feeling the presence of stool or not using the toilet when the urge is felt. An **intestinal obstruction** is a partial or complete blockage of the intestines so that contents of the intestine cannot pass through.

When peristalsis is not propelling the contents through the intestines or when there is a obstruction, such as severe fecal impaction, **paralytic ileus** may result. Patients who have undergone abdominal surgery or received general anesthesia are at increased risk. Other risk factors include the chronic use of opioids, electrolyte imbalances, bacterial or viral infections of the intestines, decreased blood flow to the intestines, or kidney or liver disease.

If an obstruction blocks the blood supply to the intestine, infection and tissue death (gangrene) can result. Symptoms of an intestinal obstruction or paralytic ileus include

- abdominal distention or a feeling of fullness
- abdominal pain or cramping
- constipation
- diarrhea
- frequent belching
- inability to pass gas
- vomiting

Because of the common occurrence of paralytic ileus in postoperative patients, nurses routinely monitor for these symptoms, and diet orders are not upgraded until the patient is able to pass gas (Phillips, 2022).

Assessment and Diagnostics

The nurse will complete a history and a physical assessment. The history will include the last time the patient had a bowel movement and the usual frequency and consistency of bowel movements. The patient's medications need to be examined for the potential of constipation. Physical assessment may reveal a tender abdomen, and stool may be palpated in the lower abdomen.

Nursing Care of the Patient with Constipation

The goal of interventions to treat constipation is to establish what is considered a normal bowel pattern for each patient and to set an expected outcome of a bowel movement at least every 72 hours, regardless of intake.

Recognizing Cues and Analyzing Cues

The prevailing cue during an assessment will be the lack of ability to have a bowel movement. There may be accompanying abdominal cramping, abdominal distention, or discomfort. The nurse may find contributing history or medications.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

The nurse will hypothesize that the patient has constipation. The exact intervention will depend on the setting and the patient's preferences. The patient may drink a hot beverage, which may stimulate peristalsis. Fiber may be added to the diet. Finally, a laxative may be used. These are available in pill form, liquid form, and as suppositories. The patient can use an enema if not contraindicated by other medical conditions such as fluid and electrolyte imbalances, cardiac history, immunocompromise, or suspected bowel perforation.

In cases of paralytic ileus, treatment may include insertion of an NG tube attached to suction to help relieve abdominal distention and vomiting until peristalsis returns. Obstructions may require surgery if the tube does not relieve the symptoms or if there are signs of tissue death.

Evaluation of Nursing Care and Outcomes for the Patient with Constipation

A successful outcome is the patient having a bowel movement. The nurse should support the patient and help develop an appropriate treatment plan. The goals evaluated may be, for example, the patient will have a bowel movement by (set a time), and the patient will verbalize a plan to prevent further constipation episodes.

The nurse will evaluate the outcomes of care. A bowel movement would indicate that treatment interventions were successful. If the patient is still struggling to have a bowel movement, further collaboration and modification of interventions may be needed.

Medical Therapies and Related Care

Treatment typically includes a prescribed daily bowel regimen, such as oral stool softeners (e.g., docusate) and a

mild stimulant laxative (e.g., a sennoside). Stronger laxatives (e.g., magnesium hydroxide [e.g., Milk of Magnesia] or bisacodyl), rectal suppositories, or enemas are implemented when oral medications are not effective.

Diarrhea

Diarrhea is defined as having more than three unformed stools in 24 hours. The Bristol Stool Form Scale may be used to assess the characteristics of stools. Diarrhea can cause dehydration, skin breakdown, and electrolyte imbalances.

LINK TO LEARNING

Read this article about the development of a new version of the Bristol Stool Form Scale (https://openstax.org/r/77stoolscale) for assessing stool.

Pathophysiology

Diarrhea is caused by increased peristalsis causing the stool to move too quickly through the large intestines for water to be effectively reabsorbed, resulting in loose, watery stools.

Many conditions can cause diarrhea, such as infectious processes, food poisoning, medications, food intolerances, allergies, anxiety, and medical conditions. Patients are at risk for dehydration due to this water loss.

Clinical Manifestations

An individual with diarrhea will present with frequent bowel movements accompanied by the need for immediate toileting, abdominal cramping, and, perhaps, nausea. Dehydration symptoms may be present, such as urinating less than usual, fatigue, thirst, and light-headedness, and an elevated temperature if the patient is infectious.

Diagnostics and Laboratory Values

The provider will determine diagnostic testing based primarily upon medical history and physical examination. Bloodwork may be done to rule out conditions that can cause diarrhea, such as certain diseases, conditions, or infections. Monitor the patient's electrolyte levels because diarrhea can cause electrolyte deficiencies. A stool specimen may be checked for the presence of blood, bacteria, or parasites. If food intolerance or food allergy is suspected, such as lactose intolerance or celiac disease, diet modifications may be recommended to see if symptoms improve. Diagnostic testing, such as endoscopy, colonoscopy, or flexible sigmoidoscopy, may be done to see if the diarrhea is from a structural issue in the digestive tract. Biopsies may be performed of the GI tract during these procedures to rule out cancer or other cell abnormalities.

Nursing Care of the Patient with Diarrhea

Maintaining adequate fluid intake is the priority of care for a patient with diarrhea. Nurses should administer IV fluids as ordered and encourage oral intake of fluids.

Recognizing Cues and Analyzing Cues

The nurse providing care to a patient with diarrhea uses both objective and patient-reported data to optimize care. The patient may report feeling thirsty along with having frequent loose stools. Assessment of skin turgor may revel dehydration, and hyperactive bowel sounds may be heard on auscultation. Vital signs should be completed with a focus on blood pressure and heart rate to monitor for dehydration (Table 19.6).

Degree	Signs and Symptoms
Mild to moderate	Increased thirst Dry mucus membrane Low urine output Dark, concentrated urine Dry, cool skin Headache Muscle cramps
Moderate to severe	Low or absent urine output Very dry skin Dizziness Tachycardia Tachypnea Hypotension Sunken eyes Sleepiness, lack of energy, confusion or irritability Fainting

TABLE 19.6 **Signs and Symptoms of Dehydration** (WebMD, 2023)

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Signs of dehydration are a high priority. Monitor laboratory values for electrolyte depletion and report abnormalities to the practitioner. The nurse will anticipate administering over-the counter antidiarrheal products, if appropriate, and encourage fluids.

Evaluation of Nursing Care and Outcomes for the Patient with Diarrhea

Symptom improvement and prevention of complications are signs of effective nursing care. The nurse evaluates how often the patient is having bowel movements to see if there is improvement in the consistency and frequency of stools. Evaluation of vital signs can help determine if the patient has adequate fluid balance. The primary outcome is resolution of the diarrhea and return to normal fluid balance. The nurse evaluates trends in the patient's intake and output, vital signs, and electrolytes to assess care.

Medical Therapies and Related Care

Treatment of diarrhea includes promoting hydration with water or other fluids (e.g., electrolyte-containing drinks) that improve electrolyte status. IV fluids may be required if the patient becomes dehydrated. Medications, such as loperamide, psyllium, and anticholinergic agents, may be prescribed to treat diarrhea that is causing dehydration. In some cases, rectal tubes may be prescribed to collect watery stool, but strict monitoring is required due to possible damage to the rectal mucosa.

Irritable Bowel Syndrome

A disorder called **irritable bowel syndrome (IBS)** affects the large intestine and causes changes in bowel movements and abdominal pain. It is the most commonly diagnosed GI disorder in the United States, with 10% to 15% of the population being affected (Patel & Shackelford, 2022), and can be broken down into more specific diagnoses: IBS-D (with diarrhea), IBS-C (with constipation), or IBS-M (with mixed bowel patterns).

Pathophysiology and Clinical Manifestations

The exact cause of IBS is unclear. It can occur after infection, be triggered by stress, or be caused by food intolerances, brain-gut interaction, and inflammatory processes (Figure 19.13).

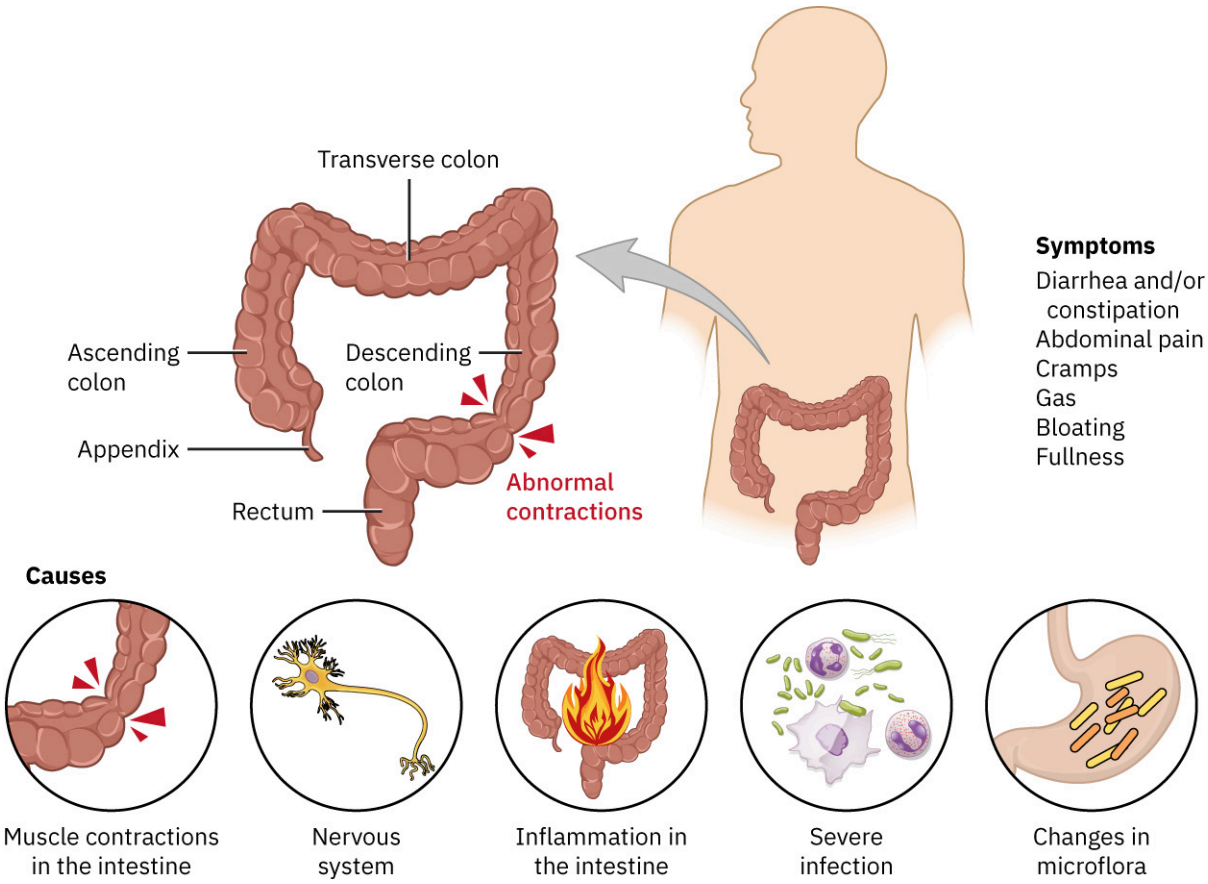

FIGURE 19.13 The exact cause of IBS is unknown; there are several suspected symptoms and causes. (credit: modification of work from *Anatomy and Physiology* 2e. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

IBS primarily presents with diarrhea and/or constipation with abdominal pain. Other symptoms include abdominal pain, cramps, gas, boating, and fullness. Pain usually increases when bowel habits change and subsides after a bowel movement.

Assessment and Diagnostics

A focused assessment on GI signs and symptoms, stressors, food intolerances, and related factors would be completed. Without any alarming findings, such as iron deficiency, weight loss, or **hematochezia** (passage of fresh blood in stool), diagnostic testing is not usually done. Serum studies to rule out infection or other disease may be performed.

Nursing Care of the Patient with IBS

The nursing care of a patient with IBS will be focused on ongoing physical assessments, creating a plan with the patient, and implementing the measures. An evaluation process will be completed with the patient.

Recognizing Cues and Analyzing Cues

The nurse will complete the history and physical assessment. The findings will be nonspecific, such as abdominal pain and constipation or diarrhea. The patient may have a history of mucus in the stool. Focused patient history information should include stool frequency, amount, and any precipitating factors. This may help determine what part of the intestines is affected.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Ulceration, vascular engorgement, and highly vascular granulation tissue can put the patient at risk for complications, such as perforation and bleeding. Signs and symptoms to report to the provider include fever, lethargy, tachycardia, and increased anxiety. Provide pain management as appropriate and monitor serum blood electrolyte and CBC values closely.

Evaluation of Nursing Care and Outcomes for the Patient with IBS

Nursing care for patients with IBS is driven primarily by symptom improvement as reported by the patient. Vital signs and laboratory values should show adequate fluid balance. The nurse will evaluate how often the patient is experiencing symptoms to see if interventions have caused symptom improvement. A decrease in pain medication use is another indication that symptoms are improving.

Medical Therapies and Related Care

Because IBS is a symptom-based disorder, treatment is aimed at symptom resolution. A combination of anticholinergics, antidepressants, antibiotics, fiber supplements, laxatives, and/or antidiarrheals may be ordered, depending on patient symptoms (Patel & Shackelford, 2022). Increased physical activity and dietary changes may also be recommended.

Celiac Disease

An autoimmune disorder, **celiac disease** is triggered by gluten ingestion, which causes damage to the small intestine; **gluten** is a protein found in the wheat plant and other grains, such as barley and rye. Approximately 1 percent of the population is affected by celiac disease (Celiac Disease Foundation, n.d.). It is hereditary and can occur at any age and any time after gluten has been consumed.

Pathophysiology

In patients with celiac disease, the ingestion of gluten causes the body's immune system to attack the **villi** (small, finger-like cells that absorb nutrients) of the small intestine. This results in permanent damage over time, causing a scalloping of the folds and a cracked appearance of the mucosa, and disrupts the absorption of nutrients (Figure 19.14). The causes are unknown, and it is present when people with a genetic predisposition consume gluten.

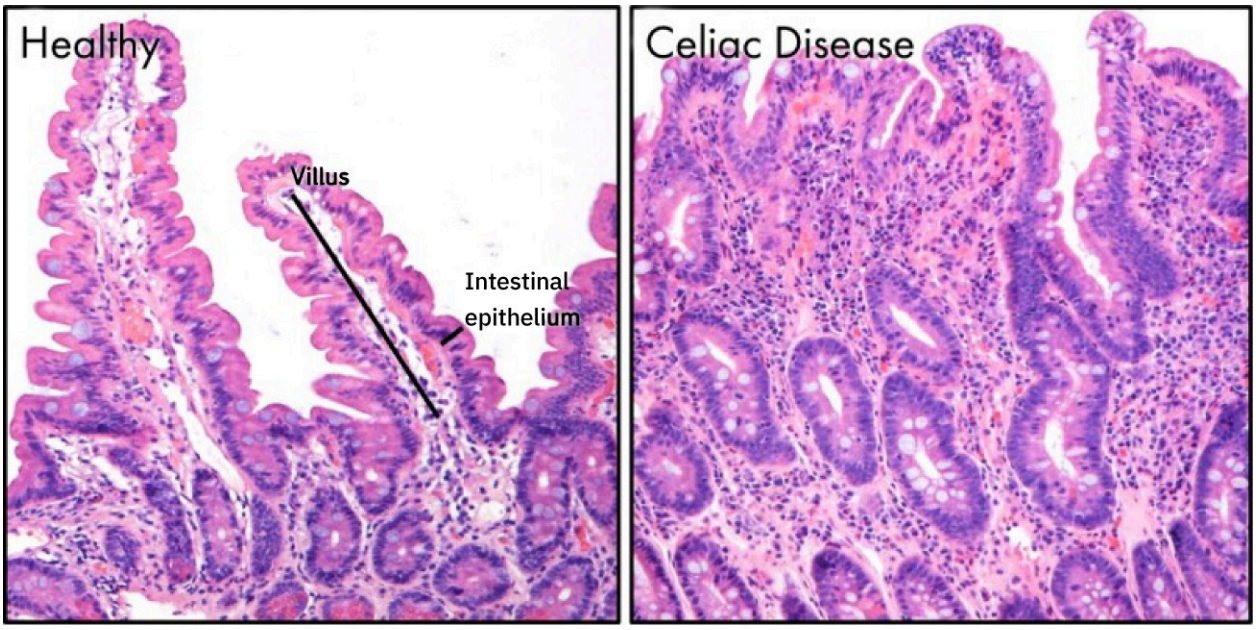

FIGURE 19.14 (a) In a healthy intestine, the villi are well-defined. (b) In patients with celiac disease, the villi are damaged, leading to malabsorption. (credit: "Histopathology of villous atrophy in celiac disease" by GeneFood/Openverse, CC BY 4.0)

Clinical Manifestations

Patients with celiac disease present with GI symptoms, including

- abdominal pain
- bloating
- chronic diarrhea
- constipation
- gas
- lactose intolerance

- nausea
- vomiting
- weight loss

Other symptoms may include fatigue, anxiety, depression, bone or joint pain, canker sores, dry mouth, or itchy rash (NIH, 2023).

Assessment and Diagnostics

Assessment will focus on the GI symptoms and detailed patient history. Diagnostic workup will include serologic studies focused on antibodies associated with celiac disease. A duodenal mucosal biopsy will confirm diagnosis. Other diagnostic tests may be completed and laboratory values evaluated to assess for complications such as vitamin deficiencies, electrolyte imbalances, anemia, or bleeding.

Nursing Care of the Patient with Celiac Disease

The nursing care of the patient with celiac disease is focused on education about a gluten-free diet (Table 19.7), identifying symptoms, and evaluating medication side effects and effectiveness.

Type of Food	Example
Gluten containing	Barley, farina, farro, rye, semolina, spelt, and wheat (e.g., durum, einkorn, emmer, graham flour, Khorasan wheat), including triticale (a blend of wheat and rye) and wheat berries
Gluten free	Amaranth, arrowroot, beans, buckwheat groats (also known as kasha), cassava, chia, corn, flax, gluten-free oats, millet, nut flours, potato, quinoa, rice, sorghum, soy, tapioca, teff, yucca

TABLE 19.7 Gluten versus Gluten Free Foods

It is important to educate the patient about the importance of reading food labels. For instance, oats are naturally gluten-free but may be contaminated when grown or processed in an area that also processes gluten-containing foods.

Recognizing Cues and Analyzing Cues

Often, symptoms of celiac disease are nonspecific. They can include abdominal pain, bloating, gas, diarrhea, weight loss, depression, fatigue, headaches, joint pain, nausea, and vomiting. A physical assessment may reveal skin rash, peripheral neuropathy, mouth ulcers, or canker sores. Vital signs should be completed with a focus on blood pressure and heart rate, especially in the patient having diarrhea, to evaluate for signs of dehydration, such as tachycardia and hypotension.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Patients with celiac disease often have malabsorption. Signs and symptoms of malabsorption include steatorrhea (fatty stools), diarrhea, and weight loss. Nurses will review results of laboratory values and administer vitamin, electrolyte, and/or mineral repletion as ordered. IV fluids may be administered to correct dehydration.

Evaluation of Nursing Care and Outcomes for the Patient with Celiac Disease

Goals for taking care of the patient with celiac disease are symptom improvement and patient education about diet modification. With symptom improvement and patient education in mind, the nurse should monitor the frequency and severity of symptoms as reported by the patient. Laboratory values and intake and output should be balanced. The patient should be able to name gluten-containing foods to avoid and understand the importance of diet adherence to prevent further disease progression.

Medical Therapies and Related Care

Treatment is a lifelong, strict, gluten-free diet. Diet maintenance will prevent symptoms from returning, as well as prevent complications, such as malabsorption, anemia, bone weakening, infertility and miscarriage, lactose intolerance, cancer, seizures, or peripheral neuropathy (Mayo Clinic, 2023).

Colorectal Cancer

Cancer with an origin in the colon or rectal tissue is called **colorectal cancer**. It accounts for about 8 percent of all new cancer cases in the United States annually and has a 5-year survival rate of 65% (National Cancer Institute, 2023). Because of an increased emphasis on prevention screening, colorectal cancer is often detected before symptoms occur. Patients who present with symptoms usually have advanced disease.

LINK TO LEARNING

The U.S. Preventive Services Task Force developed colorectal cancer screening recommendations (https://openstax.org/r/77colorectalscr) based on a patient's age and medical history in order to detect cancer at an early stage.

Pathophysiology

Abnormal or mutated cells that the immune system is unable to eliminate begin to grow on the tissue of the colon or rectum. These cells then begin to multiply. Colorectal cancer is caused by genetic factors, diet, and inflammatory conditions of the GI tract.

Clinical Manifestations

Patients with colorectal cancer may present with a change in bowel habits, bloody stools, unexplained weight loss, fatigue, gas pains, bloating, or abdominal cramping. Patients may have a history of colorectal polyps, a genetic condition such as Lynch syndrome, chronic inflammatory bowel disease, heavy alcohol use, obesity, smoking, or a family history of colorectal cancer.

Assessment and Diagnostics

Assessment may be nonspecific or may demonstrate GI symptoms, such as abdominal tenderness, a palpable abdominal mass, rectal bleeding, ascites, or hepatomegaly (Dragovich, 2023). A rectal examination and colonoscopy with biopsy will enable the health care provider to diagnose colorectal cancer. Other serum studies, such as CBC count, complete metabolic panel, and liver function studies, may be done to assess organ function (Dragovich, 2023). Imaging, such as CT and MRI scans of the abdomen and pelvis, is obtained for staging purposes.

Nursing Care of the Patient with Colorectal Cancer

Nursing care of the patient with colorectal cancer is focused on symptom management, pain relief, and prevention of complications. Collaboration with the interdisciplinary team is important to optimize care. The nurse will assist with preparing the patient for surgery, provide education about adjunct therapies prescribed, manage side effects, and administer palliative therapy, if appropriate. Patients with a stoma (see 19.7 Ostomy Care) may experience body image disturbances, and the nurse will have to help the patient manage self-esteem issues during treatment.

Recognizing Cues and Analyzing Cues

Patients with colorectal cancer will present with nonspecific GI signs and symptoms, such as a change in bowel habits, bloody stools, diarrhea, constipation, abdominal pain, unexplained weight loss, and fatigue. Vital signs may reveal hypotension or tachycardia in patients who are dehydrated. The patient may also have abdominal pain on palpation and poor skin turgor.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Signs of infection are a priority when caring for the patient with colorectal cancer. The nurse may frequently assess the patient's temperature, vital signs, pain level, surgical incision(s), and IV access site to monitor for infection, especially if the patient is receiving chemotherapy. Patient education topics include maintaining a clean environment, signs and symptoms of infection to report to the nurse or provider, and staying away from family and friends who are sick.

Evaluation of Nursing Care and Outcomes for the Patient with Colorectal Cancer

Evaluation of nursing care will be based on treatment preferences and patient goal preferences. Symptom improvement, decrease in pain, and prevention of complications are all signs of effective nursing care. A patient with colorectal cancer may have dysfunctional GI motility as a side effect of the disease process and treatment. The

patient remaining free of signs and symptoms of GI motility dysfunction (e.g., distention, cramping, pain) and maintaining normal bowel sounds and regular formed stools would indicate that the outcomes have been reached. If the patient continues to have signs and symptoms of GI motility dysfunction, interventions may need adjustment.

Medical Therapies and Related Care

Most cases of colorectal cancer require surgical intervention (Figure 19.15). Chemotherapy may be used in adjunct with surgery in patients with advanced disease. Radiation therapy is used for palliative purposes in certain cases of metastasis.

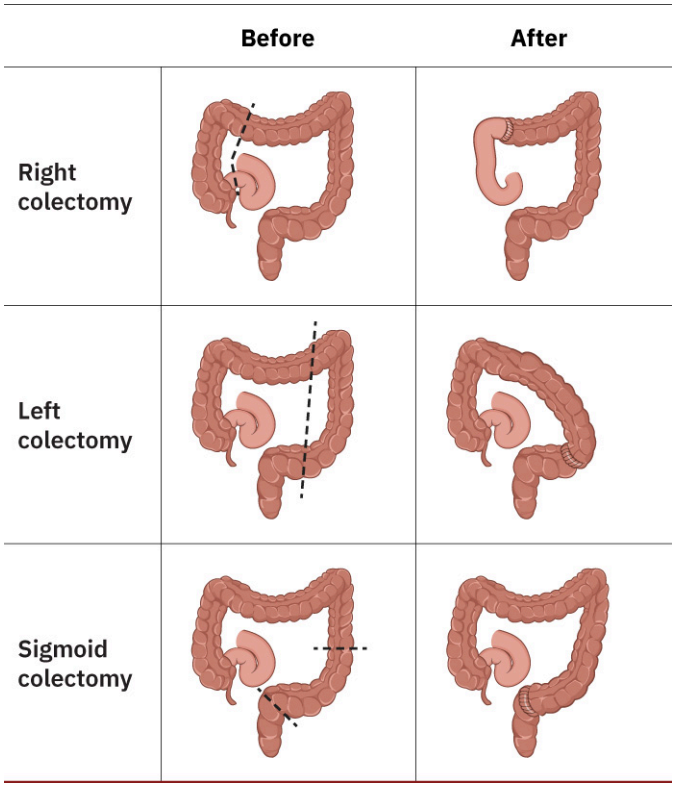

FIGURE 19.15 This illustration shows three common types of surgical resection to treat colorectal cancer. (credit: modification of work from *Anatomy and Physiology* 2e. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Appendicitis

Inflammation of the appendix is called **appendicitis**. It occurs more often in men and is most common in people aged 10 to 30 years (Jones et al., 2023). It occurs acutely without warning.

Pathophysiology

Appendicitis is most often caused by an obstruction within the appendiceal orifice. This creates an inflammatory response, which can lead to local ischemia and perforation. Perforation causes the spilling of bacteria and bowel contents into the peritoneal cavity, causing a contained abscess or peritonitis. When peritonitis is left untreated, it can lead to fatal complications, such as sepsis and septic shock.

LINK TO LEARNING

Watch this video for an explanation about the pathophysiology of appendicitis (https://openstax.org/r/77appendicitis) as well as examination, diagnosis, and treatment.

Clinical Manifestations

A patient with appendicitis will present with right lower quadrant or periumbilical pain. The patient may also report anorexia, nausea, vomiting or diarrhea, fever malaise, and urinary frequency or urgency.

Assessment and Diagnostics

An initial abdominal assessment will reveal right lower quadrant pain. A positive **Rovsing sign** (palpation of the left lower quadrant worsens right lower quadrant pain) is also an indicator of appendicitis. The patient may also have a fever, tachycardia, and tachypnea.

Common signs of acute peritonitis found during a physical assessment are:

- guarding: the patient consciously tenses the abdominal muscles in anticipation of pain
- rebound tenderness: pain that occurs after the removal of manual pressure to the abdomen
- rigid abdomen: stiffness of the abdominal muscles that the patient cannot relax

Other signs of peritonitis are fever, fluid in the abdomen, chills, abdominal distention and pain, constipation, and vomiting. Bloodwork and imaging can confirm appendicitis. The patient's white blood cell (WBC) count may be elevated, indicating infection. Ultrasound or CT scan of the abdomen may be performed for diagnosis or to visualize the extent of disease. Diagnostic tests for peritonitis include blood, urine, x-ray, and CT imaging.

Interdisciplinary Management

The patient will most likely need surgical removal of the appendix, called **appendectomy**. This can be done laparoscopically or by open surgery, depending on the severity of disease. Antibiotics will be given to treat infection. IV fluids may be necessary of the patient has to remain NPO for a time. Interdisciplinary care will involve the nurse, provider, surgeon, nutritionist, and infectious disease provider.

Treatment for peritonitis depends on the severity of the infection, and can range from IV antibiotics, surgery, medications for organ support, IV fluids, or a combination of treatments (Jones et al., 2023)

Diverticular Disease

The condition **diverticulosis** is the asymptomatic presence of **diverticula**, or sac-like protrusions, on the walls of the large intestine (Figure 19.16). Diverticulosis occurrence is 20% in adults aged 40 to 60 years, but up to 60% after the age of 60 (Pemberton & Strate, 2023). When diverticulosis becomes symptomatic, **diverticular disease** occurs; it is estimated to occur in 25% of people with diverticulosis (Tursi et al., 2020). A similar term, **diverticulitis**, refers to inflammation of the diverticula. The inflammation can remain contained or spread from the perforation to cause peritonitis.

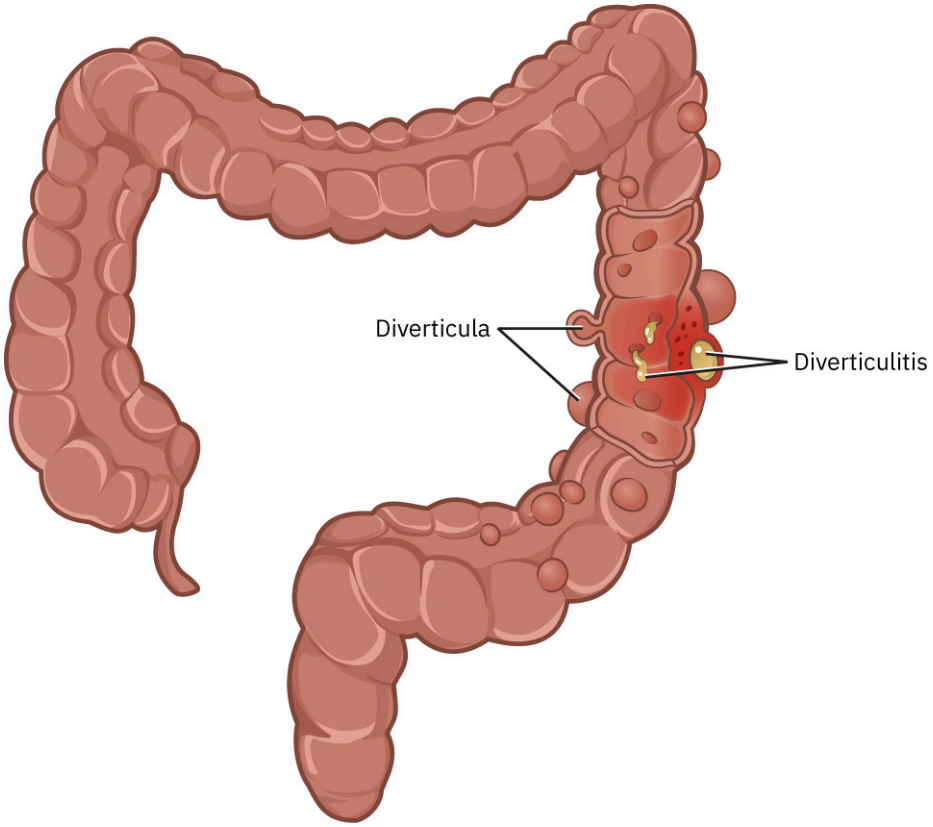

FIGURE 19.16 Diverticulosis is the asymptomatic presence of diverticula, or protrusions, on the walls of the large intestine. When the diverticula become inflamed, the condition is known as diverticulitis. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Pathophysiology

Although the exact pathophysiology of diverticular disease is unknown, it is thought to have various manifestations. Connective tissue abnormalities in the intestine are thought to be the cause of development of asymptomatic diverticulosis. Gut microbial changes and certain medications are believed to cause acute diverticulitis and diverticular hemorrhage. The disease can be acute or chronic. Risk factors for diverticulosis include older age, male sex, smoking history, and higher BMI.

Clinical Manifestations

Patients with diverticular disease may present with nonspecific GI symptoms such as lower abdominal pain, bloating, and diarrhea. In severe cases, fever or bloody stools may be present.

Assessment and Diagnostics

Subjective and objective data are gathered, and any clinical manifestations are noted. A physical assessment may reveal abdominal pain on palpation. Routine testing, such as bloodwork, urinalysis, and stool testing, may be done to narrow down a cause for symptoms. A CT scan of the abdomen can show any inflammation in the intestines. A colonoscopy and sigmoidoscopy can show the pockets of inflammation and disease within the intestines.

Interdisciplinary Management

In some cases, mild disease may resolve on its own. The interdisciplinary team, including the nurse, gastrointestinal provider, and nutritionist, work together to develop a treatment plan. Treatment may include

- a liquid diet to rest the intestines, reduce inflammation, and promote healing
- antibiotics, if infection is the suspected cause
- over-the-counter pain relief

If there is active bleeding in the intestines, the patient may need blood transfusions. If the bleeding does not resolve, surgical intervention may be necessary. Abscess drainage may be performed by a radiologist using local anesthesia. In serious instances, a **fistula** (a hole in the wall of the intestine) may occur. This requires surgical

intervention to remove the section of the colon involved.

READ THE ELECTRONIC HEALTH RECORD

Caring for a Patient with Abdominal Pain

Patient Information
Name: Johanna Dear
Age: 65 years
Sex: Female
Chief complaint:

- Severe abdominal pain, primarily in the lower left quadrant, for the past 48 hours

Medical history:

- Diagnosed with diverticular disease 5 years ago.
- History of hypertension, well-controlled with medication
- Previous episodes of mild diverticulitis, treated successfully with antibiotics

Vital signs:

- Temperature: 101.3°F (38.5°C)
- Heart rate: 95 bpm
- Blood pressure: 140/85 mm Hg
- Respiratory rate: 20 breaths per minute
- Oxygen saturation: 98% on room air

Recent laboratory results:

- WBC count: 14,000 /µL (elevated)
- Hemoglobin: 13.5 g/dL (normal)
- Hematocrit: 40.5% (normal)
- Platelets: 250,000 /µL (normal)
- C-reactive protein (CRP): 50 mg/L (elevated)
- Electrolytes:
  - Sodium: 138 mmol/L (normal)
  - Potassium: 4.0 mmol/L (normal)
  - Chloride: 102 mmol/L (normal)
  - Bicarbonate: 22 mmol/L (normal)
- Blood urea nitrogen: 18 mg/dL (normal)
- Creatinine: 1.0 mg/dL (normal)

Imaging Results

- CT scan of abdomen and pelvis: Findings consistent with acute diverticulitis. Presence of inflamed diverticula in the sigmoid colon with pericolonic fat stranding. No abscess or free air noted.

Progress notes:

- Patient reports increased severity of abdominal pain and tenderness over the past 2 days.
- Appetite has decreased, and he has experienced occasional nausea.
- No vomiting, diarrhea, or changes in bowel habits reported.
- Patient has been compliant with hypertension medications.
- Mild fever observed upon admission.

Current medications:

- Lisinopril 10 mg daily (for hypertension)
- Acetaminophen 500 mg every 6 hours as needed for pain
- Ciprofloxacin 500 mg twice daily
- Metronidazole 500 mg three times daily

1. What information in the patient's chart concerns you?
2. What information is the most concerning?
3. What is an expected finding?
4. What information should you question?

Inflammatory Bowel Disease

Chronic inflammation of the GI tract is called **inflammatory bowel disease (IBD)**. The two main types of IBD are Crohn's disease and ulcerative colitis. **Crohn's disease (CD)** is inflammation that can occur in multiple layers of the bowel, in any segment of the GI tract. The second main type, **ulcerative colitis (UC)**, is inflammation that occurs only in the innermost wall of the large intestine and colon. IBD occurs in 1.3% of adults in the United States (CDC, 2022a) and most often in people aged 15 to 30 years old (McDowell et al., 2023).

Pathophysiology

Chronic mucosal inflammation in the GI tract occurs in IBD, leading to edema, bleeding, ulcers, and electrolyte loss. In UC, inflammation usually begins in the colon, then spreads, whereas CD can begin anywhere throughout the tract and can create a **skip lesion**, or a patchy area of inflammation that skip over some areas. CD can lead to complications, such as strictures and fistulas, and can predispose patients to other diseases, such as arthritis, kidney disease, and gallstones (McDowell et al., 2023

Clinical Manifestations

The clinical manifestations of IBD are weight loss, abdominal pain and bloating, and diarrhea. There may be secondary symptoms present, such as vomiting, fever, redness or pain of the eyes, skin rash, and joint pain. Stress can worsen the symptoms but is not the cause of the disease.

Assessment and Diagnostics

As the nurse performs a physical assessment, tachycardia, fever, anxiety, pallor, and signs of dehydration may be noted. In more serious cases of IBD, anal fistulas, abscesses, or rectal prolapse may be seen. A patient may also have a history of unexplained weight loss, distended painful abdomen, and diarrhea.

An IBD diagnosis will be based on clinical and imaging findings, endoscopic biopsies, and inflammatory laboratory markers. Endoscopy, colonoscopy, or both will allow the practitioner to biopsy tissue and confirm an IBD diagnosis (Table 19.8) (McDowell et al., 2023). Parasitic diseases will also be ruled out. An abdominal x-ray may be performed to rule out bowel obstruction, free air, or **toxic megacolon** (nonobstructive dilation of the colon that is associated with systemic toxicity).

Test	Purpose	Nursing Considerations
Endoscopy	Visualizes the lining of the esophagus, stomach, and small intestines; can be used to collect tissue samples; treat small issues, such as bleeding vessels; clip growths; or remove foreign objects	Monitor the patient after testing for breathing or swallowing difficulty.
Colonoscopy	Visualizes the lining of the large intestines, colon, and rectum; can be used to collect tissue samples; treat small issues, such as bleeding vessels; clip growths; or remove foreign objects	Monitor for abdominal cramping and bloating; encourage the patient to pass gas.

TABLE 19.8 Common Diagnostic Testing for IBD

Nursing Care of the Patient with IBD

The nursing care of the patient with IBD will involve ongoing assessments and encouragement of nutrition. Patient education and reassurance about any testing or procedures will be done.

Recognizing Cues and Analyzing Cues

The nurse providing care to a patient with IBD uses both objective and patient-reported data to optimize care. Subjective data may include the patient's report of acute abdominal pain, bloating, diarrhea, nausea, and vomiting. Vital signs are evaluated, with a focus on blood pressure and heart rate. Physical assessment may reveal abdominal pain on palpation.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Signs of acute infection or bleeding are a high priority. Monitor the patient's vital signs for an increase in temperature and heart rate, or reduction in blood pressure. Review diagnostic studies and laboratory test results and assist as necessary to prepare the patient for any procedures. Provide patient education about the disease process, diagnostic testing, and treatment plan.

Evaluation of Nursing Care and Outcomes for the Patient with IBD

Symptom improvement and prevention of complications are indications of optimal nursing care. The patient should also have a good understanding of the disease process, treatment plan, and dietary modifications needed to prevent recurrence. The primary patient outcome related to IBD management is symptom improvement. The nurse should evaluate how often symptoms are occurring and note a reduction in the frequency and severity. The patient should also be able to recite information about the disease process and remain compliant with treatment and diet modifications. If these goals are not met, interventions may have to be adjusted.

Medical Therapies and Related Care

Treatment goals are to induce remission of IBD and maintain management of the disease. Drug therapy may be introduced for symptom relief, long-term remission, and to reduce risk of complications. Medications may include

- antibiotics to treat infection
- anti-inflammatory drugs to reduce inflammation
- biologics to neutralize proteins that may be causing inflammation
- immunosuppressant therapy to prevent the body's immune response from attacking healthy intestinal cells
- pain relievers, such as acetaminophen
- vitamins and supplements to treat any deficiencies

Surgery may be indicated in more severe cases to repair or remove diseased bowel. Dietary recommendations may include avoiding carbonated beverages and high-fiber foods.

19.6 Hepatic and Biliary Disorders

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations of hepatic and biliary disorders
- Describe the diagnostics for and laboratory values monitored in the management of hepatic and biliary disorders
- Apply nursing concepts and plan associated nursing care for the patient with hepatic and biliary disorders
- Evaluate the efficacy of nursing care for the patient with hepatic and biliary disorders
- Describe the medical therapies that apply to the care of hepatic and biliary disorders

The liver plays a critical role in the body. It contributes to metabolism, storage of fat-soluble vitamins, protein synthesis, detoxification, and bile production. Bile helps the body digest fats. The pancreas assists in regulation of blood sugar and in digestion of food. This section discusses jaundice, ascites, liver failure, cirrhosis, hepatic encephalopathy, pancreatitis, and pancreatic cancer.

Manifestations of Liver Dysfunction

Manifestations of liver dysfunction are jaundice, hemolytic jaundice, hepatocellular and obstructive jaundice, and portal hypertension.

Jaundice

Jaundice occurs when skin and **sclera** (whites of the eyes) (Figure 19.17) turn yellow as a result of too much bilirubin in the body. Bilirubin is a yellow chemical in hemoglobin, the substance that carries oxygen in red blood

cells. As red blood cells break down, the old ones are processed by the liver. If the liver cannot properly process the old blood cells, bilirubin builds up and causes the skin and sclera to appear yellow. New onset of jaundice should always be reported to the health care provider. Jaundice can be classified into three types: hemolytic (prehepatic), hepatocellular (hepatic), and obstructive (posthepatic). For nursing care consideration, the nurse is to monitor the underlying cause for the jaundice and report any changes in patient condition or worsening jaundice.

FIGURE 19.17 Jaundice can be seen on the skin and sclera. ("Jaundice" by OpenRN/*Nursing Skills*, 2e, CC BY 4.0)

Hemolytic Jaundice

Hemolytic occurs when there is excessive red blood cell break down that overwhelms the ability of the liver to process the breakdown. It is commonly seen in newborns and resolves rapidly. In adults, the causes can include penicillin, inherited blood disorders (sickle cell anemia or thalassemia), *Escherichia coli* infections, blood transfusion complications, bone marrow failure, and autoimmune conditions. In this instance, the nurse will continue to monitor hemolytic parameters and manage underlying causes to reduce hemolysis.

Hepatocellular and Obstructive Jaundice

Hepatocellular jaundice is a sign of dysfunction of the liver cells and indicates the liver is not properly conjugating bilirubin. Causes include infection, alcoholic liver disease, hereditary or autoimmune conditions, and cancer. Obstructive jaundice is caused by an obstruction preventing biliary drainage. The most common cause of obstructive jaundice is a gallstone blocking the common bile duct, but it can also be caused by certain cancers, strictures, or drug-induced cholestasis (Teach Me Surgery, 2022).

Portal Hypertension

Another liver condition, **portal hypertension**, is an increase in pressure within the portal venous system because of resistance to portal blood flow. This is often caused within the liver from cirrhosis, or outside the liver from thrombosis or pericarditis (Oliver et al., 2023). This increased pressure can cause **varices** (abnormal dilation of the veins) in the stomach (Figure 19.18), esophagus, spleen, and pancreas. Without treatment, portal hypertension can cause complications such as variceal bleeding, ascites, hepatorenal syndrome, infection, and cardiomyopathy.

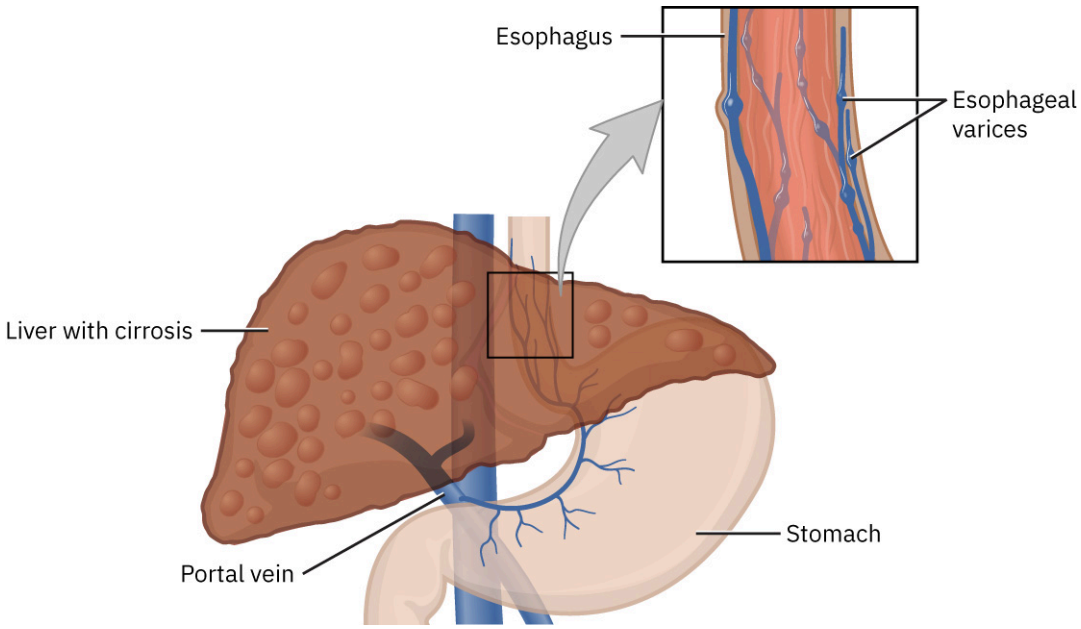

FIGURE 19.18 Varices in the esophagus caused by increased pressure in the portal vein. (credit: modification of work from *Anatomy and Physiology* 2e. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Ascites

Ascites is an accumulation of fluid in the peritoneal cavity (Figure 19.19) that is caused by cirrhosis of the liver. Less than 2 percent of the population is diagnosed with liver disease. Ascites can cause discomfort and affect the patient's quality of life as it progresses.

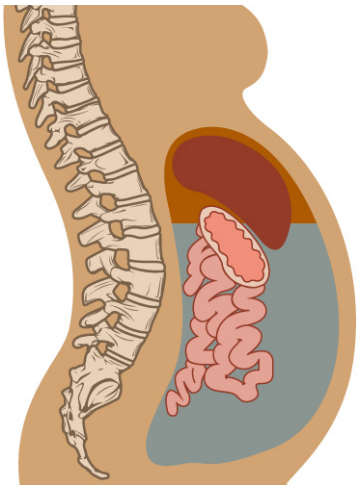

FIGURE 19.19 Ascites is a condition in which the abdominal cavity fills with fluid that shifts from the intravascular to the interstitial space, resulting in hypovolemia. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license.)

Nursing Care of the Patient with Ascites

Nursing care for the patient with ascites includes monitoring for complications, patient education, and assistance with treatment ordered. These include

- administering medications
- documenting daily weights and abdominal girth measurement
- educating patients
- monitoring laboratory values, such as sodium levels
- monitoring vital signs and intake and output

Recognizing Cues and Analyzing Cues

Physical assessment findings may include jaundice, bruises, muscle wasting, peripheral edema, tachypnea, and

abdominal distention and tenderness. Vital signs may reveal tachypnea. Provide oxygen as ordered and appropriate.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Signs of respiratory distress and inadequate oxygenation are a high priority. Lack of ability to take deep breaths can cause the patient to develop pneumonia. Encourage the patient to use an incentive spirometer and perform cough and deep breathing exercises while lying in bed to clear mucosal secretions and prevent pneumonia. Assist with obtaining any laboratory studies or blood cultures ordered, as appropriate.

Evaluation of Nursing Care and Outcomes for the Patient with Ascites

Symptom improvement is a sign of effective nursing care. The patient should have a decrease in abdominal growth, decrease in pain, improved oxygenation, and stable vital signs. It is important to monitor interventions and adjust as necessary to meet goals. The primary patient outcome related to ascites management is treatment of the underlying cause and reduction of ascites. The patient reporting an improvement in symptoms, improved laboratory studies, and the patient demonstrating knowledge of their disorder and the importance of treatment compliance are all indications of positive outcomes.

Medical Therapies and Related Care

A sodium-restricted diet will help control fluid retention. A dietitian will also be involved in the patient's care to help create a healthy meal plan that is low in sodium. Diuretics may also be prescribed to limit fluid retention. A paracentesis may need to be done periodically to remove ascetic fluid. A transjugular intrahepatic portosystemic shunt (TIPS) procedure may be performed in advanced cases of liver disease to lower portal vein pressure and decrease fluid buildup (Figure 19.20).

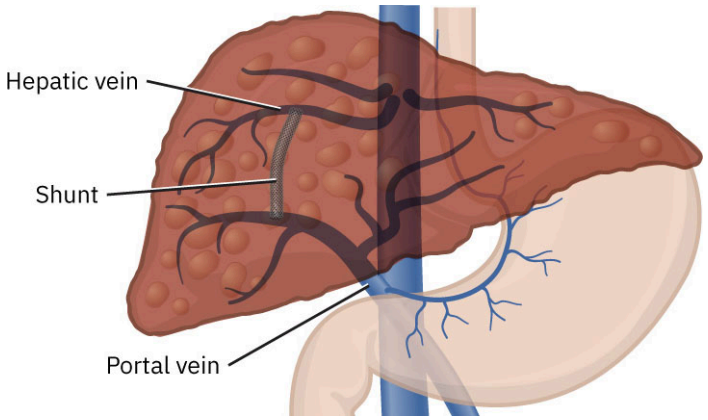

FIGURE 19.20 This illustration shows a TIPS procedure, whereby blood is shunted from the portal vein into the hepatic vein to decrease pressure and fluid buildup. (credit: modification of work from *Anatomy and Physiology* 2e. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Liver Disease

Any condition that causes damage to the liver and prevents it from properly functioning is called **liver disease**. Liver disease can be acute (occur over days or weeks) or chronic (occur gradually over months or years). In the United States, liver disease is the twelfth leading cause of death (American Liver Foundation, 2022). Chronic liver disease progresses in four stages: inflammation, fibrosis, cirrhosis, and end-stage liver disease (ESLD). Once ESLD occurs, the liver no longer can function or heal itself. Liver disease is caused by conditions, such as hepatitis (Table 19.9) or other viral infections, cancer, toxins, genetic conditions, and autoimmune disorders. Inflammation of the liver caused by exposure to drugs, alcohol, toxins, or autoimmune disease is called **nonviral hepatitis**; **viral hepatitis** is inflammation of the liver caused by a virus. The most common types of viral hepatitis are A, B, C, D, and E.

Hepatitis Virus Type	Cause	Symptoms	Treatment
C	Exposure to blood or semen of an infected person; commonly transmitted through needle sharing from drug use or tattoos; can also be transmitted to an infant born to an infected mother	Occur 2–12 weeks after exposure; can include • chronic Fatigue • depression • abdominal pain • nausea • vomiting • loss of appetite • fever • fatigue • dark urine • clay-colored bowel movements • joint pain • jaundice	95% curable within 2–3 months with medications
D	Can only infect a patient who already has hepatitis B virus infection (called superinfection) or by being exposed to both simultaneously (called coinfection); transmitted through blood or body fluids	Occur 3–7 weeks after infection; can include • abdominal pain • nausea • vomiting • loss of appetite • fever • fatigue • dark urine • clay-colored bowel movements • joint pain • jaundice	There is no cure; treatment is based on supportive care.

TABLE 19.9 **Hepatitis** (CDC, 2023)

Hepatitis Virus Type	Cause	Symptoms	Treatment
E	Fecal-oral route; transmitted by consuming contaminated or uncooked meats, such as pork, boar, venison, or seafood	Occur approximately 40 days after exposure; include • anorexia • nausea • vomiting • abdominal pain • jaundice	Self resolves without treatment
G; GB virus type C	Exposure to blood or semen of an infected person; on occasion from mother to neonate	HGV is often asymptomatic. In some cases, mild symptoms include fatigue abdominal discomfort mild jaundice GBV-C is typically asymptomatic; occasionally associated with mild hepatitis symptoms	HGV has no specific antiviral treatment required as it generally does not cause chronic liver disease; management focuses on monitoring liver function and addressing any associated liver conditions. GBV-C has no specific antiviral treatment available; typically, management involves monitoring and supportive care, especially if there is coinfection with other hepatitis viruses.

TABLE 19.9 Hepatitis (CDC, 2023)

Pathophysiology

In chronic liver disease, inflammation occurs as a natural response to injury, but liver cells are not able to properly regenerate. An overproduction of collagen is created from the persistent inflammatory state, stiffening the area and causing scarring or fibrosis to occur. Without treatment, the fibrosis continues, replacing healthy cells and leading to **cirrhosis**, or severe scarring of the liver (Figure 19.21). It is most commonly caused by chronic alcohol use and hepatitis. The cirrhosis continues until there are no healthy liver cells left and the liver is no longer able to function, causing ESLD.

Acute liver disease progresses much more quickly and begins with inflammation, massive necrosis, and autonomous cellular dismantling of liver cells. The inflammation in the liver can trigger microglia activation in the brain, cause disruptions in the blood-brain barrier, and lead to astrocyte swelling and cerebral edema (Shah et al., 2023).

Causes of cirrhosis include

- alcohol-induced hepatitis from chronic heavy alcohol use
- autoimmune diseases, such as autoimmune hepatitis, primary biliary cholangitis, or primary sclerosing cholangitis

- cardiovascular disease, such as congestive heart failure
- chronic hepatitis B infection
- chronic hepatitis C infection
- genetic disorders, such as cystic fibrosis, glycogen storage disease, or Wilson disease
- nonalcohol-related steatohepatitis (fatty liver disease) from high lipids, diabetes, or hypertension
- toxic hepatitis from long exposure to environmental toxins or use of certain medications

Treatment for liver disease includes treating the underlying cause with antivirals, corticosteroids, immunosuppressants, and substance use disorder treatment; healthy diet and lifestyle; and treating complications appropriately, such as endoscopy for esophageal varices, paracentesis for ascites, and beta blockers for portal hypertension (Cleveland Clinic, 2023a).

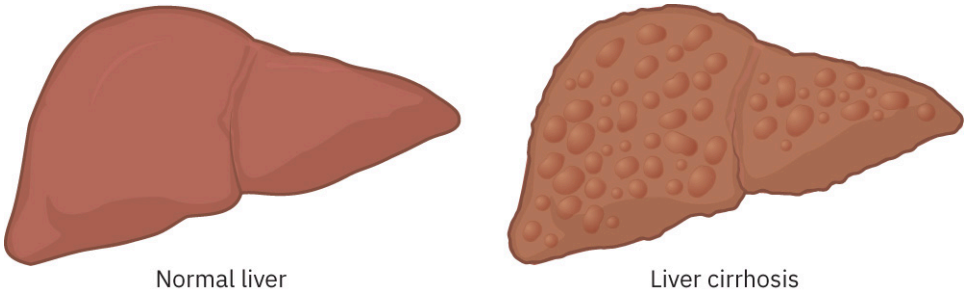

FIGURE 19.21 Compared with a normal liver, a liver with cirrhosis shows severe scarring. (credit: modification of work from *Anatomy and Physiology* 2e. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Clinical Manifestations

Signs of chronic liver disease may be nonspecific and include anorexia, weight loss, fatigue, ascites, esophageal varices, or jaundice (Sharma & Nagalli, 2023). Signs of acute liver failure may include hypotension, altered mental status, fever, jaundice, right upper quadrant pain, ascites, jaundice, or fluid overload (Shah et al., 2023). Signs and symptoms of cirrhosis include

- ascites
- dark-colored urine
- decreased urine output
- digestive problems
- edema
- hepatic encephalopathy
- jaundice
- light-colored stools
- motor dysfunction
- pruritus
- shortness of breath
- unexplained weight loss

Assessment and Diagnostics

A physical assessment may reveal a change in mental status, jaundice, ascites, peripheral edema, **gynecomastia** (enlarged breast tissue in male patients), **testicular hypertrophy** (enlarged testis), or **testicular atrophy** (testes reduced in size), muscle wasting, signs of GI bleeding, pruritus, encephalopathy, and right upper quadrant pain.

Liver function tests may show increased alanine transaminase (ALT) level and aspartate aminotransferase (AST) levels, bilirubin and prothrombin times will be increased, and albumin level decreased. Blood ammonia levels may be elevated, indicating hepatic encephalopathy (Table 19.10).

Category	Description
Symptoms	• Asterixis, or flapping movements, when the patient holds out the arms • Hyperreflexia • Muscle twitching • Cognitive impairment • Anxiety or irritability • Balance or coordination problems
Diagnosis	• Confirm liver disease. • Rule out other causes, such as alcohol withdrawal syndrome; stroke; intracranial lesions, masses, or infection; or postseizure encephalopathy. • Serum ammonia levels are often increased.
Treatment	Identify and treat the underlying cause. Treatment may include • Antibiotics • Lactulose • L-ornithine and l-aspartate preparation • Zinc • Prophylactic intubation to protect from aspiration or respiratory compromise

TABLE 19.10 Hepatic Encephalopathy (Mandiga et al., 2023)

Abdominal ultrasound can diagnose cirrhosis, portal hypertension, or thrombus. A CT or MRI scan will help the radiologist evaluate the shape and size of the liver and measure its fibrosis or elasticity (Cleveland Clinic, 2023a). A liver biopsy can confirm chronic liver disease. A toxicology screen, acetaminophen level, and serologies for viral hepatitis, HIV, and autoimmune markers may be ordered to determine causes.

Nursing Care of the Patient with Liver Disease

Nursing care of the patient with liver disease focuses on supporting body systems, reducing risk of injury, monitoring and managing complications, improving nutritional status, providing skin care, and education. The patient's mental status may range from alert to lethargic. The head of the bed should remain elevated. This helps facilitate venous drainage from the head (because of gravity), reducing intracranial pressure. Elevating the head of bed also helps with aspiration prevention during meals. Ensure the patient's skin is kept clean and dry and apply lotion to prevent itch. Educate the patient and family about the importance of maintaining a healthy diet.

Recognizing Cues and Analyzing Cues

The nurse caring for a patient in acute liver failure needs to be alert for cues. Any change could indicate a worsening in condition. Cues could include a decline in mental status, bleeding from an old venipuncture sites and orifices, or a reduction in urine output.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

A mental status decline accompanying an increase in ammonia level may indicate hepatic encephalopathy. The bleeding at a venipuncture site followed by oozing of blood from every site or orifice available could indicate coagulopathy, such as disseminated intravascular coagulation. A drop in urine output could indicate that kidney function is compromised.

Evaluation of Nursing Care and Outcomes for the Patient with Liver Disease

The evaluation of nursing care will explore all aspects of care. The first evaluation will be to determine if the goal was met. Goals may include (1) The patient will maintain urine output of at least 30 mL/hour by end of shift; and (2) the patient will experience no signs or symptoms of infection. Other goals may be written that are patient specific.

The primary patient outcome related to liver disease management is to preserve health and reduce complications. Subjective data reported by the patient can inform the nurse if symptoms of dyspnea and pain have improved.

Reviewing trends of vital signs, weight, and abdominal girth measurements can provide objective data about improvements in fluid retention. Comparing other data, such as laboratory values, can indicate trends reflecting the patient's liver function, effectiveness of medications, and nutritional status.

Medical Therapies and Related Care

Treatment of liver disease is interdisciplinary and involves stopping progression of disease and preventing complications. Although cirrhosis is not curable, treatment of the underlying cause can slow or prevent the progression to liver failure.

Common complications seen with chronic liver disease are esophageal varices, hepatic encephalopathy, **hepatorenal syndrome** (kidney dysfunction in patients with advanced liver disease), and hepatocellular carcinoma. Complications of acute liver disease can include sepsis, cerebral edema, multiorgan failure, and death.

Other specific treatments include viral suppression for viral hepatitis; alcohol abstinence; treatment of metabolic syndromes; identification and cessation of use of drugs or toxins; and immunosuppression and prescription of corticosteroids for autoimmune disorders. Once a patient has reached ESLD, organ transplantation is the final option for treatment.

ESLD and Liver Transplantation

Liver transplantation is the proven treatment for patients with ESLD. The healthy liver may be a whole liver from a deceased organ donor or a partial liver from a living donor (Figure 19.22). A partial liver can regenerate to full size within a few months. The **Model of End-Stage Liver Disease (MELD) Score** is used to predict survival of patients with cirrhosis and is a tool used to prioritize organ allocation for liver transplantation.

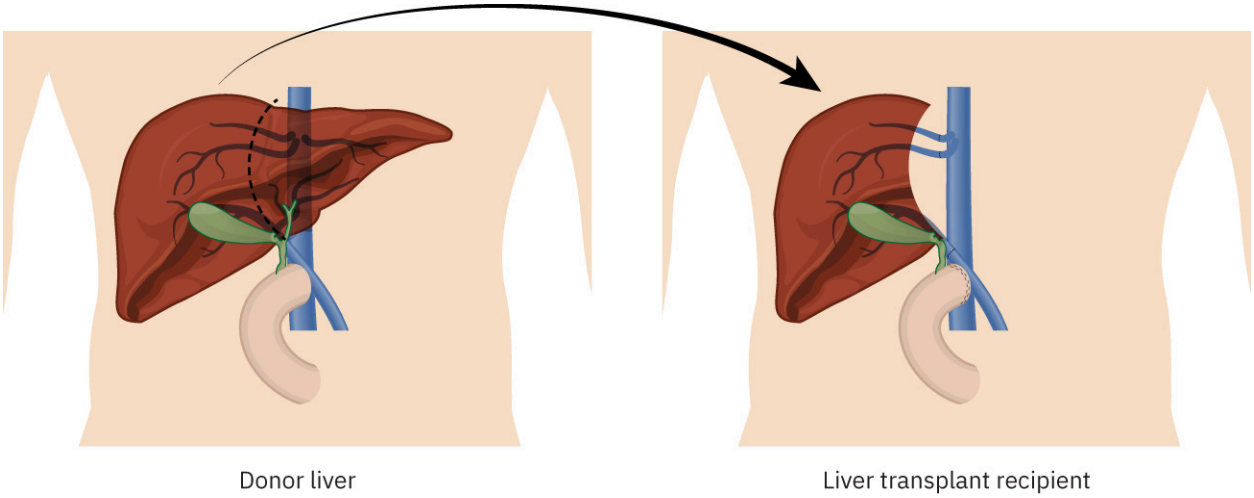

FIGURE 19.22 This illustration shows a right-side lobe, living-donor liver transplant. (credit: modification of work from *Anatomy and Physiology* 2e. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Indications

The indication for liver transplantation is ESLD. It can be caused by conditions such as:

- acute liver failure
- alcohol-related liver disease
- autoimmune hepatitis
- chronic hepatitis C
- hepatitis B
- hepatocellular carcinoma
- nonalcoholic steatohepatitis
- primary biliary cirrhosis
- primary sclerosing cholangitis
- Wilson disease

Contraindications to liver transplantation include a MELD score less than 15, advanced cardiac or pulmonary

disease, acquired immunodeficiency syndrome, active substance and/or alcohol use disorder, metastatic cancer, lack of psychosocial support, severe psychologic disease, and untreated shock or sepsis.

Immunosuppression

The goals of immunosuppression are to reduce the risk of graft rejection and minimize recurrent disease and adverse effects. Although most drug regimens are transplant-center specific, most programs use a glucocorticoid (prednisone), a calcineurin inhibitor (tacrolimus), and an antimetabolite (mycophenolate) (Vierling & Brandman, 2023). Immunosuppression medications must be taken for life, and the patient must be educated on the importance of not missing a dose and ensuring they do not run out of medication. A complication of immunosuppression is increased susceptibility to infection. Provide patient education about proper hand hygiene and avoiding large crowds.

Ethical Considerations

Alcohol-related liver disease is the leading cause for liver transplantation in the United States. There is controversy regarding the ethical issues that arise from determining which patients with a history of alcohol or drug use disorders can receive organs, especially in patients with less than 6 months of sobriety. Patients who are determined to be a high risk for future drug or alcohol use are often not considered for transplantation. Patients with poor social support systems, recent mental health crisis, and a history of medical noncompliance can also be contraindicated for transplant.

Black people and women have lower rates of referral to transplant centers, and patients with public insurance have worse post-transplant outcomes than patients with private insurance (Wahid et al., 2020). Locations of transplant centers also tend to be in predominantly White neighborhoods, causing non-White patients to have to travel farther for care.

Care of the Patient Receiving a Liver Transplant

On the inpatient side, the patient will be admitted to the ICU and will have vital signs recorded a minimum of every hour, as well as intake and output data. Any parameter that falls outside the desired will be referred to the critical care provider. This will occur for 2 to 3 days. Then, the patient will be transferred to a medical-surgical unit. The patient will have a routine postoperative experience: tolerating foods, ambulation, incentive spirometry, splinting, and lots of education on liver transplant care. The patient must know when to call the provider, signs and symptoms of an infection, organ rejection, lymph node enlargement, and skin changes. All routine cancer screenings should be completed in a timely manner.

Food and nutrition are important, and the patient should strive to eat healthy, balanced meals. Alcohol should be avoided. Consumption of water from lakes or rivers, unpasteurized milk, and raw or undercooked eggs, meats, and seafood may increase risk of infection. In addition, the patient should limit their intake of salt, cholesterol, fat, and sugar.

Disorders of the Gallbladder

The gallbladder stores and concentrates bile from the liver. The bile is then released into the duodenum, where it helps the body break down and absorb fats from food. Inflammation of the gallbladder is **cholecystitis**. A gallbladder stone is called a **cholelithiasis**. It is made from substances in the gallbladder and is benign unless it moves and blocks the common bile duct, a condition called **choledocholithiasis**, in which case, urgent surgery is required (Figure 19.23).

Women of all ages are more likely than men to have gallbladder disease and gallstones, possibly due to estrogen levels. Age and family history also are risk factors. American Indians have genes that affect cholesterol in bile, resulting in the highest rate of gallstones in the United States. Additionally, Mexican Americans are also at a significant risk of developing gallstones. Individuals with metabolic syndrome, diabetes with insulin resistance, and fast weight loss are all at elevated risk.

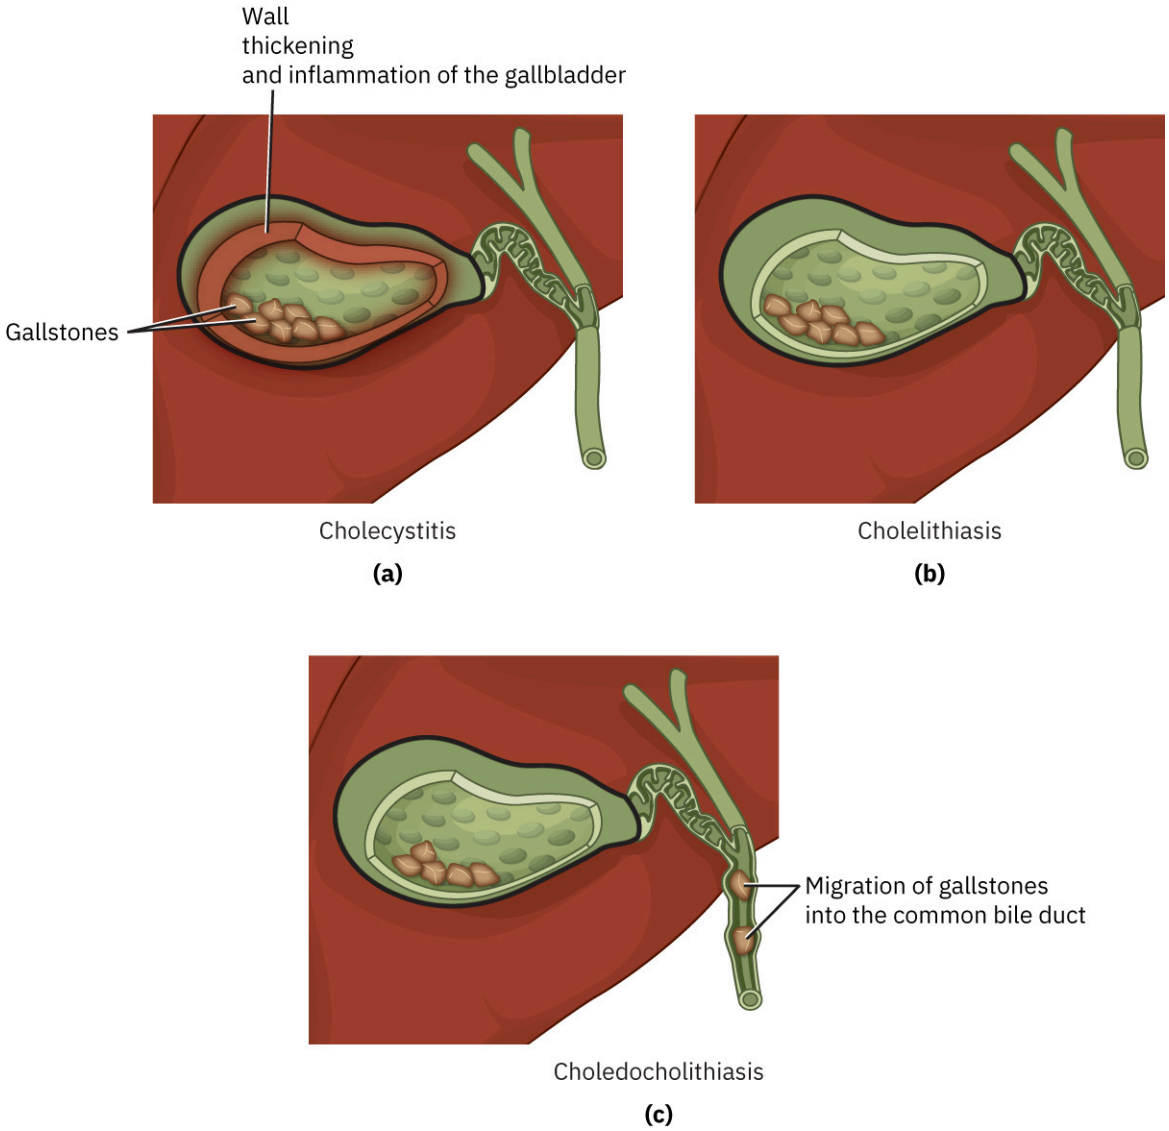

FIGURE 19.23 The illustration here shows the differences among(a) cholecystitis, (b) cholelithiasis, and (c) choledocholithiasis. (credit: modification of work from *Anatomy and Physiology* 2e. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Pathophysiology

Gallstones can be formed by cholesterol or bilirubin and can range in size. Stones may temporarily block the cystic duct or pass into the common bile duct, creating temporary symptoms called biliary colic (Steel, 2022). Occlusion of the cystic duct for an extended period can cause acute cholecystitis. Occlusion of the common bile duct causes choledocholithiasis. This can lead to infection and inflammation of the bile duct system.

Clinical Manifestations

Gallstones are often asymptomatic and do not produce symptoms unless they block the common bile duct. Symptoms can include sudden severe pain in the right upper abdomen, nausea, and vomiting. Symptoms of cholecystitis include

- abdominal bloating
- chills
- dark urine
- fever
- jaundice
- nausea, vomiting
- severe, sudden right upper quadrant pain that becomes sharp when palpated

- sharp pain when breathing in

Assessment and Diagnostics

The nurse will complete a focused subjective history and physical assessment. The patient may present with classic reports of severe right upper quadrant pain, nausea and vomiting. A physical assessment may reveal jaundice, abdominal bloating, and stiff abdominal muscles.

Although laboratory values may be normal in cases of cholelithiasis, the patient's WBC count may be elevated. AST, ALT, and alkaline phosphatase levels may also be elevated, which increase the patient's risk for bleeding. Blood cultures may be completed if the patient is febrile. Other bloodwork may be completed to rule out other conditions, such as pancreatitis. An ultrasound is the most common diagnostic imaging procedure performed to diagnose both cholecystitis and cholelithiasis. Other diagnostic imaging, such as a CT scan or hepatic 2,6-dimethyliminodiacetic acid (HIDA) scan, may be completed.

Nursing Care of the Patient with Gallbladder Disorders

Patients with gallbladder disorders are at risk for fluid volume deficit and imbalanced nutrition. Nursing care to prevent these risks include

- accurate monitoring of intake and output
- administering pain medications as ordered
- assessing for abnormal bleeding
- encouraging food intake
- monitoring for increased or continued nausea and vomiting
- providing patient education about the disease, treatment, and prevention

Recognizing Cues and Analyzing Cues

Using both subjective and objective data will help optimize care. Subjective data can include the patient's report of pain, nausea, and vomiting. Vital signs may show hypotension from fluid loss and fever caused by infection. Jaundice would indicate that the common bile duct is blocked and surgery may be required. The nurse educates the patient about treatment, assists with diagnostic testing, and prepares the patient for surgery.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Patients with gallbladder disorders are at risk for imbalanced nutrition. Interventions the nurse can do to promote adequate nutrition include administering prescribed antiemetic medications, collaborating with the nutritionist to provide foods the patient prefers, encourage ambulation to promote peristalsis, and providing nutritional supplements as ordered.

Evaluation of Nursing Care and Outcomes for the Patient with Gallbladder Disorders

In evaluating the nursing care provided, the nurse examines the goals created and evaluates if they were met. Interventions may be adjusted as needed during care to reach goals. A primary goal for patients with gallbladder disorder is pain relief. The nurse asks the patient about their pain level and if it has improved. The nurse can also look at objective data, such as pain medication use trends. If the patient is not getting adequate pain relief but is not requesting pain medications, the nurse knows that re-education may be needed about pain medication use and the healing process.

Medical Therapies and Related Care

Initially, patients will be NPO and receiving IV fluid therapy to rest the gallbladder and decrease inflammation. Surgery is the recommended treatment for cholecystitis, to either remove the gallstone causing the inflammation or to remove the gallbladder. Surgery can be emergent or scheduled, depending on the severity of symptoms. IV antibiotic therapy is also prescribed in the presence of infection. Pain medications may also be prescribed to control pain. Education about diet encourages patients to avoid foods that can increase recurrence of disease, such as fried foods, fast foods, sugary foods, foods high in saturated fat, cruciferous vegetables, and pectin.

Disorders of the Pancreas

The pancreas has two main functions in the body. It produces insulin to regulate blood sugar levels and produces enzymes to aid in food digestion. When the pancreas cannot function to produce digestive enzymes, malnutrition can occur. This section explores pancreatitis and pancreatic cancer.

Pancreatitis

Inflammation of the pancreas, **pancreatitis**, is the leading cause of GI hospitalizations in the United States (Gapp et al., 2023). Pancreatitis can be acute or chronic. Hospitalization rates for acute pancreatitis are three times higher among Black people than White people (Tang, 2021). Common risk factors to developing pancreatitis include alcohol use disorder, recent history of operative or invasive procedures, a family history of hypertriglyceridemia and gallstones.

Pathophysiology

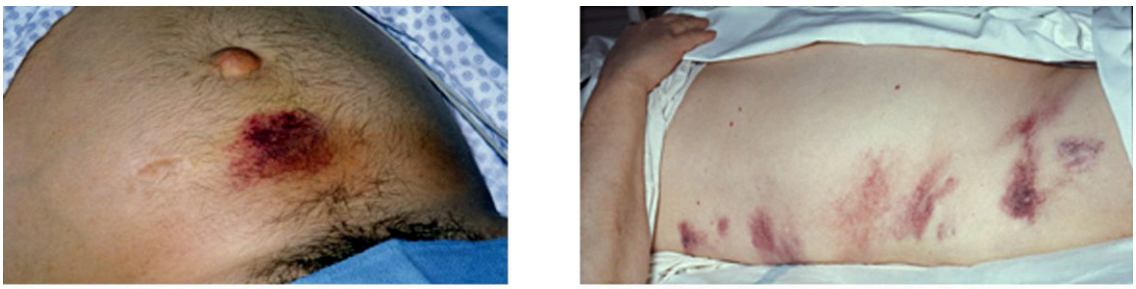
Pancreatitis is caused by an inflammatory response to a duct obstruction, pH imbalance, or problems with calcium homeostasis (Tang, 2021). These may prevent bile from being released to aid in food digestion. Inflammation of the pancreatic tissues eventually leads to tissue damage. If it continues to progress, the pancreas could become necrotic and cause multiorgan dysfunction syndrome.

Clinical Manifestations

Patients may present with severe abdominal pain that may radiate to the chest or back, accompanied by nausea, vomiting, tachycardia, fever, hypotension, and jaundice. Pain may become worse after eating fatty foods. Three assessment signs associated with bleeding in pancreatitis are the Cullen's sign, Grey-Turner's sign, and Fox's sign (Table 19.11 and Figure 19.24).

Assessment	Characterization
Cullen's sign	Ecchymosis over the periumbilical area; indicates peritoneal hemorrhage
Grey-Turner's sign	Flank ecchymosis; indicates retroperitoneal hemorrhage
Fox's sign	Bruising over the inguinal ligament (upper outer thigh); indicates retroperitoneal bleeding

TABLE 19.11 Assessments for Pancreatic Hemorrhage



(a) **(b)**

FIGURE 19.24 (a) Cullen's sign presents as ecchymosis over the periumbilical area and indicates peritoneal hemorrhage. (b) Grey-Turner's sign presents as ecchymosis over the flank area and indicates retroperitoneal bleeding. (credit: Herbert L. Fred, MD and Hendrik A. van Dijk/Wikimedia Commons, CC BY 2.0)

Assessment and Diagnostics

Patients with pancreatitis may present with nonspecific symptoms, such as nausea, vomiting, abdominal pain, tachycardia, and fever. The nature of the pain may vary, depending on the cause of the pancreatitis. Initial bloodwork would be completed to narrow down a cause of symptoms. Pancreatitis will result in an elevated lipase or amylase level. Elevation of liver enzyme levels (e.g., AST, ALT, total bilirubin) may indicate gallstones as the cause of pancreatitis. Calcium, triglyceride, and cholesterol levels will be evaluated depending on the cause of pancreatitis. Glucose levels may be elevated secondary to beta-cell injury in the pancreas. An elevated WBC count may indicate infection. Arterial blood gas samples may be obtained if the patient is experiencing dyspnea. Abdominal ultrasound can detect gallstones. Endoscopic ultrasonography can visualize the pancreas and biliary tract.

Prioritizing Hypotheses, Generating Solutions, and Taking Action
The patient with acute pancreatitis will need aggressive fluid resuscitation, pain management, and strict intake and output monitoring. Blood glucose levels will also be monitored. The patient will need frequent assessments of respiratory status and fluid and electrolytes status. Patient education will be provided on an ongoing basis.

Analysis of subjective and objective data will allow the nurse to provide optimal care. Although subjective data may be nonspecific and include abdominal pain, nausea, and vomiting, objective physical assessment data may reveal jaundice, a positive Cullen's sign, and abdominal rigidity. These would cue the nurse to suspect pancreatitis.

The nurse recognizes that fluid resuscitation is a priority for the first 24 hours. Vital signs should be monitored for signs of overhydration, such as hypertension. Strict intake and output monitoring can allow the nurse to monitor fluid balance.

Evaluation of Nursing Care and Outcomes for the Patient with Pancreatitis
The evaluation of nursing care will include determining if the patient's condition has improved and if goals have been met. Examples of goals are:

- The patient will state pain is reduced to [insert number between 0 and 10].
- The patient will state what causes pancreatitis.
- The patient will verbalize a commitment to follow-up care.

These goals are evaluated, care is adjusted, and the patient continues to receive care unless the health issue does not require the nurse to follow-up. The nurse must evaluate each intervention and the outcome. To evaluate the effectiveness of pain management, the nurse evaluates subjective data provided by the patient, such as ability to rest comfortably with pain at a tolerable level.

Medical Therapies and Related Care
For acute pancreatitis, medical management includes fluid resuscitation and nutritional support. Antibiotics may be ordered if the cause is suspected to be infection. Surgical intervention is indicated in the presence of gallstones, duct disruption, infective pancreatic necrosis, or abscess. If the patient cannot maintain nutritional needs, parenteral nutrition may be initiated.

For chronic pancreatitis, treatment goals include decreased abdominal pain and increased nutrition absorption. Nonopioid pain regimens may be used, and pancreatic enzymes will be prescribed to aid in food absorption. The provider will order a high-protein, high-calorie diet. The dietitian will assist the patient with meal planning as needed. Interventional radiology procedures or surgical resection of the pancreas may be required in certain cases, depending upon the patient's general health condition, previous procedures, and symptoms.

Pancreatic Cancer

Pancreatic cancer typically grows in the head of the pancreas and accounts for 3 percent of all cancer in the United States (Cancer.net, 2023). It is more common in men than women. Black men have a higher incidence of pancreatic cancer than other racial groups. Risk factors are cigarette smoking, diabetes, obesity, chronic pancreatitis, cirrhosis of the liver, *H. pylori* infection, work exposure to chemicals, and family history. The most common type of pancreatic cancer is pancreatic ductal adenocarcinoma. It may spread to the liver, lung, or more distant sites. The 5-year survival rate is 12.5% (Cancer.net, 2023).

Pathophysiology
The pathophysiology of pancreatic cancer is a growth, typically adenocarcinoma, of abnormal cells. The immune system does not stop the growth of the tumor.

Clinical Manifestations
Pancreatic cancer is rarely found at an early stage, because it lacks clinical manifestations until disease has advanced. Common signs and symptoms include abdominal pain, unexplained weight loss, jaundice, itching, dark urine, light-colored stools, fatigue, or history of recurring deep vein thrombosis from hypercoagulability. Patients may also have a new diagnosis of diabetes or diabetes that is harder to control than normal.

Assessment, Diagnostics, and Laboratory Values
Physical assessment may reveal the presence of a palpable mass. Clinical manifestations and assessment findings

will prompt the provider to suspect cancer. Initial laboratory findings will show elevated liver function tests and elevated levels of direct and total bilirubin, lipase, amylase, and pancreatic tumor markers.

Multidetector CT is the preferred imaging modality to evaluate the extent of disease. PET scanning can detect distant metastatic disease. ERCP with endoscopic ultrasound may be performed and suspicious tissues may be biopsied.

Nursing Care of the Patient with Pancreatic Cancer

The care of the patient with pancreatic cancer will start with teaching the patient about the biopsy process. When the results are available and the provider has given the patient the diagnosis, the nurse can provide education and emotional care. Nursing care may be to support patient's decisions on surgery, radiation, or chemotherapy. This can also progress to coordinating palliative or hospice care.

As part of nursing care, the nurse will recognize and analyze cues. The nurse will complete the history and the physical assessment. Of all the symptoms of pancreatic cancer, a significant cue is the ability to palpate an abdominal mass. The nurse will then prioritize hypotheses, generate solutions, and take action. The nurse makes the hypothesis that the problem is a pancreatic tumor. Immediate reporting is completed, and the nurse starts addressing prescriptions as they are ordered.

Evaluation of Nursing Care and Outcomes for the Patient with Pancreatic Cancer

Nursing care must be evaluated. Two examples of goals that need to be evaluated are (1) the patient will verbalize all the details for having a biopsy completed, and (2) the patient will state how to care for skin while jaundice is present.

In caring for a patient with pancreatic cancer, the outcomes may be different than those discussed in this chapter. Certainly, the patient should understand the diagnosis and the treatment options. Ultimately, the goal is for the patient to reach a place of acceptance regarding the terminal nature of their diagnosis. Success in this context is not about finding a cure but rather providing compassionate care and support throughout their journey.

Medical Therapies and Related Care

Medical treatment depends on location and advancement of disease. Surgery is an option in only 20% of pancreatic cancer cases (Cancer.net, 2023). The surgical procedure often performed is a Whipple procedure (Figure 19.25), or a pylorus-preserving Whipple procedure. The head of the pancreas, the bile duct, gallbladder, and duodenum are removed. The pancreas may even be removed, and the patient may need to take insulin.

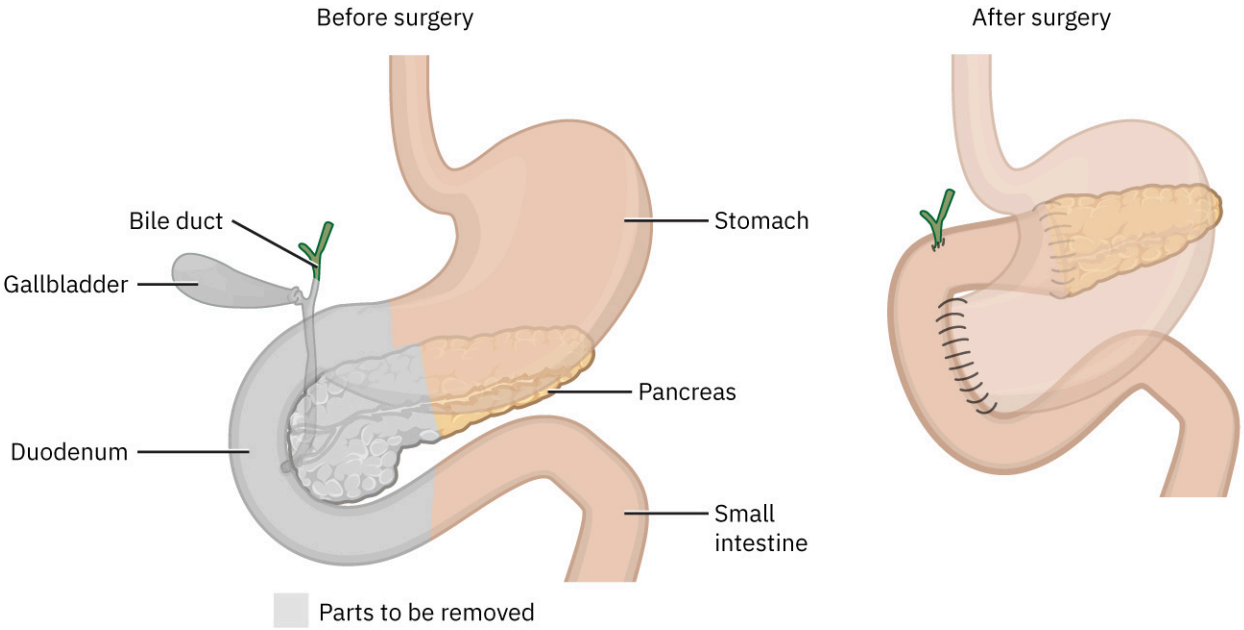


FIGURE 19.25 This image shows the parts of the body removed during a Whipple procedure. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license.)

Supportive surgery and palliative procedures are often recommended to help with symptoms affecting a patient's

quality of life. Examples of palliative procedures and surgery can include bypass surgery, stent placements, and nerve blocks to alleviate jaundice, nausea and vomiting, and tumor-associated pain.

Other therapies, such as chemotherapy and/or radiation, targeted therapies, and immunotherapy, may also be performed alone or in conjunction with other treatments. Psychological and clerical support are also an important aspect of treatment.

19.7 Ostomy Care

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the role of the nurse pre- and postoperatively for the patient with an ostomy
- Describe the nursing care of a patient with a colostomy and continent ileostomy
- Identify troubleshooting methods when skin breakdown occurs with an ileostomy

Some patients have surgical diversions for diseases such as diverticulitis or cancer. A surgical opening in the abdomen for the expulsion of stool into a bag-like appliance is called an **ostomy**. In ostomies related to elimination, a **stoma** is an opening on the abdomen that is connected to the GI or urinary system to allow waste (i.e., urine or feces) to be collected in a pouch. This unit focuses on ostomy care and the nurse's role in the patient's positive coping and self-image.

Nursing Care of the Ostomy Surgical Patient

Approximately 500,000 individuals in the United States have an ostomy. A stoma can be permanent, such as when an organ is removed, or temporary, to allow for organ healing. Ostomies are created for patients with conditions such as cancer of the bowel, inflammatory bowel diseases, or perforation of the colon.

The two common types of ostomies related to elimination are:

- **ileostomy**: the lower end of the small intestine (ileum) is attached to a stoma to bypass the colon, rectum, and anus.
- **colostomy**: the colon is attached to a stoma to bypass the rectum and the anus.

Figure 19.26 compares the anatomic locations of ileostomies and various sites of colostomies. It is important for the nurse to understand the site of a patient's colostomy because the site affects the characteristics of the waste. For example, due to the natural digestive process of the colon and absorption of water, waste from an ileostomy or a colostomy placed in the anterior ascending colon will be watery compared with waste from an ostomy placed in the descending colon.

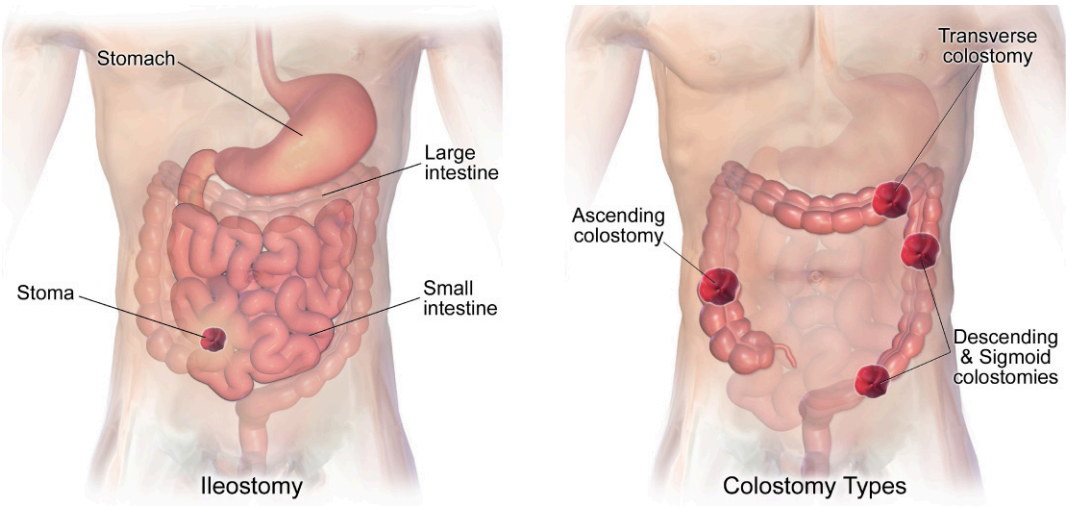

FIGURE 19.26 This diagram depicts anatomic locations of ostomy sites. (credit a: "Ileostomy.png" by BruceBlaus/Wikimedia Commons, CC BY 4.0; credit b: "Blausen 0247 Colostomy.png" byBruceBlaus/Wikimedia Commons, CC BY 3.0)

Preoperative Care

In preparing for surgery, preoperative education and ostomy site marking are completed, allowing the patient to

prepare for ostomy care and ensure optimal ostomy location (WOCN et al., 2021). This is usually done by a certified wound and ostomy nurse who collaborates with the surgeon. During the patient education session, the nurse will explain ostomy care, give an overview of the different types of supplies used, and provide the patient a rationale about the anatomic placement of the stoma (WOCN et al., 2021). It is important that the primary nurse collaborate with the surgical team to answer patient questions honestly, emphasize that a quality of life is still available with a stoma, and encourage family involvement during these education sessions.

LIFE-STAGE CONTEXT

Advanced Age with an Ostomy

Quality of life of older patients with an ostomy is an area of concern but not as much as it is for younger clients. A research study showed that patients aged 66 to 75 years had a reduced activity level when compared with other individuals of the same age. In those older than 76 years who had an ostomy, there was a reduction in social and physical functioning compared with other individuals in the same age range. The study then compared younger adults with ostomies with other individuals without an ostomy in their age range. The former were even more likely to experience decreased functionality than those of advanced age. The conclusion was that although the ostomy reduced quality of life, it actually was less of a factor for those of advanced age than for younger adults.

(Verweij et al., 2018)

Postoperative Care

The tissue of a stoma is very delicate. Immediately after surgery, a stoma is swollen, but it will shrink over several weeks. A healthy, healed stoma appears moist and dark red or pink (Figure 19.27). Stomas that are swollen, dry, have malodorous discharge, or are bluish, purple, black, or pale should be reported to the provider. The skin surrounding a stoma can easily become irritated from the pouch adhesive or leakage of fluid from the stoma, so the nurse must perform interventions to prevent skin breakdown. Any identified signs of skin breakdown should be reported to the provider. The ostomy nurse will be visiting intermittently to perform education, which should be regularly enforced by the primary nurse. The stoma should start producing stool in 2 to 3 days.

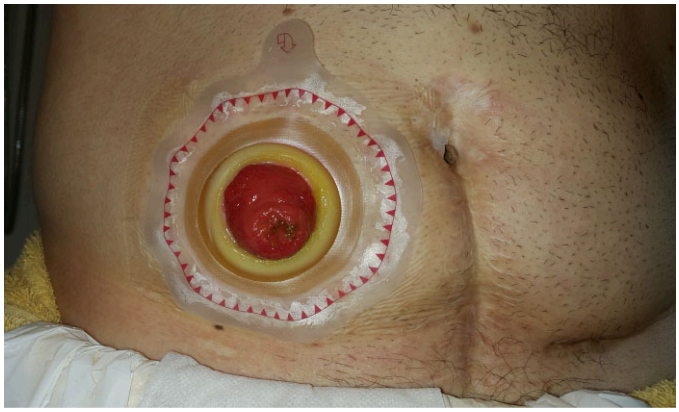

FIGURE 19.27 A healthy stoma is moist and dark pink or red. (credit: "Ostomy wafer being worn by an ileostomy patient" by Eric Polsinelli (VeganOstomy)/Wikimedia Commons, CC-BY 4.0)

Emotional Support and Education

The emotional burden of coping with an ostomy may be devastating for some patients and may affect their self-esteem, body image, quality of life, and ability to be intimate. Providing education is important throughout patient care and before discharge. It is common for patients with ostomies to struggle with body image and their altered pattern of elimination. Nurses can promote healthy coping by ensuring that the patient has appropriate referrals to a wound and ostomy nurse specialist, a social worker, and support groups. Nurses should also be aware of their nonverbal cues when assisting a patient with their appliance changes. It is vital not to show signs of disgust at the appearance of the ostomy or at the odor that may be present when changing an appliance or pouching system.

When a patient is discharged from acute care with a new ostomy, ensure they are able to empty the pouch system independently or with the assistance of the caregiver. Provide enough supplies for 2 or 3 days of home care or until

ordered supplies are expected to arrive. Provide education and evaluate the patient's and caregiver's understanding of the signs of complications. Instruct them to call the provider if the stoma becomes swollen, dry, discolored, or develops a malodorous discharge. Topics to be included are:

- adequate fluid intake
- appliance options, supply needs, and self-care process
- bag leakage prevention and troubleshooting
- colostomy irrigation, if desired
- community support
- conditions to call the provider, such as signs of infection, stoma prolapse, retraction or color change, change in stool appearance, signs of electrolyte imbalance
- exercise adaptions
- foods to avoid reducing gas
- ileostomy special needs
- sexual activity adjustment

CLINICAL SAFETY AND PROCEDURES (QSEN)

Nursing Care of a Patient with a Colostomy

Purpose: To ensure nurses provide comprehensive, safe, and patient-centered care for individuals with a colostomy, promoting optimal health outcomes and quality of life.

QSEN Competencies: Patient-Centered Care, Safety, Evidence-Based Practice (EBP), Teamwork and Collaboration

Clinical Safety and Procedures: Nursing Care of a Patient with a Colostomy

Steps:

1. Hand hygiene and PPE (Safety):
    - Perform hand hygiene thoroughly.
    - Don appropriate personal protective equipment (PPE) before handling the ostomy site to prevent infection.
2. Patient assessment (Patient-Centered Care, Safety):
    - Assess the stoma for color, size, and output. A healthy stoma should be pink to red and moist.
    - Evaluate the peristomal skin for signs of irritation, redness, or breakdown.
3. Emptying and changing the ostomy bag (Safety, EBP):
    - Empty the ostomy bag when it is one-third to one-half full to prevent leakage and skin irritation.
    - Change the ostomy bag and wafer every 3 to 5 days or as needed if there is leakage or skin irritation.
    - Use warm water and mild soap to gently clean the stoma and peristomal skin, avoiding alcohol-based or harsh products.
4. Application of a new ostomy bag (Safety, EBP):
    - Measure the stoma to ensure the opening of the new wafer is appropriately sized to fit snugly around the stoma without causing constriction.
    - Apply skin barrier products if necessary to protect the peristomal skin.
    - Attach the new ostomy bag securely, ensuring there are no gaps or leaks.
5. Monitoring and documentation (Safety, Teamwork and Collaboration):
    - Monitor the patient's ostomy output, noting any changes in color, consistency, or volume.
    - Document the stoma's appearance, condition of the peristomal skin, and any patient-reported symptoms or concerns.
6. Patient Education and Support (Patient-Centered Care, Teamwork and Collaboration):
    - Educate the patient on proper ostomy care techniques, including emptying and changing the bag, skin care, and signs of complications.
    - Provide emotional support and resources, such as support groups or counseling services, to help the patient adjust to life with an ostomy.

- Involve the patient in care planning and decision-making, respecting their preferences and needs.

Skin and Stoma Care

Stoma appliances are supplied as a one- or two-piece set (Figure 19.28). A two-piece set consists of an ostomy barrier (also called a wafer) and a pouch. The ostomy barrier is the part of the appliance that sticks to the skin; it has a hole that is fitted around the stoma. The pouch collects the waste and must be emptied regularly. It attaches to the ostomy barrier in a clicking motion to secure the two parts, similar to how a plastic storage-container cover snaps to a container to create a seal. The pouching system must be completely sealed to prevent leaking of the waste and to protect the surrounding skin. The pouch has an end with an opening where the waste is drained and is closed using a plastic clip or Velcro strip. In a one-piece stoma appliance set, the ostomy barrier and the pouch are one piece.

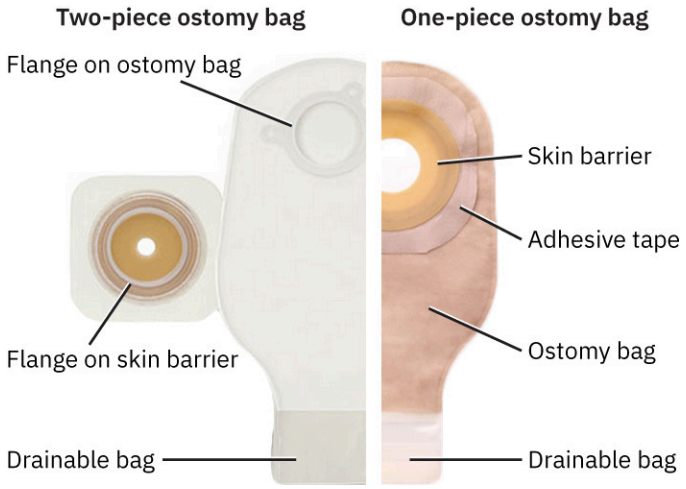

FIGURE 19.28 Ostomy bags can come in one- or two-piece units. (credit: "Short Comparison between One-Piece and Two-Piece Ostomy Bags" by Theresa Maclachlan/Flickr, CC BY 2.0)

Individuals with colostomies and ileostomies have no sensation and no control over the output of the stoma. Depending on the type of system, the ostomy appliance can last from 4 to 7 days, but the pouch must be changed if there is leaking, odor, excessive skin exposure, or itching or burning under the skin barrier. Patients with pouches can swim and take showers with the pouching system on.

LINK TO LEARNING

This video compares different types of ostomy bag systems (https://openstax.org/r/77ostomybags) and the pros and cons of each.

Irrigation

One way to help train the colon to empty at a regular time each day is **colostomy irrigation**. This can be done with a descending or sigmoid colostomy and allows the patient the freedom of fewer pouch changes and ability to wear lower-profile ostomy pouches (Hollister, n.d.). The procedure is similar to an enema in the stoma and takes about an hour to complete. To be effective, it must be done at the same time, every other day. Contraindications include stoma abnormalities such as prolapse or an irregular functioning stoma, cancer treatments such as chemotherapy or pelvic or abdominal radiation treatments, and medications that have diarrhea as a side effect (Agastya & Bettina, 2023).

Colostomy

The presence of a colostomy is a life-changing event. Evaluation of nursing care of a patient with a colostomy includes the patient providing care of the colostomy, discussion of feelings, and identifying signs to the ostomy nurse or provider. The abdominal incision should be well approximated and free of excessive redness or drainage.

Continent Ileostomy

When a continent ileostomy is formed, there is an internal pouch created inside the abdomen. There is a stoma on the abdominal wall. Approximately 3 times a day, the patient will need to empty the contents with a catheter through the stoma. There is another option called ileoanal pouch surgery. This is created by two or three surgeries. An ileal pouch is created and attached to the anus. The patient is then continent, but the bowel movements will be liquid and require six to seven bowel movements a day, including one at night; this allows continence (NIDDK, 2021).

Preventing Complications

Minor complications of ostomies include repeated appliance leakage, offensive smell, and frequent need to empty the appliance bag. The nurse can help the patient manage these through repetitive counseling on appliance application, the use of stoma deodorant drops in the collection bag, and the suggestion of dietary changes to reduce odors (e.g., avoidance of fish, eggs, onions). Other complications are skin excoriation, diarrhea, and constipation. Validating the size of the appliance, proper cleaning of the skin around the stoma site in between appliance changes, and the appropriate use of creams, skin barriers, or powders to the skin around the stoma can protect it from further irritation from stool.

Diarrhea in a colostomy can be problematic. If it persists, fluid and electrolyte imbalance may occur. Antidiarrheal medications may be ordered. The patient may be checked for infections, such as with *Clostridioides difficile* bacteria.

Frequent visual assessment of the stoma and auscultation of bowel sounds are important in the first 2 to 4 days after surgery. Serious colostomy complications include stomal gangrene, stomal retraction, colostomy prolapse, surgical site infection, herniation, dehiscence, atelectasis and pneumonia (Agastya & Bettina, 2023).

INTERDISCIPLINARY PLAN OF CARE

Recovery from Ostomy Surgery Interdisciplinary Plan of Care

The inderdisciplinary plan of care for a patient recovering from an ostomy surgery can involve several health care disciplines working collaboratively. Members of the team may include physical therapists, occupational therapists, social workers, nutritionists, case managers, and a wound and ostomy nurse, each with their own role.

The physical therapist aims to improve the patient's mobility and strength after surgery, initiating ambulation within 24 hours and conducting range of motion exercises. The occupational therapist focuses on promoting independence in daily activities despite the ostomy, teaching ostomy care techniques, and providing adaptive equipment. The social worker assesses psychosocial needs, offers emotional support, and facilitates counseling for adjustment.

The nutritionist or dietitian optimizes nutrition for wound healing and advises the patient on dietary adjustments related to the ostomy. The case manager coordinates care across disciplines, develops a comprehensive care plan, and arranges necessary services. The wound and ostomy nurse monitors stoma and skin integrity, educates the patient on proper ostomy care, and intervenes promptly in case of complications.

Together, these disciplines ensure holistic support for recovery and adjustment to living with an ostomy.

Summary

19.1 Nutritional Disorders

- Diet—both what you eat and how much you eat—has a dramatic impact on health. Eating too much or too little food can lead to serious medical issues, including cardiovascular disease, cancer, anorexia, and diabetes, among others.
- An unhealthy diet combined with unhealthy environmental conditions, such as smoking, significantly increases the potential medical complications.
- Obesity is defined as abnormal or excess fat accumulation and a state of malnutrition by excess and is the result of having a chronic positive energy balance from consuming more calories than are being used by the body.
- Diagnostics and laboratory studies for patients with obesity will generally focus on ruling out other comorbidities or health conditions.
- Care for patients with obesity is individualized, according to any underlying causes of obesity and any comorbid conditions. Treatment includes behavioral interventions, nutritional modification, medications, and surgical intervention, if appropriate.
- Bariatric surgery is a consideration for patients with a BMI of 40 kg/m^2 or patients with a BMI of 35 kg/m^2 with significant health issues that would be expected to improve with weight loss.
- Anorexia nervosa is an eating disorder characterized by the maintenance of a body weight well below average through severe dietary restriction and/or excessive exercise. Patients with anorexia nervosa have deficits in dopamine and serotonin neurotransmitters, which are responsible for eating behavior, reward, impulse control, and neuroticism.
- Psychiatric evaluation and diagnosis of anorexia nervosa is based on criteria provided by the American Psychiatric Association. These criteria include the patient having a distorted view of themselves and their condition, intense fear of gaining weight, and a significantly low body weight from severe conscious restriction of calories.
- The primary patient outcome for anorexia nervosa management is an increase in caloric intake to sustain healthy bodily function.
- Malabsorption occurs when the GI tract is unable to properly absorb nutrients, such as proteins, carbohydrates, fats, vitamins, minerals, or trace elements. This can occur with one vitamin or macronutrient, several, or all. Malabsorption can occur at any phase of the digestion and absorption of food: luminal, mucosal, or postabsorptive.
- Medical treatment of malabsorption is focused on finding and treating the underlying cause of malabsorption, avoiding any food triggers, and managing symptoms.

19.2 Disorders of the Oral Cavity

- Dental caries are common chronic oral cavity diseases, even though they are easily preventable with good oral hygiene.
- In the inpatient setting, it is important for nurses to provide mouth care for patients who are unable to perform self-care.
- Cancer of the oral cavity or oropharynx can develop on the tissue of the mouth and gums, on or under the tongue, and at the back of the mouth or throat.
- The priorities of care during treatment are maintaining a patent airway and healthy nutritional status and providing emotional support, pain relief, and patient education. Frequent airway assessments may need to be completed.
- Temporomandibular disorder (TMD) is a collection of more 30 disorders that cause pain and dysfunction of jaw movement; research suggests it is caused by a combination of psychological stressors, life stressors, genes, jaw trauma, grinding the teeth, and arthritis or other inflammatory conditions.
- TMD is usually a temporary disorder that resolves without aggressive treatment.

19.3 Parenteral and Enteral Nutrition

- Parenteral nutrition is a concentrated IV solution containing glucose, amino acids, minerals, electrolytes, and vitamins, administered via a large central IV line.

- Parenteral nutrition is typically used when the patient's intestines or stomach are not working properly and must be bypassed, such as during paralytic ileus, in which peristalsis has completely stopped, or after postoperative bowel surgeries, such as bowel resection.
- Peripheral TPN is typically used for shorter-term nutritional support or for a patient who cannot tolerate or does not desire a central line.
- Enteral nutrition (EN) refers to nutrition provided directly into the GI tract through an enteral tube that bypasses the oral cavity. EN may be indicated in patients with mental illness, neuromuscular disorders, upper GI obstruction, and traumatic injuries, such as burns or traumatic brain injury.
- Nursing management of the patient receiving parenteral nutrition includes verifying the parenteral nutrition order, assessing the patient's response to the infusion, and monitoring for complications.
- The most serious complication of enteral feeding is inadvertent respiratory aspiration of gastric contents, causing life-threatening aspiration pneumonia. Other complications include tube clogging, tubing misconnections, and patient intolerance to the feeding.

19.4 Disorders of the Upper GI System

- Barrett's esophagus is a condition in which the cells that line the esophagus change and become more like intestinal cells. It is more common in men and usually diagnosed around age 55 years.
- Barrett's esophagus is frequently asymptomatic, and patients tend to have other symptoms of GI conditions, such as frequent heartburn and acid regurgitation or reflux.
- Symptom improvement and patient understanding of the importance of diet modification and medication adherence are the goals of treatment for Barrett's esophagus.
- Patients diagnosed with Barrett's esophagus are prescribed a proton pump inhibitor (PPI), such as omeprazole or pantoprazole, to eliminate gastroesophageal reflux disease (GERD) symptoms and prevent further esophageal irritation.
- Gastritis is inflammation and redness of the lining of the stomach; it may be acute or chronic, and erosive and nonerosive. Once the underlying cause is treated, it usually resolves.
- Patients with acute gastritis may present with epigastric pain, nausea, vomiting, or a feeling of fullness in the upper abdomen after eating.
- Endoscopy with biopsy is the gold standard for diagnosing gastritis, and treatment can be singular, or a combination of antibiotics, PPIs, vitamin supplementation, immunomodulatory therapy, and dietary modifications.
- Gastric cancer, or stomach cancer, is the fifth most frequently diagnosed cancer and the third leading cause of cancer deaths worldwide; most patients with symptoms will present with advanced disease.
- Potential treatments for stomach cancer may include surgery, chemotherapy, radiation therapy, targeted drug therapy, and immunotherapy.

19.5 Disorders of the Lower GI System

- Constipation is defined as a decrease in normal frequency of defecation accompanied by difficult or incomplete passage of stool and/or passage of excessively hard, dry stool.
- In more serious cases, constipation can be a sign of fecal impaction, intestinal obstruction, or paralytic ileus; treatment typically includes a prescribed daily bowel regimen, such as oral stool softeners and a mild stimulant laxative
- Diarrhea is caused by increased peristalsis causing the stool to move too quickly through the large intestines for water to be effectively reabsorbed, resulting in loose, watery stools; many conditions can cause diarrhea.
- Maintaining adequate fluid intake is the priority of care for a patient with diarrhea.
- Irritable bowel syndrome (IBS) is a disorder of the large intestine that causes changes in bowel movements and abdominal pain. It can occur after infection, be triggered by stress, or be caused by food intolerances, brain-gut interaction, and inflammatory processes.
- Because IBS is a symptom-based disorder, treatment is aimed at symptom resolution.
- In patients with celiac disease, the ingestion of gluten causes the body's immune system to attack the villi of the small intestine; this results in permanent damage over time, causing a scalloping of the folds and a cracked appearance of the mucosa, and disrupts the absorption of nutrients.
- Treatment for celiac disease is a lifelong, strict, gluten-free diet.

- Colorectal cancer is often detected before symptoms occur; patients who present with symptoms usually have advanced disease.
- Appendicitis is most often caused by an obstruction within the appendiceal orifice. This creates an inflammatory response, which can lead to local ischemia and perforation.
- Diverticular disease occurs when diverticulosis becomes symptomatic, such as such as with lower abdominal pain, bloating, and diarrhea.
- Inflammatory bowel disease (IBD) is characterized by chronic inflammation of the GI tract; the two main types of IBD are Crohn's disease and ulcerative colitis.
- Treatment goals are to induce remission of IBD and maintain management of the disease.

19.6 Hepatic and Biliary Disorders

- Jaundice is a symptom of gallbladder or liver disease. It is yellowing of the skin or sclera.
- Liver failure causes bleeding and jaundice, contributes to blood sugar management, can cause decreased level of consciousness and neurological status, and medication toxicity. It can be acute.
- Hepatic encephalopathy causes impairment of judgment and coordination; in later stages, coma can occur.
- Cirrhosis is a hardening of the liver, causing blood flow through the liver to be difficult.
- Hepatitis can occur from viruses and nonviral causes, including toxins and being drug induced. The liver is inflamed.
- A liver transplant may be considered for many conditions. The challenges with a transplant are the possibility of organ rejection and living with being immunocompromised.
- Gallbladder dysfunctions can include cholecystitis and cholelithiasis. These disorders may also cause jaundice and pain. Endoscopic retrograde cholangiopancreatography (ERCP) to remove a gallstone or gallbladder removal surgery (usually laparoscopically) may be required.
- Pancreatitis dysfunction includes pancreatitis and pancreatic cancer. Pancreatitis can be acute or chronic. Pancreatitis refers to inflammation of the pancreas. Acute pancreatitis treatment focuses on fluid and electrolyte balance, pain management, GI rest, glucose management, and nutritional support. For chronic pancreatitis, pancreatic enzymes will be taken daily.
- Pancreatic cancer is usually far progressed before it is diagnosed. Most patients are past the point of being eligible for surgery when diagnosed. The mortality rate is low at the 5-year mark (12.5%). Hyperglycemia may be present. The surgical procedure that can be performed is called the Whipple procedure.

19.7 Ostomy Care

- Ostomies are surgically placed when the bowel is unable to work or is diseased.
- Placement of a stoma may be an ileostomy (connects to the ileum) or a colostomy (connects to the colon above the ileum).
- Extensive teaching is required, including appliance use, self-catheterization of a continent ileostomy, or frequent bowel movements for the ileal pouch.
- Emotional adjustment is a factor.

Key Terms

amenorrhea cessation of the menstrual period
anorexia nervosa eating disorder characterized by the maintenance of a body weight well below average through starvation and/or excessive exercise
appendectomy surgical removal of the appendix
appendicitis inflammation of the appendix
bariatrics branch of medicine that researches and treats obesity
Barrett's esophagus condition in which the cells that line the esophagus change and become more like intestinal cells
body dysmorphia mental illness characterized by constant worrying over a perceived or slight defect in appearance
body mass index (BMI) measurement calculated by dividing weight by height, using the formula kg/m^2
calorie-dense foods that have more calories per unit mass than do carbohydrates or proteins
cariogenic bacteria those that cause tooth decay

celiac disease autoimmune disorder that is triggered by gluten ingestion, which causes damage to the small intestine
cholecystitis inflammation of the gallbladder
choledocholithiasis occlusion of the common bile duct
cholelithiasis gallbladder stone
chyme food bolus in the stomach that has been broken down and mixed with acidic gastric juices
cirrhosis severe scarring of the liver
colorectal cancer cancer with an origin in the colon or rectal tissue
colostomy colon is attached to a stoma to bypass the rectum and the anus
colostomy irrigation way to help train the colon to empty at a regular time each day
Crohn's disease inflammation that can occur in multiple layers of the bowel in any segment of the GI tract
dental caries one of the most common chronic oral cavity diseases, it is the breakdown or demineralization of tooth enamel
diverticula sac-like protrusions on the walls of the large intestine
diverticular disease symptomatic diverticulosis
diverticulitis inflammation of the diverticula
diverticulosis asymptomatic presence of diverticula on the walls of the large intestine
enteral nutrition (EN) nutrition provided directly into the GI tract through an enteral tube that bypasses the oral cavity
fecal impaction blockage that occurs when stool accumulates in the rectum, usually due to the patient not feeling the presence of stool or not using the toilet when the urge is felt
fistula hole in the wall of the intestine
gastric cancer stomach cancer; cancer that has an origin in the stomach
gastric residual volume (GRV) volume of stomach contents
gastritis inflammation and redness of the lining of the stomach
ghrelin hormone that makes one feel hungry
gluten protein found in the wheat plant and other grains such as barley and rye
gynecomastia enlarged breast tissue in men and boys
hematochezia passage of fresh blood in stool
hepatorenal syndrome kidney dysfunction in patients with advanced liver disease
ileostomy lower end of the small intestine (ileum) is attached to a stoma to bypass the colon, rectum, and anus
immunomodulatory therapy medications that change the body's immune response
inflammatory bowel disease (IBD) chronic inflammation of the GI tract
intestinal obstruction partial or complete blockage of the intestines so that contents of the intestine cannot pass through
intravenous fat emulsion IV administration of fat; commonly used with parenteral nutrition
irritable bowel syndrome (IBS) disorder of the large intestine that causes changes in bowel movements and abdominal pain
leptin hormone that makes one feel full
liver disease any condition that causes damage to the liver and prevents it from properly functioning
malabsorption occurs when the GI tract is unable to properly absorb nutrients, such as proteins, carbohydrates, fats, vitamins, minerals, or trace elements
mastication chewing food
metastasis secondary malignant growths in other parts of the body
microbiome all microorganisms in the GI tract
Model of End-Stage Liver Disease (MELD) Score used to predict survival of patients with cirrhosis, and a tool used to prioritize organ allocation for liver transplantation
nonviral hepatitis inflammation of the liver caused by exposure to drugs, alcohol, toxins, or autoimmune disease
obesity abnormal or excess fat accumulation and a state of malnutrition by excess characterized as having a BMI of 30 or greater
odynophagia painful swallowing
ostomy surgical opening in the abdomen for the expulsion of stool into a bag-like appliance
pancreatitis inflammation of the pancreas

paralytic ileus condition in which peristalsis is not propelling the contents through the intestines
parenteral nutrition concentrated IV solution containing glucose, amino acids, minerals, electrolytes, and vitamins
peptic ulcer disease (PUD) defect in the lining of the stomach or duodenum
peristalsis coordinated muscle movements in the esophagus
plaque sticky film on the teeth made up of leftover food particles and bacteria
pneumothorax collapsed lung
portal hypertension increase in pressure within the portal venous system
proton pump inhibitor (PPI) medication that binds to the hydrogen-potassium ATPase enzyme system of the parietal cell, thereby pumping hydrogen ions into the stomach
Roux-en-Y gastric bypass weight loss surgery that involves bypassing the duodenum to connect the gastric pouch to the lower segment of the small intestine
Rovsing sign palpation of the left lower quadrant worsens right lower quadrant pain
sclera whites of the eyes
skip lesion patchy area of inflammation that skip over some areas
steatorrhea fatty stool
stoma opening on the abdomen that is connected to the gastrointestinal system to allow waste to be collected in a pouch
testicular atrophy testis reduced in size
testicular hypotrophy enlarged testis
total parental nutrition (TPN) parenteral nutrition that includes IV fat emulsions and is considered complete nutrition
toxic megacolon nonobstructive dilation of the colon that is associated with systemic toxicity
ulcerative colitis inflammation that occurs only in the inner most wall of the large intestine and colon
varices abnormal dilation of the veins
vertical sleeve gastrectomy weight loss surgery in which a portion of the stomach is removed and the size of the stomach is reduced to 3 to 4 ounces
villi small, finger-like cells that absorb nutrients
viral hepatitis inflammation of the liver caused by a virus
visceral fat abdominal fat

Assessments

Review Questions

1. The nurse is caring for a patient with anorexia. What is an example of an intervention would be most effective?
   a. Have the nutrition department send a meal on the standard menu with two desserts.
   b. Suggest the patient order food of choice when they are hungry.
   c. Reinforce mealtimes to get in the habit of eating on a schedule.
   d. Request patient drink two glasses of water before every meal.

2. What assessment would be of most concern to a patient with obesity?
   a. a BMI of 32
   b. presence of a gait abnormality
   c. a large abdominal circumference
   d. joint pain

3. A patient is admitted to the emergency department with abdominal pain and diarrhea. Your clinical assessment reveals positive Chvostek and Trousseau signs. What electrolyte deficiency do you suspect this patient may have?
   a. a low calcium level
   b. a high calcium level
   c. a low potassium level

d. a low iron level

4. A patient states they have constant pain in the jaw joint when eating. Which is the most probable cause?
   a. dental caries
   b. TMD
   c. salivary calculi
   d. oral cancer

5. When doing an oral assessment, the nurse observes a discolored portion of the inside of the cheek. What intervention should the nurse take?
   a. Notify the provider of the finding.
   b. Instruct the patient to brush teeth and floss.
   c. Encourage patient to increase water intake.
   d. Assess for jaw clicking.

6. The nurse is caring for a patient receiving enteral feeding through a nasogastric tube. What is an example of an assessment that would cause the nurse to intervene?
   a. The head of bed is elevated 30°.
   b. The GRV is 10 mL at the beginning of the shift.
   c. The NG tube is longer than recorded on previous shift.
   d. The continuous tube feeding is running via a pump.

7. When the nurse is administering medications through a gastrostomy tube, what is an example of a finding that would cause the nurse to intervene?
   a. An enteric coating tablet is ordered.
   b. Most medications ordered are in liquid form.
   c. The patient's blood pressure (BP) is 130/90 mm Hg and their BP medication is due.
   d. The medications are all labeled.

8. The nurse is preparing to hang a new bag of TPN. What is an example of a finding that would concern the nurse?
   a. The TPN bag provided matches the latest provider's orders.
   b. The patient's last blood glucose was 90 mg/dL.
   c. The central line site is red and hot.
   d. The tubing for the TPN was changed this morning.

9. Your patient is postoperative after a complicated bowel surgery for Crohn's disease. Because the patient will be allowed nothing by mouth (NPO) for a few days, what type of nutrition would you expect to be ordered?
   a. TPN
   b. PEG tube feedings
   c. IV fluids
   d. NG tube feedings

10. The nurse is caring for a patient with stomach cancer. What assessment finding would be of greatest concern?
   a. The patient states they feel tired.
   b. The patient is vomiting.
   c. The patient has hypoactive bowel sounds.
   d. The patient has bloody stools.

11. Your patient is admitted with a suspicion of Barrett's esophagus. What diagnostic test would you expect to be performed?
   a. upper endoscopy with biopsy
   b. colonoscopy with biopsy

c. barium swallow study
d. stool culture

12. You are educating your patient with gastritis prior to discharge. What is an example of a statement made by the patient that would indicate that they have a good understanding of the condition?
a. "It's OK that I eat greasy foods because it will soothe my stomach."
b. "I'll make the switch to decaffeinated coffee and limit my caffeine intake."
c. "After smoking, I'll rinse my mouth out so my stomach doesn't get irritated."
d. "I don't need stress management if I'm going to take medications."

13. What electrolyte would you expect to be ordered for your patient who has been receiving long-term PPI therapy?
a. sodium
b. calcium
c. magnesium
d. phosphate

14. What treatment is a possible option for patients with Barrett's esophagus whose reflux symptoms are not controlled by PPI therapy?
a. chemotherapy
b. fundoplication
c. radiation therapy
d. antiviral medication

15. The nurse performs a fecal occult stool test. Noting a positive sample, what laboratory result will the nurse check next?
a. WBC count
b. hemoglobin
c. electrolytes
d. liver enzyme levels

16. A lethargic patient with cool skin is passing bright red blood from the rectum. Vital signs are blood pressure, 86/56 mm Hg; temperature, 98°F; heart rate, 120 bpm; respiratory rate, 22 breaths/minute. What action should the nurse take next?
a. Notify provider for IV fluid orders.
b. Insert nasogastric tube.
c. Administer IV antibiotics.
d. Administer loperamide.

17. The nurse is providing patient education about a gluten-free diet to a patient who has been newly diagnosed with celiac disease. What should the nurse emphasize as important when shopping for groceries?
a. Low amounts of gluten are OK.
b. Nutrition labels should always be checked before purchasing food items.
c. If a food is naturally gluten-free, nutritional labels are not important.
d. Asking the store manager if a food is gluten-free is good enough.

18. What should the nurse monitor to evaluate the effectiveness of dietary modifications for a patient with IBS?
a. frequency and consistency of bowel movements
b. patient's heart rate
c. blood pressure levels
d. patient's pain level

19. Your patient with liver disease begins to become irritable, forgetful, and is having coordination problems.

What disorder is the patient showing symptoms of?

a. cirrhosis
b. portal hypertension
c. hepatic encephalopathy
d. jaundice

20. What is an example of effective nursing care for a patient with cholelithiasis?

a. The patient continues to choose fatty foods from the hospital menu.
b. The patient is reluctant to take prescribed medications.
c. The patient ambulates in the hallways to encourage peristalsis.
d. The patient eats large meals.

21. The nurse is developing a plan of care for their patient with ascites. What would be an appropriate goal for care of the patient?

a. Check pupil reaction.
b. Monitor for rebound tenderness.
c. Provide foods high in fiber.
d. Monitor daily weights and abdominal girth measurements.

22. A patient with acute pancreatitis is describing the symptoms that caused them to seek medical attention. The patient explains that they experienced nausea, a rapid pulse, and vomiting. What other patient statement should the nurse recognize as a symptom of pancreatitis?

a. "After I ate some ice cream, my stomach started hurting really badly."
b. "My hands started shaking uncontrollably for about 5 minutes."
c. "I noticed that I had a severe headache after I started vomiting."
d. "I had diarrhea for 2 days after I started feeling poorly."

23. The nurse is providing ostomy care and notices that the stoma is ashen in color. What action should the nurse take after the completion of ostomy care?

a. Encourage fluid intake.
b. Notify the surgeon.
c. Consult a dietitian.
d. Call the ostomy nurse.

24. The nurse is caring for a patient who had a colostomy placed 2 days earlier. The nurse notes that the stoma is moist and beefy red. What action should the nurse be expected to take based on these findings?

a. Notify the physician of the findings immediately.
b. Remove the bag and apply pressure to the stoma.
c. Document the assessment findings of the stoma.
d. Change the appliance pouch and clean the skin.

25. The nurse is providing patient education on the care of an ostomy. What is an example of a statement by the patient that would indicate that further education is necessary?

a. "I should plan to replace the pouch system every 4 to 7 days."
b. "Wafer should be cut 1/16″ to 1/8″ larger than the stoma."
c. "It is important to chew all foods completely and slowly."
d. "I will keep a diary of the foods I eat and my stool pattern."

Check Your Understanding Questions

1. Which key diagnostics are used in the management of obesity, anorexia nervosa, and malabsorption? How do they differ for each condition?

2. You are caring for a patient receiving enteral feeding. The morning weight shows the patient gained 1 lb. over

the past week. What does this mean?

3. When caring for a patient with gastric cancer, what symptoms would you expect to find?
4. Describe how medical therapies for hepatic and biliary disorders are designed to manage symptoms and improve patient outcomes. Consider the challenges of tailoring treatments to meet individual patient needs and conditions.

Reflection Questions

1. What information might you need to detail regarding a patient who presents with mouth pain?
2. Which medical therapies might a nurse anticipate for a patient recently diagnosed with mouth cancer?
3. If you were on a liver transplant team, how would you feel about a patient with chronic liver disease from alcohol abuse receiving a liver? Discuss it with two peers. The activity should last 5 minutes.

What Should the Nurse Do?

1. Anna, a patient with anorexia nervosa, is being monitored by her nurse, who has noticed some improvement in Anna's condition. Although Anna reports feeling better, she struggles with eating enough and is fearful of gaining weight. The nurse acknowledges these challenges and reassures Anna about the goal of achieving a healthy and strong state.
   How can the nurse determine if the implemented nutritional strategies are effective for Anna?

John, a patient recently diagnosed with mouth cancer, has just completed his first week of radiation therapy. He reports experiencing severe oral pain and difficulty swallowing, which have made it hard for him to maintain adequate nutrition. The nurse caring for John notes he appears fatigued, and he complains of weight loss.

2. Which diagnostics and laboratory tests will the nurse review first for John to determine the next steps in care?
3. How will the nurse evaluate the effectiveness of John's care plan?

You are caring for a patient who has recently undergone ileostomy surgery. Despite initial success with ostomy care, you notice during your assessment the peristomal skin around the ileostomy is red and irritated, and the patient complains of itching and burning in the area.

4. Describe how you would approach this scenario to provide effective care and support for the patient.
5. The patient refuses to look at the stoma or participate in changing the pouching system. What are some suggestions to help your patient adjust to the stoma?

Competency-Based Assessments

1. Prepare a table to compare nursing actions for patients with obesity, anorexia nervosa, and malabsorption. Identify what interventions work for more than one disorder.
2. Write a list of problems and the interventions expected in a patient with gastritis.
3. Compare and contrast IBD using the following format. Compare with your peers. In which areas were there were differences, and why? Teach in small group the areas one student knows that another does not.

Disorder	Ulcerative Colitis	Crohn's Disease
Pathology		
Risk factors		
Clinical manifestations		
Diagnostic tests		
Laboratory values		

Nursing concepts		
Nursing care		

4. Use the internet to develop a 5-minute presentation about liver disease and the impact a poor diet can have on liver health.
5. Go to the skills laboratory during open hours on your own or with peers and gather ostomy supplies and a mannequin. Practice applying supplies. Teach the "patient" as you progress.

CHAPTER 20

Genitourinary and Reproductive Systems

FIGURE 20.1 The genitourinary and reproductive systems are assessed during a well-woman exam. (credit: Deidre Smith/Naval Hospital Jacksonville/Tricare, CC0)

CHAPTER OUTLINE

INTRODUCTION In addition to sexual function and reproduction, the genitourinary and reproductive systems serve many important functions, including filtration and excretion of waste products, fluid and electrolyte balance, and blood pressure control. These two systems are frequently assessed together because the male urethra shares the same anatomic tube for elimination as the reproductive transmission of sperm. Impairment of either of these systems can result in unpleasant effects, including infertility, sexual dysfunction, or the inability to urinate effectively. These effects are not only physically detrimental, they can also have devastating effects on mental and social health. Nurses caring for patients with disorders of the genitourinary and reproductive systems must be able to adequately treat the physical conditions and effectively provide emotional support and comfort.

20.1 Brief Review of Genitourinary and Reproductive Anatomy and Physiology

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the anatomy and physiology of the male genitourinary and reproductive systems.
- Discuss the anatomy and physiology of the female genitourinary and reproductive systems.

Because of their anatomic proximity, the term **genitourinary system** is used to describe organs of both the reproductive and urinary systems. The reproductive portion of the genitourinary system consists of the male or female genitalia and associated components involved in biological reproduction of offspring. The urinary portion of the genitourinary system, also known as the renal system, includes the kidneys, ureters, bladder, and urethra, all of which play a major role in fluid and electrolyte balance and the excretion of waste as urine. Because of the anatomic proximity of these organs, it is not uncommon for a disorder of one system to potentially affect the other organs.

Anatomy and Physiology of the Male Genitourinary and Reproductive Systems

The male genitourinary system consists of two major organs—the penis and the testicles—in addition to several other internal structures, which are depicted in Figure 20.2. The penis is located external to the body, and its components include the glans, urethra, and external urethral opening. The urethra is a long, thin tube that runs the length of the penis and carries semen or urine for eventual excretion from the body. It is approximately 20 cm (7–8 inches) long, on average, and transports both urine and semen. The glans is the bulbous structure at the distal end of the penis and is responsible for excreting both semen during **ejaculation** and urine as waste from the external urethral opening. Urine is normally carried from the urinary bladder through the urethra for excretion, but this function ceases during times of sexual arousal and semen ejaculation. Therefore, although the penis can release both urine and semen from the same urethral opening, they cannot be excreted simultaneously (Cleveland Clinic, 2020b).

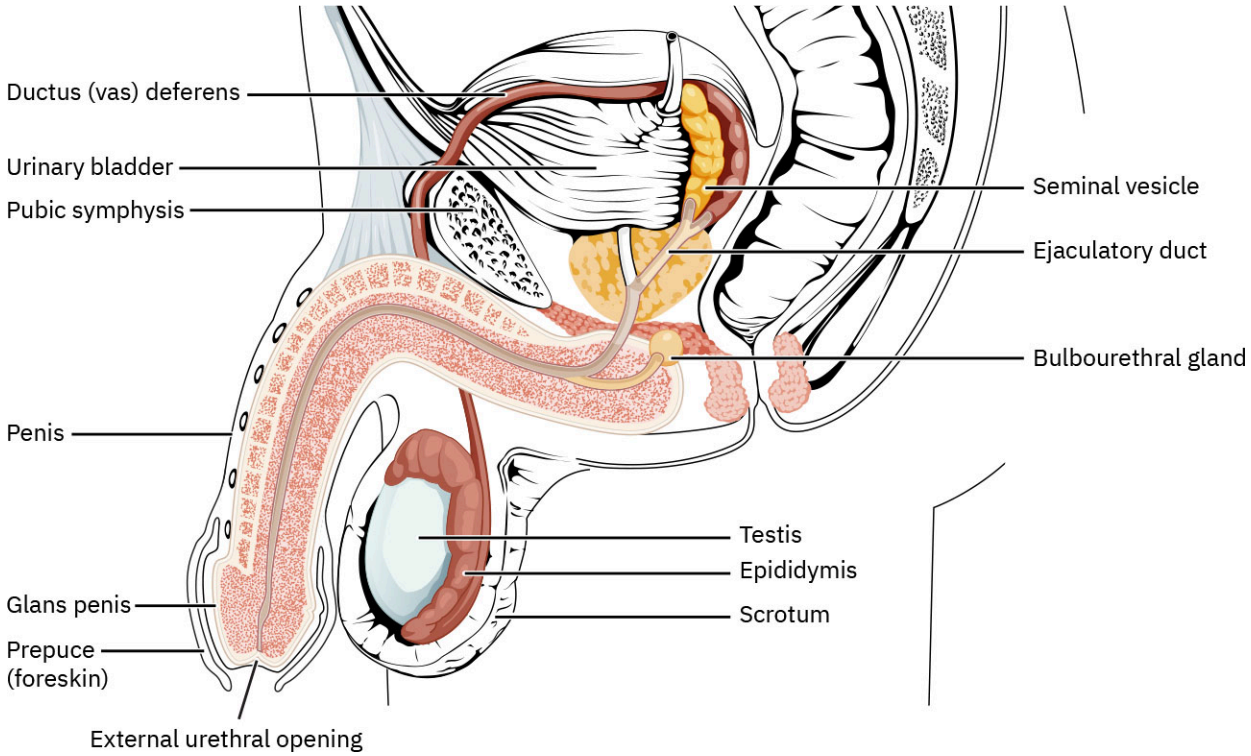

FIGURE 20.2 The male genitourinary and reproductive systems consist of the penis, testicles, and several internal components. (credit: modification of work from *Anatomy and Physiology 2e*. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Male reproduction is a complicated process with several internal components that affect the function. The testicles (testes), referred to as the male sex glands, are found in the scrotum, which is an outpouching of skin located below the penis. The testes contained in this sac are at a slightly lower temperature than the rest of the body, allowing for

spermatogenesis, or sperm production, to occur at the ideal temperature, which is approximately 4 degrees lower than normal internal human temperature. In addition to producing sperm, the testicles are also responsible for secreting testosterone, the male sex hormone, which affects male secondary sex characteristics and libido. The testicles secrete sperm into the epididymis, a tube where sperm can grow and mature. After maturation, the sperm is sent from the epididymis through the vas deferens to the seminal vesicle, where sperm collects in preparation for eventual ejaculation through the urethral opening. Two small glands, known as bulbourethral (or Cowper's) glands are located on either side of the urethra and secrete fluid, called pre-ejaculate, for lubrication and movement through the urethra during ejaculation. Another important part of the male reproductive system is the prostate gland. This gland sits just below the urinary bladder and is responsible for secreting a substance that helps lubricate, nourish, and expel the sperm during ejaculation.

Anatomy and Physiology of the Female Genitourinary and Reproductive Systems

The female genitourinary system consists of several parts; these are depicted in Figure 20.3 and Figure 20.4. The female urinary bladder connects to the urethra, which is approximately 3 to 4 cm (1.5 inches) long, and allows for excretion of urine as waste. The clitoris, a small mound of tissue that is highly sensitive to stimulation, is directly above the urethral opening. Directly below the urethral opening is the vaginal opening, through which blood exits the body during **menstruation** and through which the infant is delivered during childbirth. In contrast to male anatomy, which only provides one opening for both urine and semen for reproduction, the female anatomy consists of two different openings, one for urine excretion and one for reproductive function (Cleveland Clinic, 2022).

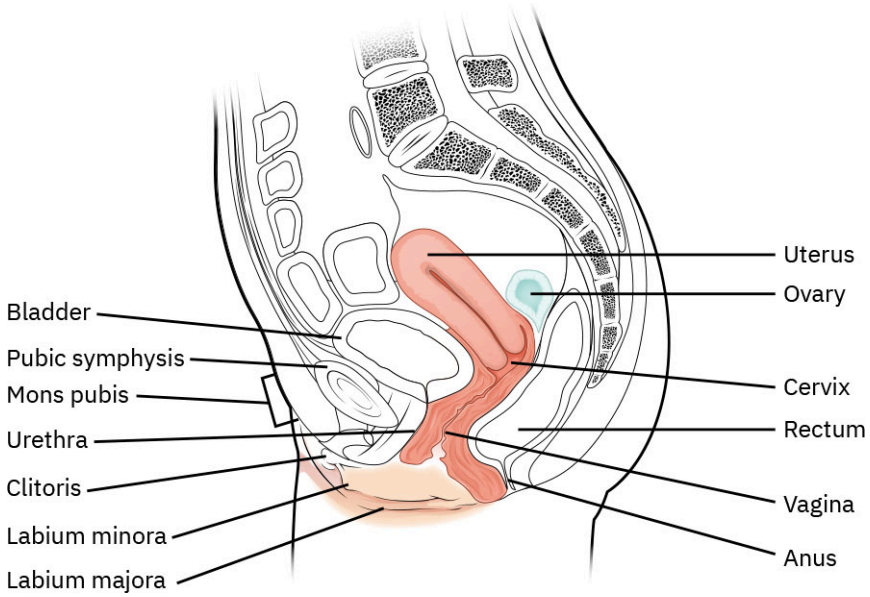

FIGURE 20.3 The internal portions of the female genitourinary and reproductive systems include the uterus, ovaries, fallopian tubes, vagina, bladder, and urethra. (credit: modification of work from *Anatomy and Physiology 2e*. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

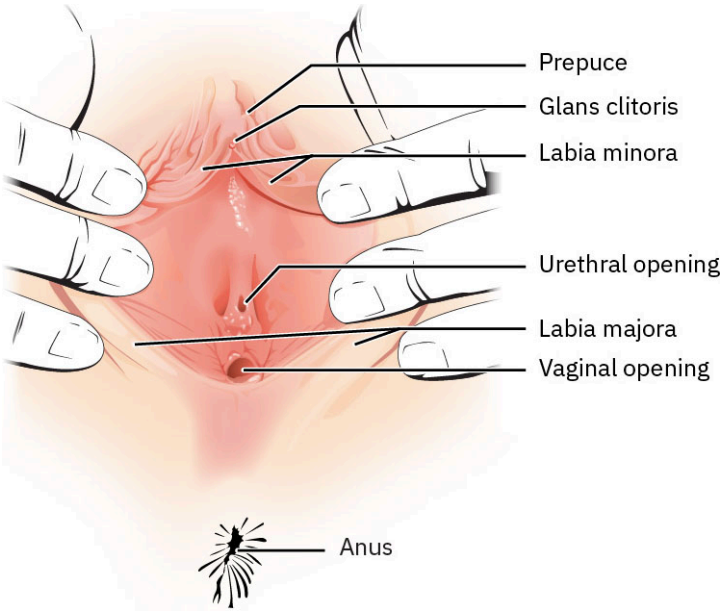

FIGURE 20.4 The external parts of the female genitourinary and reproductive systems include the clitoris, labia, urethral opening, and vagina. (credit: modification of work from *Anatomy and Physiology 2e*. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

The vagina is a tube-like muscular organ, also known as the vaginal canal or birth canal. The external opening of the vagina is surrounded by connective tissue, divided into two folds of tissue called the labia majora and labia minora. The vagina is connected to the cervix, which is the lower opening of the uterus. The cervix serves as a barrier between the vaginal canal and the uterus, which helps protect a growing fetus from developing an infection during pregnancy. The uterus is a large, hollow organ that holds the fetus during pregnancy, allowing it to grow and mature in preparation for childbirth. The female reproductive system also includes the ovaries and the fallopian tubes. The ovaries produce eggs for reproduction and estrogen, the female sex hormone. It is estimated that each ovary contains up to 1 million eggs at birth and begins a cycle of maturation and release after puberty. The release of an egg from one of the ovaries is known as **ovulation** and occurs generally once a month based on the cycle of female hormones. The egg travels through one of the fallopian tubes to the uterus. If the egg is joined by sperm from a male, fertilization and conception may occur, resulting in pregnancy.

Menstrual Cycle

The female reproductive system is controlled by a monthly hormone fluctuation referred to as the menstrual cycle. Cycle lengths vary, but a typical cycle lasts for approximately one month, or about 28 days. Figure 20.5 depicts the different phases and hormones associated with each day of the cycle. The first 14 days of the menstrual cycle represent the follicular phase. During the first three to seven days of this phase, menstruation, or the shedding of the uterine lining through the vagina, is occurring. While this is happening, the ovaries develop mature eggs for potential reproduction. Approximately 11 to 15 days after menstruation, one of the eggs matures enough to be released, resulting in ovulation. The transition from menstruation to ovulation is triggered by changes from estrogen to progesterone and follicle-stimulating hormone made in the anterior pituitary gland. The egg travels from the ovary through a fallopian tube to the uterus for possible fertilization with a sperm. After ovulation, the luteal phase begins. This phase marks the second half of the menstrual cycle, lasting approximately 14 days. Levels of follicle-stimulating hormone and luteinizing hormone decrease, which triggers the next phase. During this phase, the hormone progesterone is produced in large amounts, which results in thickening of the uterine lining in readiness for the possible implantation of a fertilized egg. If the egg does become fertilized, it will implant into the uterine wall, which will result in pregnancy, cessation of the menstrual cycle, and eventual childbirth. If the egg is not fertilized by sperm during this phase, pregnancy does not occur and the uterine lining begins to break down in preparation of shedding, marking the start of a new menstrual cycle.

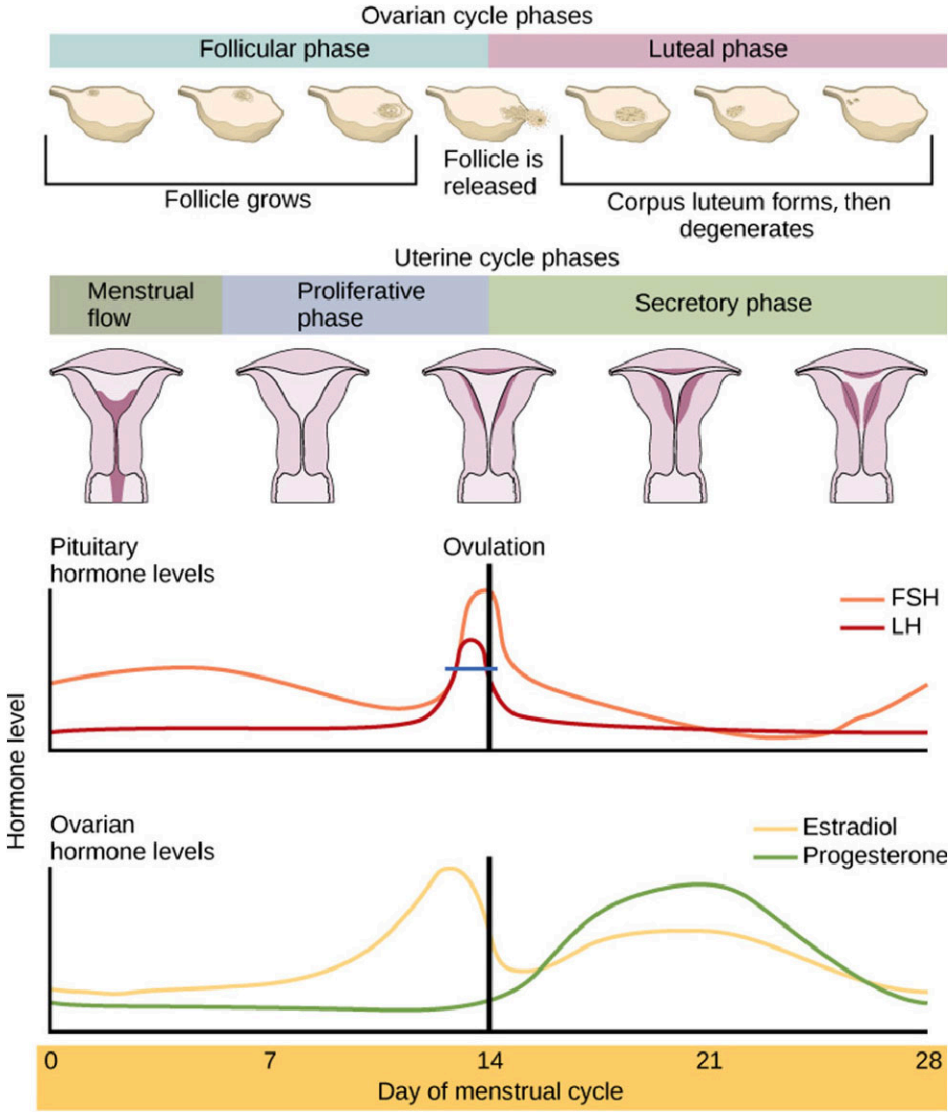

FIGURE 20.5 Hormone levels vary throughout the menstrual cycle by day as the uterus prepares for a possible pregnancy. The uterine lining is shed if implantation does not occur. (credit: Warren et al./*Frontiers in Global Women's Health*, CC BY 4.0)

Both the male and female genitourinary systems are complex and consist of many different structures and organs that must function optimally for reproduction to occur. Some of the many disorders and conditions that can affect both systems will be discussed in more detail in this chapter.

CULTURAL CONTEXT

Gender Identity Considerations

It is important to understand that a patient's biological sex may not always match their gender identity. Gender identity is "one's innermost concept of self as male, female, a blend of bother or neither—how individuals perceive themselves and what they call themselves" (HRC Foundation, n.d.). For example, a patient who is assigned male sex at birth may identify with socially traditional characteristics and interests of women and wish to identify as a woman. Although some patients may simply identify as a different gender than their assigned birth gender, other patients may actively pursue medical treatment and interventions to physically change their body and sex organs to match their preferred gender. Every patient is unique, and nurses should approach each patient in a nonjudgmental manner to ensure optimal care and improved patient outcomes. It is important to note that during medical care, it is reasonable for clinicians to ask a person about their biological sex at birth, because implications of sex hormones are relevant in many health conditions and knowing a patient's biological sex helps direct guidelines for preventive

screenings.

20.2 Sexually Transmitted Infections

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations of sexually transmitted infections.
- Describe the diagnostics and laboratory values in sexually transmitted infections.
- Apply nursing concepts and plan associated nursing care for the patient with a sexually transmitted infection.
- Evaluate the efficacy of nursing care of the patient with a sexually transmitted infection.
- Describe the medical therapies that apply to the care of patients with sexually transmitted infections.

A **sexually transmitted infection (STI)** may develop after transmission of bodily fluids from an infected individual to a sexual partner. These infections can range from asymptomatic to severe, depending on the specific type of infection and the baseline health status of the infected person. Safe sex practices, such as limiting one's number of sexual partners or using appropriate protection (e.g., condoms), can decrease the risk for contracting STIs. Nurses caring for patients at risk for STIs must be able to adequately treat the physical condition and symptoms, as well as provide counseling and education regarding effective prevention strategies.

Overview and Pathophysiology of Common STIs

According to the Centers for Disease Control and Prevention (CDC) (2024d), there are approximately 68 million current cases of STIs in the United States. People aged 15 to 24 years account for approximately 50 percent of all new cases. These numbers indicate that nearly one in five Americans has been diagnosed with an STI. However, these numbers may be skewed due to asymptomatic individuals unknowingly transmitting infections to their sexual partners.

STIs cost the US health care system billions of dollars each year, account for major losses in societal productivity, and result in increased morbidity and mortality rates (CDC, 2021). Some of the most encountered STIs and their associated clinical manifestations, assessment findings, and diagnostic criteria are discussed in the next several sections.

Chlamydia and Gonorrhea

Chlamydia trachomatis, commonly known as chlamydia, is a bacterium that is spread through infected bodily fluids, including vaginal fluid and semen, and is transmitted orally and rectally. Often, patients who become infected with chlamydia also have a coinfection with gonorrhea, a bacterial infection caused by the bacterium *Neisseria gonorrhoeae.* These bacterial STIs can be spread through all kinds of sexual contact, including vaginal, anal, and oral sex, and the sharing of sex toys. They can also be spread from a parent to child during a vaginal childbirth.

Chlamydia (CDC, 2024a) and gonorrhea (CDC, 2024b) infections are often asymptomatic especially in female individuals, but if symptoms do occur, they will likely become evident between a week and three months after transmission. Clinical manifestations of chlamydia and gonorrhea in women often mimic those of a urinary tract infection (UTI), such as foul-smelling vaginal discharge, painful urination, increased urinary frequency, itching, or burning of the vagina, and a dull ache or pain in the lower abdomen. As many as 15% of untreated women will develop **pelvic inflammatory disease (PID)** (Jennings & Kryko, 2023). In men, symptoms may manifest as a white, yellow, or green discharge from the penis and painful urination. Both chlamydia and gonorrhea are diagnosed by using specific tests, such as Gram stains or nucleic acid amplification tests, to detect the presence of bacteria in the urine or from vaginal or urethral swabs. Additionally, the provider or nurse should obtain a full sexual history and perform a physical examination to look for symptoms that assist in confirming the diagnosis. Typically, patients with a suspected STI are tested and treated for both chlamydia and gonorrhea at the same time because they often occur together and cause similar symptoms. Standard guidelines for treatment are doxycycline for chlamydia and single-dose ceftriaxone intramuscular injection for gonorrhea (American Family Physician, 2022).

Herpes Simplex Virus

Herpes simplex virus (HSV) causes a viral infection that can be classified into two different types: herpes simplex type 1 (HSV-1) and herpes simplex type 2 (HSV-2). Although both types of herpes are caused by the same virus,

they cause different symptoms. HSV-1, known as oral herpes, causes cold sores on the mouth and lips (Figure 20.6) and HSV-2 ("genital herpes") results in a type of sore called a **genital vesicle**, or a painful fluid-filled lesion on the genitals. The herpes virus is spread through sexual contact, including vaginal, anal, and oral sex, or contact with a sore (either on the mouth or on the genitals). Although usually asymptomatic, individuals infected with HSV will have "outbreaks" during which they develop oral or genital sores that last approximately one week. Occasionally, these outbreak periods are accompanied by flu-like symptoms, such as a fever or chills. Typically, the first outbreak is the worst one, and there may be long periods of remission between outbreaks. Herpes virus infection is a lifelong condition, and the frequency and severity of outbreaks will vary depending on the person and health status. Diagnosis is made by the provider or nurse through clinical assessment of active sores on the mouth or genitals. If a diagnosis is unable to be made based on clinical assessment alone, a swab of the sore can be tested to determine the presence or absence of the virus. Additionally, there is an antibody test that can be used to detect whether the body has previously made antibodies to HSV, indicating that the individual has been exposed before.

FIGURE 20.6 Cold sore lesions are caused by the HSV-1 virus. (credit: Robert E. Sumpter/CDC/Public Health Image Library, Public Domain)

Human Papillomavirus

Human papillomavirus (HPV) is the most common STI in the United States. There are more than 100 different types of HPV, encompassing a wide range of severity. Most types do not cause symptoms or require treatment, but more severe types can result in the development of genital warts. The most severe types of HPV can cause cancers of the cervix, vagina, or anus. Human papillomavirus has also been linked to the development of oral-laryngeal cancers, especially in men. Because even asymptomatic infections can eventually cause cancer, it is important for sexually active individuals to be tested for HPV frequently. Current practice guidelines recommend testing every three years between the ages of 21 and 29. For patients who test positive for HPV, further testing may be indicated to identify the specific type and determine if early cancer screening should be instituted. Fortunately, a vaccine for HPV was developed in 2009 that decreases the risk of contracting the virus. This vaccine is recommended for all children between the ages of 11 and 12 years as a prophylactic measure to prevent HPV infection and potential cancers later in life (Quinlan, 2021).

Syphilis

Syphilis is a bacterial STI caused by *Treponema pallidum*. It is transmitted through sexual contact, blood exposure, and close contact with open skin lesions. The first clinical sign of a syphilis infection is the presence of a **chancre**, a painless sore that develops where the organism entered the body (Figure 20.7). Chancres are most commonly found on or around the penis, vagina, anus, lips, and/or mouth. Typically, the chancre becomes noticeable within a few weeks of the initial infection and heals on its own.

FIGURE 20.7 A chancre is the first clinical sign of a syphilis infection. (credit: CDC/Public Health Image Library, Public Domain)

If the chancre goes undetected, the patient may not be aware they are infected and may not seek treatment until further symptoms occur months later, marking the more severe, secondary phase of the infection. In this stage of infection, the patient will exhibit flu-like symptoms, such as fever, sore throat, swollen lymph nodes, and headaches. They also usually develop a skin rash on the palms of the hands or soles of the feet. Figure 20.8 shows an image of a typical syphilis rash on the palms of the hands. The lesions of the rash are highly contagious and should not be touched with bare hands. This rash will clear up on its own within a few months, marking the start of the latent phase of infection. During this phase, the patient does not have any noticeable symptoms, but the infection remains present in the body. The later stage of syphilis, also called the tertiary stage, is systemic and life-threatening, and is characterized by neurological dysfunction. Symptoms during this stage include headache, uncoordinated muscle movements, mental status changes, and dementia. Because syphilis can be effectively treated with antibiotics, it does not typically enter the tertiary stage. This stage of the disease is possible, however, especially in populations with limited access to health care and other resources.

FIGURE 20.8 A syphilis rash on the palms of the hands may be seen during the secondary stage of infection. (credit: CDC/Public Health Image Library, Public Domain)

Nursing Care of the Patient with an STI

Caring for patients with STIs is complex, and treatment and nursing interventions will vary depending on the specific infection. Nursing goals always include early detection, intervention, and initiation of effective treatment options. A mnemonic to help you remember are the "Five P's" approach of questions, which reminds you to ask about partners, practices, prevention of pregnancy, protection against STIs, and past history Table 20.1. The first step in caring for patients at risk for or recently diagnosed with an STI is obtaining a complete health and sexual history. This allows the nurse to identify factors that place the patient at risk for developing STIs, such as unsafe sexual practices or lack of knowledge related to infection transmission modes. For example, individuals with concurrent substance use or mental health disorders are at higher risk for STIs related to increased risk-taking behaviors. Based on these findings, the nurse can determine if there is a need for further assessment, intervention, and/or counseling.

P	Assessment Questions to Ask Patient
Partners	• How many sexual partners have you had? How many sexual partners do you currently have?
Practices	• Tell me about your sexual practices? • Have ever been tested for STIs? • Have you used strategies to reduce the risk for STI exposure (e.g., use of condoms or diaphragms)? • Do you have genital, anal, and/or oral sex? • Have you or any of your partners used drugs? • Have you exchanged sex for needs?
Protection	• Do you and your partner talk about STI prevention? • What prevention methods have you used? How often? • Have you received any vaccines (e.g., HPV, hepatitis A, hepatitis B vaccines)?
Past history of STIs	• Have you ever been treated for STIs or human immunodeficiency virus (HIV)? • Have you been diagnosed with an STI in the past? • Do you have any symptoms that come back? • Has your current partner or former partner even been diagnosed with an STI?
Pregnancy intention	• Would you like children at some point? • When would you like to become pregnant? • How important is pregnancy prevention to you? • What contraception measures do you practice? (CDC, n.d.)

TABLE 20.1 5 P's of Patient Conversation for STI Screening

Recognizing and Analyzing Cues

Though many STIs can be asymptomatic, most do have some associated symptoms that should be assessed for by the nurse. To effectively detect and diagnose STIs in their early stages, the nurse must be able to recognize specific symptoms associated with each type of infection. Common clinical manifestations of different types of STIs are listed in Table 20.2.

Sexually Transmitted Infection	Clinical Manifestations
Chlamydia	• Abnormal, foul-smelling discharge from vagina or penis (typically white, yellow, or gray) • Irregular vaginal bleeding • Painful urination with itching or burning • Pelvic or abdominal pain • rinary frequency
Gonorrhea	• Same as chlamydia, but discharge is typically white or yellow and does not have a foul smell
Herpes simplex virus	• Itching or tingling sensation called prodrome noticed a few days before outbreak of sores • Presence of blisters or sores on mouth/lips or genitals • Flu-like symptoms (e.g., headaches, fever, chills)
Human papillomavirus	• Warts on or near the genitalia
Syphilis	• Presence of chancres in the oral mucosa or near genitalia • Rash on the hands and/or feet

TABLE 20.2 Clinical Manifestations Associated with Different Types of STIs

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Once the nurse identifies symptoms of an STI, the nurse should refer the patient to the appropriate resources for further diagnostic testing. If the patient is being cared for in the hospital setting, the next step would be to notify the care team and request any necessary further testing and treatment. In outpatient centers, the nurse may be able to perform point-of-care STI testing and initiate a request for immediate treatment by a provider with antibiotics or other medications. Actions taken by the nurse will vary depending on the practice setting and specific STI present, but the goals of care include early diagnosis and intervention to effectively eradicate the infection. Another important aspect of nursing care of patients with STIs is caring for the mental aspects associated with the disorder. There is a stigma associated with STIs that can negatively affect the mental health of those affected, so nurses must be aware of this stigma and treat patients without judgment.

Medical Therapies and Related Care

Most STIs can be treated effectively on an outpatient basis, but if the infection is caught late and/or has become severe, it is possible that nursing care will need to be provided in the hospital setting. Additionally, it is common for patients who present to the hospital for other medical reasons to be diagnosed with an STI during their stay. This highlights the importance of all nurses being familiar with and recognizing common STIs, regardless of their specific practice setting. Treatments for common STIs are listed in Table 20.3. Nurses are often tasked with administering them either orally, intramuscularly, or intravenously, so it is important that the nurse is familiar with the different treatment options they may see in clinical practice.

Sexually Transmitted Infection	Treatments
Chlamydia	• Antibiotics (usually azithromycin or doxycycline) • Longer course of antibiotics indicated if patient also has gonorrhea
Gonorrhea	• Antibiotics (usually intramuscular ceftriaxone and oral azithromycin) • Longer course of antibiotics indicated if patient also has chlamydia
Herpes simplex virus	• Analgesic medications for painful lesions • Antiviral medications (e.g., acyclovir)
Human papillomavirus	• Colposcopy can be used to biopsy cervix for potential cancerous lesions • Procedures to remove genital warts (e.g., cryotherapy, electrocautery, laser removal) • Topical treatments for genital warts (e.g., salicylic acid)
Syphilis	• Antibiotics (most often a penicillin)

TABLE 20.3 Treatment Options for Common STIs

Evaluation of Nursing Care of the Patient with an STI

When caring for a patient with an STI, the nurse will need to review the patient's care and make decisions about the effectiveness of the interventions. This can include physical and psychological care, as well as patient education and resource identification. Nurses will evaluate treatment efficacy and screen for symptom resolution or progression of infection.

Evaluating Outcomes

The purpose of evaluating outcomes after a patient has been treated for an STI is to determine whether the treatment was effective and if the patient requires further care. During the evaluation,

- The nurse should ask the patient about their symptoms and if they feel as though they have been fully resolved.
- The nurse will also perform a physical assessment to determine if the physical symptoms such as rashes or warts have cleared up completely.
- If treatment appears to have been effective, the next step in the evaluation process is to provide counseling and appropriate resources to the patient. Patient education should include information about safe sexual practices to help limit their risk of developing another STI in the future.
- The nurse will provide information about the future course of the disease. Although some STIs, like chlamydia and gonorrhea, can be effectively treated with antibiotics, other infections, such as herpes, are lifelong conditions with chronic symptoms and flare-ups.
- Nurses should evaluate the patient's knowledge about symptoms of **infertility**. In these cases, the nurse should provide information about testing and treatments that may be necessary throughout the patient's lifetime so they are prepared and know what to expect in the future.

CULTURAL CONTEXT

Human Trafficking Victims

At-risk populations, such as victims of sex trafficking, are at an especially high risk for STIs. The nurse must ensure privacy while conducting a thorough comprehensive history, inquiring about any history of pregnancy, previous STIs,

and any gaps in gynecological care. Sex-trafficking victims often have other conditions, including undiagnosed comorbidities such as heart disease and diabetes, and may have nutritional deficiencies. A psychiatric history should include an assessment of substance use and domestic partner abuse, as well.

20.3 Male-Specific Disorders of the Reproductive Tract

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations of disorders of the male reproductive tract.
- Describe the diagnostics and laboratory values for disorders of the male reproductive tract.
- Apply nursing concepts and plan associated nursing care for the patient with disorders of the male reproductive tract.
- Evaluate the efficacy of nursing care for the patient with disorders of the male reproductive tract.
- Describe the medical therapies that apply to the care of disorders of the male reproductive tract.

The male reproductive system consists of both external and internal genitalia. The external structures include the penis and scrotum, and the major internal parts are the tests and prostate gland. The major functions of the male reproductive system are the production of the male sex hormone, testosterone; control of sexual function and characteristics; and production and secretion of sperm, which is used for biological reproduction.

Pathophysiology of Common Disorders of the Male Reproductive Tract

Common disorders of the male reproductive system include erectile dysfunction (ED), testicular cancer, and testicular torsion. These types of disorders are often highly personal because they can significantly affect the patient's sexuality and reproductive function. It is important that nurses and other health care professionals promote an environment that is nonjudgmental and comfortable for the patient to allow them to fully express their concerns and obtain adequate treatment and support.

Erectile Dysfunction

One of the most common disorders of the male reproductive system is **erectile dysfunction**. Erectile dysfunction, also referred to as "impotence," is a condition in which the man cannot maintain a full erection of the penis for sexual intercourse Mayo Clinic, 2022a). This condition affects nearly 30 million men in the United States and may cause distressing feelings such as guilt, rejection, shame, and frustration (CDC, 2022). These feelings tend to negatively affect intimate relationships, with both the patient and their partner expressing sexual dissatisfaction. Erectile dysfunction can be caused by many different conditions, including

- benign prostatic hyperplasia (BPH)
- diabetes
- heart disease
- hyperlipidemia
- hypertension
- low testosterone levels
- medications (e.g., antidepressants, antihypertensives)
- neurological disorders (e.g., Parkinson's disease, multiple sclerosis)
- obesity
- penile trauma
- psychological disorders (e.g., depression, anxiety, stress)
- substance misuse

Testicular Disorders

There are two main disorders of the male reproductive system that affect the testicles: testicular cancer and testicular torsion. Testicular cancer is rare, affecting only 1 of every 250 male individuals in the United States (American Cancer Society, 2023b). This cancer is typically diagnosed in men in their 20s or 30s, but there have been some cases diagnosed in children and older men. Risk factors for the development of testicular cancer include

- **cryptorchidism** (undescended testicle)

- family or personal history of testicular cancer
- human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS) infection
- marijuana use

The condition **testicular torsion** occurs when the spermatic cord, the supplier of blood to the testicles, becomes twisted (Figure 20.9). This is a medical emergency and, without immediate intervention, could result in irreversible damage to the testicles and infertility (Mayo Clinic, 2022b). This condition may occur spontaneously, most often in young male individuals between the ages of 12 and 18 years, or because of physical trauma to the testicles. Without treatment, the testicle tissue may die, resulting in infertility.

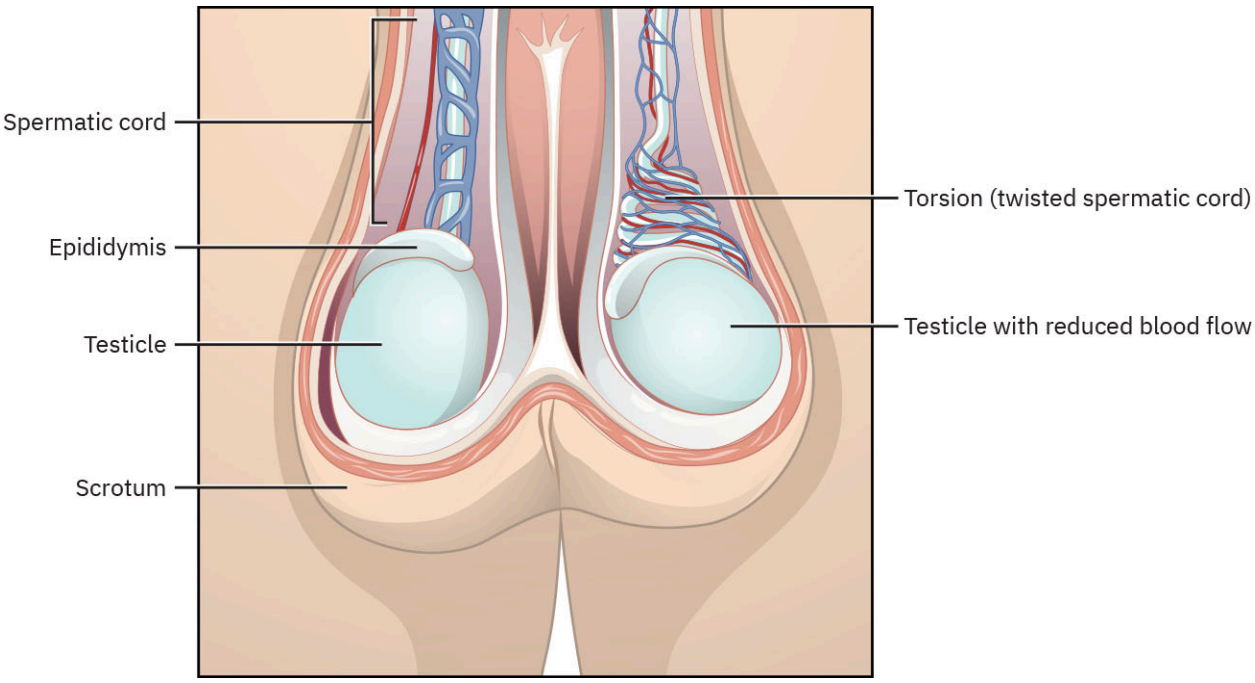

FIGURE 20.9 Testicular torsion occurs when the spermatic cord becomes twisted, resulting in reduced blood flow to the testicle. (credit: modification of work from *Anatomy and Physiology 2e*. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Assessment and Diagnostics

Initial steps in caring for a patient with a male reproductive system disorder is obtaining a thorough health history and performing a physical examination. It is important to remember that many patients are uncomfortable discussing sexual function with others, so nurses must attempt to provide a comfortable, friendly environment that allows for open and honest discussion.

Recognizing and Analyzing Cues

Clinical manifestations associated with disorders of the male reproductive tract vary depending on the specific condition. Common clinical manifestations associated with testicular cancer, testicular torsion, and ED are listed in Table 20.4.

Disorder	Clinical Manifestations
Erectile dysfunction	• Decreased libido • Patient reports inability to initiate and/or maintain penile erection during sexual intercourse.
Testicular cancer	• Dull ache in the lower abdomen • Gynecomastia • "Heavy" feeling in the scrotum • Painless, hard lump in testicle • Some patients may report testicular pain, but this is rare. • Sudden swelling in the testicle
Testicular torsion	• Sudden, severe pain in the testicles • Lower abdominal pain • Nausea/vomiting • Scrotal swelling and erythema • Urinary frequency

TABLE 20.4 Clinical Manifestations of Disorders of the Male Reproductive System

Diagnostics

There are not many diagnostic tests available for most disorders of the male reproductive system. For example, for ED, a diagnosis is made based on the symptoms reported to the provider by the patient. The provider may order blood tests after a diagnosis is made, but this is mostly to determine if there might be an underlying medical cause of ED, not to diagnose ED itself. Additionally, sometimes an ultrasound of the penis is performed to determine if there might be a physical blood flow issue that is not allowing a full erection to occur. Most patients diagnosed with ED are also screened for psychological disorders, such as anxiety or depression, that may be contributing to the condition.

When a patient presents with symptoms that indicate the possibility of testicular torsion (e.g., sudden lower abdominal pain), an emergent ultrasound of the scrotum is ordered. This imaging test is used to check for blood flow to the testicles and determine the extent of any damage. It is important that this imaging be performed quickly in case the patient requires surgery to restore blood flow to the testicles. Diagnosis of testicular cancer is also often made with the use of ultrasound imaging. If the patient reports a lump in the testicles, ultrasound can be used to further investigate its characteristics and determine if it appears to be cancerous. In addition to imaging, blood tests can be performed to look at various tumor markers that may be indicative of cancer. Markers that may indicate the presence of testicular cancer include

- alpha-fetoprotein
- beta–human chorionic gonadotropin
- lactate dehydrogenase

Medical Therapies and Related Care

Most male reproductive disorders are easily treated with medications or surgical procedures. Treatment options for male reproductive system disorders are described in Table 20.5.

Disorder	Treatments
Testicular cancer	• Nonsurgical therapy options (e.g., chemotherapy, radiation therapy) • Surgical removal of affected testicle, called **orchiectomy**
Testicular torsion	• Urgent surgical intervention • Manual manipulation if surgery is not available immediately
Erectile dysfunction	• Lifestyle changes to fix underlying cause (e.g., weight loss, blood pressure management) • Oral medications (e.g., phosphodiesterase-5 inhibitors) • Penile implants • Penile injections with prostaglandins • Vacuum-assisted erection devices

TABLE 20.5 **Treatment Options for Common Disorders of the Male Reproductive System**

Nursing Care of the Patient with Disorders of the Male Reproductive Tract

Care for a male patient with a reproductive disorder may be complex and can include physical interventions, psychological screening, and patient education. The nurse needs to create an open environment for the patient while also focusing on proper diagnosis, intervention, and initiation of effective treatment options

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Nursing care of patients with male reproductive system disorders must be delivered in a nonjudgmental, friendly manner. This assists the nurse to develop rapport with the patient so they are more comfortable sharing information about their condition. Specifically, care for the male patient with ED requires the nurse to provide a safe environment where the patient can discuss their sexual concerns comfortably. Other nursing interventions for the patient with ED include providing education about lifestyle modifications, medications, and psychotherapy, all three of which are main treatment options. Education about medications for ED is an especially important aspect of nursing care. For example, patients receiving current antihypertensive therapy should be educated about their potential cumulative effects, to prevent serious episodes of hypotension and syncope. Additionally, patients taking medications for ED should be instructed to never take nitrates for chest pain, because this could also result in severe hypotension.

One of the main nursing interventions in the care of patients with testicular torsion is immediate referral for imaging and potential surgery. As mentioned, this condition is an emergency and must be treated immediately to restore blood flow and function to the affected testicle. Patients with testicular torsion are often encountered in the emergency department and present with new-onset, severe lower abdominal or scrotal pain. Nurses must be aware of this common clinical manifestation and understand the severity of this condition. If the nurse suspects a patient is experiencing testicular torsion, they will need to contact the provider quickly for immediate medical intervention.

Most of the nursing care of patients with testicular cancer is performed as part of the patient's hospital stay following orchiectomy, because this is the most common treatment option for this disorder. Preoperative care is similar to that of most other surgical procedures, including obtaining informed consent, ensuring the patient ingests nothing by mouth for the number of hours ordered by the provider, and preparing the patient for surgery. Postoperative care of the patient after orchiectomy may involve caring for an indwelling catheter until the patient is ready to void on their own. The nurse will provide meticulous cleaning and care to the catheter site to prevent infection and other complications. Additionally, these patients will require education about the importance of maintaining follow-up appointments and the potential impact of the surgery on their fertility.

LIFE-STAGE CONTEXT

Testicular Cancer

Because testicular cancer is often diagnosed in young males in their early 20s or 30s, they may not be thinking about their future fertility yet. However, it is important that they are provided education about the potential for orchiectomy to negatively affect fertility. Most often, only one testicle is removed, allowing for the other to compensate and produce adequate testosterone and sperm. However, sometimes the remaining testicle does not function adequately, or both testicles are affected and must be removed. In any case, it is important to counsel the patient about these potential outcomes and give them the option to undergo cryopreservation, or "sperm banking." As part of this process, before the orchiectomy, the patient will provide a sperm sample that can be frozen for future reproduction.

Evaluation of Nursing Care of the Patient with Disorders of the Male Reproductive Tract

As a nurse, evaluation is an important part of patient care. The nurse must determine whether the treatment was effective and if the patient requires further care or education. The nurse can determine if there has been resolution of symptoms or if further learning needs require further support.

Evaluating Outcomes

During evaluation of a patient who has been treated for ED, the nurse will ask about the patient's sexual function to determine whether prescribed medications or lifestyle modifications have helped improve the condition. If the patient reports the interventions have not been effective, this would warrant further investigation and possible referral to specialists who may be able to prescribe different medications or therapies. For patients recovering from orchiectomy, it is important for the nurse to inquire about postoperative pain or discomfort to evaluate their recovery process. Although minimal postsurgical pain is common, if the patient reports experiencing more severe or frequent pain than expected, the nurse should report the findings to the surgeon to determine next steps.

Patients who have experienced disorders of the male reproductive system often require lifelong counseling or psychotherapy, because these conditions can have negative effects on both mental and social health. It is important for the nurse to facilitate these experiences by providing the patient with appropriate referrals for counseling and therapy. Though nurses are not trained to provide official psychotherapy or counseling, it is important that they create a safe space where the patient can openly discuss their health and sexual concerns free from judgment and without embarrassment.

CLINICAL SAFETY AND PROCEDURES (QSEN)

Patient-Centered Care: Testicular Self-Examinations

Disclaimer: Always follow agency policy.

Definition: Recognize the patient or designee as the source of control and full partner in providing compassionate and coordinated care based on respect for the patient's preferences, values, and needs.

Male patients between the ages of 14 and 45 years are at risk for testicular cancer. Nurses can help patients with primary prevention by teaching testicular self-examination. The nurse can advise the following correct method for testicular self-exam:

1. Perform a testicular self-exam once a month during or right after a warm shower.
2. Examine each testicle with thumbs and middle fingers, rolling gently, noting lumps, nodules, or changes or pain.
3. Examine each testicle in the mirror, looking for swelling or redness (Testicular Cancer Society, n.d.).

(QSEN Institute, n.d.)

20.4 Disorders of the Prostate

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations of disorders of the prostate.
- Describe the diagnostics and laboratory values for disorders of the prostate.
- Apply nursing concepts and plan associated nursing care for patients with disorders of the prostate.
- Evaluate the efficacy of nursing care for the disorders of the prostate.
- Describe the medical therapies that apply to the care of patients with disorders of the prostate.

The prostate gland is a major organ of the male reproductive system and is located just below the urinary bladder and anterior to the rectum (see Figure 20.2). Though it is quite small at only 3 cm long, it is very important for male reproduction. The major function of the prostate gland is the production of fluid that is mixed with sperm for ejaculation as semen (InformedHealth.org, 2016). The muscles of this gland also assist with the mechanical expulsion of semen during ejaculation. The two most common pathological conditions associated with the prostate gland are benign prostatic hyperplasia (BPH) and prostate cancer, both of which are discussed in more detail in this section.

Pathophysiology of BPH

Benign prostatic hyperplasia is quite common, affecting over half of men between the ages of 51 and 60 years and 70% of men older than 60 years (National Institute of Diabetes and Digestive and Kidney Diseases, 2014). This condition is benign and results when the prostate becomes enlarged as a normal side effect of aging. As the prostate gland grows larger, it eventually presses against the urethra, resulting in urinary dysfunction and difficulty with the stream of urine flow.

Pathophysiology of Prostate Cancer

Prostate cancer is the most common type of cancer in males, with about 288,300 new cases diagnosed in 2023 in the United States (American Cancer Society, 2023a). Approximately one of every eight men will be diagnosed with prostate cancer in their lifetime, highlighting its significant prevalence. Though it is a common cancer, most patients diagnosed do not die of the condition, because of the availability of advanced treatment options. The underlying pathophysiology of prostate cancer involves a mutation in the normal prostate cells that results in overproduction of cancerous cells within the gland, known as hypertrophy. A disparity of prostate cancer identification affects more Black men than White men, with earlier manifestation, aggressive disease, and a higher mortality rate (Lillard et al., 2022).

Assessment and Diagnostics

The best way to physically assess the size and shape of the prostate gland is by performing a **digital rectal examination (DRE)**. During this assessment, the provider inserts a gloved, lubricated finger into the rectum to feel the prostate gland and determine if it is enlarged or has any other abnormalities, such as nodules. Enlargement of the prostate gland often indicates BPH, whereas the palpation of a hard nodule on the prostate may indicate prostate cancer. If either of these abnormalities is noted during the DRE, further tests will be ordered to assist in confirming the diagnosis.

Often, the next diagnostic test used after an abnormality is noted during the DRE is the prostate-specific antigen (PSA) test. This blood test checks for the presence of PSA which is a protein made by the prostate gland. If this value is elevated, it can be indicative of either BPH or prostate cancer. Occasionally, the provider may also order a urinalysis at this time to check for additional urinary system problems, including UTI and kidney stones, which often occur because of BPH. Current screening guidelines recommend prostate cancer retesting every two years for men with a PSA level less than 2.5 ng/mL and annual testing for men with a PSA level greater than 2.5 ng/mL.

If prostate cancer is suspected, other diagnostic tests may be ordered to confirm the diagnosis and determine its severity. First, imaging is usually ordered to better visualize the gland. This is typically done with use of a transrectal ultrasound. During this procedure, the provider will insert a small ultrasound probe into the rectum to look at the prostate gland and determine if there are any nodules present that are indicative of cancer. If a nodule is noted at this time, a biopsy specimen is usually taken and sent to the laboratory for further analysis. Once the laboratory

confirms the diagnosis of prostate cancer, the patient will often undergo other imaging such as computed tomography scan or magnetic resonance imaging to determine if the cancer has spread beyond the prostate gland or if it remains localized.

Recognizing and Analyzing Cues

Because of the high prevalence of BPH and prostate cancer in older adult males, it is important for nurses to be aware of symptoms that may indicate the patient has either of these conditions. Often, while obtaining the health history, the nurse will use a standardized questionnaire to determine whether the patient is exhibiting symptoms indicative of BPH or prostate cancer. The most used scale is the International Prostate Symptom Score (I-PSS). There are also some key assessment findings that the nurse should look for during a physical assessment, including

- chronic urinary retention and inability to fully empty bladder
- **hematuria** (blood in urine) – this is a *late* sign of prostate cancer
- increased urinary frequency
- **nocturia** (increased urinary frequency during nighttime hours)
- pain during intercourse or ejaculation
- recurrent UTIs and/or kidney stones due to urinary stasis
- **urinary hesitancy** (difficulty starting urinary stream)
- urinary leaking and incontinence
- urine flow "dribbling" at end of stream
- urine stream that starts and stops intermittently

LINK TO LEARNING

The International Prostate Symptom Score (IPSS) (https://openstax.org/r/77IPSS) is used widely to assess for BPH and severity of symptoms of the lower urinary tract. This calculator provides a quick method for the assessment.

Medical Therapies and Related Care

Though BPH and prostate cancer often cause similar symptoms, treatment goals and options differ between the two conditions. These treatments are discussed in more detail in the following two sections.

Medical Treatment for BPH

Before attempting any invasive procedures to treat BPH, there are some behavioral changes and pharmacological therapies that are offered to the patient. First, patients with BPH are counseled about fluid intake, especially caffeine and alcohol, which have diuretic effects. Patients with BPH should drink enough fluids to maintain adequate hydration but refrain from drinking too much, especially within four hours of bedtime, which can contribute to worsening urinary frequency and retention, and nocturia. A voiding schedule, whereby the patient is instructed to void every two hours, is another helpful intervention to avoid urinary dribbling. In addition to limiting fluid, caffeine, and alcohol intake and trying a voiding schedule, patients with BPH are often prescribed medications to help improve BPH symptoms. Common medication classes prescribed for BPH as well as their mechanisms of action and common adverse effects are listed in Table 20.6.

Drug Class	Mechanism of Action	Common Adverse Effects
α_1-Adrenergic antagonists • terazosin • doxazosin • prazosin • tamsulosin • alfuzosin	Relaxation of smooth muscle in the bladder and prostate gland, which allows easier flow of urine	• Dizziness • Headache • Hypotension, especially orthostatic • Syncope • Weakness
5-α-Reductase inhibitors • finasteride • dutasteride	Decreased production of dihydrotestosterone, which causes reduced growth of prostate gland	• Decreased ejaculatory volume • Decreased libido • Dizziness • ED • Gynecomastia • Orthostatic hypotension • Weakness
Phosphodiesterase-5 inhibitors* • tadalafil (Cialis)	Relaxation of smooth muscle in the urinary tract, which can aid effective urine flow	• Abdominal pain • Diarrhea • Facial flushing • Headache • Nasal congestion • Nausea • Upper respiratory infection

*Note: This class of medications is typically only used to treat ED, but it has been shown to have some effectiveness for treating symptoms associated with BPH.

TABLE 20.6 Common Medication Classes Prescribed for BPH

If behavior modifications and medications are ineffective for treating symptoms associated with BPH, more invasive procedures can be considered. These procedures are described in Table 20.7.

Procedure	Description
Transurethral needle ablation (TUNA)	Low-radiofrequency needles are placed through the urethra and into the excess prostate tissue. Waves are sent through the needles, which kill prostate tissue and decrease the size of the prostate gland.
Transurethral microwave thermotherapy (TUMT)	A small microwave antenna is inserted through the urethra toward the prostate, where microwave energy is delivered to destroy excess prostate tissue.
Photovaporization of the prostate (PVP)	GreenLight laser is used to vaporize excess prostate tissue.

TABLE 20.7 Procedures for the treatment of BPH

Procedure	Description
Transurethral resection of the prostate (TURP)	A resectoscope is inserted through the urethra and small parts of prostate tissues are trimmed away (Figure 20.10). These pieces are then flushed out with irrigation fluid at the end of the procedure. This procedure requires an indwelling catheter immediately after surgery and usually a one- to two-day postoperative hospital stay. Some patients require a three-way foley that promotes continuous bladder irrigation, if clinically required.
Transurethral incision of the prostate (TUIP)	Small incisions are made in the prostate tissue where it meets the bladder. This allows for improved flow of urine.
Prostatic urethral lift (UroLift)	Permanent implants are placed in the urethra where it is obstructed, to hold back the enlarged prostate tissue and improve urine flow through the urethra.
Simple prostatectomy	Removal of excess prostate tissue through incisions in the lower abdomen or perineum. This is one of the most invasive treatment options and requires a two- to four-day postoperative hospital stay, with a longer recovery period.

TABLE 20.7 Procedures for the treatment of BPH

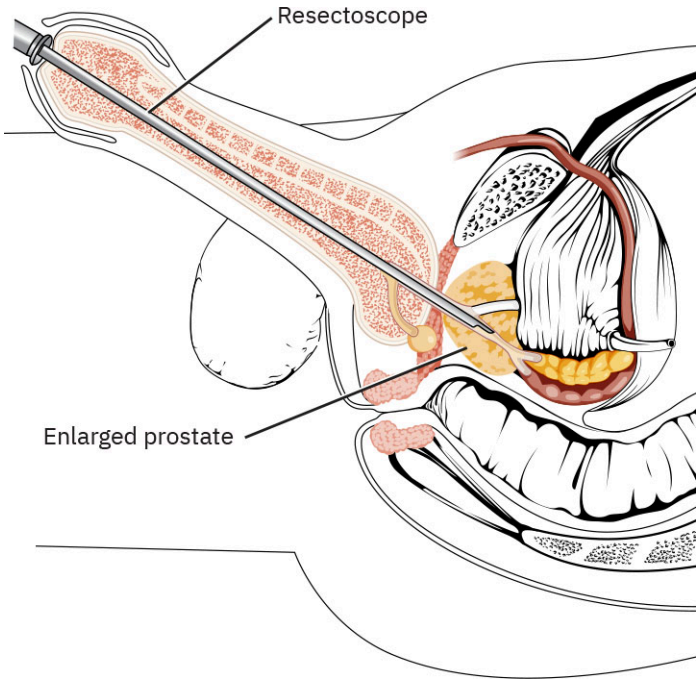

FIGURE 20.10 Through a TURP, a resectoscope is placed into the patient's urethra and the prostate is surgically resected by this canulated scope and fully removed. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Medical Treatment for Prostate Cancer

Because prostate cancer grows slowly and often does not affect men until later in life, treatment is not always required. In these situations, the provider may choose a "wait and see" approach. During this time, the patient is monitored at regular intervals with DREs and PSA tests. If symptoms become bothersome or the cancer progresses, further intervention may be warranted.

Radiation therapy is usually the first treatment option for patients with prostate cancer that is in an early stage and

localized to the prostate gland. The two main types of radiation used for treatment of prostate cancer are external beam radiation therapy (EBRT) and brachytherapy (internal radiation). EBRT involves using radiation beams on the external skin located over the prostate gland. Typically, patients receive this kind of radiation therapy five days a week for several weeks on an outpatient basis. This procedure is quick, painless, and highly effective for curing early-stage prostate cancer. An approach called brachytherapy involves placement of radioactive seeds inside the prostate tissue that are left in place and give off radiation to kill excess prostate tissue over several weeks to months. The amount of radiation emitted by the seeds is low, so there is minimal risk of damage to surrounding healthy tissue with this kind of procedure. With radiation therapy, adverse side effects may include ED, urinary incontinence, fatigue, and **radiation proctitis**, or inflammation of the rectum lining, which can result in diarrhea and rectal leakage.

Pharmacological interventions, including hormone therapy and chemotherapy, can also be used in the treatment of prostate cancer. Hormone therapy includes the use of luteinizing hormone-releasing hormone agonists and antiandrogens. Luteinizing hormone-releasing hormone agonists work by preventing the production of testosterone, which results in slower cancer cell growth. Antiandrogens, also known as androgen deprivation therapy, prevent the body from being able to use the male sex hormones, and this can also assist in slowing cancer growth. Chemotherapy is a systemic pharmacological treatment option typically reserved for patients with more severe and metastatic prostate cancer. Depending on the severity of the cancer and other specific patient characteristics, surgery may be another treatment option considered for prostate cancer. A radical prostatectomy (removal of the entire prostate gland) or bilateral orchiectomy (removal of both testicles) is performed in some cases.

Nursing Care of the Patient with BPH

The two main priorities of care for patients with BPH are related to improving urinary elimination flow and providing psychosocial support. The nurse should take both aspects of care into consideration when planning intervention for a patient with BPH.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

To assist with the improvement of urinary elimination, the nurse should provide education about lifestyle changes such as limiting fluid and caffeine intake, especially before bedtime, to prevent nocturia and other BPH-associated symptoms. If the patient has been prescribed medications for the treatment of BPH symptoms, the nurse should ensure the patient understands how to take the medications correctly and any adverse effects to monitor for. Additionally, the nurse should emphasize the importance of taking medications as prescribed and reporting their effectiveness to the provider so changes in dosing can be made as necessary.

When caring for a patient with BPH who is scheduled to undergo a more invasive procedure such as a TURP or TUNA, the nurse will ensure the patient understands the nature of the procedure and obtain informed consent. During this process, the nurse confirms that the patient understands the information the provider gave them about the procedure, because the provider ultimately has the legal responsibility associated with procedural education. Postoperatively, the nurse will provide care that is tailored to the specific procedure performed. In most cases, the patient will return to the unit with an indwelling urinary catheter, so one of the main nursing interventions is to complete meticulous catheter care to prevent infection. Occasionally, these patients will also be receiving **continuous bladder irrigation (CBI)**, a procedure in which a three-way urinary catheter is used to constantly irrigate the bladder and allow for adequate urinary drainage (Figure 20.11). The nurse will need to adjust the flow of the bladder irrigation solution to maintain patency and monitor for complications such as severe bleeding. Color of the urine may direct urethral patency; urine that is pink tinged and few to no clots is an ideal response with continuous bladder irrigation.

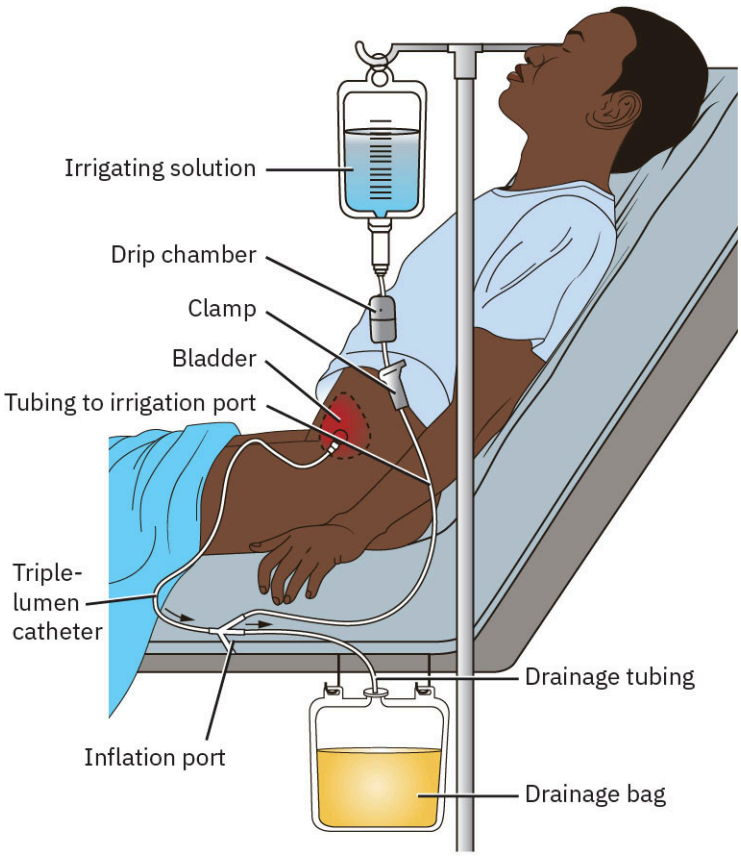

FIGURE 20.11 Continuous bladder irrigation uses a three-way catheter to irrigate the bladder to allow for adequate urinary drainage. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

In addition to providing care that addresses physical symptoms, the nurse is also tasked with providing psychosocial support to the patient. Disorders of the male reproductive and urinary systems are highly personal and can have a significant impact on mental health. It is important for nurses to remain empathetic to these feelings and provide care that is nonjudgmental and supportive. These patients may also benefit from referrals to various social support groups, so it is important for the nurse to be knowledgeable about these options and provide referrals to this extra support as needed or requested by the patient.

Evaluation of Nursing Care of the Patient with BPH

As part of patient care, the nurse must evaluate interventions and treatment options. The nurse should make sure to assess and consider all aspects of the patient's well-being, including psychological and educational needs.

Evaluating Outcomes

After treatment, the best outcome is that patients will report improvement in urinary elimination patterns. If the patient reports that symptoms have not improved, the nurse should be sure to escalate the patient's concerns to the provider and formulate a new plan of care with different treatment options to attempt to improve elimination patterns. While evaluating patient outcomes, the nurse should also assess the patient's feelings about their disorder. A major part of caring for patients with BPH involves treating the psychosocial aspect of the illness, so the nurse would hope to see improvements in this area as well. If this is not the case, the nurse can refer the patient to counseling or other supportive services that can assist the patient in coping with their disorder.

Nursing Care of the Patient with Prostate Cancer

The nurse will be one member of an interprofessional health care team that will provide care for the patient with prostate cancer. The nurse plays a vital role on the team by creating a comfortable environment and providing necessary interventions, ensuring the best possible outcome.

Recognizing and Analyzing Cues

During the physical examination of a patient with prostate cancer, the nurse should assess for signs that would indicate the condition is not improving, such as worsening nocturia or an inability to empty the bladder completely. It is also important that the nurse assess the patient's mental health and coping strategies. Though prostate cancer is typically curable, it can still cause feelings of fear and anxiety. The nurse should allow the patient to express and explore these feelings as needed.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Patients diagnosed with prostate cancer are often faced with many treatment options, so one of the main nursing interventions is to help guide the patient through this decision-making process. The nurse will not make the treatment decision for the patient, but it is important that they assist the patient in fully understanding their treatment options and the associated risks and benefits. With this information, the patient can make a better-informed decision about their health. If the patient chooses to try pharmacological options, the nurse should provide education about the medications, their mechanisms of action, and associated side effects. If the patient plans to undergo surgery, the nurse will ensure the patient understands the procedure and obtain an informed consent. Postoperative care for prostate cancer surgery will likely involve catheter care and interventions for reducing postoperative pain.

Evaluation of Nursing Care of the Patient with Prostate Cancer

As with other conditions, the nurse must evaluate any interventions and treatment options for the patient with prostate cancer. The nurse should be sure to assess all aspects of the patient's well-being, including psychological and educational needs, throughout all of the patient's follow-up care.

Evaluating Outcomes

After receiving treatment for prostate cancer, the nurse should assess the patient for optimal outcomes, including improved urinary elimination patterns and the complete eradication of cancer cells. It is also important for the nurse to stress the importance of maintaining follow-up appointments even after receiving cancer treatment, because recurrence may occur, necessitating repetition of the procedure or treatment interventions.

INTERDISCIPLINARY PLAN OF CARE

Interprofessional Care of the Patient Receiving Treatment for Prostate Cancer

- Dietitian: formulates nutritional plan, which is especially important for patients receiving cancer treatment because they often lose weight from lack of appetite associated with treatment
- Medical physicist: assists oncologist in creating treatment plan for patients opting to receive radiation therapy
- Nurse: provides holistic care for the patient and is a facilitator of both physical and psychosocial interventions
- Oncologist: determines presence and severity of the cancer and oversees the treatment planning process
- Pharmacist: assists in selecting appropriate pharmacological options and doses for cancer treatment
- Social worker: assists patient with psychosocial and financial aspects of cancer treatment

20.5 Female-Specific Disorders of the Reproductive Tract

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations of disorders of the female reproductive tract
- Describe the diagnostics of and laboratory values seen in disorders of the female reproductive tract
- Apply nursing concepts and plan associated nursing care of patients with disorders of the female reproductive tract
- Evaluate the efficacy of nursing care of the patient with disorders of the female reproductive tract
- Describe the medical therapies that apply to the care of disorders of the female reproductive tract

Common disorders of the female reproductive system discussed in this section include pelvic inflammatory disease, endometriosis, and uterine fibroids. These conditions may be highly personal to the patient because they often

result in issues relating to sexuality and fertility. Care of the patient with disorders of the female reproductive system should be provided in a gentle, empathetic manner. These patients often require not only physical interventions and medical care but also psychosocial support.

Pathophysiology of Common Disorders of the Female Reproductive Tract

One of the most common disorders of the female reproductive system is pelvic inflammatory disease (PID), which affects nearly one million women annually (Pennsylvania Department of Health, 2023). This condition results from an infection within the reproductive tract that causes permanent scarring in the tissues. The infection is typically caused by a bacterium but can also be due to a virus, fungus, or parasite. Often, the infectious disease that results in PID is either gonorrhea or chlamydia, both of which are transmitted through sexual contact. This is significant because this condition often results in infertility and an increased risk of **ectopic pregnancy** (pregnancy occurring outside of the uterus, most often in the fallopian tube) which can be life-threatening.

Another common condition of the female reproductive tract is **endometriosis**, which affects approximately 10 percent of female individuals, or 190 million, annually (World Health Organization, 2023). The underlying pathophysiologic mechanism of this disorder is growth of uterine tissue in areas located outside of the uterus (Figure 20.12), which results in severe pain and possible infertility. The cause of this abnormal tissue growth is unknown and there is no cure, but there are treatments available for its associated symptoms.

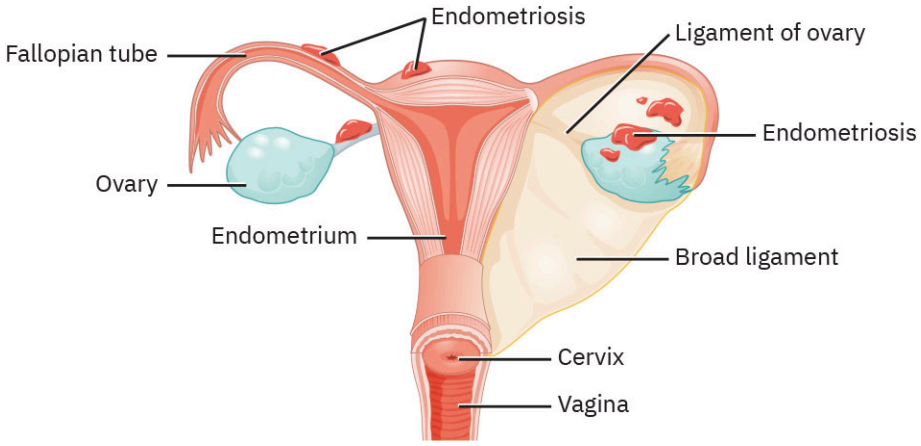

FIGURE 20.12 Common sites of endometriosis include the fallopian tubes and ovaries. (credit: *Anatomy and Physiology 2e.* attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

The most common type of benign tumor affecting women is the **uterine leiomyoma**, more commonly called a **uterine fibroid**. More than half of all women will experience a uterine fibroid by the time they turn 50 years old (Mayo Clinic, 2022c). The exact cause of these slow-growing, noncancerous tumors is unknown, but they result from an inappropriate growth pattern of the smooth muscle located within the uterus.

Assessment and Diagnostics

One of the first steps in caring for a patient with a female reproductive system disorder is obtaining a thorough health history and performing a physical examination. It is important to remember many patients are uncomfortable discussing sexual function and details about menstrual cycles; therefore, the nurse should promote a warm, safe environment to facilitate an open dialogue with the patient.

Recognizing and Analyzing Cues

Clinical manifestations associated with disorders of the female reproductive tract vary depending on the specific condition. Common clinical manifestations associated with PID, endometriosis, and uterine fibroids are listed in Table 20.8.

Disorder	Clinical Manifestations
Pelvic inflammatory disease	• Abnormal vaginal discharge • Fever • Irregular menstrual bleeding • Lower abdominal pain • Painful sexual intercourse • Reported history of STI
Endometriosis	• Bloating • Fatigue • Heavy periods or bleeding between periods • Infertility • Nausea • Painful sexual intercourse • Painful urination • Pelvic or general abdominal pain that is worse during menstrual periods
Uterine fibroids	• Abdominal bloating/distension • Anemia • Constipation • Heavy menstrual cycles • Long menstrual cycles (e.g., longer than one week) • Pelvic pain • Spotting or bleeding between periods • Urinary frequency • Urinary retention and difficulty emptying the bladder

TABLE 20.8 **Clinical Manifestations of Disorders of the Female Reproductive System**

Diagnostics

Pelvic inflammatory disease is typically diagnosed on the basis of symptoms alone, but, if necessary, diagnostic tests or procedures such as sonograms or biopsies can be used to confirm the diagnosis. Endometriosis is also diagnosed mostly on the basis of symptoms; occasionally, the provider can confirm the diagnosis by palpation of pelvic nodules. If pelvic nodules are felt, the provider is likely to order a laparoscopic exploratory procedure and collect a biopsy specimen to confirm the diagnosis and determine its severity. If uterine fibroids are suspected, they can be confirmed and diagnosed with use of a transvaginal ultrasound to assist the provider in visualizing the tumors. There are no specific laboratory tests for any of the disorders of the female reproductive system, often making them difficult to accurately diagnose and treat. A full laboratory workup of female hormones is often completed because female reproductive system disorders are often affected by the normal menstrual cycle hormones. Additionally, if a patient has a heavy menstrual cycle, a complete blood cell count often is ordered to determine if the patient has anemia as a result.

Medical Therapies and Related Care

Most female reproductive disorders can be treated with medications or surgical procedures. Treatment options for female reproductive system disorders are described in Table 20.9. Additionally, because these disorders may result in infertility, it is common for women with these disorders to seek fertility treatments when they reach reproductive age and decide that they would like to try to get pregnant.

Disorder	Treatments
Pelvic inflammatory disease	• Antibiotics (usually a combination of ceftriaxone, doxycycline, and metronidazole) • Treatment of STIs in sexual partner is indicated.
Endometriosis	• Analgesic medications • Gonadotropin-releasing hormone agonists • Hormonal therapy (e.g., oral contraceptives) • Surgical removal of lesions
Uterine fibroids	• Analgesic medications • Blood transfusions or iron supplementation if condition is causing heavy menstrual cycles • Endometrial ablation, surgical removal of smaller fibroids, or hysterectomy (for larger fibroids) • Gonadotropin-releasing hormone agonists • Hormonal contraceptives

TABLE 20.9 Common Female Reproductive Disorders and Treatments

Nursing Care of the Patient with Disorders of the Female Reproductive Tract

Complex care is often needed for a patient with a disorder of the female reproductive tract, and can include physical interventions, psychological screening, and patient education. The nurse needs to address these areas with the patient while also creating a welcoming environment for the patient, and focusing on proper diagnosis, intervention, and initiation of effective treatment options

Recognizing and Analyzing Cues

During the health history and physical examination process, it is important that the nurse assess for symptoms that may indicate a female reproductive disorder. Specifically, the nurse should ask about any changes or irregularities of the patient's menstrual cycle. Symptoms such as a heavier menstrual flow or increased abdominal cramps may be the first indicators of a female reproductive disorder.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Because of the sensitive nature of female reproductive system disorders, it is important for nurses to provide gentle and supportive care to promote a comfortable environment for the patient. Psychosocial needs of the patient with a female reproductive disorder will vary, but in all cases, the nurse should remain sensitive to the patient's feelings and let them fully express their concerns. In some cases, the nurse may need to initiate referrals to social work or counseling to better help the patient navigate their condition and develop adequate coping skills.

One of the main nursing interventions when caring for patients with female reproductive system disorders is related to patient education. First, nurses must educate the female patient about expected physical symptoms associated with each disorder and when to seek help. The nurse will let the patient know that certain symptoms indicate a possible emergency and should be reported to the provider immediately. For example, bleeding between periods is an expected symptom of many female reproductive disorders, and the patient needs to report significantly heavier menstrual bleeding immediately because this may indicate a sign of more severe disease and could become life-threatening if left untreated. Typically, saturating one tampon or pad per hour is indicative of a heavy flow and should be reported to the provider for follow-up and intervention. Another important aspect of patient education as it relates to female reproductive disorders is their potential effects on future fertility. It is important that the nurse obtain appropriate referrals for these patients for counseling and fertility treatments as needed or as requested by the patient.

Evaluation of Nursing Care of the Patient with Disorders of the Female Reproductive Tract

To ensure proper patient care, the nurse must evaluate interventions and treatment options. This includes the patient's psychological and educational needs, as well as any immediate or future physical needs.

Evaluating Outcomes

The main purpose of evaluating outcomes after a patient has been treated for a female reproductive system disorder is to determine whether the treatment was effective and if the patient requires further care or education. The nurse should perform a physical assessment and collect subjective data from the patient to determine whether symptoms such as heavy menstrual bleeding have improved. Ideally, symptoms will be gone or will at least be tolerable, but if not, the nurse should relay the information to the provider so a new treatment plan can be established. During the follow-up and evaluation period after receiving treatment, the nurse should also conduct a psychosocial assessment. As mentioned, these disorders can have negative impacts on fertility, which can significantly affect the female patient's mental health. If, during the assessment, the nurse feels the patient is having difficulty coping with the diagnosis, the nurse can provide the patient additional resources, such as names of counselors or support groups.

20.6 Disorders of the Breast

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations of disorders of the breast.
- Describe the diagnostics of and laboratory values seen in disorders of the breast.
- Apply nursing concepts and plan associated nursing care for patients with disorders of the breast.
- Evaluate the efficacy of nursing care for disorders of the breast.
- Describe the medical therapies that apply to the care of patients with disorders of the breast.

Breast cancer is the second most common cancer experienced by women, second only to skin cancer. This cancer affects more than two million women in the annually in the United States, highlighting its significant prevalence (World Health Organization, 2024. Fortunately, there are many treatment options available, and the five-year survival rate remains greater than 90 percent, which is higher than for most other types of cancer. In recent years, there has been much research and focus on developing better treatment options and improving access to early screening, which should improve survival rates. Black women, unfortunately, develop more aggressive breast cancers with lower survival rates in comparison to White women, with a 42 percent increased risk of breast cancer mortality (Yedjou et al., 2019).

Pathophysiology of Breast Cancer

The breasts are considered part of the female reproductive system and are composed of tissue that produces and secretes breast milk to feed offspring. Each breast contains approximately 15 to 20 lobes that branch into several lobules where milk is produced (Johns Hopkins Medicine, 2023). The lobules are connected via small ducts to the nipple, which is located centrally in the breast and contains openings for the milk to be secreted. Figure 20.13 shows an illustration of the different parts of the breast.

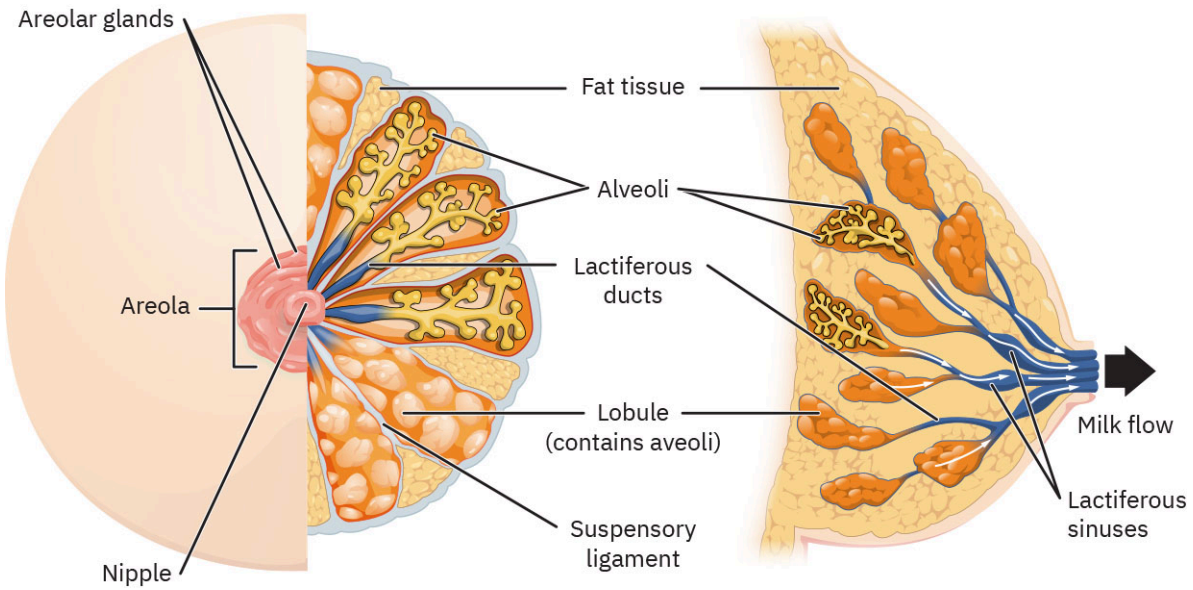

FIGURE 20.13 The main function of the female breast is to produce and secrete milk to feed offspring. (credit: *Anatomy and Physiology 2e*. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

The underlying pathophysiology of breast cancer is intricate and thought to be multifactorial, caused by a combination of genetics, hormones, and environmental risk factors. There are several specific types of breast cancer that are classified by their anatomic location and **histology**, or the study of the microanatomy of cell and tissue types, but all types involve an overgrowth of cancerous cells within the breast tissue. The growth rate of these cancerous cells can also be influenced by the presence of the female sex hormone, estrogen. The following are risk factors for breast cancer development (Alkabban et. al., 2022):

- alcohol and tobacco use
- *BRCA1* or *BRCA2* genetic mutations
- early menarche and/or late menopause
- environmental factors (e.g., contaminated water, radiation exposure, some pesticides)
- female sex
- first-degree relative with or personal history of breast or ovarian cancer
- history of using hormone replacement therapy
- increasing age
- **nulliparity** (having no children) or late age at birth of first child
- obesity and/or high-fat diet

Clinical Manifestations of Breast Cancer

The most common and often first clinical manifestation of breast cancer is the development of a lesion (or lump) within the breast tissue. Because screening has become more readily available, breast cancer nodules are often found before any other signs or symptoms of cancer appear.

Assessment and Diagnostics

After a lump in the breast has been palpated by the patient or provider, further diagnostic tests are indicated. These screening tests are also indicated for patients without the presence of a palpable lesion but who have multiple risk factors for developing breast cancer. Current screening recommendations suggest that women should begin mammograms as early as age 40 years and every other year from ages 40 to 74 (Breast Cancer Research Foundation, 2023). For women at especially increased risk because of family history or genetic mutations, annual screening may start at an even earlier age.

Mammograms are usually the first diagnostic test indicated. This procedure involves taking low-dose X-ray images of the breast tissue. These X-rays can enable visualization of growths in the breast that may be indicative of cancer. It is important for women to obtain mammograms as suggested by current screening guidelines, because tumors may be detected on X-ray before they are physically palpable, allowing for earlier intervention and effective

treatment. If suspicious lesions are found on the mammogram, it is likely the patient will need to undergo further imaging tests, such as an ultrasound of the breast tissue to confirm the presence and characteristics of the tumor. If the presence of a tumor(s) has been confirmed, the next step is a biopsy of the mass or tumor.

During the biopsy procedure, breast tissue and fluid are removed and sent to the pathology laboratory for analysis and staging of the cancer. The different types of biopsy procedures are described in Table 20.10.

Biopsy Procedure	Description
Fine needle aspiration (FNA)	A thin, hollow needle is attached to a syringe to withdraw a small amount of tissue and/or fluid from the breast.
Core needle biopsy	Large, hollow needle is used to withdraw tissue or fluid samples from the breast tissue.
Surgical biopsy	Surgical removal of the entire tumor and surrounding margins for cancer analysis.
Lymph node biopsy	Removal of axillary lymph nodes to monitor for cancer spread outside of breast tissue. This is often performed in conjunction with biopsy of breast tissue.

TABLE 20.10 Types of Biopsy Procedures for Diagnosis and Staging of Breast Cancer

Medical Therapies and Related Care

With focused research over the past several years, treatment options for breast cancer have become more readily available and much more effective. In some cases, treatment can even be provided before the patient receives an official cancer diagnosis. The complete removal of breast tissue before any cancer diagnosis is known as **prophylactic mastectomy** and greatly decreases the patient's risk of developing breast cancer. This procedure should be considered for patients with certain risk factors, including a strong family history of breast cancer, presence of genetic mutations, or personal history of other cancers. In most cases, the patient will undergo the prophylactic procedure and immediately undergo reconstructive breast surgery for cosmetic benefits.

Mastectomy can also be performed after receiving a breast cancer diagnosis and is used to treat more invasive types of cancer that affect large portions of the breast tissue. This can be performed as a **total mastectomy** (removal of the entire breast and surrounding tissue), or a mastectomy with breast conservation, for which the aim is to remove as much of the tumor as possible while maintaining as much breast tissue as possible for cosmetic purposes. The surgical procedure is made with consideration of the cancer's stage and characteristics, surgeon recommendations, and patient preferences.

In addition to surgery, treatment with radiation therapy or chemotherapy may be considered. These therapies may be instituted after surgery or as a standalone therapy, depending on specific patient and cancer characteristics. There are two main types of radiation therapy that can be used: EBRT and brachytherapy. External beam radiation therapy is administered externally, meaning it is noninvasive and administered on top of the skin to treat the underlying breast tissue. This therapy is typically administered daily (5 days/week) for a month or two. The goal of this therapy is to irradiate cancer cells within the breast tissue to completely destroy the cancer and cause remission. Brachytherapy, on the other hand, is administered internally. Radioactive seeds are placed within the breast tissue and continuously give off radiation, killing cancer cells in the breast. The type of radiation therapy to be used depends on the specific cancer type present and its stage and severity. Both types of radiation therapy have some associated adverse effects, including pain or redness at radiation site, infection, breast tissue damage, and fatigue.

Chemotherapy is another option for the treatment of breast cancer. This therapy is systemic, meaning it is administered throughout the entire body as opposed to just treating localized breast tissue, like with radiation therapy. Chemotherapy involves the administration of powerful drugs that kill the fast-growing cells in the body, which includes cancer cells. It is often performed as an adjuvant therapy, meaning that it is given in conjunction with

another therapy, often before or after surgical intervention. When administered before surgery (neoadjuvant chemotherapy), the goal of therapy is to shrink the tumor so it is easier to remove during surgery. If administered after surgery (adjuvant chemotherapy), the goal is to eliminate any residual cancer cells that may not have been fully removed during the initial surgical intervention. Chemotherapy is typically administered through a central venous catheter, most often an implanted port in the patient's chest. This allows for easy and quicker administration into the patient's systemic circulation. Though highly effective at destroying cancer cells, chemotherapy is also potent to healthy cells, which can result in unpleasant side effects, including

- anemia
- fatigue
- gastrointestinal disturbances (e.g., anorexia, nausea, vomiting, diarrhea)
- hair loss
- immunosuppression (and associated low white blood cell count)
- mouth sores

Hormone therapy is another treatment option that may be indicated for breast cancer. This therapy is also usually a type of adjuvant therapy and involves the administration of medications that either lower levels of estrogen in the body or block estrogen from binding to receptors. By limiting the amount and function of estrogen in the body, cancer cell growth can be slowed or stopped. These medications are administered in oral pill form and are usually prescribed to be taken for approximately five years to prevent cancer recurrence. Common side effects of these medications include hot flashes, vaginal dryness, and muscle pain.

Nursing Care of the Patient with Breast Cancer

Because of the nature of cancer care, patients will often require an interprofessional team of providers to ensure the best possible outcome. The nurse plays a vital role on the team by creating a comfortable environment and providing necessary interventions.

Recognizing and Analyzing Cues

Common lesions may be found by the patient during a self-breast exam or by the provider during a physical examination. These nodules can be found anywhere within the breast but are often found in the upper outermost portion of the tissue. Their shape and characteristics may vary slightly, but they are usually immobile, hard, and nontender. The later signs of breast cancer include skin dimpling, nipple retraction, and changes in skin color and texture, likely due to stretching of the skin to accommodate growth of the tumor. Other late clinical manifestations associated with breast cancer are depicted in Figure 20.14.

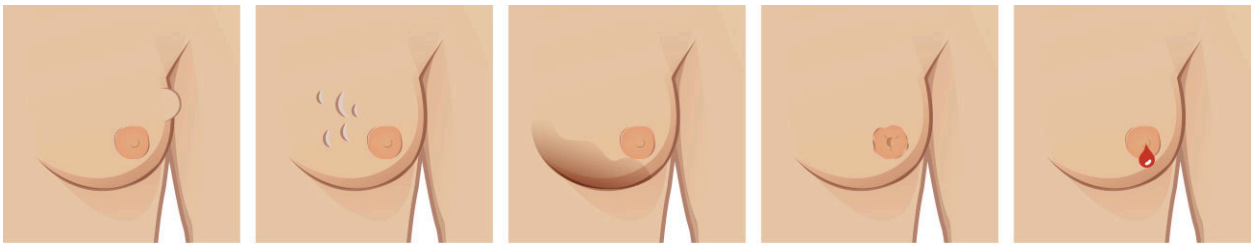

FIGURE 20.14 Late physical breast changes that may indicate the development of breast cancer include lumps, skin dimpling, changes in skin color or texture, change in nipple appearance, and clear or bloody nipple discharge. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Nursing care of the patient with breast cancer is complex and should be tailored to the specific type of treatment the patient are receiving. Important nursing interventions for each type of cancer treatment are described in Table 20.11. Regardless of the type of treatment initiated, it is important for nurses to provide supportive care, especially within the psychosocial realm. Receiving a cancer diagnosis can be scary and produce feelings of anxiety, so the nurse should provide a comfortable environment for the patient to explore their feelings. It is also important that nurses connect these patients to resources such as counseling or support groups to help them through their journey

with cancer and treatment.

Treatment for Breast Cancer	Nursing Considerations and Interventions
Surgical intervention (e.g., biopsy, mastectomy)	• Obtain informed consent for procedure. • Assist patient in scheduling and navigating preoperative appointments and postoperative follow-up care. • Help alleviate patients fears and anxiety before procedure. • Administer analgesic medications pre- and postoperatively as needed. • Promote positive body image and help patient cope with structural breast changes after surgery. • Monitor and treat potential complications such as **lymphedema** (swelling of the affected limb on the same side of the cancer), hematoma formation, or infection
Radiation therapy	• Educate patient regarding expected side effects and when to contact provider. • Help patient maintain skin integrity following treatment; avoid use of perfumed soaps and tight clothing on treated skin. • Educate patient regarding the importance of avoiding sun exposure on treated skin areas.
Chemotherapy	• Provide antiemetic medications as needed during and after treatment. • Promote positive body image, especially for patients experiencing hair loss. • Interventions to decrease pain associated with mouth sores (e.g., avoid spicy foods, use a soft-bristled toothbrush) • Educate patient about expected side effects and interventions that may improve them.
Hormone therapy	• Help patient manage side effects of medications (e.g., use of vaginal lubrication during sexual intercourse, wearing breathable clothing for comfort during hot flashes). • Educate patient about the importance of taking medications as prescribed.

TABLE 20.11 Selected Nursing Interventions for Different Types of Breast Cancer Treatments

Evaluation of Nursing Care of the Patient with Breast Cancer

Nurses, as part of the patient's care team, will be involved with the patient long after the initial treatment is complete. The nurse will be part of the patient's follow-up care, including the patient's physical and emotional needs.

Evaluating Outcomes

The optimal patient outcome after receiving treatment for breast cancer is the complete destruction and elimination of the cancer cells and a state of remission without cancer recurrence. Part of the follow-up process for patients who receive treatment for breast cancer involves close monitoring of breast tissue for the development of more tumors. These follow-ups will vary in frequency depending on provider preference and specific patient characteristics. Additionally, as part of the evaluation process, the nurse should assess how the patient is coping. Even after being treated effectively for breast cancer, there are still uncertainties about whether the cancer will come back, so it is important that patients are able to effectively cope with these unknowns. If the patient expresses concerns or difficulties with coping, the nurse can spend some time discussing these with the patient and finding resources such as support groups, which may help the patient improve their coping skills for the future.

CLINICAL SAFETY AND PROCEDURES (QSEN)

Patient-Centered Care: Breast Self-Examinations

Disclaimer: Always follow agency policy.

Definition: Recognize the patient or designee as the source of control and full partner in providing compassionate and coordinated care based on respect for the patient's preferences, values, and needs.

Breast self-exams are noninvasive, facilitate intimate familiarization of native breast tissue, and increase breast self-awareness. Guidelines from the American College of Obstetricians and Gynecologists and American Cancer Society recommend that individuals begin breast exams as early as age 25 years. Nurses can provide education on the correct methods for conducting a breast exam.

- Exams can be done in the shower, at least every month.
- The patient should be instructed to place hands on hips and observe for discoloration, rashes, and nipple inversion.
- Educate the patient that it is normal for one breast to be larger than the other.
- After inspection is complete, educate the patient to lay with the arm of breast being examined under the neck. With the other hand, use one of the two following methods: (1) Use the pads of the finger in a zig-zag or "lawn-mowing method" across the breast tissue; and (2) use a concentric motion starting around the nipple and palpate the tissue.
- Axillary assessment should also be conducted, noting any hard, nontender lymph nodes. The patient performing the breast self-exam should observe any fixed, nontender hard lumps.

20.7 Renal Function and Chronic Kidney Disease

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations of acute tubular necrosis (ATN) and chronic kidney disease.
- Describe the diagnostics and laboratory values used to diagnose ATN and chronic kidney disease.
- Apply nursing concepts and plan associated nursing care of patients with ATN and chronic kidney disease.
- Evaluate the efficacy of nursing care of patients with ATN and chronic kidney disease.
- Describe the medical therapies that apply to the care of patients with ATN and chronic kidney disease.

The kidneys are arguably one of the most important body organs because they participate in many functions necessary for life. The major functions of the kidney include

- blood pressure control
- erythropoietin production for red blood cell regulation
- filtration of waste products and excretion as urine

- regulation of acid-base balance
- regulation of electrolytes
- regulation of water/fluid balance
- synthesis of vitamin D to its active form

Most individuals are born with two kidneys, which are located within the abdominal cavity. They are composed of several different components that are labeled in Figure 20.15. Each kidney has approximately one million nephrons (the functional unit of the kidneys), which assist in the formation of urine for excretion. Without optimal functioning of the kidneys, patients are unable to maintain blood pressure, fluid and electrolyte balance, and many other life-sustaining body system processes. This highlights the importance of providing effective treatment and care for disorders that result in dysfunction of the renal system. Two of the most common disorders that affect the kidneys are acute tubular necrosis (ATN) and chronic kidney disease (CKD), both of which are discussed in more detail in this section.

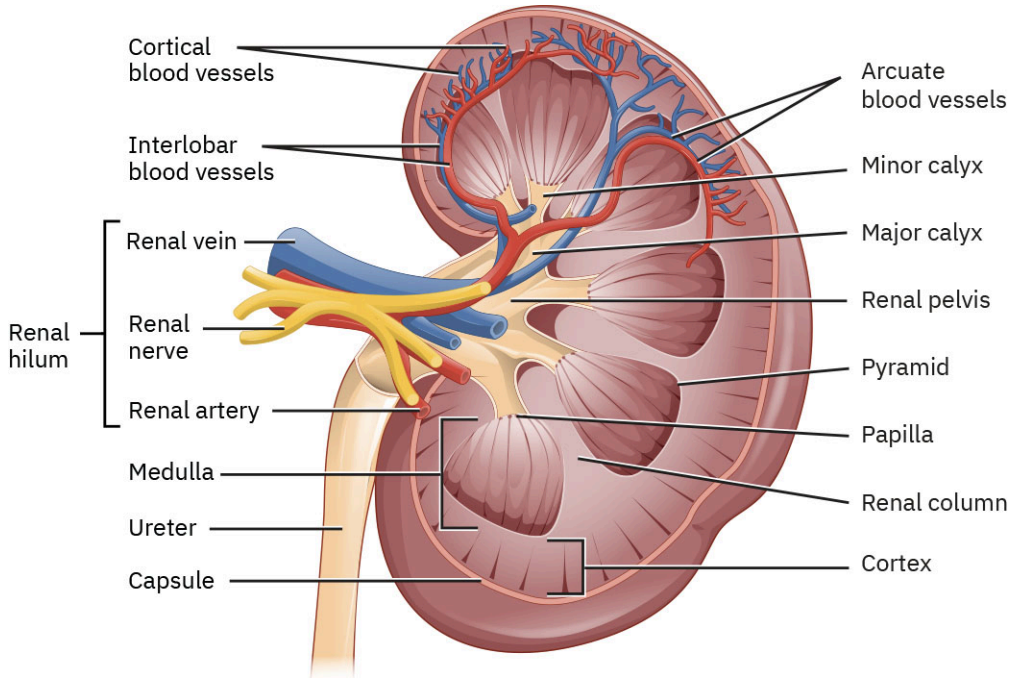

FIGURE 20.15 The kidneys participate in many functions necessary for life, including urine formation, blood pressure regulation, and fluid and electrolyte balance. (credit: *Anatomy and Physiology 2e*. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Patient Populations at Risk for Kidney Disease

One of the biggest risk factors for kidney disease is diabetes mellitus because this condition often results in **nephropathy**, or problems with the kidney vasculature. Other major risk factors for kidney disease are (American Kidney Fund, n.d.):

- African, American Indian, or Asian heritage
- diabetes mellitus
- family history of kidney disease
- glomerulonephritis
- hypertension
- increasing age
- medication use (e.g., nonsteroidal anti-inflammatory drugs, antibiotics)
- obesity
- polycystic kidney disease
- pyelonephritis
- smoking
- urinary tract obstruction (e.g., urinary tumors, enlarged prostate, kidney stones)

Pathophysiology of ATN

Acute tubular necrosis occurs when there is a lack of adequate oxygen and nutrients being delivered to the kidneys. Without adequate oxygen and perfusion, the kidneys can quickly become necrotic, resulting in kidney failure. Often, the cause of ATN is related to thrombosis, or clot formation, or a buildup of myoglobin that blocks blood flow to the kidneys. This condition is transient, but without prompt intervention and adequate treatment, it can become permanent, resulting in chronic kidney problems.

Clinical Manifestations of ATN

Recognizing and Analyzing Cues

Clinical manifestations of ATN are directly related to a lack of blood flow and perfusion to the kidneys, resulting in their suboptimal functioning. Common clinical manifestations of ATN are

- cardiac dysrhythmias
- confusion
- edema in the extremities
- electrolyte imbalances (e.g., hyperkalemia, elevated serum creatinine and blood urea nitrogen levels, decreased glomerular filtration rate)
- fatigue
- nausea/vomiting
- **oliguria** (urine output less than 30 mL/h)
- weight gain

Pathophysiology of CKD

The term **chronic kidney disease** is used to describe long-standing kidney dysfunction lasting longer than three months (Cleveland Clinic, 2020a). If left untreated, CKD can quickly turn into end-stage renal disease, which may require permanent dialysis or even a kidney transplant. Although the specific pathophysiologic mechanism of CKD is poorly understood, specific risk factors have been linked to its development. Patients with any of the risk factors listed in Table 20.12 are at a higher risk than the general population for developing CKD.

Clinical Manifestations of CKD

In many cases, the early stages of CKD are asymptomatic. Symptoms may not even become noticeable until the patient is in the later stages of the disorder that require complex intervention and medical care. Some of the clinical manifestations of CKD are like those seen with ATN, because both conditions result in kidney dysfunction and eventual failure. Clinical manifestations associated with CKD are the following:

- anorexia, nausea, and/or vomiting
- chest pain
- confusion
- edema and swelling of hands and feet
- fatigue
- hypertension
- muscle cramps
- oliguria
- shortness of breath (from fluid build-up in the lungs)

Assessment and Diagnostics

The diagnoses of both ATN and CKD are usually made on the basis of certain laboratory findings. Specific laboratory values that can indicate how well the kidneys are functioning include serum creatinine and blood urea nitrogen (BUN) level, and glomerular filtration rate (GFR). Serum creatinine is a byproduct of skeletal muscle metabolism and breakdown, and this value remains stable from person to person. If the kidneys are unable to filter and excrete creatinine effectively, it can build up in the blood and increased values may indicate kidney damage. Blood urea nitrogen is a byproduct of protein metabolism; elevations of this value may also indicate poor functioning of the kidneys and an inability to excrete the protein product in the urine. However, it is important to note that serum

creatinine tends to be a more specific indicator of renal dysfunction than BUN, because other conditions (e.g., dehydration, increased protein intake) can also increase BUN levels. The GFR represents how quickly the kidneys can filter the blood and excrete it as urine. With kidney dysfunction, GFR increases, indicating that it takes a lot longer for the kidneys to filter out and excrete waste products.

Medical Therapies and Related Care

The underlying principles for the treatment of kidney disorders are restoring optimal functioning and treating the underlying cause and associated symptoms. Because the kidneys play such an important role in the maintenance of fluid balance, treatment often revolves around interventions that help to restore optimal fluid balance. Most patients with kidney disorders will experience fluid overload because the kidneys are unable to filter out excess fluid effectively, resulting in manifestations such as edema and weight gain. These patients are often prescribed diuretic medications to remove the excess fluid from the body as urine. However, these medications are used cautiously because they may inadvertently cause worsening of the renal disease. It is important to closely monitor patients receiving diuretic therapy for electrolyte imbalances (e.g., hypokalemia), worsening renal failure, and hypotension, the latter two of which are common with the use of diuretics.

One of the most common electrolyte imbalances associated with kidney disease is hyperkalemia, or elevated potassium levels in the blood. Hyperkalemia occurs because the kidneys are unable to effectively excrete the potassium from the body, so it builds up in the blood. This is a significant issue because hyperkalemia can result in deadly ventricular dysrhythmias and, eventually, cardiac arrest, if left untreated. Often, the provider will order medications (e.g., sodium polystyrene [Kayexalate]), which work to pull out excess potassium, in turn excreted in the feces, bringing the electrolyte level back into normal range. If the potassium level is dangerously high, intravenous medications, including regular insulin, intravenous dextrose, and calcium can be administered to quickly cause an influx of potassium out of the vessels and into cells, restoring potassium balance much more quickly than with medications that cause potassium to be excreted in the feces. Another type of medication commonly used to treat patients with kidney disorders is phosphate binders (e.g., sevelamer [Renvela]). These medications bind with phosphate to prevent hyperphosphatemia that commonly occurs with kidney disorders.

For patients with more severe or end-stage kidney disease, **dialysis**, or the use of a dialyzer machine to filter the blood and remove toxins when kidney function is decreased, is often indicated. There are three main types of dialysis; they are described in Table 20.12. Though they all work by slightly different mechanisms, the goal of their use is to remove toxins and electrolytes that the kidneys are unable to excrete and to restore fluid volume to a normal level. Hemodialysis (HD) can be performed as an emergency procedure or as a long-term intervention for patients with CKD. For emergency situations such as life-threatening fluid overload or hyperkalemia, a temporary dialysis catheter can be placed in a central vein, allowing for immediate vascular access. Figure 20.16 shows a picture of a temporary dialysis catheter. For more permanent, long-term dialysis solutions, an **arteriovenous fistula** can be created. Arteriovenous (AV) fistulas are created through the surgical connection of an artery and a vein in the patient's arm and can be used to perform HD on a long-term basis. The downside to using an AV fistula is that they take several months to mature before they can be used, so a temporary dialysis catheter often must be used first until the fistula is ready. An illustration of an AV fistula is depicted in Figure 20.17.

Type	Description
Hemodialysis	Artificial kidney (hemodialyzer) machine is used to filter the blood and remove excess fluid and toxins. These treatments typically occur three times a week.
Peritoneal dialysis (PD)	Catheter is placed into peritoneal space in the abdomen. Dialysate fluid is administered through catheter into peritoneal space, where it remains in place for several hours to filter out toxins. Dialysate is then drained from the catheter into a drainage bag. The benefit of PD is it can occur while the patient sleeps in the comfort of their home.
Continuous renal replacement therapy	Similar mechanism to HD but filtration occurs continuously, allowing for slower removal of fluid and toxins. This type of dialysis is indicated for patients who are hemodynamically unstable and unable to tolerate large amounts of fluid and waste removal over a short time.

TABLE 20.12 Types of Dialysis

Nursing Care of the Patient with ATN and CKD

While evaluating interventions and the effectiveness of treatment options, the nurse should also be constantly aware of the signs of complications of ATN or CKD. Complications can quickly lead to poor patient outcomes, and the nurse must be ready to address issues as they arise. The nurse should also be prepared to handle the patient's psychosocial and educational needs, and provide resources for the patient as needed.

Recognizing and Analyzing Cues

When caring for patients with kidney disorders, the nurse will assess for signs and symptoms indicating the kidney damage is progressing. One of the first signs may be a decreased urine output, highlighting the need for maintaining accurate intake and output documentation. Other signs to monitor for include alterations in laboratory values (e.g., elevated serum creatinine level or decreased GFR) and mental status changes, which are most likely related to electrolyte imbalances.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Caring for patients with kidney disorders is complex and involves a high level of attention to detail. The nurse must monitor the patient closely for signs and symptoms that indicate worsening kidney function. Without prompt intervention, kidney disorders can quickly become life-threatening, highlighting the importance of thorough assessments and attention to small changes in the patient's condition.

As part of the assessment process, the nurse will closely monitor fluid balance through accurate recording of intake and output as well as electrolyte balance with regular assessments of kidney values, including serum creatinine and BUN levels, and GFR. The nurse should monitor the patient closely for signs of fluid overload, such as edema, shortness of breath, or crackles in the lungs. In these situations, the nurse must act quickly, such as by elevating the head of the bed to alleviate the shortness of breath and improve the pulmonary congestion. The nurse will also alert

the provider so appropriate interventions may be started to restore optimal fluid balance and hemodynamics. Nurses caring for patients receiving dialysis must be alert to potential complications associated with this kind of treatment. Hypotension is one of the most common complications because dialysis often removes large amounts of fluid from the body at one time. With these quick fluid shifts, the patient may experience low blood pressure and associated symptoms such as lightheadedness or dizziness. For this reason, the nurse should consider withholding medications such as antihypertensives before dialysis treatment to prevent hypotension. The nurse should also monitor for cardiac dysrhythmias during and after dialysis that may result from the changes in electrolyte balance, so continuous telemetry monitoring is often indicated. Though most hospitals have specialized dialysis units and nurses, patients will often return to their initial room right after treatment, so all nurses need to be aware of these potential complications and be ready to intervene appropriately.

Evaluation of Nursing Care of the Patient with ATN and CKD

When evaluating care of a patient with ATN and CKD, the nurse must consider the effectiveness of any intervention and treatment options. The nurse should assess all aspects of the patient's well-being, including psychological and educational needs, as well as assessing for any signs of complications of ATN or CKD.

Evaluating Outcomes

The optimal patient outcome for patients with kidney disorders is restoration of kidney function to baseline level. With ATN, this is often possible if treatment is initiated early and complications do not occur. This would be indicated by normal serum creatinine and BUN levels, and GFR values, as well as a normal urine output. Patients with CKD have more advanced disease, so it is unlikely that their kidney function will return to baseline. With CKD, the goal would be to maintain as much function of the kidneys as possible, even if that means using therapies such as HD on a long-term basis. Other nursing goals include maintaining a baseline "dry" weight, reducing edema, and maintaining normal electrolyte balance. It is important for the nurse to evaluate how the patient is coping with their CKD, especially if they are receiving long-term HD. This disorder significantly affects everyday life, often requiring HD to be performed multiple times a week for several hours at a time. The nurse should provide these patients with the necessary social support and resources like support groups to help improve coping skills and life outlook.

READ THE ELECTRONIC HEALTH RECORD

Laboratory Profile of a Patient with Chronic Kidney Disease

Nurse's note: Patient arrived to ED at 0700 with complaints of nausea and vomiting and sudden weight gain. Patient reports a new onset of shortness of breath when walking.
0730 Vital signs and laboratory test results:
BP: 145/87 mm Hg
HR: 99
O_2: 92 percent
Laboratory test results: Serum creatinine (1.4 mg/dL), BUN (28 mg/dL), GFR (45 mL/min/1.73 m^2)
0930 Vital signs and laboratory test results:
BP: 155/92 mm Hg
HR: 110
O_2: 89 percent
Laboratory test results: Serum creatine (1.8 mg/dL), BUN (35 mg/dL), GFR (41 mL/min/1.73 m^2)

1. What condition does the nurse suspect and what interventions would the nurse anticipate?

Summary

20.1 Brief Review of Genitourinary and Reproductive Anatomy and Physiology

- The major organs of the male genitourinary system are the penis and testicles. Other structures in the genitourinary system are the bulbourethral glands and the prostate gland.
- Sperm production occurs in the testicles.
- The major organs of the female genitourinary system are the uterus and ovaries. Other structures are the vagina, urinary bladder, and urethra.
- Ovulation occurs when an egg is released from the ovary and generally occurs once a month.
- The menstrual cycle lasts approximately 28 days and is controlled by the release of follicle-stimulating hormone and luteinizing hormone.

20.2 Sexually Transmitted Infections

- STIs are transmitted through close sexual contact and are quite common worldwide. They can range from being completely asymptomatic to life-threatening, if not effectively treated. Other clinical manifestations include lesions, discharge, painful urination, or difficulty with conception.
- The diagnostics of STIs include urine analysis, culture, and sensitivity, and by visualization. Some patients may have delayed diagnosis because they are asymptomatic.
- Caring for patients with STIs is complex, and intervention and treatments will vary depending on the specific infection. Interventions center around counseling, education, and administering certain treatments.
- Nursing goals for the care of patients with STIs include thorough assessment and detection, early intervention, and effective treatment.
- Medical therapies can be pharmacological through antibiotics or antivirals, and surgical intervention may be required to remove lesions, if indicated.

20.3 Male-Specific Disorders of the Reproductive Tract

- Common disorders of the male reproductive system include testicular torsion, testicular cancer, and erectile dysfunction. These conditions surface from chronic comorbid disease, genetics, or acute injury.
- Erectile dysfunction is a condition in which the male individual cannot maintain a full erection of the penis for sexual intercourse. It is generally diagnosed based on the patient's subjective symptoms
- Testicular cancer is rare and is typically diagnosed in young men in their 20s and 30s. Signs and symptoms include a painless hard lump or sudden swelling in the testicle.
- Testicular torsion occurs when the spermatic cord, the supplier of blood to the testicles, becomes twisted. It is characterized by sudden severe pain in the testicles and scrotal swelling. It is a medical emergency.
- It is imperative that nurses and other health care professionals be able to recognize common symptoms, initiate appropriate interventions, and provide follow-up and education to ensure the best patient outcomes.
- Most male reproductive disorders are easily treated with medications or surgical procedures.
- The nurse needs to create an open environment for the patient while also focusing on proper diagnosis, intervention, and initiation of effective treatment options.

20.4 Disorders of the Prostate

- The prostate gland is an important part of the male reproductive system because it assists with the hydration and elimination of sperm for reproduction.
- The two main medical conditions that affect the prostate gland are benign prostatic hyperplasia (BPH) and prostate cancer. Both conditions can result in abnormal urinary elimination patterns and have a negative impact on mental and social health.
- Prostate cancer is diagnosed through digital rectal exams and a prostate-specific antigen blood test.
- BPH and prostate cancer are both quite common, especially in older men, but several treatment options exist, making them some of the most treatable conditions seen in the male population.
- Nursing care of patients with prostate disorders centers around improving urinary elimination patterns and providing psychosocial and educational support to the patient.

20.5 Female-Specific Disorders of the Reproductive Tract

- Disorders of the female reproductive system include PID, endometriosis, and uterine fibroids.
- Disorders of the female reproductive system can be difficult to diagnose because there are no specific diagnostic tests associated with any of the disorders. Diagnosis is typically symptom based.
- Nurses must manage all aspects of patient care, which can be complex and include the patient's physical, psychological, and educational needs. Nurses must also evaluate care and determine the effectiveness of treatments and interventions.
- Treatment options range from pain control with medications to eradication of the disorder with surgical procedures.
- These disorders can have a significant impact on female fertility and mental health, so it is important for nurses to provide these patients with supportive and empathetic care.

20.6 Disorders of the Breast

- Breast cancer remains a problematic disease affecting women, with higher incidence of mortality in the Black community. Risk factors include genetics, nulliparity, obesity, use of hormone replacement therapy, and excessive alcohol and nicotine use.
- The gold standard of diagnostics for breast cancer is the mammogram. Patients can perform self-breast exams to assess for presence of lumps.
- Nursing care of the patient with a breast disorder includes thorough history, scheduling mammograms, providing education about self-breast exam, and supporting the patient requiring surgical intervention, such as a mastectomy.
- Evaluation is tailored around monitoring the patient's response to therapy and goals of eradicating cancer. Nurses must also extend psychosocial support to the patient with breast cancer.
- Medical therapies include administration of chemotherapeutics, hormone therapy, and radiation. Surgical options may be a lumpectomy or a mastectomy.

20.7 Renal Function and Chronic Kidney Disease

- The kidneys play a vital role in many body functions, including fluid and electrolyte balance and blood pressure control. Kidney disease arises from damage to the nephron unit, impaired blood flow to the kidney, or outward flow from the urethra. Symptoms of kidney disease include fluid overload, oliguria, electrolyte disturbance, fatigue, and weight gain.
- Diagnosis of kidney disease encompasses noting the patient's subjective complaints while also monitoring BUN and creatinine levels, urine analysis, and results of certain diagnostic tests that can uncover kidney disease.
- Nurses caring for patients with kidney disease must assess for cues that further damage is occurring, through surveillance of laboratory tests and objective clinical findings. The responsibilities include monitoring hemodynamic stability, monitoring electrolytes, and specialty skills of dialysis when clinically appropriate.
- Evaluation of nursing care of patients with kidney disease includes monitoring improvement or worsening of renal studies, and normalization of fluid and hemodynamic status.
- Medical therapies vary in the treatment of kidney disease, from restoring perfusion to the renal unit through administration of fluids, treatment of hyperkalemia, to more invasive therapies such as dialysis.

Key Terms

arteriovenous fistula surgical joining of an artery and a vein in the arm to be used for performing hemodialysis on a long-term basis

chancre painless sore associated with a syphilis infection that develops where the organism entered the body

chronic kidney disease long-standing kidney dysfunction lasting longer than three months

continuous bladder irrigation (CBI) procedure in which a three-way urinary catheter is used to constantly irrigate the bladder and allow for adequate urinary drainage

cryptorchidism undescended testicles in an adult man

dialysis use of a dialyzer machine to filter the blood and remove toxins when kidney function is decreased

digital rectal exam (DRE) assessment conducted by a provider noting the size, shape, and regularity of a prostate

ectopic pregnancy pregnancy occurring somewhere in the reproductive tract other than the uterus (most often in a fallopian tube)
ejaculation release of sperm from the penis
endometriosis condition resulting in growth of uterine tissue in areas located outside of the uterus, resulting in severe pain and possible infertility
erectile dysfunction condition in which the male individual cannot maintain a full erection of the penis for sexual intercourse
genital vesicle painful, fluid-filled sac on the genitals
genitourinary system encompasses the organs of both the reproductive and urinary systems
hematuria blood in the urine
histology study of the microanatomy of cell and tissue types
infertility inability to conceive despite frequent and unprotected sexual intercourse for at least a year
lymphedema swelling that occurs to the affected limb from the same side of the breast cancer
menstruation process of a discharge of blood and other materials from the uterus through the vagina as part of the female menstrual cycle that lasts from puberty to menopause
nephropathy problems with kidney vasculature
nocturia increased urinary frequency experienced during nighttime hours
nulliparity having no children
oliguria decreased urine output (typically less than 30 mL/h)
orchiectomy surgical removal of the testicle(s)
ovulation release of an egg from one of the ovaries
pelvic inflammatory disease disease that surfaces in the pelvic unit after untreated STIs
prophylactic mastectomy complete removal of breast tissue prior to a cancer diagnosis
radiation proctitis inflammation of the rectum lining, which can result in diarrhea and rectal leakage
sexually transmitted infection (STI) infection that is transmitted through close sexual contact
spermatogenesis production of sperm in the testes
testicular torsion occurs when the spermatic cord, the supplier of blood to the testicles, becomes twisted
total mastectomy complete removal of breast tissue
urinary hesitancy difficulty starting urinary stream
uterine fibroid another name for uterine leiomyoma
uterine leiomyoma most common benign tumor affecting women

Assessments

Review Questions

1. What part of the male reproductive system is responsible for the production of male sex hormones?
   a. penis
   b. testes
   c. urethra
   d. epididymis

2. On approximately what day of the menstrual cycle does ovulation, or release of an egg from the ovary, occur?
   a. day 1
   b. day 7
   c. day 14
   d. day 28

3. The emergency department nurse received a handoff report on a patient newly diagnosed with syphilis. What is an example of an assessment finding the nurse would expect during the physical exam?
   a. cold sores around the mouth
   b. genital warts
   c. rash on the hands
   d. painful urination

4. What schedule is endorsed as the current guideline for screening for HPV?
   a. annually
   b. every 2 years
   c. every 3 years
   d. every 4 years

5. The nurse is caring for a patient in the urgent care clinic who was just diagnosed with HSV infection. What treatment would the nurse anticipate for the patient?
   a. antiviral medications
   b. intramuscular antibiotics
   c. cryotherapy
   d. colposcopy procedure

6. What finding would indicate to the nurse that treatment for HPV was effective?
   a. Rash on the hands is gone.
   b. Genital warts or blisters have cleared up.
   c. Patient is afebrile.
   d. Patient reports no pain with urination.

7. The nurse is caring for a patient recently diagnosed with testicular cancer. What component of the patient's medical history would the nurse note as a risk factor for this type of cancer?
   a. substance misuse
   b. HIV infection
   c. hypertension
   d. low levels of testosterone

8. What condition of the male reproductive system would the nurse identify as the most emergent?
   a. testicular cancer
   b. erectile dysfunction
   c. testicular torsion
   d. benign prostatic hyperplasia

9. What assessment finding would the nurse anticipate when caring for a patient diagnosed with testicular cancer?
   a. abdominal pain
   b. hard lump in the testicle
   c. nausea and vomiting
   d. decreased sex drive

10. The nurse is caring for a male patient with elevated levels of lactate dehydrogenase. What condition would the nurse suspect?
   a. testicular cancer
   b. erectile dysfunction
   c. testicular torsion
   d. testicular cyst

11. The nurse is caring for a patient with BPH who is prescribed tamsulosin (Flomax). What is an example of a statement the nurse would in the discharge teaching about this medication?
   a. "This medication may cause you to have issues maintaining an erection."
   b. "Be mindful of standing up too quickly while taking this medication."
   c. "A headache should be reported to your provider right away."
   d. "Nasal congestion is a common side effect of this medication."

12. What statement reflects the pathophysiologic cause of endometriosis?
   a. cancer of the endometrium
   b. abnormal uterine tissue growth
   c. benign tumor growths in the uterus
   d. infection that results in tissue scarring

13. What diagnostic tests would the nurse anticipate for a female patient diagnosed with PID? Select all that apply.
   a. pregnancy test
   b. positive gonorrhea swab
   c. a reduced hematocrit
   d. elevated white blood cell count
   e. history of an STI

14. What treatment would the nurse anticipate for a female patient diagnosed with PID?
   a. antibiotics
   b. oral contraceptive pills
   c. endometrial ablation
   d. analgesic medications

15. The nurse is providing education to a patient about the risks associated with developing breast cancer. What risk factor would the nurse include in the teaching?
   a. young age
   b. male sex
   c. early menopause
   d. having no children

16. What symptom is often the earliest physical sign of breast cancer?
   a. lump in breast
   b. skin dimpling
   c. skin color changes
   d. nipple discharge

17. What is an example of a statement that would indicate to the nurse the patient understands modifiable risk factors for breast cancer?
   a. “My mom didn’t have breast cancer, so I am okay.”
   b. “I will reduce my alcohol intake.”
   c. “My sister had breast cancer so I must have mammograms.”
   d. “I will take a daily aspirin.”

18. What is a risk factor for the development of kidney disease?
   a. diabetes insipidus
   b. young age
   c. White race
   d. pyelonephritis

19. What assessment finding would the nurse anticipate for a patient diagnosed with CKD?
   a. increased urination
   b. weight loss
   c. hypokalemia
   d. crackles in lungs

20. What laboratory trend would indicate chronic kidney disease?

a. increased glomerular filtration rate
b. decreased glomerular filtration rate
c. decreased blood urea nitrogen
d. increased sodium

21. What pharmacological therapy can the nurse anticipate for a patient with AKI and hyperkalemia?
a. rapid-acting insulin
b. regular insulin
c. Sevelamer
d. sodium bicarbonate

22. A patient with CKD has been undergoing peritoneal dialysis for the past month. What finding would indicate the patient is having a good response to treatment?
a. achieving a weight within 1 lb. of their dry weight
b. crackles in the lungs
c. 2+ lower extremity edema
d. creatinine 2.0 ng/mL

Check Your Understanding Questions

1. Describe typical medical therapies prescribed for STIs.

2. What treatment options are available to patients with erectile dysfunction? What are some key patient education points about each of the treatment options?

3. You are caring for a patient scheduled for a TURP. How would you explain this procedure to the patient so they understand what to expect?

4. In a review of the patient's blood test results during a routine wellness exam, the nurse notices the patient's PSA value is 2.2 ng/mL. What would the nurse anticipate for the patient?

5. What are some cues the nurse would anticipate for a menstrual disorder?

6. What statements made by the patient would cue the nurse the treatment was effective for management of painful periods?

7. The nurse is caring for a patient scheduled for a fine needle aspiration biopsy of the breast. How would you describe this procedure to the patient? How might you assess that the patient understands the information you provided?

8. What are the major functions of the kidneys and what can happen if these functions are affected by the development of kidney disease?

9. Which clinical assessment findings would indicate to the nurse the patient's renal failure is worsening?

Reflection Questions

1. You are caring for a patient who was assigned female at birth. The patient tells you that they identify as a man. What steps would you take to ensure you provide culturally sensitive and nonjudgmental care?

2. Being diagnosed with an STI can be frightening and cause severe anxiety. What are some effective communication strategies you could use that might help alleviate a patient's fears and anxiety when telling them they are positive for an STI?

3. How would a nurse provide education to a group of teenagers about the spread of STIs?

4. What are some communication strategies the nurse could use to promote a comfortable and safe environment when caring for patients with male reproductive system disorders?

5. What are some examples of how a nurse would evaluate the nursing care delivered to a patient who received teaching on performing a testicular self-exam?

6. A nurse preceptor is teaching a new graduate nurse about CBI. What are some things the nurse would want to evaluate for effective teaching?
7. A patient has called the clinical upset the genetic marker came back positive for *BRCA1* mutation. How would the nurse engage in therapeutic communication to support the patient?

What Should the Nurse Do?

Sarah, a 25-year-old female, presents to the clinic reporting symptoms of lower abdominal pain, dysuria, and vaginal discharge. She discloses a recent change in sexual partners and inconsistent condom use. Sarah's medical history indicates no known allergies, but she mentions a previous diagnosis of chlamydia treated six months ago. Current vital signs reveal a slightly elevated temperature of 99.8°F. Diagnostics include positive nucleic acid amplification test for *Chlamydia* and *N. gonorrhoeae*.

1. What specific verbal and nonverbal cues did Sarah provide during the initial assessment that indicated the possibility of a recurrent sexually transmitted infection?
2. In addition to antibiotic therapy, what educational interventions would you recommend to Sarah regarding safe sex practices, and how would you tailor these interventions to her individual needs?

Mark, a 45-year-old male, presents to the emergency department with a chief complaint of ED. He reports recent onset of difficulty achieving and maintaining an erection, causing distress in his intimate relationship. Mark has a history of hypertension and is currently taking antihypertensive medication. Vital signs reveal blood pressure within the normal range, but Mark appears anxious and visibly uncomfortable discussing his symptoms. He mentions occasional chest discomfort during exertion but has not sought medical attention for it.

3. Given Mark's history of hypertension and occasional chest discomfort, how would you further analyze these cardiovascular cues to understand their potential impact on his erectile function?
4. As a nurse, what specific actions would you take to facilitate further diagnostic evaluations for Mark's potential cardiovascular risks associated with ED?

David, a 60-year-old male, presents to the urology clinic with complaints of urinary frequency, urgency, and difficulty initiating a stream. He reports occasional nocturia and a sensation of incomplete emptying of the bladder. David's medical history includes hypertension and a family history of prostate cancer. Vital signs are within normal limits, but a DRE reveals an enlarged and firm prostate. A PSA test is ordered, and the result indicates a significantly elevated PSA level.

5. What specific cues in David's case initially prompted you to consider the possibility of a prostate disorder, and how did you differentiate these cues from common age-related urinary changes?
6. As a nurse, what specific actions would you take to ensure David's understanding of the diagnostic procedures and support him through the potential diagnosis of a prostate disorder?

Emily, a 35-year-old female, presents to the breast health clinic with a chief complaint of a palpable lump in her left breast. She reports discovering the lump during a routine self-breast examination. Emily has no prior history of breast issues, and her family history is negative for breast cancer. On further inquiry, Emily mentions occasional breast tenderness and notes changes in the appearance of her left nipple. Her vital signs are stable, and a physical examination reveals a firm, nonmobile mass in the upper outer quadrant of the left breast, with nipple retraction.

7. What specific cues in Emily's case initially prompted you to consider the possibility of a breast disorder, and how did you differentiate these cues from normal breast changes?
8. Given Emily's age, medical history, and symptoms, what potential risk factors for breast disorders should be considered in the analysis of her case?

Competency-Based Assessments

1. In what ways might an understanding of reproductive anatomy and physiology influence the nursing care of a patient undergoing fertility treatment?
2. How do the anatomy and physiology of the male and female reproductive systems intersect during fertilization and early pregnancy?
3. Identify three modifiable and three nonmodifiable risk factors for testicular cancer.
4. As a clinical nurse, develop a nursing care plan for a patient diagnosed with ED. Include three priority nursing

interventions.

5. Develop a nursing care plan for a patient with uterine fibroids. Include three priority nursing interventions.
6. As a nurse, how would you prioritize nursing interventions for a patient with concurrent endometriosis and fertility concerns, considering the potential impact on the patient's physical and emotional well-being?

CHAPTER 21

Endocrine System and Endocrine System Disorders

FIGURE 21.1 The endocrine system, which includes the pituitary gland, ovaries, testes, thyroid, parathyroid, and adrenals, and their hormones coordinate and control growth, metabolism, temperature regulation, the stress response, reproduction, and many other functions. (credit: Airman 1st Class Rhett Isbell/Little Rock Air Force Base, Public Domain)

CHAPTER OUTLINE

INTRODUCTION The endocrine system is a complex network of cells, tissues, glands, and organs that can be intimidating to understand. While the organs of the endocrine system may be small (pituitary gland, ovaries, testes, thyroid, parathyroid, and adrenals), their contribution to homeostasis is huge. The endocrine system works behind the scenes to help regulate common body functions, and without a healthy endocrine system, problems that affect metabolism, puberty, energy, weight, stress, bone strength, and fertility can occur. This chapter provides an overview of the endocrine system and common endocrine disorders encountered in clinical care settings, and applies nursing concepts to plan nursing care for patients with endocrine disorders.

21.1 Review of Endocrine Anatomy and Physiology

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Explain the anatomy of the endocrine system
- Discuss common endocrine hormones and their functions
- Summarize the steps of a targeted endocrine system assessment

The endocrine system is responsible for regulating major biological processes in the body, such as digestion, metabolism, and the stress response, but is often overlooked. It is similar to the nervous system because it can send signals throughout the body, but instead of neurotransmitters, it releases hormones as the mode of communication. Disruptions to this communication process can cause major problems with the biologic functions of the body. As a nurse, it is important to have a basic understanding of the endocrine system in order to provide quality patient care.

Overview of the Endocrine System

The **endocrine system** consists of cells, tissues, and organs that secrete hormones as a primary or secondary function. Among the most important of these structures are the endocrine glands, including the pituitary, thyroid, parathyroid, adrenal, and pineal glands (Figure 21.2). The primary function of these ductless glands is to secrete their hormones directly into the surrounding fluid. The interstitial fluid and the blood vessels then transport the hormones throughout the body.

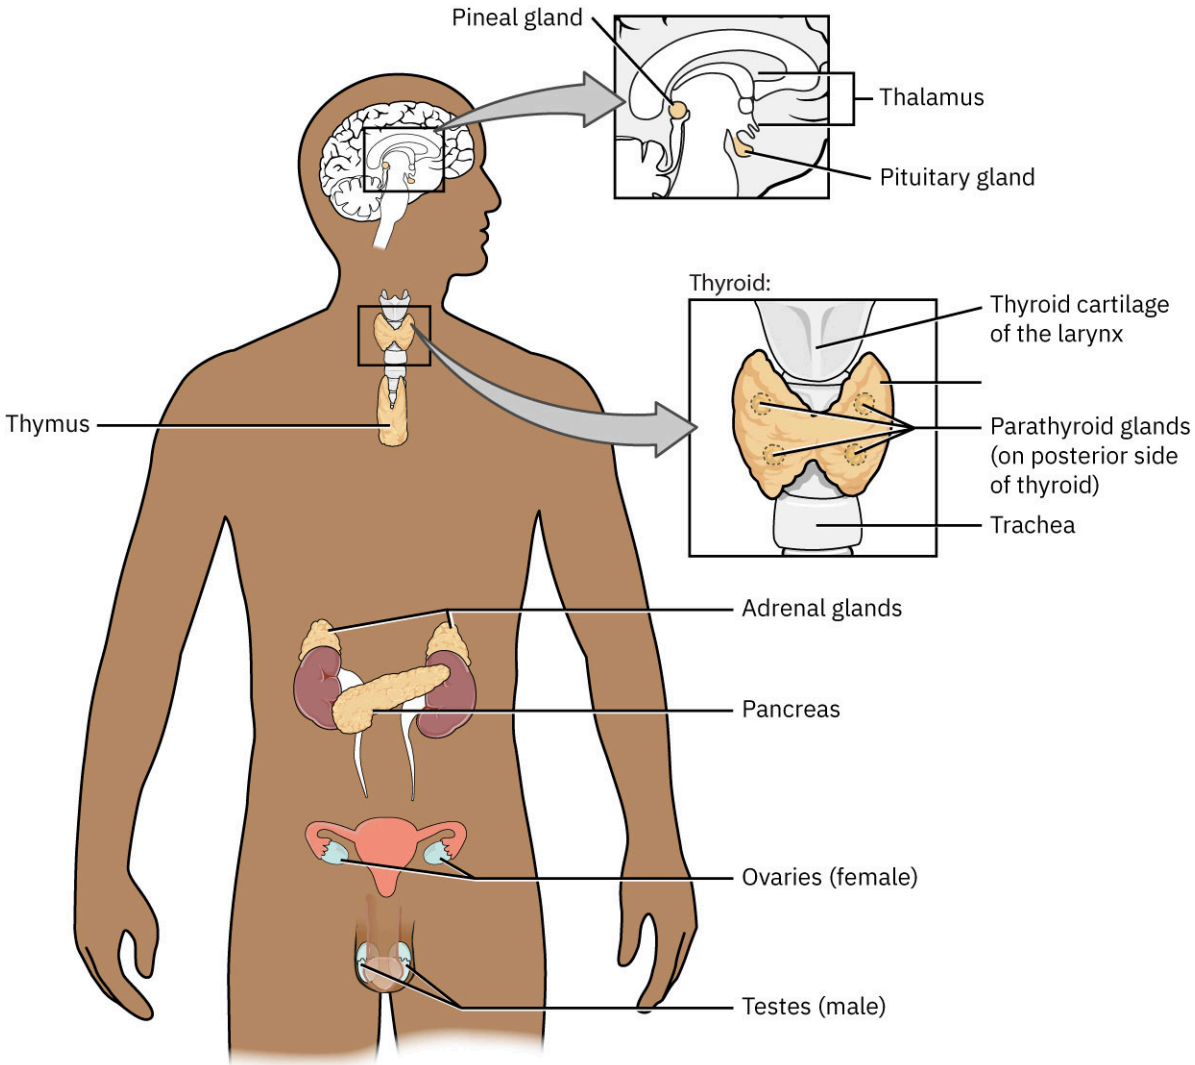

FIGURE 21.2 Endocrine glands and cells are located throughout the body and play an important role in homeostasis. (modification of work

from *Anatomy and Physiology* 2e. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Some glands in the endocrine system have both endocrine and non-endocrine functions. For example, the pancreas contains cells that function in digestion as well as cells that secrete the hormones insulin and glucagon, which regulate blood glucose levels. The hypothalamus, thymus, heart, kidneys, stomach, small intestine, liver, skin, ovaries, and testes are other organs that contain cells with endocrine function. Adipose tissue (body fat) has long been known for producing hormones that help regulate various bodily functions. Recent research has expanded our understanding by revealing that bone tissue also has endocrine functions, meaning it can produce hormones that influence metabolism and other physiological processes (Newman, 2024).

The ductless endocrine glands are not to be confused with the body's **exocrine system**, whose glands release their secretions through tubes called ducts. Examples of exocrine glands include the sebaceous and sweat glands of the skin. The pancreas also has an exocrine function: most of its cells secrete pancreatic juice through the pancreatic and accessory ducts to the lumen of the small intestine.

Neural and Endocrine Signaling

The nervous system uses two types of intercellular communication—electrical and chemical signaling—either by the direct action of an electrical potential, or in the latter case, through the action of chemical neurotransmitters such as serotonin or norepinephrine. Neurotransmitters act locally and rapidly. When an electrical signal in the form of an action potential arrives at the synaptic terminal, they diffuse across the synaptic cleft (the gap between a sending neuron and a receiving neuron or muscle cell). Once the neurotransmitters interact (bind) with receptors on the receiving (post-synaptic) cell, the receptor stimulation is transduced into a response such as continued electrical signaling or modification of cellular response. The target cell responds within milliseconds of receiving the chemical "message;" this response then ceases very quickly once the neural signaling ends. In this way, neural communication enables body functions that involve quick, brief actions such as movement, sensation, and cognition.

In contrast, the endocrine system uses just one method of communication: chemical signaling. These signals are sent by the endocrine organs, which secrete chemicals—the hormones—into the extracellular fluid. Hormones are transported primarily via the bloodstream throughout the body, where they bind to receptors on target cells, inducing a characteristic response. As a result, this process, known as **endocrine signaling**, requires more time than neural signaling to prompt a response in target cells, though the precise amount of time varies with different hormones. For example, the hormones released when you are confronted with a dangerous or frightening situation, called the fight-or-flight response, occur by the release of adrenal hormones—epinephrine and norepinephrine—within seconds. In contrast, it may take up to 48 hours for target cells to respond to certain reproductive hormones.

In addition, endocrine signaling is typically less specific than neural signaling. The same hormone may play a role in a variety of different physiological processes depending on the target cells involved. For example, the hormone oxytocin promotes uterine contractions in people in labor. It is also important in breastfeeding and may be involved in the sexual response and in feelings of emotional attachment in humans.

In general, the nervous system involves quick responses to rapid changes in the external environment, and the endocrine system is usually slower acting—taking care of the internal environment of the body, maintaining homeostasis, and controlling reproduction. So how does the fight-or-flight response happen so quickly if hormones are usually slower acting? It is because the two systems are connected. It is the fast action of the nervous system in response to the danger in the environment that stimulates the **adrenal glands** to secrete their hormones. As a result, the nervous system can cause rapid endocrine responses to keep up with sudden changes in both the external and internal environments when necessary.

Hormones

A chemical substance called a **hormone** travels throughout the body in the bloodstream and affects the activity only of their target cells: that is, cells with receptors for that particular hormone. Once a hormone binds to a receptor, a chain of events is initiated that leads to the target cell's response. Hormones play a critical role in the regulation of physiological processes because of the target cell responses they regulate. These responses contribute to reproduction, growth and development of body tissues, metabolism, fluid and electrolyte balance, sleep, and many

other body functions. The major hormones of the human body and their effects are identified in (Table 21.1).

Endocrine Gland	Associated Hormones	Effect
Pituitary (anterior)	Growth hormone (GH)	Promotes growth of body tissues
	Prolactin (PRL)	Promotes milk production
	Thyroid-stimulating hormone (TSH)	Stimulates thyroid hormone release
	Adrenocorticotropic hormone (ACTH)	Stimulates hormone release by adrenal cortex
	Follicle-stimulating hormone (FSH)	Stimulates gamete production
	Luteinizing hormone (LH)	Stimulates androgen production by gonads
Pituitary (posterior)	Antidiuretic hormone (ADH)	Stimulates water reabsorption by kidneys
	Oxytocin	Stimulates uterine contractions during childbirth
Thyroid	Thyroxine (T4), triiodothyronine (T3)	Stimulate basal metabolic rate
	Calcitonin	Reduces calcium (Ca^{2+}) levels in the blood
Parathyroid	Parathyroid hormone (PTH)	Increases calcium (Ca^{2+}) levels in the blood
Adrenal (cortex)	Cortisol, corticosterone, cortisone	Increase blood glucose levels
Adrenal (medulla)	Epinephrine, norepinephrine	Stimulate fight-or-flight response
Pineal	Melatonin	Regulates sleep cycles
Pancreas	Insulin	Reduces blood glucose levels
	Glucagon	Increases blood glucose levels

TABLE 21.1 Endocrine Glands and Their Major Hormones

Endocrine Gland	Associated Hormones	Effect
Testes	Testosterone	Stimulates development of male sex characteristics including a deeper voice, increased muscle mass, development of body hair, and sperm production
Ovaries	Estrogen, progesterone	Stimulate development of female sex characteristics, including the development of adipose and breast tissue, and prepare the body for childbirth

TABLE 21.1 Endocrine Glands and Their Major Hormones

Hormones are divided into two major groups based on their chemical structure. Hormones derived from amino acids include amines, peptides, and proteins. Hormones derived from lipids include steroids. These chemical groups affect a hormone's distribution, the type of receptors it binds to, and other aspects of its function.

LINK TO LEARNING

Watch this video to gain further understanding about endocrine glands and their functions (https://openstax.org/r/77EndocrneGlnds) as an NCLEX review.

Pathways of Hormone Action

The message a hormone sends is received by a **hormone receptor**, a protein located either inside the cell or within the cell membrane. The receptor processes the message by initiating other signaling events or cellular mechanisms that result in the target cell's response. Hormone receptors recognize molecules with specific shapes and side groups and respond only to those hormones that are recognized. For example, cells contain insulin receptors and glucose channels. A cell's glucose channel will not open to accept glucose until insulin unlocks the insulin receptor, and only insulin will "fit" into the insulin receptor. The process is similar to using a specific key to unlock a door before opening it (Figure 21.3).

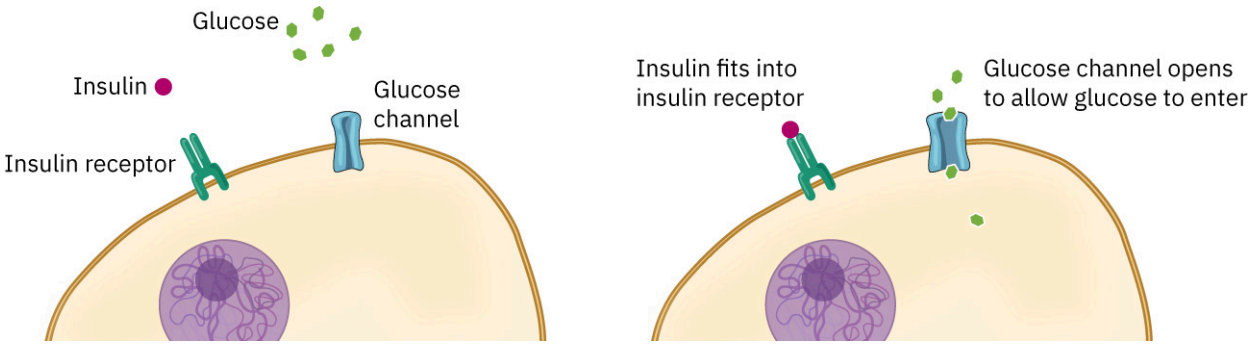

FIGURE 21.3 Insulin regulates the body's metabolism and is the "key" that "unlocks" a cell's glucose channel. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Once the target cell receives the hormone signal, it can respond in a variety of ways. The response may include the stimulation of protein synthesis, activation or deactivation of enzymes, alteration in the permeability of the cell membrane, altered rates of mitosis and cell growth, or stimulation of the secretion of products. A single hormone may be capable of inducing different responses in a given cell. Moreover, the same type of receptor may be located on cells in different body tissues and trigger somewhat different responses in each location. Thus, the response triggered by a hormone depends not only on the hormone but also on the target cell.

Regulation of Hormone Secretion

To prevent abnormal hormone levels and a potential disease state, hormone levels must be tightly controlled. The body maintains this control by balancing hormone production and degradation, or breakdown. Feedback loops govern the initiation and maintenance of most hormone secretion in response to various stimuli.

Role of Feedback Loops

A **positive feedback** loop is characterized by the release of additional hormone in response to an original hormone release. For example, the release of oxytocin during childbirth is a positive feedback loop. The initial release of oxytocin begins to signal the uterine muscles to contract, which pushes the fetus toward the cervix, causing it to stretch. This, in turn, signals the pituitary gland to release more oxytocin, causing labor contractions to intensify. The release of oxytocin decreases after the birth of the child.

The more common method of hormone regulation is the **negative feedback loop**. A negative feedback loop is characterized by the inhibition of further secretion of a hormone in response to adequate levels of that hormone. This allows blood levels of the hormone to be regulated within a narrow range. An example of a negative feedback loop is the release of glucocorticoid hormones from the adrenal glands, as directed by the hypothalamus and pituitary gland. As glucocorticoid concentrations in the blood rise, the hypothalamus and pituitary gland reduce their signaling to the adrenal glands, preventing additional glucocorticoid secretion (Figure 21.4).

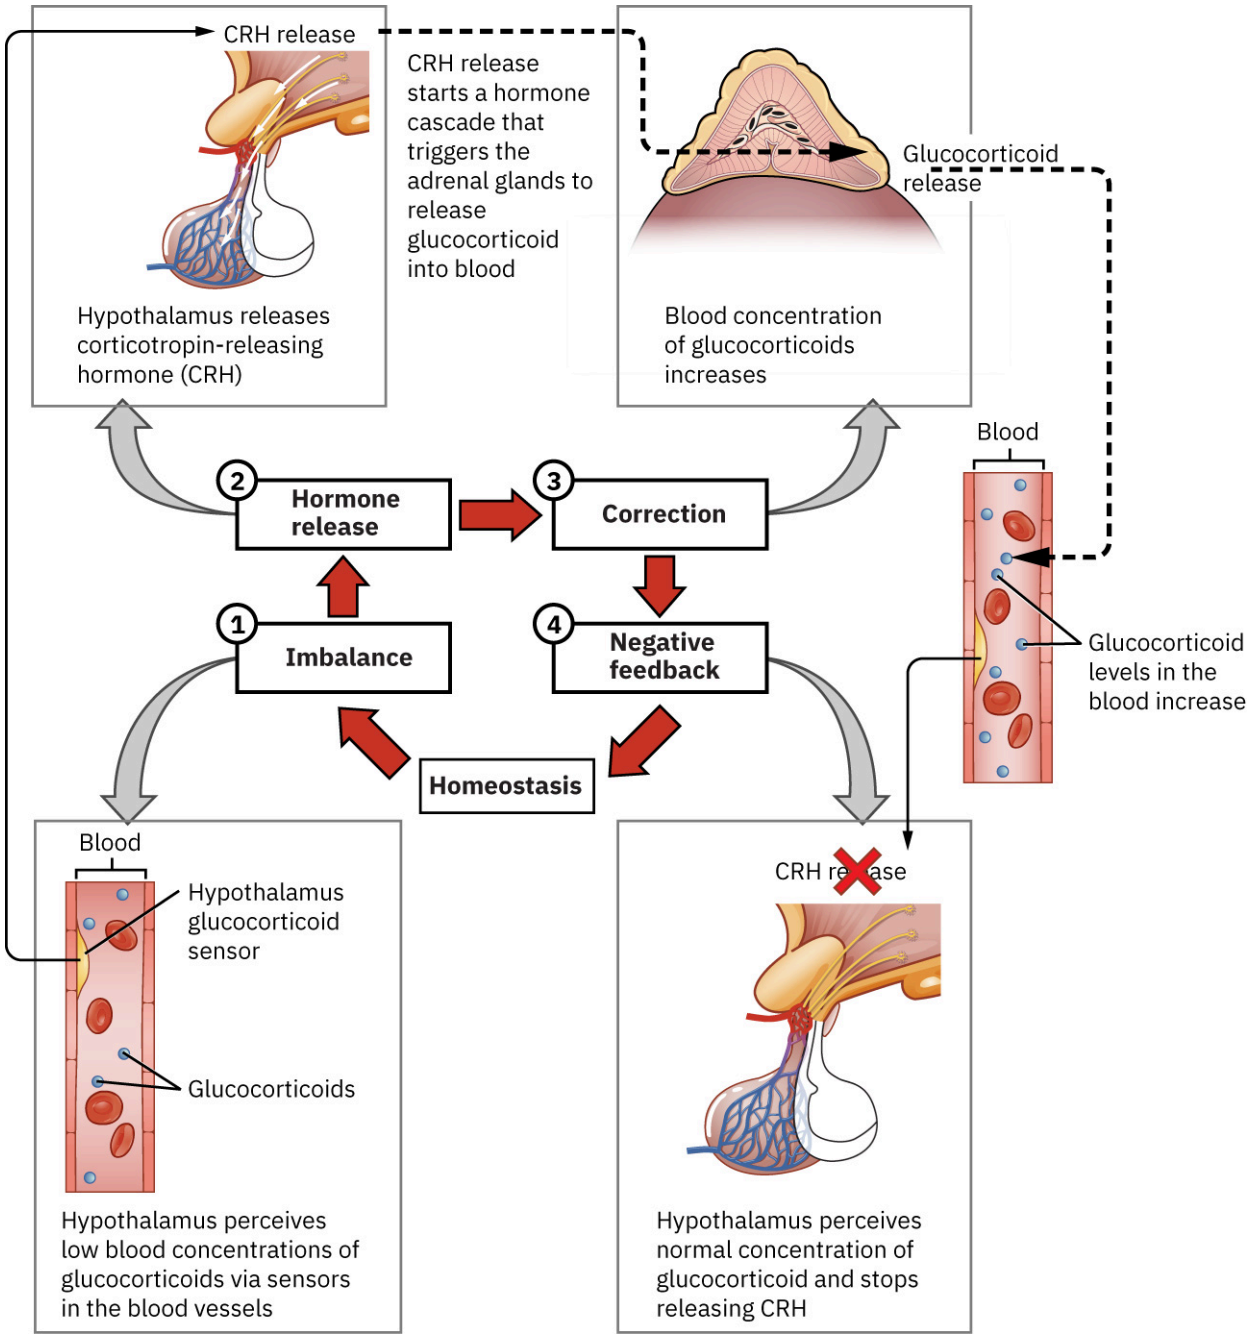

FIGURE 21.4 The release of adrenal glucocorticoids is stimulated by the release of hormones from the hypothalamus and pituitary gland.

This signaling is inhibited when glucocorticoid levels become elevated, a state that sends negative signals to the pituitary gland and hypothalamus. (modification of work from *Anatomy and Physiology* 2e. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Role of Endocrine Gland Stimuli

Reflexes triggered by both chemical and neural stimuli control endocrine activity. These reflexes may be simple, involving only one hormone response, or they may be more complex and involve many hormones, as is the case with the hypothalamic control of various anterior pituitary-controlled hormones.

Changes in blood levels of nonhormone chemicals, known as **humoral stimuli**, such as nutrients or ions, cause the release or inhibition of a hormone to, in turn, maintain homeostasis. For example, osmoreceptors in the hypothalamus detect changes in blood osmolarity (the concentration of solutes in the blood plasma). If blood osmolarity is too high, the blood is not diluted enough, so osmoreceptors signal the hypothalamus to release antidiuretic hormone (ADH). The hormone causes the kidneys to reabsorb more water and reduce the volume of urine produced. This reabsorption causes a reduction of the osmolarity of the blood, diluting the blood to the appropriate level. The regulation of blood glucose is another example. High levels of blood glucose cause the release of insulin from the pancreas, which increases glucose uptake by cells and liver storage of glucose as glycogen.

An endocrine gland may also secrete a hormone in response to the presence of another hormone produced by a different endocrine gland. Such hormonal stimuli often involve the hypothalamus, which produces releasing and inhibiting hormones that control the secretion of a variety of pituitary hormones.

In addition to these chemical signals, hormones can also be released in response to **neural stimuli**. A common example of neural stimuli is the activation of the fight-or-flight response by the sympathetic nervous system. When an individual perceives danger, sympathetic neurons signal the adrenal glands to secrete norepinephrine and epinephrine. The two hormones dilate blood vessels, increase the heart and respiratory rate, and suppress the digestive and immune systems. These responses boost the body's transport of oxygen to the brain and muscles, thereby improving the body's ability to fight the threat or flee from it.

Assessment of the Endocrine System

Clinical assessment of the endocrine system is a process that incorporates a patient history, physical examination, and diagnostic testing. The metabolic functions of endocrine glands can be monitored through the evaluation of the hormones they release.

Patient History

A patient history can provide targeted subjective data to the nurse and provider to evaluate the endocrine health of the patient. Table 21.2 lists questions that might be included in such a history.

Category	Focused Questions
Current health	What are your current goals for your health? Are there any other issues affecting your current health or the ability to complete your daily activities? If yes, tell me more. Are there any symptoms such as unexplained weight changes, fatigue, or changes in mood that concern you? If yes, please describe them in detail.
Medications	What are your current medications, including prescriptions, over-the-counter medications, vitamins, and herbal supplements, and why are you taking them? (Note: This is to establish the patient's understanding of their medications.) Do you take your medications as prescribed? (Note: If the response is "no" or "sometimes," follow up with an open-ended question such as, "Tell me more about the reasons for not taking the medications as prescribed.")

TABLE 21.2 Sample Focused Questions for Current and Past Health History

Category	Focused Questions
Allergies	Do you have any allergies to medications, food, latex, or other items? (Note: If yes, ask the patient to describe the allergic reaction.)
Childhood illnesses	Tell me about any significant childhood illnesses that you had. Do you recall what childhood vaccines you received? When did these illnesses occur? Were you hospitalized? Did you experience any complications?
Family health history	Tell me about the health of your blood relatives. Does anyone have diseases like cancer, thyroid problems, heart problems, diabetes, or respiratory problems? Have any of your blood relatives died? If so, do you know the cause of death? What age did they die?
Chronic illnesses	Tell me about any chronic illnesses you currently have or have experienced (such as cancer, cardiac or respiratory issues, diabetes, or arthritis). When were you diagnosed? Do you see a specialist for this chronic illness? If so, what is their name and location? How is this condition currently being treated? How has the chronic illness affected you? How do you cope with it? Have you experienced any complications or disability from this chronic illness? If so, tell me more.
Acute illnesses, surgeries, accidents, or injuries	Tell me about any acute illnesses or surgeries that you have experienced. Have you had any accidents or injuries? Did you experience any complications?
Reproductive health	For females: When was your last menstrual period? Have you ever been pregnant? Are you pregnant now, or is there any chance of being pregnant now? Tell me about your pregnancies. Were there any issues or complications? For females of age: At what age did you first experience symptoms of menopause? Perimenopause? For males: Have you ever experienced any testicular disorders? Impotence or sexual dysfunction?

TABLE 21.2 Sample Focused Questions for Current and Past Health History

Physical Examination

Endocrine conditions can be nonspecific and varied, and they can affect many body systems. Apart from thyroid disease, diabetes mellitus, and some reproductive disorders, they are also relatively uncommon. Table 21.3 lists possible medical diagnoses of common clinical features seen in endocrine conditions (Crafa et al., 2022).

Sign or Symptom	Possible Medical Diagnoses
Altered facial appearance	Cushing's syndrome, polycystic ovary syndrome (PCOS), acromegaly, hypothyroidism, dwarfism
Bone fragility	Hyperthyroidism, hypogonadism, Cushing's syndrome

TABLE 21.3 Common Clinical Features in Endocrine Conditions

Sign or Symptom	Possible Medical Diagnoses
Delayed puberty	Hypothyroidism, hypopituitarism, primary gonadal failure, polycystic ovary syndrome
Diffuse neck swelling	Hashimoto's thyroiditis, simple goiter, Graves' disease
Erectile dysfunction	Diabetes mellitus, primary or secondary hypogonadism, non-endocrine systemic disease
Excessive thirst	Conn's syndrome, diabetes mellitus or insipidus, hyperparathyroidism
Flushing	Carcinoid syndrome, hypogonadism, perimenopause, menopause
Hirsutism (excessive hair growth)	PCOS, Cushing's syndrome, congenital adrenal hyperplasia
Menstrual disturbance	Thyroid dysfunction, PCOS, hyperprolactinemia
Muscle weakness	Osteomalacia (soft bones), hyperthyroidism, hyperparathyroidism, Cushing's syndrome
Resistant hypertension	Renal artery stenosis, acromegaly, Cushing's syndrome, Conn's syndrome, phaeochromocytoma
Skin pigmentation changes (e.g., hyperpigmentation, bruising, pigmented spots)	Lentiginosis, primary adrenal insufficiency, Cushing's syndrome, Addison's disease, diabetes mellitus type I
Sweating	Acromegaly, hyperthyroidism, hypogonadism, phaeochromocytoma
Weight gain	Cushing's syndrome, hypothyroidism, PCOS
Weight loss	Adrenal insufficiency, hyperthyroidism, diabetes mellitus

TABLE 21.3 Common Clinical Features in Endocrine Conditions

LINK TO LEARNING

Watch this video to review common endocrine disorders (https://openstax.org/r/77EndcrnDisOrd) and their common clinical features.

When completing a physical assessment, inspect the patient's neck for asymmetry, redness, swelling, surgical scars, or masses by having the patient turn their head slowly from side to side. Ask the patient to take a sip of water, tilt their head back to elongate the neck, and swallow. Watch for any lumps or protrusions as the patient swallows (Alomari, n.d.). Movement of the neck should be uniform and symmetrical when swallowing.

Palpate the neck for symmetry, noting any masses. Standing behind the patient, find and palpate the thyroid gland, using a circular motion, and note any enlargement, asymmetry, or masses. Palpate for any tracheal deviation or cervical lymph nodes. Auscultate each lobe of the thyroid for any bruits.

LINK TO LEARNING

Click here to watch how to perform a full clinical examination of the thyroid gland (https://openstax.org/r/77ThyroidExam) from introduction through palpation of the thyroid.

Have the patient extend their arms, place their palms up, and assess for any minor tremors or sweaty palms. Check the patients' eyes to see if they bulge, a condition known as **exophthalmos** (Figure 21.5).

FIGURE 21.5 Exophthalmos is a clinical sign of an endocrine disorder. (credit: "Proptosis and lid retraction from Graves' Disease" by Jonathan Trobe, M.D., University of Michigan Kellogg Eye Center/Wikipedia, CC BY 3.0)

Diagnostic Testing

Diagnostic testing is targeted based on the findings of a history and physical exam. Serum hormone levels can assess under- or over-activity. Blood glucose and hemoglobin A1C (HbA1c) levels can determine diabetes mellitus. Urinalysis can evaluate for diabetes mellitus, urine electrolytes, and kidney damage. Imaging may be performed to visualize the physical appearance of different endocrine glands and organs and evaluate them for tumors. Fine needle biopsy may also be performed to assess any nodules for malignancies. Table 21.4 lists common diagnostic tests for endocrine assessment.

Diagnostic Test	Indication/Significance
Laboratory Testing	
Urinalysis	Glycosuria (excess glucose in the urine) or proteinuria may indicate diabetes mellitus and/or kidney disease
Blood glucose	High levels indicate diabetes mellitus
Serum calcium	High levels indicate hyperparathyroidism Low levels indicate hypoparathyroidism
Serum cortisol	Low levels indicate hypoadrenalism High levels indicate Cushing's disease
Gonadotrophins	High levels indicate primary hypogonadism
Imaging	
CT scan	View the adrenal glands and pancreas

TABLE 21.4 Targeted Diagnostic Testing in Endocrine Assessment

Diagnostic Test	Indication/Significance
MRI	View the pancreas and pituitary gland
Ultrasound	View the thyroid, parathyroid, testes, and ovaries
Positron emission tomography (PET) scan	Evaluate thyroid and neuroendocrine tumors
Radionuclide imaging	Uses an isotope to better assess endocrine function, circulation, and tumors
Invasive Procedures	
Inferior petrosal sinus sampling	Evaluate for a pituitary tumor by sampling adrenocorticotropic hormone (ACTH) from the veins that drain from the pituitary gland
Fine needle aspiration biopsy	Evaluate the cytology of a thyroid or adrenal nodule

TABLE 21.4 Targeted Diagnostic Testing in Endocrine Assessment

21.2 Diabetes Mellitus

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations for diabetes mellitus
- Describe the diagnostics and laboratory values for diabetes mellitus
- Apply nursing concepts and plan associated nursing care for patients with diabetes mellitus
- Evaluate the efficacy of nursing care for diabetes mellitus
- Describe the medical therapies that apply to the care of patients with diabetes mellitus

Pathophysiology of Diabetes Mellitus

The endocrine function of the pancreas is to produce hormones that help to regulate blood sugar levels and appetite. The two main hormones produced by the pancreas are insulin and glucagon. Produced by beta cells in the pancreas, **insulin** helps cells absorb glucose for energy, lowering the body's blood sugar levels, and stimulates protein synthesis and the storage of free fatty acid in adipose tissue. Released by alpha cells of the pancreas when the body's blood glucose is too low, **glucagon** triggers the liver to release stored glucose to raise glucose levels.

Characterized by inappropriately levels of high blood glucose, **diabetes mellitus (DM)** is a disease caused by an imbalance of insulin and glucagon. The most common types of DM are **Type 1 diabetes mellitus (T1DM)**, **Type 2 diabetes mellitus (T2DM)**, and **gestational diabetes (GDM)** (ADA, 2024a). The pathologies of the different types of DM vary (Table 21.5) (Plows et al., 2018).

Type of Diabetes Mellitus	Pathology
Type 1 diabetes mellitus (T1DM)	• This autoimmune disease damages the beta cells of the pancreas so they do not produce insulin; thus, synthetic insulin must be administered by injection or infusion. • T1DM typically begins in childhood or adolescence.
Type 2 diabetes mellitus (T2DM)	• T2DM accounts for approximately 95 percent of all cases and is highly correlated with obesity and inactivity. • The cells of the body become resistant to the effects of insulin, so the pancreas increases its production of insulin. • Over time, the pancreas may no longer be able to produce insulin.
Gestational diabetes (GDM)	• GDM affects up to 14 percent of all pregnancies; it manifests as spontaneous hyperglycemia. • Beta cells in the pancreas become unable to compensate for the demands of pregnancy, causing a dysfunction in the production of insulin and a reduced insulin sensitivity resulting in high blood glucose levels. • Function usually returns to normal after pregnancy, but the condition can increase the risk of developing T2DM.

TABLE 21.5 Pathophysiology of Different Types of Diabetes Mellitus

Because of the imbalance of insulin and glucagon, patients with DM have a risk for **hyperglycemia** (high blood glucose levels), which can further impair beta cell function and insulin secretion (Dapra & Bhandari, 2023). Hyperglycemia can lead to an impaired metabolic state, causing increased urination, or **osmotic diuresis**, due to the excess glucose concentrations in the kidneys. Chronic hyperglycemia also causes excess fatty acids and pro-inflammatory cytokines, contributing to further insulin resistance and inappropriate glucagon production. The excess glucose also bonds to proteins and lipids, causing damage to blood vessels in the eyes, kidneys, and peripheral nerves. The damage can cause complications such as diabetic neuropathy, kidney disease, and peripheral neuropathy (Dapra & Bhandari, 2023).

Risk Factors

Known risk factors for T1DM are age or family history. A person is more likely to develop T1DM at a young age, or if they have a close family member with the disease. In some circumstances, research has shown it can also be caused by certain viral infections (Rajsfus et al., 2023). However, scientists do not fully understand the risk factors for T1DM since it is viewed as a complex autoimmune disease.

Risks for T2DM include being overweight, age 45 or older, or of American Indian, Black, Hispanic, Latinx, or Alaska Native descent (CDC, 2022b). Having a sedentary lifestyle, a personal history of GDM, or a family history of T2DM are also risk factors (CDC, 2022b).

GDM risk factors include being overweight, age 25 and older, or of American Indian, Black, Hispanic, Latinx, Native Hawaiian, Pacific Islander, or Alaska Native descent. Having a personal history of GDM or polycystic ovary syndrome or a family history of T2DM are also risk factors (CDC, 2024; Mayo Clinic, 2022).

Clinical Manifestations

Common symptoms associated with DM are polyuria, increased thirst, unplanned weight loss, increased hunger, blurry vision, tingling or numbness in hands or feet, decrease in energy, dry skin, increased infections, and slow wound healing (CDC, 2023). Patients may also experience symptoms of hypoglycemia, such as the following:

- Shakiness (tremors) or jitteriness
- Feeling nervous or anxious

- Sweating (diaphoresis), chills, and clamminess
- Irritability or mood swings
- Confusion
- Fast heartbeat (tachycardia)
- Dizziness or lightheadedness
- Hunger
- Nausea
- Color draining from the skin (pallor)
- Feeling sleepy
- Weakness, fatigue, or having no energy
- Blurred/impaired vision
- Tingling or numbness in the lips, tongue, or cheeks (paresthesia)
- Headaches
- Coordination problems (ataxia) or clumsiness
- Irregular heart rate (arrythmia)

Symptoms that indicate a medical emergency include seizures, inability to eat or drink, and loss of consciousness.

LINK TO LEARNING

Watch this video to learn more about the pathophysiology of hypoglycemia (https://openstax.org/r/77Hypoglycemia) and its etiology and classification.

Patients with T1DM may experience nausea, vomiting, and abdominal pain. Symptoms may not be present in patients with T2DM, since symptoms can take years to develop. GDM usually doesn't have any symptoms but is often diagnosed in the second or third trimester of pregnancy.

Complications

There are many complications associated with DM, regardless of what type a patient has. Most complications are microvascular (affect small blood vessels) or macrovascular (affect larger vasculature):

- Microvascular complications include diabetic retinopathy, blindness, and neuropathy.
- Macrovascular complications include nephropathy, cardiovascular disease, and myocardial infarction.
- Other complications include end-stage kidney disease, limb amputations, hypoglycemia, gastroparesis (delayed gastric emptying), and increased risk for certain types of cancer, such as pancreatic, liver, kidney, and gallbladder (Zhu & Qu, 2022).

Emergent complications of DM are **diabetic ketoacidosis (DKA)** and **hyperosmolar hyperglycemic state (HHS)**. DKA is an acute condition with a low mortality rate. HHS develops slowly, sometimes in weeks, but has a much higher mortality rate. Treatment occurs in the intensive care unit (ICU) and is the same in both cases. Table 21.6 provides additional information about DKA and HHS (Sapra & Bhandari, 2023).

	Diabetic Ketoacidosis (DKA)	Hyperosmolar Hyperglycemic State (HHS)
Pathophysiology	• Typically occurs in T1DM • Develops within 24 hours • Caused by sepsis, infection, stress, or missed insulin dose • Chronic lack of insulin causes the metabolism of lipids as energy, turning them into ketones • About 1% mortality rate	• More common in T2DM • Slow developing; within days to weeks • Caused by illness and infection • Chronic hyperglycemia leads to severe dehydration, weakness, and confusion • Up to 20% mortality rate
Symptoms	• Blood glucose above 250 mg/dL • Blood pH 7.3 or lower • Ketones in blood and urine • Increased anion gap (approximately >12 mEq/L) • Causes metabolic acidosis, diuresis, vomiting, acute kidney injury, dehydration, and electrolyte abnormalities	• Blood glucose higher than 600 mg/dL • Blood pH remains normal • No ketones in blood or urine • Normal anion gap (approximately 8-12 mEq/L) • Can cause seizures, coma, and organ failure
Treatment	• Intravenous insulin administration (titrated according to blood glucose and ketone levels) • Aggressive IV fluid hydration • Monitor and correct electrolyte imbalances, especially potassium • Evaluating for underlying cause	• Intravenous insulin administration • Aggressive IV fluid hydration • Monitor and correct electrolyte imbalances, especially potassium • Evaluating for underlying cause

TABLE 21.6 Diabetic Ketoacidosis and Hyperosmolar Hyperglycemic State

This video provides a comparison of DKA and HHS (https://openstax.org/r/77DKAandHHS) as an effective NCLEX review.

Diagnostics and Laboratory Values

DM symptoms can vary according to type and severity. Accurate assessment is important to provide an accurate diagnosis and prevent complications. Diagnostic testing can provide information about disease type and severity. DM is diagnosed primarily through evaluation of fasting serum glucose levels, hemoglobin A1c levels, or oral glucose tolerance testing (OGTT). A patient can be diagnosed with DM with any one of the following results (ADA, 2024a):

- A fasting blood glucose level test result of 126 mg/dL or higher
- A glycosylated hemoglobin (A1c) level greater than or equal to 6.5%
  - A1C, used to assess long-term blood glucose levels over 3 months
- An OGTT value greater than or equal to 200 mg/dL during a 75-g OGTT
- Random blood glucose level of greater than or equal to 200 mg/dL in the presence of symptomatic hyperglycemia or a hyperglycemic crisis
- A urinalysis may be positive for glucose and ketones

An OGTT is performed in all pregnant patients between 24 to 28 weeks' gestation as a screening tool for GDM. The patient has their blood glucose level drawn, then drinks glucose and has another blood glucose level drawn at 1 hour, 2 hours, and/or 3 hours. The patient is diagnosed based on the results of the blood glucose levels.

REAL RN STORIES

Nurse: Mary, MSN
Years in Practice: Seven
Clinical Setting: Labor and delivery unit
Geographic Location: South New Jersey

One day, I was assisting the outpatient clinic with GDM testing, and I was assigned to prep a patient, Janine, for a glucose tolerance test. She had worked night shift, so she came in very tired but appropriately alert. She was a healthy 29-year-old patient, with a normal weight and measurements for a patient at 25 weeks' gestation. Janine didn't have a family history of GDM, but her mother and older brother both had T2DM. Since she was arriving after her overnight shift, we decided to perform a 2-step method glucose tolerance test. Her 1-hour result was 155 mh/dL, indicating that we'd have to do an overnight fast and second glucose tolerance test.

The next week, Janine had her repeat test and her glucose was 200 mg/dL after an hour, confirming that she had GDM. She was surprised and scared over the results. She said she was nervous about the health of her baby and didn't understand how she could possibly have GDM. I took the time to explain everything to her, including a nutritional plan to follow and instructions on how she could check her glucose levels at home. I also gave her information about support groups, as well as the phone number to the nurses' station if she had any questions. Janine was able to maintain healthy glucose levels through diet modification and the use of insulin throughout her pregnancy. Soon after delivery, her GDM resolved.

Nursing Care of the Patient with Diabetes Mellitus

While diabetes is a manageable condition, there is the potential for serious complications. Lifestyle changes, robust patient education, and timely intervention are key interventions to optimize outcomes.

Recognizing and Analyzing Cues

The nurse providing care to a patient with DM utilizes both objective and patient-reported data to optimize care. Subjective assessment findings may include a patient or family history of obesity, DM, unplanned weight loss, neuropathic pain, polyuria, or polydipsia. Possible physical findings may include decreased touch and temperature sensation, blurred vision, hypertension, **Kussmaul respirations** (rapid, deep breathing at a consistent pace), loss of deep tendon reflexes in ankles, weak dorsalis pedis and posterior tibialis pulses, dry skin, muscle atrophy, foot ulceration, obesity, candida infections, thick hyperpigmentation of the skin under creases or folds, and poor skin turgor.

LIFE-STAGE CONTEXT

Vision Loss in Older Patients

Visual acuity changes are a common cause of vision loss in older patients with DM. It is important to assess the visual acuity of older patients with DM while in the hospital setting, and to provide sufficient lighting for the patient to carry out activities and prevent falls. Reinforce to these patients at time of discharge the importance of regular eye exams by an optometrist (CDC, 2022a).

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Patients with DM should be continuously monitored for complications, such as signs of hypoglycemia and hyperglycemia. When a person is fighting illness, their body releases extra glucose into the bloodstream to combat disease. Extra insulin is then produced to balance the extra glucose. A patient with DM that is experiencing stress or an infection doesn't have the ability to provide that balance, so the nurse should plan to assess the blood glucose

levels more frequently. A nursing care plan for a patient with DM may include monitoring glucose levels, medication management, nutrition therapy, and thorough patient education. When educating your patient, consider covering the following topics:

- Fundamentals of DM: Explain the underlying mechanisms of DM, including what the condition is, the typical ranges for normal blood glucose levels, and the goals for target blood glucose levels.
- Treatment strategies: Provide guidance on prescribed treatments, such as how to correctly use insulin and oral antidiabetic medications. Also, discuss strategies for meal planning and techniques for monitoring blood glucose levels and urine ketones.
- Management of acute complications: Educate the patient on how to identify, address, and prevent acute complications, including both hypoglycemia and hyperglycemia.

The nurse should follow facility policy for safe insulin administration. Onset and peak times of insulin and sulfonylureas, in association with anticipated mealtimes, should always be considered to avoid hypoglycemia episodes. In the hospital setting, patients may be temporarily taken off oral agents and treated exclusively with insulin, since insulin can be easily adjusted to manage hyperglycemia. If a hypoglycemic episode occurs, the nurse should intervene quickly using the facility's established hypoglycemia protocol, and the event should be reported to the provider and in handoff or shift report. Symptomatic hyperglycemia should be immediately reported to the provider.

Evaluation of Nursing Care of the Patient with Diabetes Mellitus

Evaluating nursing care for patients with DM focuses on glucose monitoring and control. Accurately understanding the patient's understanding of the disease and willingness to participate in care can increase the nurse's ability to evaluate outcomes.

Evaluating Outcomes

The nurse should evaluate the outcome of the care provided with the patient and family. Sometimes interventions and timelines need to be adjusted to meet care goals. In caring for the patient with DM, questions that the nurse can ask themselves to evaluate care are:

- Did the patient's fluid volume status normalize to target ranges?
- Did the patient's electrolytes normalize to target ranges?
- Did the patient maintain adequate blood glucose levels?
- Did the patient experience a hypoglycemic/hyperglycemic episode?
- Did the patient seem engaged during education, and did they retain the information given?

Medical Therapies and Related Care

Treatment of DM is patient-specific and involves education and patient engagement, medication, lifestyle changes, and glucose monitoring (ADA, 2024b). Treatment is lifelong in order to prevent complications.

Patients with T1DM require insulin for treatment, while patients with T2DM may use insulin if other treatments are insufficient. The primary therapeutic effect of diabetes medications is to maintain serum blood glucose levels within the normal range and achieve an individualized target level of A1C, often set around 7 percent. However, patients should be aware of potential adverse and side effects associated with these treatments. Common side effects include hypoglycemia, characterized by abnormally low blood glucose levels, and hypokalemia, a deficiency of potassium in the blood. Additionally, specific medications, such as Afrezza, an inhaled insulin, can cause acute bronchospasm, especially in individuals with pre-existing respiratory conditions.

There are several different types of insulins that vary in terms of onset, peak, and duration (Table 21.7). It is critical for the nurse to be knowledgeable of these differences to help prevent episodes of hypoglycemia due to mismatched administration of insulin with food intake.

Class and Subclass	Prototypes and Generics	Onset/Peak/ Duration	Administration Considerations
Rapid-acting insulin	Insulin lispro (Humalog) Insulin aspart (Novolog) Inhaled insulin (Afreeza)	Onset: 15-30 minutes Peak effect: 1-3 hours Duration: 3-5 hours	• Administer within 15 minutes before a meal or immediately after a meal • Afrezza is contraindicated in patients with asthma or COPD
Short-acting insulin	Humulin R Novolin R	Onset: 30 minutes Peak effect: 3 hours Duration: 8 hours	• Administer 30 minutes before a meal
Intermediate-acting insulin	Humulin N Novolin N	Onset: 1-2 hours Peak effect: 6 hours (range 2.8-13 hours) Duration: up to 24 hours	• Administer once or twice daily • Only administer subcutaneously • Gently roll or invert vial/pen several times to re-suspend the insulin before administration
Combination: Intermediate-acting/Rapid-acting	Humalog Mix 50/50* Humalog Mix 75/25* Novolog Mix 70/30* *First number is % intermediate-acting insulin, second number is % rapid-acting	Onset: 15-30 minutes Peak effect: 1-5 hours Duration: 11-22 hours	• Administer twice daily, 15 minutes before a meal or immediately after a meal • Only administer subcutaneously • Gently roll or invert vial/pen several times to re-suspend the insulin before administration

TABLE 21.7 Types of Insulin

Class and Subclass	Prototypes and Generics	Onset/Peak/ Duration	Administration Considerations
Combination: Intermediate-acting/Short-acting	Humulin 70/30 Novolin 70/30	Onset: 30-90 minutes Peak effect: 1.5-6.5 hours Duration: 18-24 hours	• Administer twice daily, 30-45 minutes before a meal • Only administer subcutaneously • Gently roll or invert vial/pen several times to re-suspend the insulin before administration • Do not mix with other insulin
Long-acting insulin	Insulin glargine (Lantus) Insulin detemir (Levemir)	Onset: 3-4 hours Peak effect: none Duration: >24 hours	• Administer once daily (sometimes dose is split and administered twice daily) • Only administer subcutaneously • Do not mix with other insulin

TABLE 21.7 Types of Insulin

There are several different classes of oral antihyperglycemic drugs used in conjunction with a healthy diet and exercise for the management of T2DM. According to the American Diabetes Association, metformin is the preferred initial pharmacologic agent for the treatment of T2DM (ADA, 2024b). Three of the most-used antihyperglycemic classes and prototypes are sulfonylureas (glipizide), biguanide (metformin), and DPP-IV (sitagliptin). Administration considerations for each of these prototypes are described in Table 21.8.

Class	Prototype	Administration Considerations	Adverse/Side Effects
Sulfonylureas	Glipizide	Time with meals; peak plasma concentrations occur 1 to 3 hours after administration	Hypoglycemia; may be potentiated by nonsteroidal anti-inflammatory agents and other drugs that are highly protein-bound
Biguanide	Metformin	Contraindicated in renal and hepatic diseases Should be temporarily discontinued in patients undergoing radiologic studies involving intravascular administration of iodinated contrast materials	Stop immediately if signs of lactic acidosis or any condition associated with hypoxemia, dehydration, or sepsis occur Common adverse effects: diarrhea, nausea/vomiting, weakness, flatulence, indigestion, abdominal discomfort, and headache
DPP-IV inhibitor	Sitagliptin	Can be given with or without food	Hypoglycemia Report hypersensitivity reactions, blisters/erosions, headache, or symptoms of pancreatitis, heart failure, severe arthralgia, or upper-respiratory infection

TABLE 21.8 Oral Antihyperglycemics

Lifestyle changes play a crucial role in managing DM effectively and improving overall health. For individuals with DM, adopting a balanced diet rich in whole grains, lean proteins, and vegetables while reducing the intake of refined sugars and saturated fats can help control blood glucose levels and prevent complications. Regular physical activity, such as walking, cycling, or swimming, enhances insulin sensitivity and helps maintain a healthy weight. Additionally, managing stress through techniques like mindfulness or yoga can positively impact blood sugar levels. Monitoring blood glucose regularly and making informed adjustments to diet and exercise based on these readings further supports effective DM management. By integrating these lifestyle changes, individuals with DM can achieve better glycemic control and enhance their quality of life.

Oral antihyperglycemic medications have historically not been recommended during pregnancy because they cross the placenta and may pose risks to the developing fetus, potentially leading to harmful effects. Instead, insulin has traditionally been the preferred treatment for managing DM during pregnancy, as it does not cross the placenta and is considered safe for both the mother and the fetus. While some oral medications, like metformin, may be used cautiously in specific cases, insulin remains the standard choice to effectively control blood glucose levels and minimize risks to fetal development.

Regular screenings are crucial for preventing complications in DM management. Diabetic retinal exams should be performed annually to monitor for signs of diabetic retinopathy. Neurologic exams, including assessments for neuropathy, are typically recommended at least once a year. Urinalysis should be conducted periodically, often annually, to check for signs of nephropathy or urinary tract infections. Blood pressure should be monitored at each visit, with treatment adjustments made as needed to maintain control. Lipid levels are generally assessed annually to manage cardiovascular risk. Additionally, patients should conduct frequent self-inspections of their feet and have them checked regularly by a health-care professional, as often as every visit or at least every three to six months, to detect and address any sores or breakdowns promptly.

In addition to regular screenings and monitoring, comprehensive DM care includes several other essential standards. Routine vaccinations, such as those for influenza, pneumococcal disease, and hepatitis B, are crucial for preventing infections that could complicate DM management. Support for smoking cessation is also vital due to the increased risk of cardiovascular disease associated with smoking. Regular nutrition counseling helps individuals manage their diet effectively, while mental health support addresses psychological challenges related to DM. Additionally, monitoring kidney function through tests like serum creatinine and urine albumin-to-creatinine ratio helps in the early detection of diabetic nephropathy.

In DM management, the frequency of blood glucose monitoring varies depending on the type of DM and the treatment regimen. For individuals with T1DM, frequent monitoring is essential due to the need for precise insulin dosing. Typically, blood glucose should be checked multiple times a day, including before and after meals, before exercise, and at bedtime, to effectively manage insulin levels and prevent hypo- or hyperglycemia. For those with T2DM, the frequency of monitoring can vary based on the treatment approach. Patients who are on insulin therapy or other glucose-lowering medications may need to monitor their blood glucose levels several times a day, similar to T1DM patients. However, those managing their DM with oral medications alone or through lifestyle changes may only need to check their blood glucose levels once a day or a few times a week. The specific frequency should be tailored to each individual's treatment plan and glycemic control needs, as determined by their health-care provider.

It is crucial to reinforce to the patient the importance of keeping a detailed log of blood glucose results and to consistently check levels before meals and at bedtime. Regular monitoring and logging help provide valuable data for health-care providers, allowing for more accurate adjustments to treatment plans. This approach ensures better management of DM and contributes to improved overall health outcomes. Regular A1C testing, usually every three to six months, further helps assess long-term glucose control and informs any necessary changes in the monitoring routine.

21.3 Thyroid and Parathyroid Disorders

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations for thyroid and parathyroid disorders
- Describe the diagnostics and laboratory values for thyroid and parathyroid disorders
- Apply nursing concepts and plan associated nursing care for patients with thyroid and parathyroid disorders
- Evaluate the efficacy of nursing care for thyroid and parathyroid disorders
- Describe the medical therapies that apply to the care of patients with thyroid and parathyroid disorders

Thyroid disorders arise when the thyroid gland secretes hormones in incorrect amounts, disrupting the processes that regulate metabolism of proteins, fats, and carbohydrates. This imbalance affects the body's energy utilization, oxygen consumption, and heat production. On the other hand, parathyroid disorders occur when the parathyroid glands produce abnormal levels of parathyroid hormone (PTH), which is essential for regulating calcium levels in the body. This module connects the function of the thyroid and parathyroid with common disorders caused by inappropriate function and discusses diagnostic testing, therapies, and nursing care of patients with thyroid or parathyroid disorders.

Pathophysiology of the Thyroid and Parathyroid

The **thyroid** is a gland in the neck, just below the larynx and in front of the trachea (Figure 21.6). It is a butterfly-shaped gland with two lobes that are connected by a band of tissue called the isthmus. It has a dark-red color due to its extensive vascular system. When the thyroid swells due to dysfunction, it can be felt under the skin of the neck.

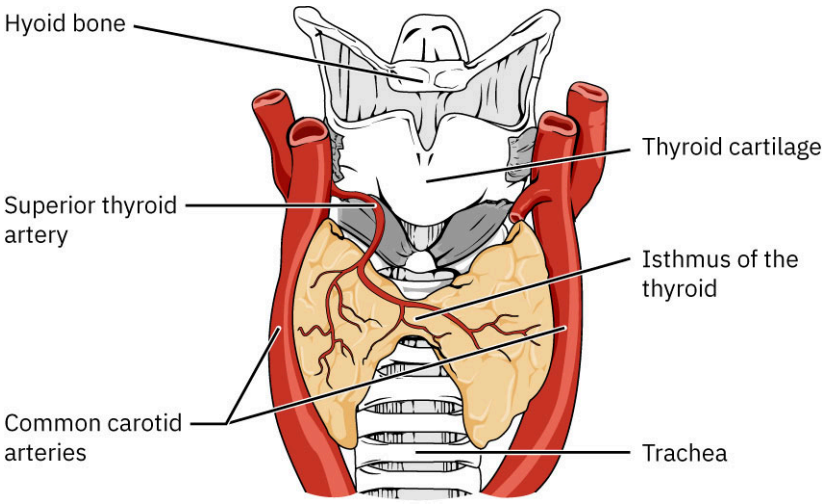

FIGURE 21.6 The thyroid, shown here in tan, is a butterfly-shaped gland that sits below the larynx and in front of the trachea. (modification of work from *Anatomy and Physiology* 2e. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

The thyroid gland is made up of many spherical thyroid follicles, which are lined with a simple cuboidal epithelium. These follicles contain a viscous fluid, called **colloid**, which stores the glycoprotein thyroglobulin, the precursor to the thyroid hormones. The follicles produce hormones that can be stored in the colloid or released into the surrounding capillary network for transport to the rest of the body via the circulatory system.

Thyroid follicle cells synthesize the hormone thyroxine, known as T4 because it contains four atoms of iodine, and triiodothyronine, known as T3 because it contains three atoms of iodine. Follicle cells are stimulated to release stored T3 and T4 by thyroid stimulating hormone (TSH), which is produced by the anterior pituitary. These thyroid hormones increase the rates of mitochondrial ATP production.

A third hormone, calcitonin, is produced by parafollicular cells of the thyroid either releasing or inhibiting hormones. Calcitonin release is not controlled by TSH; instead, it is released when calcium ion concentrations in the blood rise. Calcitonin functions to regulate calcium concentrations in body fluids. It acts in the bones to inhibit osteoclast

activity and in the kidneys to stimulate excretion of calcium. The combination of these two events lowers body fluid levels of calcium.

The **parathyroid** is a gland that is located on the posterior surface of the thyroid gland. Most people have four parathyroid glands; however, the number can vary from two to six. (Figure 21.7). Normally, there is a superior gland and an inferior gland associated with each of the thyroid's two lobes. Each parathyroid gland is covered by connective tissue and contains many secretory cells that are associated with a capillary network.

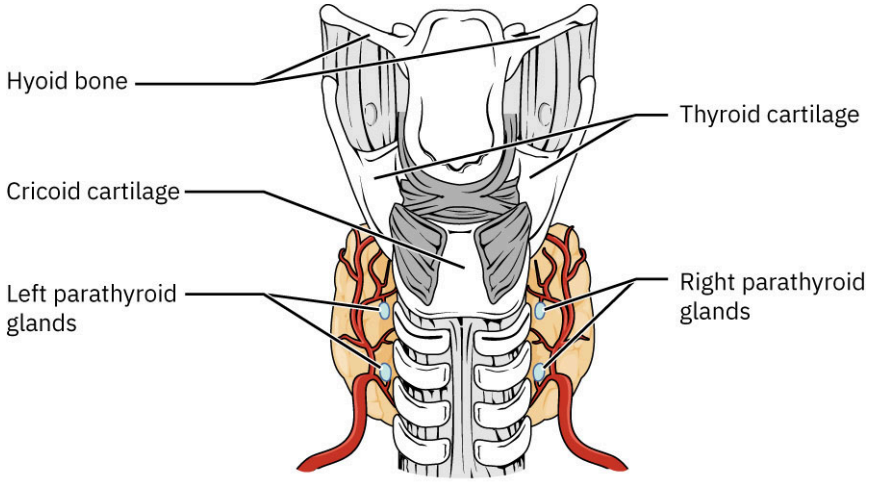

FIGURE 21.7 The parathyroid glands are located on the posterior of the thyroid gland. (modification of work from *Anatomy and Physiology* 2e. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

The parathyroid glands produce parathyroid hormone (PTH). PTH increases blood calcium concentrations when calcium ion levels fall below normal. PTH is produced by chief cells of the parathyroid. PTH and calcitonin work in opposition to one another to maintain homeostatic Ca^{2+} levels in body fluids. Another type of cell, oxyphil cells, exists in the parathyroid, but their function is not currently known.

Dietary Iodine

Dietary iodine is required for the synthesis of T3 and T4. But for much of the world's population, foods do not provide adequate levels of this mineral. The amount in crops varies according to the level in the soil in which the food was grown, as well as the irrigation and fertilizers used. Marine fish and shrimp tend to have high levels because they concentrate iodine from seawater, but many people in landlocked regions lack access to seafood. Thus, the primary source of dietary iodine in many countries is iodized salt. Fortification of salt with iodine began in the United States in 1924, and international efforts to iodize salt in the world's low-income nations continue today (Cavanaugh, 2024).

Dietary iodine deficiency can result in the impaired ability to synthesize T3 and T4, leading to a variety of severe disorders. Normally, the body controls T3 and T4 levels through a feedback loop. The hypothalamus releases thyrotropin-releasing hormone (TRH) which stimulates the pituitary gland to release TSH, which stimulates the thyroid to release T3 and T4. When T3 and T4 cannot be produced, the loop becomes broken and TSH is secreted in increasing amounts. As a result of this hyperstimulation, thyroglobulin accumulates in the thyroid gland follicles, increasing their deposits of colloid. The accumulation of colloid increases the overall size of the thyroid gland, causing a condition called a **goiter** (Figure 21.8). Iodine deficiency can also cause impaired growth and development, decreased fertility, and prenatal and infant death. Moreover, iodine deficiency is the primary cause of preventable intellectual disabilities worldwide.

FIGURE 21.8 A visible goiter on a person's neck is caused by an accumulation of colloid. (credit: "Goiter" by Jerry Kirkhart/Flickr, CC BY 2.0)

Hyperthyroidism

The overproduction of thyroid hormones, **hyperthyroidism** can lead to an increased metabolic rate and its effects: weight loss, excess heat production, sweating, and an increased heart rate. **Graves' disease** is the most common cause of hyperthyroidism. In Graves' disease, the hyperthyroid state results from an autoimmune reaction in which antibodies overstimulate the follicle cells of the thyroid gland. The person's eyes may bulge (exophthalmos) as antibodies produce inflammation in the soft tissues of the orbits. The person may also develop a goiter. Complications of Graves' disease include heart arrhythmias, heart failure, miscarriage, preterm birth, preeclampsia, maternal heart failure, osteoporosis, and thyroid storm.

Thyroid Storm

Also known as thyroid crisis or thyrotoxic crisis, **thyroid storm** is when the thyroid gland releases a large amount of thyroid hormone in a short period of time. It can be caused by sudden events such as infection, trauma, abrupt discontinuation of antithyroid medication, acute illness, stroke, or giving birth. Symptoms include:

- confusion/delirium
- fever
- nausea/vomiting/diarrhea
- agitation
- anxiety
- tachycardia
- shakiness
- jaundice
- loss of consciousness

Thyroid storm is a medical emergency and requires immediate care. Complications include blood clots, heart failure, seizures, delirium, and coma. If not promptly treated, death from heart failure, cardiac arrhythmias, or multiple organ failure can occur. Up to 30 percent of thyroid storm cases are fatal. Management involves providing antithyroid medications to decrease the creation and release of thyroid hormone and supportive care to treat the body systems affected. It is also important to treat the underlying cause of the thyroid storm (Cleveland Clinic, 2022b).

Hypothyroidism

Inflammation of the thyroid gland, known as **hypothyroidism**, is the more common cause of low blood levels of

thyroid hormones and is characterized by a low metabolic rate, weight gain, cold extremities, constipation, reduced libido, menstrual irregularities, and reduced mental activity. Females are more likely than men to develop hypothyroidism, and it occurs in approximately 5 out of 100 Americans over the age of 12 (NIDDK, 2021). The condition of **congenital hypothyroidism** is characterized by cognitive deficits, short stature, and sometimes deafness and muteness in children and adults born to mothers who were iodine-deficient during pregnancy.

Thyroid Cancer

Thyroid cancer affects approximately 44,000 Americans yearly, and most types have an overall 5-year survival rate of at least 90 percent (American Cancer Society, 2023). It is three times more common in females and 70 percent more common in White people than Black people (American Cancer Society, 2023). Risk factors for thyroid cancer include radiation exposure, low iodine diet, obesity, family history, and certain hereditary conditions. While thyroid cancer is a treatable cancer with a high survival rate, some patients develop hypothyroidism as a result from thyroidectomy or radiation treatment.

Hyperparathyroidism

Abnormally high activity of the parathyroid gland can cause **hyperparathyroidism**, a disorder caused by an overproduction of PTH, which results in excessive calcium reabsorption from bone. The two main causes of hyperparathyroidism are an abnormality or tumor on the parathyroid gland or a secondary condition, such as chronic kidney disease or vitamin D deficiency, that affects the function of the parathyroid gland. Hyperparathyroidism can significantly decrease bone density, leading to spontaneous fractures or deformities. As blood calcium levels rise, cell membrane permeability to sodium is decreased, reducing the responsiveness of the nervous system. At the same time, calcium deposits may collect in the body's tissues and organs, impairing their functioning.

Hypoparathyroidism

Abnormally low blood calcium levels may be caused by parathyroid hormone deficiency, also known as **hypoparathyroidism**, which may develop following injury or surgery involving the thyroid gland, certain autoimmune disorders, abnormal development of the parathyroid tissues, mutation of calcium-sensing receptors, or PTH resistance (Hans & Levine, 2022). Low blood calcium increases membrane permeability to sodium, resulting in muscle twitching, cramping, spasms, or convulsions. Severe deficits can paralyze muscles, including those involved in breathing, and can be fatal.

Clinical Manifestations of Thyroid and Parathyroid Disorders

The thyroid controls metabolism, heart rate, and body temperature. Clinical signs and symptoms of thyroid disorders typically involve either hyperactivity (hyperthyroidism) or hypoactivity (hypothyroidism) of the thyroid gland. Table 21.9 lists signs of symptoms of hyperthyroidism and hypothyroidism.

Hyperthyroidism	Hypothyroidism
• Nervousness/irritability • Fatigue/muscle weakness • Mood swings • Heat intolerance • Insomnia • Tremors • Tachycardia/irregular heart rhythm • Weight loss • Diarrhea • Goiter	• Depression • Fatigue • Dry skin • Dry, thinning hair • Cold intolerance • Puffy face • Joint/muscle pain • Bradycardia • Decreased sweating • Constipation • Heavy/irregular menstrual periods and fertility problems

TABLE 21.9 Signs and Symptoms of Hyperthyroidism and Hypothyroidism (George Washington University Hospital, 2024)

Clinical manifestations of parathyroid disease are unusual in the early stages. Signs and symptoms vary and are dependent on the type of disorder present. A patient with hyperparathyroidism may present with muscle weakness, fatigue, depression, chronic thirst, frequent urination, loss of appetite, abdominal pain, trouble concentrating, and

mild confusion. If hypercalcemia is present, the patient may have muscle spasms, bone/joint pain, drowsiness, confusion, cardiac arrhythmias, hypertension, osteoporosis, kidney stones, gastric ulcers, or pancreatitis. Patients with hypoparathyroidism may present with muscle cramps, spasms, or numbness or tingling in their toes, fingers, or lips.

LIFE-STAGE CONTEXT

Older Patients and Thyroid Disease

Patients over 60 years of age are more likely to develop hypothyroidism than younger adults, as TSH production increases with age. Thyroid dysfunction can also be more difficult to identify in older adults because symptoms, such as memory loss or cognitive function changes, are often attributed to advanced age. An extensive patient history is important to distinguish between normal age changes and thyroid dysfunction.

Diagnostics and Laboratory Values

An accurate assessment is important in the diagnosis of thyroid and parathyroid disorders. Diagnostic testing can further support diagnosis and provide information about the disease severity. Diagnostic testing for thyroid or parathyroid disorders includes bloodwork, imaging, and biopsy; the specific tests depend on what the subjective and objective data reveal. TSH, T3, T4, thyroglobulin, PTH, and calcitonin levels can help determine thyroid and parathyroid function. Calcium and other electrolyte levels may be checked to rule out imbalances. Imaging tests—such as ultrasound, radioiodine scan, chest X-ray, computed tomography (CT) scan, magnetic resonance imaging (MRI) scan, and positron emission tomography (PET) scan—can help to find suspicious areas that may be malignant, to see if a malignancy has spread, and to determine if a treatment is working. A fine needle aspiration biopsy of the thyroid may also be done to rule out cancer.

Nursing Care of the Patient with Thyroid Disorder

Care of the patient with a thyroid or parathyroid disorder involves educating the patient and family, following the plan of care, and monitoring for complications.

Recognizing Cues and Analyzing Cues

Begin a subjective assessment by asking the patient focused questions to determine if the patient is experiencing any symptoms or has a previous medical history of neck issues. Some questions to ask may include:

- Have you ever been diagnosed with a medical condition related to your neck, such as a thyroid or swallowing issue? Please describe.
- Are you currently taking any medications, herbs, or supplements for your thyroid?
- Have you ever had any radiation exposure? Please describe.
- Do you have a family history of thyroid problems? Please describe.
- Are you experiencing any joint/muscle pain, weakness, anxiety, insomnia, cold/heat intolerance, weight loss/gain, change in bowel habits, or mood swings? Please describe.

Utilize the information gathered from your subjective assessment to guide your physical assessment, as follows:

- Inspect the face and neck. The face should not be overly rounded, eyes should be normally set and not bulging, the trachea should be midline, and there should not be any noticeable enlargement of the thyroid gland.
- Note the patient's speech. They should be able to speak clearly with no slurring or garbled words.
- Assess the patient's skin, hair, and nails for dryness, brittleness, or thinness.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Prevention of complications, such as thyroid storm and myxedema coma, are a high priority during treatment. To monitor for thyroid storm, the nurse should monitor the patient for signs of hyperthermia, tachycardia, and hypertension; thyroid storm is a medical emergency that requires ICU level of care. Supplemental therapies include cooling blankets, telemetry, and pharmacological therapies (such as methimazole or PTU) to both treat hemodynamic instability and excessive production of thyroid (Pokhrel et al., 2022).

For patients with hypothyroidism, nursing management includes:

- Monitoring of the patient's weight, appetite, intake, and output
- Dietary consult and constipation management
- Providing skin moisturizer for dry skin
- Encouraging exercise
- Mental health consultation and support
- A bowel regimen to treat constipation
- Low-fat diet to prevent or manage hyperlipidemia

Severe cases of hypothyroidism, known as **myxedema coma**, require vigilant monitoring for hypothermia, bradycardia, and respiratory depression. Patients with myxedema coma also need continuous cardiac monitoring due to the risk of bradycardia. Medical management typically involves intravenous thyroid hormone replacement to quickly restore thyroid levels. Additionally, careful assessment of neurological status is crucial, as symptoms may include altered mental status, lethargy, and potential confusion. Similar to thyroid storm, patients with myxedema coma require ICU-level care to address these critical needs effectively. In chronic management of thyroid disorders, the nurse should be sure to report any symptoms of overtreatment to the provider. Older adults beginning thyroid replacement therapy should be educated to report any chest pain, as this could be an adverse effect. Routine blood work should be completed six to eight weeks after initiation of hormone adjustment therapy to evaluate the response.

Educate the patient and family about any diagnostic testing or procedures being completed, why they're being done, and what the results can mean. Teach about the therapies and treatments being done and why it's important for the patient to stick to prescribed regimens. For patients with hyperthyroidism, nursing management includes:

- Monitoring vital signs, cardiac rhythm, intake and output, and daily weights
- Teaching the patient relaxation techniques
- Providing oxygen as ordered and appropriate
- Providing a cooling blanket for fevers
- Utilization of eye lubricant to keep mucous membranes intact in the eyes
- High-calorie meals to meet metabolic demands.

Evaluation of Nursing Care for the Patient with Thyroid Disorder

Evaluating nursing care for patients with thyroid or parathyroid disorders centers around symptom assessment and management. The patient should be able to state the importance of therapy compliance, maintain a positive body image, and state what symptoms should be reported to the provider, such as changes in weight, energy levels, and mood, with specific attention to symptoms like rapid heartbeat or tremors in hyperthyroidism, and fatigue or weight gain in hypothyroidism.

Evaluating Outcomes

The primary outcome of disease management in thyroid disorders is symptom resolution and restoration of hormone levels to a normal range. The nurse evaluates the patient for symptom improvement throughout treatment. Laboratory values, such as TSH, T3, and T4 will be monitored to see if there is improvement in response to treatment. Vital signs, cardiac rhythm, fluid intake and output, and daily weight are monitored for fluctuations or abnormalities.

Medical Therapies and Related Care for the Patient with Thyroid Disorder

In hyperthyroidism, treatment depends on the underlying cause of the disease, the patient's overall health, and personal preference (Mathew et al., 2023). Treatment may include the following interventions:

- Anti-thyroid medications include methimazole and propylthiouracil. Initial therapy can last 12 to 18 months, then gradually taper off if symptoms resolve and bloodwork shows normal hormone production. It is essential to monitor patients for potential side effects, including agranulocytosis, a serious condition marked by a dangerously low white blood cell count. Regular blood work is necessary to detect this and other adverse effects early, ensuring timely intervention and adjustment of treatment if needed.
- Beta blockers may be prescribed for symptomatic treatment of palpitations, tachycardia, and tremor. Once

thyroid hormones are at a more normal level, beta blockers may no longer be needed.
- Radioiodine therapy (RAI) is an oral medication that may be used to shrink the thyroid gland and slow thyroid activity, either prior to surgery or as a standalone treatment, eventually making the thyroid gland underactive. Over time, patients may have to take thyroid hormone replacement therapy.
- Thyroidectomy (removal of part or all of the thyroid gland) may be performed in patients who cannot take anti-thyroid medications or RAI therapy. Patients who have a thyroidectomy need lifelong thyroid hormone replacement therapy. If parathyroid glands are removed during the procedure, the patient also has to take medications to regulate blood calcium levels.

Hypothyroidism is primarily treated with thyroid hormone replacement therapy, such as levothyroxine. Initial bloodwork to monitor thyroid hormone levels and taper levothyroxine dosing are completed every four to eight weeks until a target level is reached, then bloodwork is checked at six months, then yearly. In complex scenarios such as pregnancy, heart disease, congenital or pediatric hypothyroidism, or other endocrine disorders, an endocrinologist may be consulted. Other specialists in psychiatry, pediatrics, cardiology, or obstetrics/gynecology may also be involved (Patil et al., 2023).

Nursing Care of the Patient with Parathyroid Disorder

Similar to nursing care of a patient with thyroid disease, nursing care of the patient with parathyroid disease involves educating the patient and family, following the plan of care, and monitoring for complications.

Recognizing Cues and Analyzing Cues

The nurse utilizes subjective and objective data to optimize care in patients with parathyroid disorders. Subjective data may include weakness, depression or forgetfulness, anxiety, bone and joint pain, severe muscle cramps, abdominal pain, insomnia, increased thirst, loss of appetite, constipation, or tingling in the mouth, hands, or feet. Vital signs are evaluated with a focus on heart rhythm, blood pressure, and lung sounds. A positive Chvostek's sign (facial muscle twitching when the facial nerve is tapped) or Trousseau's sign (hand and wrist spasm when a blood pressure cuff is inflated) is an indicator of hypocalcemia.

LINK TO LEARNING

Hypocalcemia decreases the threshold for the activation of neurons, causing increased neuromuscular excitability, or tetany. Learn how to assess for indicators of hypocalcemia (https://openstax.org/r/77Hypocalcemia) called Chvostek's sign and Trousseau's sign.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

For patients being treated for hyperparathyroidism, targeted nursing care includes:

- Monitoring vital signs, calcium levels, intake, and output
- Obtaining baseline bloodwork, such as serum calcium, potassium, magnesium, and phosphate levels before treatment and as ordered
- Ensuring the patient receives information about all treatments for hyperparathyroidism
- Monitoring for bone pain, fractures, and gastrointestinal symptoms
- Providing emotional support and collaborate with psychology, as appropriate

Nurses should also monitor for signs and symptoms of **hungry bone syndrome**, a complication that occurs from prolonged hypocalcemia following surgical correction for hyperparathyroidism. This hypocalcemia is due to the sudden drop in PTH production and serum calcium being quickly incorporated into new bone. It is often accompanied by hypophosphatemia, hypomagnesemia, and elevated alkaline phosphatase (Pokhrel et al., 2022). Symptoms include:

- Seizures
- Paresthesia
- Arrhythmias
- Numbness
- Cardiomyopathy

- Laryngospasms

Treatment includes high levels of oral calcium and vitamin D supplementation, but intravenous calcium may be given in severe cases (Pokhrel et al., 2022).

For patients with hypoparathyroidism, targeted nursing care includes:

- Administering prescribed drugs, such as calcium
- Obtaining bloodwork as ordered, such as serum calcium and phosphorous levels
- Monitoring cardiac rhythm
- Instituting safety precautions and monitoring the patient for seizure activity
- Providing airway management by preparing for possible interventions like tracheostomy, oxygen administration, and suctioning if the patient develops severe respiratory issues or requires airway support

Evaluation of Nursing Care for the Patient with Parathyroid Disorder

The process of evaluating nursing care requires the nurse to evaluate each intervention, including how the patient responded, whether goals were met, and what could have been done differently to improve the patient's state. Goals of nursing care for a patient with a parathyroid disorder may include:

1. The patient will not experience signs and symptoms of calcium disorder.
2. The patient will collaborate with psychiatry to develop positive coping mechanisms.
3. The patient will express understanding of the disease process, treatment, and importance of follow-up care.
4. All goals should have a timeline, with a new goal made with the patient to direct the next portion of care.

Evaluating Outcomes

For a patient with a parathyroid disorder, one outcome should be the patient's serum calcium returning to normal levels. If not, the nurse should determine whether the patient followed the interventions that were chosen. Monitoring laboratory trends may reveal improvement in calcium levels, indicating that the treatment is working.

Medical Therapies and Related Care for the Patient with Parathyroid Disorder

A total or subtotal parathyroidectomy is the preferred treatment for hyperparathyroidism because it cures the underlying condition. Patients who undergo surgery are monitored routinely and often do well taking calcium and vitamin D supplementation. Patients who are unable or unwilling to undergo surgery must take medications to control hypercalcemia and low bone density. A calcium-sensing receptor drug, such as cinacalcet, may be prescribed to reduce circulating PTH levels and lower serum calcium levels. Bisphosphonates and rank ligand inhibitors (decrease osteoclast production to prevent bone breakdown and fractures) may also be prescribed to treat low bone density (Pokhrel et al., 2022).

Correction of calcium and electrolyte imbalance is the primary treatment for hypoparathyroidism. Patients are typically prescribed calcium and vitamin D supplementation, in addition to magnesium replacement, if appropriate. Recombinant human PTH may also be prescribed, along with adjunct therapy to help control hypocalcemia. If there is an underlying cause, such as a tumor, surgery may be necessary.

21.4 Pituitary Disorders

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations for pituitary disorders
- Describe the diagnostics and laboratory values for pituitary disorders
- Apply nursing concepts and plan associated nursing care for patients with pituitary disorders
- Evaluate the efficacy of nursing care for pituitary disorders
- Describe the medical therapies that apply to the care of patients with pituitary disorders

The **pituitary gland** is a bean-sized organ suspended from the hypothalamus that produces, stores, and secretes hormones in response to hypothalamic stimulation. When the pituitary gland produces insufficient levels of hormones, disorders occur. This section explores common pituitary disorders, along with their treatments and nursing care of patients with these disorders.

Pathophysiology of Pituitary Disorders

The pituitary gland consists of two lobes that arise from distinct parts of embryonic tissue: the posterior pituitary lobe (neurohypophysis) is neural tissue, whereas the anterior pituitary lobe (also known as the adenohypophysis) is glandular tissue that develops from the primitive digestive tract (Figure 21.9). The posterior pituitary lobe is actually an extension of the neurons of the paraventricular and supraoptic nuclei of the hypothalamus.

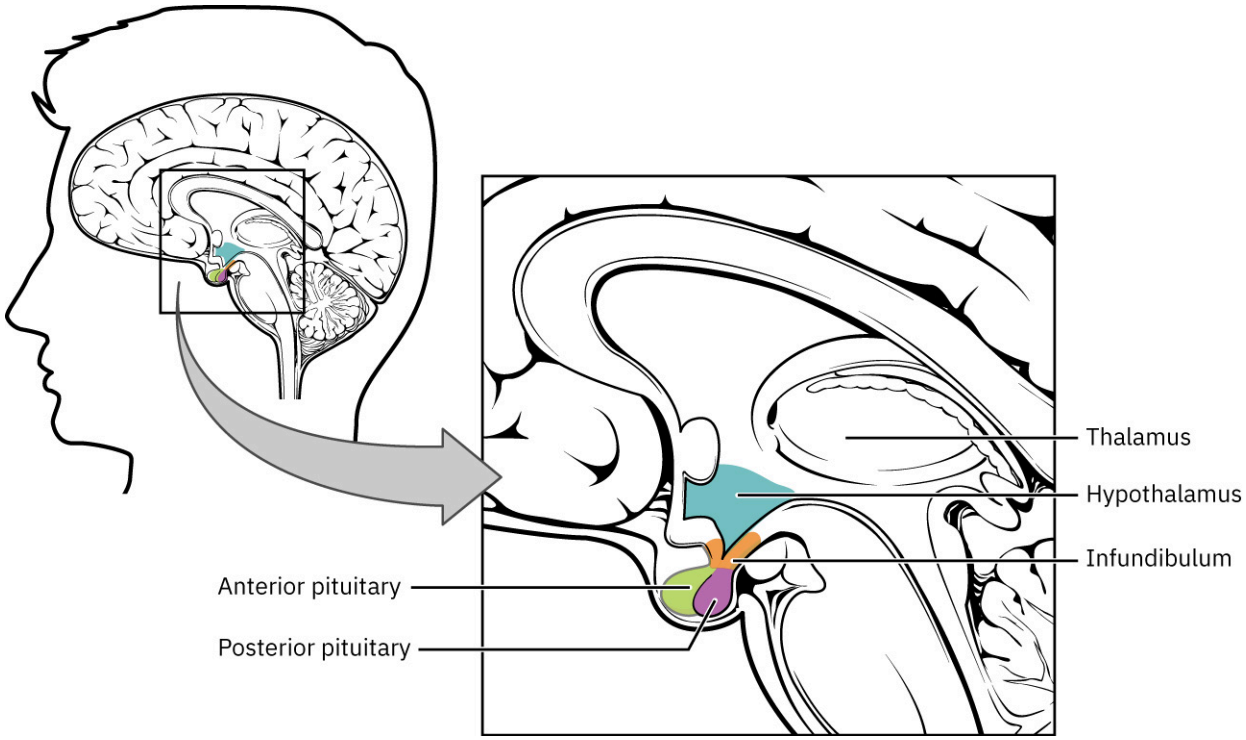

FIGURE 21.9 The pituitary gland is an extension of the hypothalamus. (modification of work from *Anatomy and Physiology* 2e. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

The cell bodies of these regions rest in the hypothalamus, but their axons descend as the hypothalamic–hypophyseal tract within the infundibulum and end in axon terminals that comprise the posterior pituitary lobe. This lobe does not produce hormones, but rather stores and secretes hormones produced by the hypothalamus (Table 21.10).

Pituitary Lobe	Associated Hormones	Effect
Anterior	Growth hormone	Promotes growth of body tissues
	Prolactin (PRL)	Promotes milk production from mammary glands
	Thyroid-stimulating hormone (TSH)	Stimulates thyroid hormone release from thyroid
	Adrenocorticotropic hormone (ACTH)	Stimulates hormone release by adrenal cortex
	Follicle-stimulating hormone (FSH)	Stimulates gamete production in gonads
	Luteinizing hormone (LH)	Stimulates androgen production by gonads
Posterior	Antidiuretic hormone (ADH)	Stimulates water reabsorption by kidneys
	Oxytocin	Stimulates uterine contractions during childbirth

TABLE 21.10 Pituitary Hormones

Any malfunction in the production or secretion of pituitary hormones can cause conditions of the pituitary gland. Common pituitary disorders include diabetes insipidus (DI) and syndrome of inappropriate antidiuretic hormone release (SIADH). Both disorders are related to inappropriate ADH activity within the body.

Diabetes Insipidus

Chronic underproduction of ADH or a mutation in the ADH receptor results in **diabetes insipidus (DI)**, also referred to as arginine vasopressin deficiency (AVP-D). If the posterior pituitary does not release enough ADH, water cannot be retained by the kidneys and is lost as urine. This causes increased thirst, but water taken in is lost again and must be continually consumed. If the condition is not severe, dehydration may not occur, but severe cases can lead to electrolyte imbalances due to dehydration (Buiser Schnur, 2021).

Clinical Manifestations

The main clinical manifestations of DI are extreme thirst (**polydipsia**) and the production of large amounts of urine (**polyuria**)—more than 3 liters in a 24-hour period. This occurs both day and night, making them distinguishing features of DI (Perkins, 2020). Other common signs and symptoms are dehydration, hypernatremia, fatigue, hypotension, tachycardia, dizziness, weakness, fatigue, and loss of consciousness. Patients with DI are also at risk for hypovolemic shock.

Diagnostics and Laboratory Values

Assessing for DI relies on a thorough patient history and assessment. Diagnostic testing can confirm a parathyroid disorder when signs and symptoms are present. Diagnosis of DI involves confirming polyuria, determining which type of DI is present, and figuring out the underlying cause (Perkins, 2020). A 24-hour urine sample will be collected to identify polyuria. Urine and blood osmolality will also be measured, showing a decreased urine osmolality and increased serum osmolality. Serum sodium levels will also be evaluated. Other assessments that may be completed include the fluid deprivation test and the hypertonic saline infusion test.

A **fluid deprivation test** involves restricting the patient's fluid intake while monitoring the patient's body weight and urine concentration. A positive test will show continued urine dilution and decreased urine osmolality.

Nursing Care of the Patient with Diabetes Insipidus

When caring for patients with DI, it is important to closely monitor intake and output, daily weights, vital signs, changes in level of consciousness, skin turgor, mucus membranes, and laboratory values. Accurate, strict intake and output is important to monitor the patient for dehydration. It is also important to monitor the patient at the same time each day, using the same scale if possible. Assessment of skin turgor and mucus membranes can also be quick indications of the patient's hydration status. Evaluation of laboratory values is also important to monitor for electrolyte imbalances and kidney dysfunction.

Recognizing Cues and Analyzing Cues

A patient constantly requesting water to drink and taking multiple trips to the bathroom is a cue for the nurse that the patient may have DI. It is important to utilize acute assessment skills along with targeted subjective questions to gather the appropriate data. When completing a subjective assessment, ask the patient targeted questions about their quality of life. Questions may include:

- Do you struggle with fatigue or feeling unwell?
- Are you having problems with irritability or concentration?
- How often do you urinate? Does it interfere with sleep?
- Have you had unplanned weight loss?

Obtain an accurate list of all medications the patient is currently taking, as some medications can cause polydipsia, polyuria, and hyponatremia. An objective assessment of a patient with DI may reveal tachycardia, hypotension, and dry skin and mucous membranes.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Additional cues, such as large volumes of clear urine, poor skin turgor, and dry mucus membranes, may further support a hypothesis that the patient has DI. The nurse should be sure to collaborate with the interdisciplinary team to identify and treat the underlying cause, implement appropriate interventions, re-evaluate therapies and plan of care, and include the patient and family in the plan of care.

When educating the patient and family, be sure to emphasize the following points:

- Importance of monitoring intake and output at home
- Daily weight checks at the same time and using the same scale
- Signs and symptoms of dehydration to report to the practitioner (e.g., dry skin and mucous membranes, persistent and intense thirst, reduced urine output or concentrated dark-colored urine, low blood pressure with associated dizziness or lightheadedness, a rapid heart rate)
- Benefits of wearing a medical alert bracelet stating the patient has DI

Evaluation of Nursing Care of the Patient with Diabetes Insipidus

The nurse should evaluate the outcomes of care with both the patient and their family. For patients with DI, positive outcomes would be intake, output, and electrolyte balance. If these outcomes are not met, the nurse should evaluate what could have been done differently. Was the patient engaged in during their treatment? How could the nurse modify care interventions to meet goals?

Evaluating Outcomes

Effective nursing care prevents complications of DI, provides the patient with education about the disease, and identifies signs and symptoms of dehydration or hypovolemic shock. Questions the nurse can ask to evaluate nursing care include:

- Did the patient maintain a balanced intake and output?
- Did the patient actively participate in monitoring their intake and output?
- Did the patient experience any electrolyte imbalances?
- Did communication remain open between the patient, nurse, and practitioner throughout care?

Medical Therapies and Related Care

Treatment strategies for DI include treating the underlying cause and ensuring the patient drinks enough fluids to maintain hydration. Desmopressin is typically administered to replace vasopressin in the body and act as an antidiuretic hormone to treat polyuria. If a tumor is present, the pituitary gland may be removed—a procedure called a **hypophysectomy**. Discontinuing nephrotoxic medications may return the kidneys to normal function. A thiazide diuretic may be prescribed in cases of low ADH production to reduce urine production (Perkins, 2020).

Syndrome of Inappropriate Antidiuretic Hormone Release

Unsuppressed or over-release of ADH results in **syndrome of inappropriate antidiuretic hormone release (SIADH)**. The excess ADH prevents the production of urine in the kidneys, impairs water secretion, and leads to excess water in the body (hypervolemia) and hyponatremia (Yasir & Mechanic, 2023). SIADH may be caused by certain cancers, central nervous system disturbances, certain medications, pulmonary disease, vascular diseases, and myocardial infarction. In some cases, SIADH can also be hereditary.

Clinical Manifestations

Clinical manifestations of SIADH are usually due to decreased extracellular fluid osmolality and hyponatremia. This causes cerebral edema. Early signs and symptoms of SIADH are malaise, nausea, and vomiting. As sodium levels continue to fall, lethargy, headache, obtundation, and seizures may occur, followed by coma and respiratory arrest if sodium levels fall below 120 mEq/L.

Diagnostics and Laboratory Values

A subjective assessment for SIADH involves asking the patient targeted questions about their quality of life. Diagnostic testing can further evaluate disease progression. Serum osmolality and serum sodium will both be low in patients with SIADH. Urine sodium levels will be elevated due to increased free water absorption in the renal collecting tubules. The state of having a normal volume of fluids in the body, or **euvolemia**, will be present.

Diagnostic testing should rule out underlying causes, such as hypothyroidism or adrenal insufficiency. Other tests—such as kidney and liver function testing, thyroid profile, fasting lipid profile, serum electrolytes, and serum cortisol levels—should also be evaluated. Patients with pulmonary symptoms or a history of smoking may have a CT scan or chest X-ray to rule out lung cancer (Yasir & Mechanic, 2023).

Nursing Care of the Patient with SIADH

Similar to DI care, the nurse should closely monitor intake and output, daily weights, vital signs, changes in level of consciousness, mental status, and laboratory values. It is also important to assess for Cheyne-Stokes respirations and to monitor the patient's weight at the same time each day, using the same scale if possible. Evaluation of laboratory values is also important to monitor for electrolyte imbalances and acute kidney injury.

Recognizing Cues and Analyzing Cues

When completing a subjective assessment, questions may include:

- Do you struggle with headaches, lethargy, dizziness, or confusion?
- Are you having GI problems, such as nausea and vomiting?
- Have you had unplanned weight gain?
- Are you having any chronic pain?
- Have you had any head trauma?

Obtain an accurate list of all medications or illicit drugs the patient is currently taking.

An objective assessment of a patient with suspected SIADH may reveal normal skin turgor, moist mucus membranes, and absence of edema. A detailed neurological assessment may show lethargy, speech difficulties, sluggish deep tendon reflexes, and tremor. A respiratory assessment may show **Cheyne-Stokes respirations** in severe cases. These are characterized by cyclical episodes of hyperventilation and apnea and are a sign of cardiac damage.

LINK TO LEARNING

Watch this video to hear the pattern of respiratory rhythm (https://openstax.org/r/77RespRhythm) of Cheyne-Stokes respirations.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Signs of fluid overload and heart failure are a high priority. The nurse will closely monitor the patient's cardiac output through blood pressure, heart rate, respiratory rate, and absence of chest pain. Intake and output, as well as daily weights, are also important to monitor fluid balance. Because of the excess water in the body, patients with SIADH are at risk for cerebral edema and seizures from low levels of sodium, so patient safety measures such as seizure precautions should be initiated. The nurse should ensure the proper administration of prescribed loop diuretics to aid in the elimination of excess water.

When educating the patient and family, be sure to include:

- The importance of monitoring intake and output at home
- Daily weight checks at the same time and using the same scale
- Signs and symptoms of hyponatremia to report to the practitioner

Evaluation of Nursing Care of the Patient with SIADH

Nursing interventions should always remain flexible in order to meet goals. Modifications to the nursing plan of care should be based upon the evaluation of the effectiveness of measures implemented to correct SIADH. A patient who isn't compliant with a fluid restriction, for example, may need re-education about its importance and goal adjustment to increase compliance.

Evaluating Outcomes

Effective nursing care prevents complications of SIADH, provides the patient with education about the disease, and identifies signs and symptoms of severe hyponatremia. A primary patient outcome related to SIADH management is to prevent further accumulation of excess water in the body. This can be evaluated through intake and output monitoring. Laboratory values can also show trending sodium and osmolality. Questions the nurse can ask to evaluate nursing care include:

- Did the patient maintain a balanced intake and output?
- Did the patient actively participate in monitoring their intake and output?

- Did the patient experience any signs or symptoms of hyponatremia?
- Was the patient compliant with fluid restrictions?
- Did communication remain open between the patient, nurse, and practitioner throughout care?

Medical Therapies and Related Care

Treatment for SIADH involves treating the underlying condition (such as pulmonary or CNS infection) and preventing any further decrease in sodium levels. For patients with mild symptoms of hyponatremia, an oral fluid restriction of less than 800 ml/day is initiated. If hyponatremia persists, oral or intravenous sodium chloride is given. Loop diuretics, such as furosemide, may be given to increase water excretion and decrease urine concentration.

Patients with severe symptoms, such as seizures and delirium, are given 100 mL IV boluses of hypertonic saline over three to four hours in addition to a water restriction. Serum sodium levels are closely monitored in between boluses to prevent rapid sodium increase. The brain is able to adjust to chronic hyponatremia and protect itself from severe brain swelling from the increase in water. When sodium levels raise too rapidly, the brain is unable to adjust and water is pulled from the nerve cells, causing dehydration damage to the brain that can be permanent.

Vasopressin receptor agonists, such as tolvaptan or conivaptan, may be prescribed for persistent SIADH. These medications prevent free water retention caused by ADH excess and help correct hyponatremia.

21.5 Adrenal Disorders

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations for adrenal disorders
- Describe the diagnostics and laboratory values for adrenal disorders
- Apply nursing concepts and associated nursing care for patients with adrenal disorders
- Evaluate the efficacy of nursing care for adrenal disorders
- Describe the medical therapies that apply to the care of patients with adrenal disorders

Adrenal hormones (Table 21.11) are secreted by the cortex of the gland and released into the circulation via the left and right suprarenal veins. The adrenal cortex produces several key steroid hormones, including glucocorticoids like cortisol, which help regulate metabolism and the body's stress response; mineralocorticoids such as aldosterone, which are crucial for managing blood pressure and electrolyte balance; and androgens, which influence sexual development and function. Additionally, the adrenal medulla, the inner part of the adrenal gland, secretes catecholamines such as adrenaline and norepinephrine, which are critical for the body's fight-or-flight response.

Associated Hormone	Effect
Aldosterone	Increases blood sodium levels
Cortisol, corticosterone, cortisone	Increase blood glucose levels
Epinephrine, norepinephrine	Stimulate fight- or flight- response

TABLE 21.11 Hormones of the Adrenal Glands

One of the major functions of the adrenal gland is to respond to stress. Stress can be either physical or psychological or both. Physical stresses include exposing the body to injury, walking outside in cold and wet conditions without a coat on, and malnutrition. Psychological stresses include the perception of a physical threat, a fight with a loved one, and a bad day at school or work.

The body responds in different ways to short-term stress and long-term stress, following the pattern of General Adaptation Syndrome (GAS). Stage one of GAS is called the **alarm reaction**, also known as the fight-or-flight response. This short-term response is mediated by the hormones epinephrine and norepinephrine from the adrenal medulla via the sympathomedullary (SAM) pathway. Their function is to prepare the body for extreme physical exertion. Once this stress is relieved, the body quickly returns to normal.

If the stress is not soon relieved, however, the body adapts to the stress in the second stage of GAS, the **stage of**

resistance. If a person is starving, for example, the body may send signals to the gastrointestinal tract to maximize the absorption of nutrients from food.

If the stress continues for a longer term, the body enters the third stage of GAS, the **stage of exhaustion**. In this stage, individuals may begin to experience depression, the suppression of their immune response, severe fatigue, or even a fatal heart attack. These symptoms are mediated by the hormones of the adrenal cortex, especially cortisol, released as a result of signals from the hypothalamic-pituitary-adrenal (HPA) axis.

Adrenal hormones also have several non–stress-related functions, including the increase of blood sodium and glucose levels. Several disorders are caused by the dysregulation of the hormones produced by the adrenal glands. Two of the most common are Addison's disease and Cushing's syndrome.

Adrenal Insufficiency

An **adrenal insufficiency** is a primary insufficiency of the adrenal glands from complete or partial destruction of the adrenal cortex. This damage prevents the adrenal glands from producing adequate amounts of cortisol and aldosterone. The cortisol deficiency can result in low blood glucose levels, as it prevents the formation of glucose from molecules that aren't carbohydrates (gluconeogenesis), which is necessary for the body to maintain steady glucose levels. The aldosterone deficiency causes increased sodium loss from the kidneys, leading to hypotension and increased potassium reabsorption.

Causes of adrenal insufficiency include:

- Autoimmune disease and creation of antibodies that react against adrenal tissue (also known as Addison's disease)
- Infection (such as HIV, syphilis, tuberculosis, and histoplasmosis)
- Bilateral adrenalectomy
- Inherited disorders
- Trauma to the adrenal glands
- Malignant cancer that has spread to the endocrine system
- Certain medications that affect serum cortisol levels (such as ketoconazole, etomidate, or phenytoin)

LINK TO LEARNING

This video provides an overview of Addison's disease (https://openstax.org/r/77AddisonDis) as an effective NCLEX review

Clinical Manifestations

Patients with adrenal insufficiency may initially have symptoms such as fatigue, weight loss, generalized weakness, abdominal pain, nausea, vomiting, and dizziness. These symptoms tend to get progressively worse over time. As the disease progresses, hyperpigmentation of the skin (Figure 21.10) occurs in almost all patients (Munir et al., 2023). Female patients may also have decreased axillary and pubic hair.

FIGURE 21.10 This woman has hyper-pigmentation due to adrenal insufficiency. (credit: "F1: Facial and scar pigmentation" by Department of Diabetes and Endocrinology, Clinical Sciences Centre, University Hospital Aintree, Liverpool, CC BY 2.0)

Adrenal Crisis

An adrenal crisis is an acute, rapid onset of severe cortisol and aldosterone insufficiency, causing the patient to become critically ill and go into shock. It can be caused by abrupt discontinuation of steroid therapy or inadequate dosing of current steroid therapy in patients with adrenal insufficiency or by recent infection or trauma. Signs and symptoms include rapid, progressive onset of adrenal insufficiency symptoms such as nausea, vomiting, abdominal pain, hypotension, altered mental status, or obtundation. The crisis is initially treated by administering intravenous fluids, dextrose, and hydrocortisone, followed by diagnostic testing to discover and treat the underlying cause. Adrenal crisis is an emergency and should be reported to the provider immediately. Mortality is approximately 25 percent (Cleveland Clinic, 2022a).

Diagnostics and Laboratory Values

Diagnosis of adrenal insufficiency is confirmed by low serum cortisol and aldosterone levels, a blunt cortisol response with ACTH stimulation, and an elevated renin activity test. A morning serum cortisol level less than 3 mcg/dL will be present. Serum chemistry results may reveal hyponatremia, hypoglycemia, hypercalcemia, and hyperkalemia. Thyroid stimulating hormone (TSH) may also be elevated, secondary to low cortisol levels.

Other diagnostic testing may be completed to rule out alternative causes of the low hormone levels: for example, a chest X-ray to confirm tuberculosis, or abdominal CT scan to confirm adrenal tumor, mass, or calcification. A biopsy of the adrenal gland may be completed to confirm malignancy.

Nursing Care of the Patient with Adrenal Insufficiency

Nursing care of the patient with adrenal insufficiency involves maintaining nutrition and fluid balance, improving symptoms, and preventing complications, such as adrenal crisis. Careful monitoring, robust patient education, and timely intervention are key interventions to optimize outcomes.

Recognizing and Analyzing Cues

When completing a subjective assessment, ask the patient targeted questions, especially if the patient is experiencing a host of nonspecific symptoms (Munir et al., 2023). Specific questions related to adrenal insufficiency may include:

- Have you experienced fatigue and unexplained weight loss? Has it gotten worse over a period of time?
- Have you been experiencing a loss of appetite, nausea, or chronic abdominal pain?

An objective assessment may reveal generalized hyperpigmentation, especially at the elbows, palmar creases, lips, knuckles, posterior neck, nail beds, nipples, breast areola, and gingival mucosa (Munir et al., 2023). The patient may also have poor coordination, **vitiligo** (patches of skin without pigment), hypotension, and a weak, irregular pulse.

A slow progression of symptoms indicates a chronic adrenal disease, while a rapid progressive onset indicates an

acute, emergent condition. Nurses can analyze the degree of symptom burden incorporating all cues related to cardiovascular stability. Insufficient adrenal activity also predisposes patients to hypoglycemia; therefore, it is important for nurses to recognize symptomatic hypoglycemia such as weakness, tremors, confusion, diaphoresis, and in severe cases, seizures. Rapid identification of abnormal cues will guide clinical intervention if they become of an emergent nature.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Priorities of patient care include ensuring the patient follows treatment orders and monitoring the patient for adrenal crisis. Care of the patient with adrenal insufficiency includes prioritization of cardiovascular needs, monitoring of electrolyte imbalance, and close monitoring of glucose levels. Nurses should monitor hemodynamic stability with trending blood pressures, heart rate, and laboratory data. Serum sodium levels should be monitored since low levels of aldosterone can cause hyponatremia. Often, patients are placed on telemetry to identify any triggered dysrhythmias from electrolyte disturbance or hypovolemia. Any deviations of these physiological parameters can be catastrophic if this leads to adrenal crisis. An interdisciplinary, collaborative approach is mainstream when delivering care to the patient with adrenal complications. The care team may include a nutritionist to ensure the patient's diet includes sufficient sodium and potassium to maintain balance. If the patient has a decreased appetite, encourage frequent, small meals throughout the day to maintain a healthy caloric intake. For a patient experiencing fatigue, try to cluster care or activities so the patient has adequate periods of rest. Providing antiembolism stockings or a sequential compression device can prevent VTE in patients who are bedridden.

Patient teaching should include information about adrenal insufficiency, especially the importance of medication and treatment compliance. Avoidance of stress and healthy coping mechanisms to reduce stress and increase relaxation should also be discussed with the patient and family. Other teaching should include:

- Signs and symptoms to report to the provider, such as adrenal crisis
- Infection prevention measures, such as staying away from people who are sick
- Utilization of an alert bracelet stating the patient has adrenal insufficiency
- Technique for self-administering an emergency hydrocortisone injection in times of stress

Evaluating Nursing Care of the Patient with Adrenal Insufficiency

To evaluate the effectiveness of nursing actions, the nurse should review any goals created and see if they were achieved and by the set deadline. For example, if the patient was experiencing a decrease in appetite, were they still able to maintain a healthy caloric intake throughout the day? Re-assessment should compare current status to initial status. If the patient was not able to maintain a healthy caloric intake, inquire as to reasons for inability or barriers. Were the patient's food preferences taken into consideration? Were frequent, small meals offered to the patient throughout the day? If the goal is not met, the nursing care will need to be modified.

Evaluating Outcomes

Evaluating outcomes looks at the patient from a larger view. Questions the nurse can ask may include:

- Did the patient experience a decrease in the symptoms of adrenal insufficiency?
- Are the patient's cortisol levels, electrolytes, and vital signs within normal limits?
- Is the patient able to state the importance of following the treatment plan?

If these outcomes were not achieved, the plan will need to be re-evaluated and modified.

Medical Therapies and Related Care

Treatment of adrenal insufficiency involves repletion of low cortisone and aldosterone with synthetic versions of the hormones. Hormonal replacement is a lifelong therapy. A glucocorticoid, such as hydrocortisone or prednisone, will be prescribed to replace low levels of cortisone. For low aldosterone levels, fludrocortisone acetate, a mineralocorticoid, will be prescribed to help control sodium and potassium levels in the body. Medication dosages are determined by clinical response and return of electrolyte balance.

In situations of high stress, such as fever, infection, and pregnancy, an increase of glucocorticoid therapy will be required to compensate for a stress response. It is important for the patient to maintain all appointments with the endocrinologist and receive adequate patient education about the disease, treatment, and symptoms to report to the practitioner.

Cushing's Syndrome

Cushing's syndrome is a condition in which the body is exposed to too much circulating cortisol over a long period of time. The excess cortisol increases gluconeogenesis as well as creates insulin resistance. It also disrupts the Kreb's cycle and negatively affects the body's ability to metabolize glycogen and fats and synthesize proteins. This causes poor wound healing, osteoporosis, and poor immune function.

Cushing's syndrome is most commonly caused by long-term use or high doses of glucocorticoids (exogenous Cushing's syndrome) but can also be caused by excess production of cortisol by the adrenal glands (endogenous Cushing's syndrome). **Cushing's disease** is when the excess cortisol is produced because of a tumor or adenoma on the pituitary gland. The tumor causes the pituitary gland to produce an excess of ACTH, triggering the adrenals to produce excess cortisol. Cushing's disease is the cause of 80 percent of endogenous Cushing's syndrome (Chaudhry & Singh, 2023).

Clinical Manifestations

Clinical manifestations of Cushing's syndrome include weight gain, water retention, weakness, fatigue, headache, delayed wound healing, easy bruising, bone pain, loss of height, hirsutism (excess hair growth), impotence, decreased libido, menstrual irregularities, and frequent infections (Figure 21.11). Patients may also have depression, cognitive dysfunction, or peptic ulcer disease.

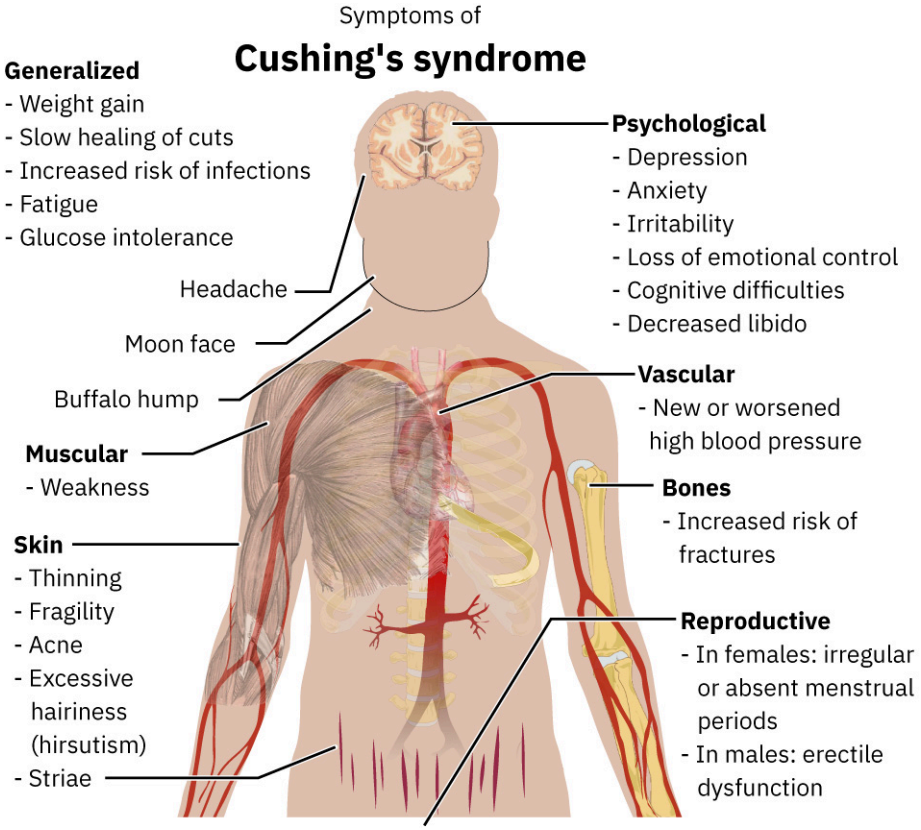

FIGURE 21.11 Cushing's syndrome affects many body systems. (credit: " Cushing's syndrome (vector image)" by Mikael Häggström/ Wikimedia Commons, CC0 1.0)

Diagnostics and Laboratory Values

Signs and symptoms of Cushing's syndrome may vary depending on the level of extra cortisol in the body (Belleza, 2023). An accurate assessment during initial diagnosis can prevent complications. Diagnostic testing can provide information about the underlying cause and severity of the disease.

A dexamethasone suppression test is done by giving the patient a low dose of dexamethasone at night, then collecting a serum cortisol level the next morning. A patient with Cushing's syndrome will not have the ability to suppress cortisol production, resulting in a high serum cortisol level. A 24-hour urine collection for free cortisol can detect overproduction of cortisol in the body. Serum electrolytes may show hypokalemia and hypocalcemia, and

fasting blood glucose levels may be elevated.

A CT scan or ultrasound of the kidneys may reveal an adrenal tumor. MRI of the brain may be done to evaluate for a pituitary tumor. X-rays may also be completed to evaluate for osteoporosis.

Nursing Care of the Patient with Cushing's Syndrome

Nursing care should be based on assessment data with the goal to reduce symptoms. For example, patients with Cushing's syndrome are more prone to pressure injuries and falls secondary to weakness, fatigue, and poor healing (Belleza, 2023). To decrease risk for pressure injury, the nurse should ensure the patient changes positions frequently while in bed. To protect skin integrity, the nurse can also frequently inspect the patient's skin and teach the patient how to care for their skin and avoid anything that can irritate or tear it. To prevent falls, institute fall precautions, provide assistance to the patient when ambulating, and ensure frequently used items are within the patient's reach.

Recognizing Cues and Analyzing Cues

Subjective questions during the initial nursing assessment to target symptoms of Cushing's syndrome may include:

- Have you had unexplained weight gain or water retention?
- Do you bruise easily?
- Have you been experiencing any bone pain, fatigue, or muscle weakness?
- Have you noticed any increase in hair growth on your face, chest, or abdomen?
- Have you noticed a decrease in libido or sexual dysfunction?
- Are your periods regular? (Female patients)

Be sure to obtain an accurate medication history. In some instances, Cushing's syndrome may be caused by certain medications, such as prednisone, used to treat other conditions. Physical findings may show fatty deposits around the face ("moon face") and between the shoulders ("buffalo hump"), hirsutism, thin extremities, muscle wasting, swollen ankles, purplish striae, skin atrophy, acne, and central obesity. Patients who have physical signs, such as moon face or a buffalo hump, may be experiencing body image issues. Listen to the patients' concerns and discuss how physical signs may fade with treatment (Vera, 2023). Talk to the patient about dietary changes they can make to decrease fluid retention, such as a low sodium diet.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Based upon the findings, the nurse may hypothesize Cushing's syndrome. The nurse will discuss the findings with the patient, then collaborate with the practitioner about a plan of care. Since the diagnostic priority is to evaluate cortisol production and discover the underlying cause, the nurse would expect to draw serum bloodwork and possibly prep the patient for imaging, such as X-ray, CT scan, or MRI.

Patients should be educated about the disease, testing, and treatment. Be sure to include:

- importance of monitoring daily weights and proper nutrition
- ways to prevent infection, such as avoiding large crowds, using proper hand hygiene, and keeping away from people who are sick
- injury prevention strategies
- stress reduction and relaxation techniques
- the importance of keeping all follow-up appointments
- wearing a medical alert bracelet stating the patient has Cushing's syndrome

In addition to improving symptoms, the nurse must monitor for complications. Similar to adrenal insufficiency, adrenal crisis can occur in Cushing's syndrome if glucocorticoid medications are abruptly stopped. The nurse should also monitor vital signs, electrolytes, daily weights, intake and output, and serum blood glucose for imbalances (Vera, 2023).

Evaluating Nursing Care of the Patient with Cushing's Syndrome

An improvement in symptoms and prevention of complications would indicate adequate nursing care. For instance, if the patient does not experience any falls or skin breakdown during treatment, nursing interventions were adequate for care. If the nurse notices a patient has an area of redness over a bony prominence, nursing care should be adjusted to prevent any further injury; the nurse may initiate a strict turn/repositioning schedule or request an

overlay mattress to further prevent pressure to that area.

Evaluating Outcomes

Any goals created during the nursing care process should be evaluated. Interventions are fluid and should be adjusted as appropriate during the care process. To support this process, the nurse may ask questions such as:

- Did the patient's skin remain free from injury?
- Did the patient's blood sugar achieve target norms?
- Did the patient remain free from infection?
- Did the patient's nutrition meet their ideal body weight?

Constant collaboration with the interdisciplinary team and open communication with the patient and family are also key to supporting nursing care goals.

Medical Therapies and Related Care

Treatment is dependent on the underlying cause. If Cushing's disease is exogenous, then the patient may be tapered off steroid therapy. The taper is done slowly, sometimes over months, to prevent adrenal crisis and give the adrenal glands a chance to return to normal function (Chaudhry & Singh, 2023). Mifepristone, a cortisol receptor blocker, may be prescribed to control blood glucose levels until adrenal function improves.

In endogenous cases caused by an adrenal tumor, surgery is the first therapy of choice for treatment. Patients are then closely monitored to evaluate if normal cortisol production is present. If the cause is a pituitary tumor, hypophysectomy surgery may be done; radiation therapy may also be performed. In some cases, if a tumor cannot be completely resected, a bilateral adrenalectomy may be performed; the patient will then require lifelong glucocorticoid and mineralocorticoid replacement therapy. Bisphosphonates may also be prescribed to prevent osteoporosis. Additional medications may be prescribed to control signs and symptoms, such as potassium supplements, diuretics, and antihypertensives.

Summary

21.1 Review of Endocrine Anatomy and Physiology

- The endocrine system consists of cells, tissues, and organs that secrete hormones critical to homeostasis.
- Endocrine glands are ductless glands that secrete hormones.
- Endocrine communication involves chemical signaling via the release of hormones into the extracellular fluid. From there, hormones diffuse into the bloodstream and may travel to distant body regions, where they elicit a response in target cells. Hormones are chemical substances that travel throughout the body in the bloodstream and affect the activity only of its target cells: that is, cells with receptors for that particular hormone.
- Hormones play a critical role in the regulation of physiological processes because of the target cell responses they regulate. Reflexes triggered by both chemical and neural stimuli control endocrine activity.
- Clinical assessment of the endocrine system is a process that incorporates a patient history, physical examination, and diagnostic testing.
- Endocrine conditions can be nonspecific and varied, and they can affect many body systems.
- Diagnostic testing is targeted based on the findings of a history and physical exam and can include laboratory testing, imaging, and invasive testing.

21.2 Diabetes Mellitus

- Diabetes mellitus (DM) is a disease characterized by inappropriately high blood glucose levels, caused by an imbalance of insulin and glucagon. There are three main types: Type 1 (T1DM), Type 2 (T2DM), and gestational diabetes (GDM).
- T1DM is an autoimmune disease that damages the beta cells of the pancreas so they do not produce insulin; thus, synthetic insulin must be administered by injection or infusion. Risk factors include age, family history, or history of viral infection.
- T2DM occurs when the cells of the body become resistant to the effects of insulin, causing the pancreas to increase its production of insulin. Risk factors include obesity, family history, and inactivity.
- Gestational diabetes (GDM) occurs when beta cells in the pancreas become unable to compensate for the demands of pregnancy, causing a dysfunction in the production of insulin and a reduced insulin sensitivity resulting in high blood glucose levels. Risk factors include obesity, family history, and polycystic ovary syndrome.
- Common symptoms associated with DM are polyuria, increased thirst, unplanned weight loss, increased hunger, blurry vision, tingling or numbness in hands or feet, decrease in energy, dry skin, increased infections, and slow wound healing.
- DM is diagnosed primarily through evaluation of fasting serum glucose levels, hemoglobin A1c levels, or oral glucose tolerance testing (OGTT).
- Patients with DM should be continuously monitored for complications, such as signs of hypoglycemia and hyperglycemia. When a patient with diabetes is experiencing stress or an infection, the nurse should plan to assess their blood glucose levels more frequently. Patients should also be thoroughly educated about their condition.
- Treatment of DM is patient-specific and involves education and patient engagement, medication, lifestyle changes, and glucose monitoring. Patients with T1DM are prescribed insulin. Patients with T2DM and GDM may be prescribed oral antihyperglycemics or insulin based on their individual blood glucose control needs and response to initial treatments.

21.3 Thyroid and Parathyroid Disorders

- Thyroid disorders occur when the thyroid gland releases inappropriate levels of hormones. This creates imbalance in the functions that regulate how the body metabolizes proteins, fats, and carbohydrates, as well as in how efficiently the body uses energy, consumes oxygen, and produces heat.
- Dietary iodine deficiency can result in the impaired ability to synthesize T3 and T4, leading to a variety of severe thyroid disorders.
- Common disorders of the thyroid include hyperthyroidism, hypothyroidism, and thyroid cancer. Because the thyroid controls metabolism, heart rate, and body temperature, clinical signs and symptoms of a thyroid

disorder usually involve hyper- or hypo-activity with these functions.

- Parathyroid disorders, such as hyperparathyroidism and hypoparathyroidism, develop when parathyroid glands release inappropriate levels of PTH hormone, which controls calcium levels in the body.
- Clinical manifestations of parathyroid disease are unusual in the early stages. Signs and symptoms vary and are dependent on the type of disorder present, but they usually mimic signs and symptoms of hypercalcemia and hypocalcemia.
- To determine whether a patient has a thyroid or parathyroid disorder, begin with a subjective assessment that asks focused questions to determine if the patient is experiencing any symptoms or has a previous medical history of neck issues. The information gathered from this subjective assessment can then guide a physical assessment.
- Diagnostic testing for thyroid or parathyroid disorders includes bloodwork, imaging, and biopsy. The type of testing depends on what the subjective and objective data reveal.
- Care of the patient with a thyroid or parathyroid disorder involves educating the patient and family, following the plan of care, and monitoring for complications.
- Medical therapies for a thyroid disorder include medications to correct inappropriate levels of thyroid hormone and thyroidectomy. Medical therapies for a parathyroid disorder include removal of the parathyroid and medications to correct electrolyte imbalances and bone density problems.

21.4 Pituitary Disorders

- The pituitary gland is a bean-sized organ suspended from the hypothalamus that produces, stores, and secretes hormones in response to hypothalamic stimulation.
- Chronic underproduction of antidiuretic hormone (ADH) or a mutation in the ADH receptor results in diabetes insipidus (DI). If the posterior pituitary does not release enough ADH, water cannot be retained by the kidneys and is lost as urine.
- The main clinical manifestations of DI are extreme thirst (polydipsia) and the production of large amounts of urine (polyuria).
- Diagnosis of DI involves confirming polyuria and figuring out the underlying cause. Common tests include a 24-hour urine collection, fluid deprivation test, and hypertonic saline infusion test.
- When caring for patients with DI, it is important to closely monitor intake and output, daily weights, vital signs, changes in level of consciousness, skin turgor, mucus membranes, and laboratory values.
- Treatment strategies for DI include treating the underlying cause and ensuring the patient drinks enough fluids to maintain hydration.
- Unsuppressed or over-release of ADH results in syndrome of inappropriate antidiuretic hormone release (SIADH). The excess ADH prevents the production of urine in the kidneys, impairs water secretion, and leads to hypervolemia and hyponatremia.
- Clinical manifestations of SIADH are usually due to decreased extracellular fluid osmolality and hyponatremia. This causes cerebral edema, and symptoms tend to be neurological.
- Diagnostic testing for SIADH should rule out underlying causes, such as hypothyroidism or adrenal insufficiency. Serum osmolality and serum sodium will both be low. Urine sodium levels will be elevated due to increased free water absorption in the renal collecting tubules.
- In patients with SIADH, it's important to closely monitor intake and output, daily weights, vital signs, changes in level of consciousness, mental status, and laboratory values. It is also important to assess for Cheyne-Stokes respirations.
- Treatment for SIADH involves treating the underlying condition (such as pulmonary or CNS infection) and preventing any further decrease in sodium levels.

21.5 Adrenal Disorders

- The adrenal glands are wedges of glandular and neuroendocrine tissue adhering to the top of the kidneys by a fibrous capsule. One of their major functions is to respond to stress. Adrenal hormones also have several non–stress-related functions, including the increase of blood sodium and glucose levels.
- Adrenal insufficiency is a primary insufficiency of the adrenal glands from complete or partial destruction of the adrenal cortex. This damage prevents the adrenal glands from producing adequate amounts of cortisol and aldosterone. It also causes low glucose levels, low sodium levels, and high potassium levels.

- Patients with adrenal insufficiency have progressive, nonspecific symptoms that include fatigue, weight loss, generalized weakness, abdominal pain, nausea, vomiting, and dizziness. Hyperpigmentation and vitiligo may be present.
- Diagnosis of adrenal insufficiency is confirmed by low serum cortisol and aldosterone levels, a blunt cortisol response with ACTH stimulation, and an elevated renin activity test.
- Treatment of adrenal insufficiency involves hormonal replacement, which is a lifelong therapy.
- Cushing's syndrome is a condition in which the body is exposed to too much circulating cortisol over a long period of time. The cause can be exogenous or endogenous.
- Clinical manifestations of Cushing's syndrome include weight gain, water retention, weakness, fatigue, headache, delayed wound healing, easy bruising, bone pain, loss of height, hirsutism (excess hair growth), impotence, decreased libido, menstrual irregularities, and frequent infections. Additional physical findings may show moon face, buffalo hump, hirsutism, thin extremities, muscle wasting, swollen ankles, purplish striae, skin atrophy, acne, and central obesity.
- A low-dose dexamethasone suppression test is done to confirm Cushing's syndrome. Imaging may also be completed to rule out cancer or pituitary involvement.
- Nursing care for patients with adrenal disorders is based on the assessment data, with the goals of reducing symptoms and preventing complications. Patient teaching should include information about the disease, testing, treatment, and signs and symptoms to report to the provider.
- Treatment for exogenous Cushing's disease includes a slow taper off steroid therapy. In endogenous cases, surgery or radiation therapy may be done. If a bilateral adrenalectomy is performed, the patient must be placed on lifelong hormone replacement therapy.

Key Terms

adrenal glands small, triangular-shaped endocrine glands located on top of each kidney that produce and release a variety of hormones that are essential for regulating several vital functions in the body

adrenal insufficiency insufficiency of the adrenal glands caused by complete or partial destruction of the adrenal cortex, which prevents the adrenal glands from producing adequate amounts of cortisol and aldosterone; also known as Addison's disease

alarm reaction first stage of GAS, in which a response to short-term stress is mediated by the hormones epinephrine and norepinephrine from the adrenal medulla via the SAM pathway; also called the fight-or-flight response

Cheyne-Stokes respirations respiration characterized by cyclical episodes of hyperventilation and apnea

colloid viscous fluid that stores the glycoprotein thyroglobulin, the precursor to the thyroid hormones

congenital hypothyroidism disorder characterized by cognitive deficits, short stature, and sometimes deafness and muteness in children and adults born to mothers who were iodine-deficient during pregnancy

Cushing's disease condition characterized by excess production of circulating cortisol; caused by a tumor or adenoma on the pituitary gland

Cushing's syndrome condition in which the body makes too much cortisol over a long period of time

diabetes insipidus (DI) disorder in which water cannot be retained by the kidneys and is lost as urine; caused by chronic underproduction of ADH or a mutation in the ADH receptor; also known as arginine vasopressin deficiency (AVP-D)

diabetes mellitus (DM) disease characterized by inappropriately high levels of blood glucose

diabetic ketoacidosis (DKA) serious complication of diabetes characterized by high blood glucose, ketone production, and metabolic acidosis due to insufficient insulin

endocrine signaling process by which hormones secreted into the extracellular fluid diffuse into the blood or lymph, enabling them to travel great distances throughout the body

endocrine system network of cells, tissues, and organs that secrete hormones as a primary or secondary function

euvolemia state of having a normal volume of fluids in the body

exocrine system network of glands that release their secretions through ducts

exophthalmos bulging eyes

fluid deprivation test assessment for diagnosing diabetes insipidus; involves restricting the patient's fluid intake while monitoring their body weight and urine concentration

gestational diabetes (GDM) beta cells in the pancreas become unable to compensate for the demands of

pregnancy, causing a dysfunction in the production of insulin and a reduced insulin sensitivity resulting in high blood glucose levels

glucagon hormone released when the body's blood glucose is too low, triggering the liver to release stored glucose to raise glucose levels

goiter enlarged thyroid gland

Graves' disease hyperthyroid state that results from an autoimmune reaction in which antibodies overstimulate the follicle cells of the thyroid gland

hormone chemical substance that travels throughout the body in the bloodstream and affects the activity only of its target cells

hormone receptor protein that receives and responds to messages from a particular type of hormone

humoral stimuli changes in blood levels of non-hormone chemicals, such as nutrients or ions, which cause the release or inhibition of a hormone to, in turn, maintain homeostasis

hungry bone syndrome complication that occurs from prolonged hypocalcemia following surgical correction for hyperparathyroidism

hyperglycemia high blood glucose levels

hyperosmolar hyperglycemic state (HHS) severe condition associated with extremely high blood glucose and increased plasma osmolality, but without significant ketone production or metabolic acidosis, commonly occurring in type 2 diabetes

hyperparathyroidism disorder caused by an overproduction of PTH, resulting in excessive calcium reabsorption from bone

hyperthyroidism overproduction of thyroid hormones, characterized by an increased metabolic rate and consequential weight loss, excess heat production, sweating, and increased heart rate

hypoparathyroidism disorder characterized by abnormally low blood calcium levels; may be caused by parathyroid hormone deficiency

hypophysectomy removal of the pituitary gland

hypothyroidism underproduction of thyroid hormones, characterized by a low metabolic rate, weight gain, cold extremities, constipation, reduced libido, menstrual irregularities, and reduced mental activity

insulin hormone that helps cells absorb glucose for energy and lowers the body's blood sugar levels

Kussmaul respirations rapid, deep breathing at a consistent pace

myxedema coma severe case of hypothyroidism that causes respiratory depression, hypothermia, and bradycardia

negative feedback loop process characterized by the inhibition of further secretion of a hormone in response to adequate levels of that hormone

neural stimuli release hormones in response to neural stimulation

osmotic diuresis increased urination caused by increased concentration of glucose in the kidneys

parathyroid gland located on the posterior surface of the thyroid gland

pituitary gland bean-sized organ suspended from the hypothalamus that produces, stores, and secretes hormones in response to hypothalamic stimulation

polydipsia extreme thirst

polyuria excessive urination volume

positive feedback loop process characterized by the release of additional hormones in response to an original hormone release

stage of exhaustion third stage of GAS, in which individuals may begin to experience depression, the suppression of their immune response, severe fatigue, or even a fatal heart attack

stage of resistance second stage of GAS, in which the individual's body tries to adapt to stress

syndrome of inappropriate antidiuretic hormone release (SIADH) disorder in which unsuppressed or over-release of ADH prevents the production of urine in the kidneys and impaired water secretion and leads to hypervolemia and hyponatremia

thyroid butterfly-shaped gland with two lobes that are connected by the isthmus

thyroid storm medical emergency caused when the thyroid gland releases a large amount of thyroid hormone in a short period of time

type 1 diabetes mellitus (T1DM) condition where autoimmune disease damages the beta cells of the pancreas so they do not produce insulin; thus, synthetic insulin must be administered by injection or infusion

type 2 diabetes mellitus (T2DM) condition where cells of the body become resistant to the effects of insulin, so the pancreas increases its production of insulin

vitiligo patches of skin without pigment

Assessments

Review Questions

1. Hormones travel throughout the body and affect the activity of what?
    a. blood osmolality
    b. target cells
    c. paracrine
    d. neural stimuli

2. What should the nurse do during a physical assessment of the thyroid?
    a. Push on the side of the neck to feel the thyroid.
    b. Ask the patient to tilt the head down while drinking water.
    c. Palpate the thyroid gland using a circular motion, while standing behind the patient.
    d. Assess the patient's arms and palms for tremors.

3. What is the function of the hormone glucagon?
    a. to increase blood sugar levels
    b. to decrease blood sugar levels
    c. to increase insulin levels
    d. to decrease insulin levels

4. What would be a symptom that the body was producing too much melatonin?
    a. increased agitation
    b. increased metabolism
    c. excessive sleepiness
    d. excessive hair production

5. The nurse is caring for a patient with T1DM. While developing a teaching plan about hypoglycemia as a complication of therapy, what sign or symptom should the nurse include?
    a. fruity breath
    b. increased thirst
    c. shakiness
    d. headache

6. The nurse is preparing to discharge a patient who is newly diagnosed with DM. The patient asks the nurse if they can eat a candy bar or cup of ice cream every time they feel shaky, hungry, or nauseated. How should the nurse respond?
    a. Yes, a candy bar or cup of ice cream is needed to treat the hypoglycemia.
    b. No, if your blood sugar reading is low, these snacks contain too much sugar; a few hard candies or a cup of skim milk would be better choices.
    c. Yes, you can eat the snack, but then have a meal as soon as possible.
    d. No, the snack will cause hyperglycemia; you should quickly eat a meal instead.

7. The nurse is reviewing a patient's fasting serum blood results. What result would indicate to the nurse that the patient may have diabetes?
    a. Potassium level of 4.2 mmol/L
    b. Hemoglobin level of 15 g/dl
    c. A1C level 6.1%
    d. Fasting glucose of 129 mg/dL

8. What behaviors are likely symptoms of hyperthyroidism?
   a. heat intolerance, slow heart rate, sleepiness
   b. fatigue, central obesity, cold intolerance
   c. irritability, mood swings, fatigue
   d. confusion, heat intolerance, slow movements

9. What should the nurse be sure to monitor for in order to prevent hungry bone syndrome?
   a. prolonged hypercalcemia
   b. dehydration
   c. prolonged hypocalcemia
   d. fluid overload

10. A patient with a history of hyperthyroidism is admitted to the hospital with thyroid storm. What should the nurse expect to be included in the plan of care?
   a. warming blankets
   b. antithyroid medications
   c. insulin
   d. diuretics

11. A nurse is caring for a patient with SIADH. What type of electrolyte imbalance would the nurse expect to find in this situation?
   a. hyponatremia
   b. hypocalcemia
   c. hyperkalemia
   d. hypermagnesemia

12. DI results from a chronic underproduction of ADH, which in turn does what to the body?
   a. increases glucagon production
   b. increases water retention
   c. decreases the amount of water retained
   d. causes hypernatremia

13. Cheyne-Stokes respirations are characterized by what?
   a. cyclical episodes of hyperventilation and apnea
   b. constant, rapid breathing
   c. long, slow, deep breaths
   d. shallow breathing

14. A patient diagnosed with adrenal insufficiency would be expected to have what laboratory value?
   a. low glucose
   b. elevated glucose
   c. elevated sodium
   d. low potassium

15. A nurse is teaching a patient about treatment for adrenal insufficiency. What should the nurse tell the patient about hormone therapy?
   a. Hormone therapy is a temporary measure.
   b. Hormone therapy does not have to be taken daily.
   c. Hormone therapy is a lifelong therapy.
   d. Hormone therapy is not an adequate treatment.

16. In some cases of Cushing's disease, a CT of the brain may be completed for what reason?
   a. to rule out dementia

b. to identify pituitary tumors
c. to identify frontal lobe tumors
d. to rule out temporal lobe damage

Check Your Understanding Questions

1. Why should a patient with DM be referred to an ophthalmologist?
2. When are the best times for a patient with DM to check their blood glucose levels?
3. Explain how a physical assessment can reveal signs of hypocalcemia.
4. What would you expect to see as part of the treatment plan for a patient being treated for DI?
5. What would be some signs and symptoms of rapid serum sodium correction and clinical assessment findings?
6. You are caring for a patient with Cushing's disease, and they are having body image disturbances. What can you do to help the patient properly cope with body changes?

Reflection Questions

1. Why is it important to complete a targeted subjective assessment on a patient with a suspected endocrine disorder?
2. In managing patients with SIADH, how might ethical considerations influence treatment decisions, especially when balancing fluid restriction and the risk of rapidly correcting sodium levels?

What Should the Nurse Do?

A 55-year-old patient has recently been diagnosed with T2DM and is being started on the sulfonylurea agent glipizide. The patient is very concerned about her new diagnosis and says she feels incompetent because she has no knowledge about DM.

1. What should the nurse include in the patient's education and support system?
2. How would the nurse evaluate the efficacy of the prescribed medication glipizide?

Ms. S.P. is a 44-year-old patient who noticed that she has gained weight and that her face and body are round, while her legs and arms have become thinner. A tentative diagnosis of Cushing's disease is made.

3. The nurse knows that Cushing's disease causes clinical manifestations. What routine assessments would the nurse make a priority in the plan of care?
4. The nurse notices that the patient seems depressed because she needs surgery and will not get out of bed to ambulate. What can the nurse do to prevent further complications?
5. Ms. S.P. is scheduled for discharge. What information does the nurse need in order to provide adequate patient teaching?

Competency-Based Assessments

1. Design a teaching tool that you would use to teach your newly diagnosed patient about the disease process of GDM. How would you check their understanding?
2. Develop a handout that you would use to help educate your patient about hypoparathyroidism.

CHAPTER 22

Infection and Infectious Diseases

FIGURE 22.1 Two health-care professionals treat a patient with COVID-19. The COVID-19 pandemic has highlighted the need for preparedness and knowledge about effectively treating worldwide infections. (credit: "U.S. Navy Doctors, Nurses and Corpsmen Treat COVID Patients in the ICU Aboard USNS Comfort" by Navy Medicine / Flickr, Public Domain)

CHAPTER OUTLINE

INTRODUCTION Infections are one of leading causes of death and disability globally, with more than 7.7 million deaths in 2019 from bacterial pathogens alone (GBD 2019 Antimicrobial Resistance Collaborators, 2022). The total number of deaths that year from fatal infections was even higher, given that infections can also be caused by viruses, parasites, and fungi. During the COVID-19 pandemic, which started in 2019, we saw firsthand the destruction that widespread infections can cause both to human life and the economy. Additionally, we are starting to see the development of "superbugs" that are resistant to commonly prescribed antibiotics, making it even more difficult to effectively treat infections. Nurses are on the frontlines of these battles, which highlights the need for knowledge regarding the causes of and treatments for various infections.

22.1 Infectious Process

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the transmission of an infective antigen into the host
- Describe the key components of the immune system's response to infection
- Explain the important roles played by the lymphatic system in infection protection

Have you ever wondered how nurses can be exposed to patients with communicable diseases day after day but not become ill? Many factors affect the body's ability to defend against infection, and some individuals are at greater risk of developing an infection. When an infection does occur, early recognition is important to prevent it from spreading within the individual, as well as to others. Protecting people from developing an infection, as well as preventing the spread of infection, are major concerns for nurses. This section discusses the anatomy and physiology of the immune and lymphatic systems and their roles in fighting infection.

The **immune system** is the complex collection of cells and organs that destroy or neutralize pathogens that would otherwise cause disease or death. The immune system is associated with the lymphatic system to such a degree that the two are virtually indistinguishable. However, they are separate body systems with distinct components and functions. The **lymphatic system** is the system of vessels, cells, and organs that carry excess fluids to the bloodstream and filter pathogens from the blood. The swelling of lymph nodes during an infection and the transport of lymphocytes via the lymphatic vessels are but two examples of the many connections between these critical organ systems.

Infection

An **infectious disease** is caused by a **pathogen**—an agent such as a bacterium, virus, parasite, or fungus—that enters a human host, multiplies, and causes infection that can spread via direct or indirect transmission (CDC, 2022a). Two models—the epidemiologic triad and the chain of infection—are vital to understanding transmission of infectious diseases. The epidemiologic triad includes the host, agent, and environment, and describes the who, what, and where of the infectious process. The chain of infection builds on this triad; a disease is considered communicable or **contagious** (capable of spreading from one person to another) if the infected host has a portal of exit, a means of transmission, and a portal of entry into another susceptible host. Some infectious diseases can be spread by germs in the air, food, water, or soil and by vectors or by animals to humans. Although these diseases are still considered infectious, because they are caused by bacteria, viruses, parasites, or fungi, they are not considered communicable from person to person.

The agent's **pathogenicity** (the potential ability to cause disease in a susceptible host) depends on the agent's infectivity and its ability to invade the host, destroy host body cells, and produce toxins that result in the **virulence**, or severity, of the infectious disease. The human immune system has evolved over thousands of years to be able to control many pathogens, but the pathogens themselves have also evolved ways to evade the immune response. The first step in the immune response is for the body to recognize the presence of an **antigen**, or a molecule on the cell surface of a pathogen that is recognized as an invader by the immune system. However, pathogens mutate constantly, and some mutations change the chemical structure of an antigen sufficiently, so the immune response no longer recognizes it. This explains why a new strain of bacteria can evade the immune response of a body that has already been exposed to an older strain: the new strain is characterized by a structurally distinct antigen. This also explains why a new flu vaccine must be developed each year: each flu season, a new variant of the influenza virus, with a unique antigen, may have evolved.

The susceptibility of a host is a key component in the epidemiologic triad and chain of infection (CDC, 2022a). Susceptibility depends on many factors, such as age, sex, physical health, and immune status. Portals of entry and exit can include the skin, conjunctiva, respiratory tract, gastrointestinal (GI) tract, genital tract, and vertical transmission during the birthing process (CDC, 2022a). The environment is a component common to both the epidemiologic triad and the chain of infection. In this context, the environment refers to reservoirs of infectious agents, which may be humans, animals, plants, insects, water, and soil. The environment and any environmental changes can have a significant impact on the transmission of waterborne, foodborne, and vector-borne agents. Transmission of infectious agents includes airborne, direct contact, indirect contact, and droplet transmission. If an environment is favorable for the survival of an infectious agent and there is an opportunity for the host to be exposed to the agent, infection and disease will ensue. Thankfully, there are many pharmacologic treatments available for most infections, but, as you will see later in the chapter, in some cases, the established treatments are becoming ineffective, making it difficult to completely eradicate the pathogen.

LIFE-STAGE CONTEXT

Older Adults and Susceptibility to Infection

Older adults are at an increased risk for infections for many reasons. First, with aging, the effectiveness of the immune system decreases, making it harder for the body to fight off infections. Additionally, many older adults reside in facilities that put them in regular, close contact with a variety of people. This puts them at higher risk for developing infections that are passed from person to person. Although older adults are more susceptible to most infections, the most common ones seen in this population include pneumococcal disease and influenza, which are often acquired while receiving care for other conditions. Infections acquired in this manner are called nosocomial (health care–associated) infections (Cristina at al., 2021).

Functions of the Immune System

The immune system is a collection of barriers, cells, and soluble proteins that interact and communicate with each other in extraordinarily complex ways (CDC, 2022a). The modern model of immune function is organized into three phases based on the timing of their effects:

- A **barrier defense**, such as the skin and mucous membranes, acts instantaneously to prevent pathogenic invasion into body tissues.
- The rapid but nonspecific **innate immune response** consists of a variety of specialized cells and soluble factors, such as vascular endothelial growth factor or certain hormones, that can bind to receptors as part of the immune response.
- The slower but more specific and effective **adaptive immune response** involves many cell types and soluble factors. However, it is primarily controlled by white blood cells (WBCs) known as lymphocytes, which help control immune responses.

For the purpose of this chapter, we will focus on the respective functions of barrier defenses and WBCs.

Review how the immune system works (https://openstax.org/r/77immune) with this video.

Barrier Defenses

Physical barriers are defense mechanisms that prevent pathogens from entering the body, destroy them after they enter, or flush them out before they can establish themselves as an infection. These barriers are among the body's most basic defense mechanisms. They are not themselves a response to infection, but they are continuously working to protect against a broad range of pathogens.

The different modes of barrier defenses are associated with the external surfaces of the body, where pathogens may try to enter. The primary barrier is the skin. The outer skin consists of a layer of cells that are too dry for bacteria to grow in; furthermore, these outer cells are continuously sloughed off, carrying with them bacteria and other pathogens. Skin secretions such as sweat physically wash microbes away; they also contain lipids and other chemicals that contribute to a toxic environment for pathogens—for example, by lowering pH, creating an acidic environment in which the pathogen can no longer survive. The acidic environment of the stomach, which is fatal to many pathogens, is also a barrier. Additionally, the mucus layers of the gastrointestinal tract, respiratory tract, reproductive tract, eyes, ears, and nose trap microbes and a wide range of debris and facilitate their removal.

Leukocytes

Another name for a WBC is a **leukocyte**. They are the primary cells of the immune system, tasked with fighting off pathogens to prevent infection (Tigner et al., 2022; University of Rochester Medical Center, 2024). There are several specific types of leukocytes, which are listed in Table 22.1.

Type of Leukocyte (normal percentage of all WBCs)	Description
Monocyte (2%–8%)	• Made in the bone marrow • Eventually becomes a macrophage (a cell that surrounds and kills microorganisms and ingests foreign materials) or a dendritic cell (a cell that presents antigens for recognition to lymphocytes)
Lymphocyte (20%–40%)	• A mature B or T cell that has not yet encountered an antigen for the first time • Develops a specific response to a specific antigen, making it the most effective type of cell to fight infection
Neutrophil (40%–60%)	• A phagocytic cell that is recruited from the bloodstream to the site of infection • A nonspecific part of the body's first line of defense, meaning it shows up regardless of what kind of pathogen is present
Basophil (0.5%–1%)	• The least common type, comprising less than 1 percent of the total WBC count • Mainly acts to intensify the inflammatory response
Eosinophil (1%–4%)	• Protects the body from allergies, parasitic infections, and some autoimmune diseases

TABLE 22.1 Types of Leukocytes

Functions of the Lymphatic System

A major function of the lymphatic system is to drain body fluids and return them to the bloodstream. These processes happen via a series of vessels, trunks, and ducts. The term **lymph** is used to describe interstitial fluid once it has entered the lymphatic system. When the lymphatic system is damaged in some way (e.g., blocked by cancer cells or destroyed by injury), protein-rich interstitial fluid accumulates in the tissue spaces. This inappropriate accumulation of fluid, or lymphedema, may lead to serious medical consequences, such as pain and limited mobility. The main organs and other components of the lymphatic system include the lymph nodes, spleen, bone marrow, and thymus (Figure 22.2).

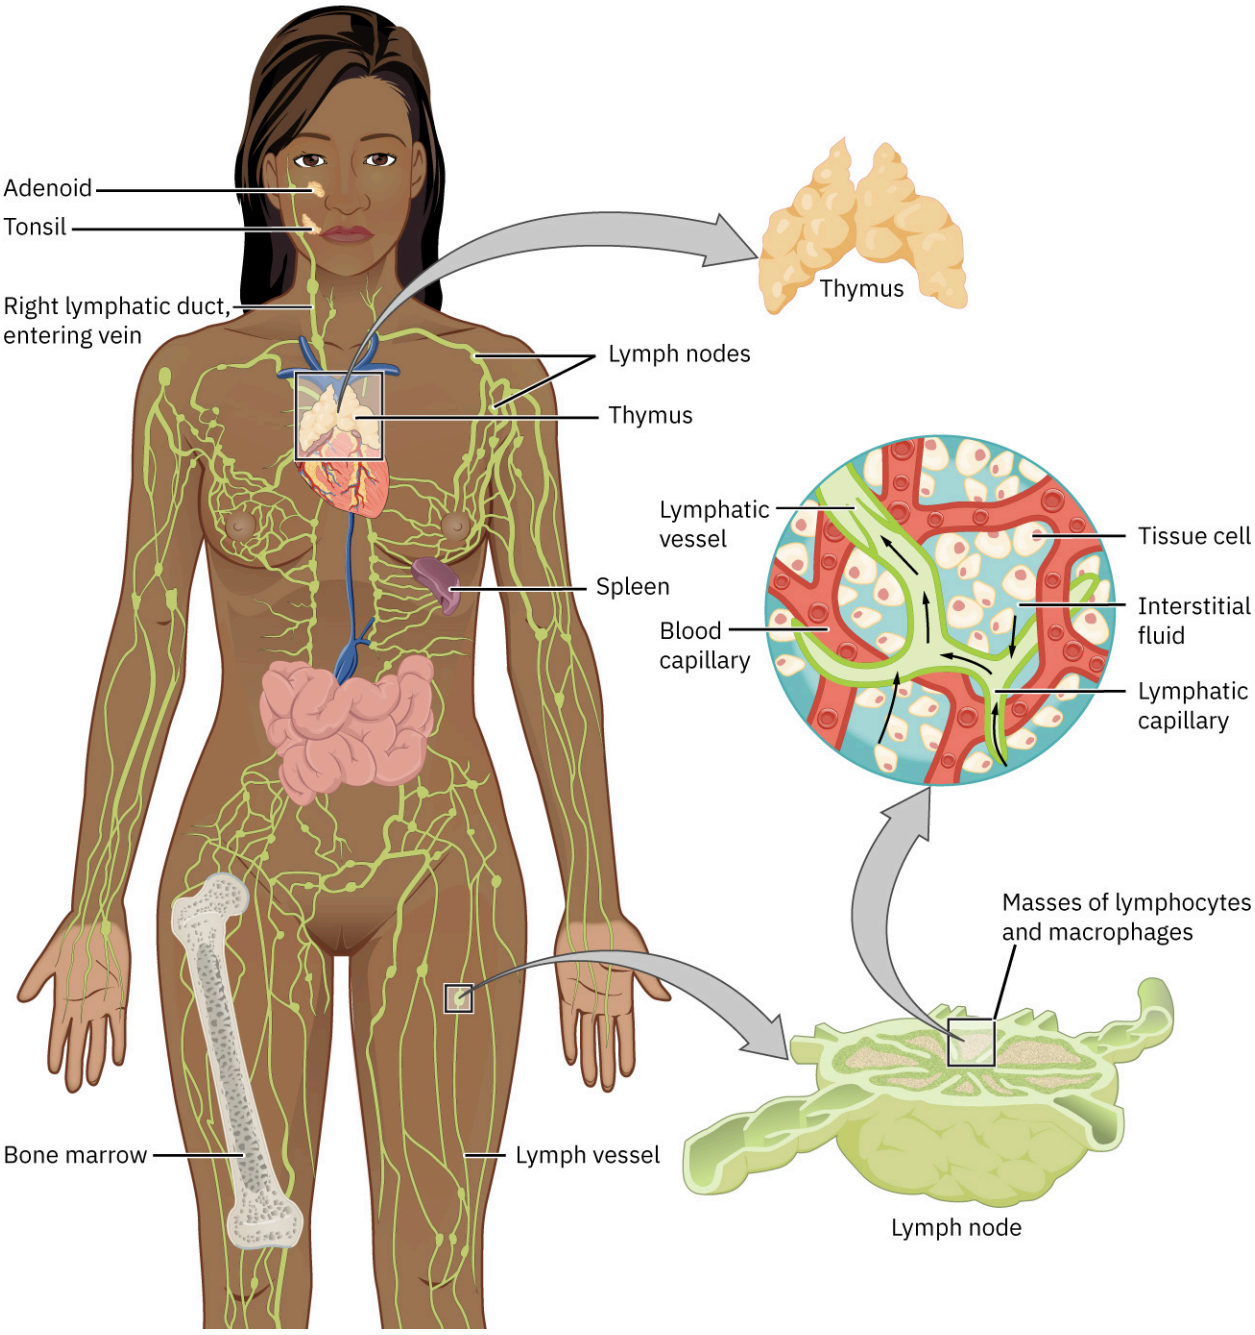

FIGURE 22.2 The lymphatic system is composed of organs, glands, and other structures that are connected via lymphatic vessels and ducts. (credit: modification of work from *Anatomy and Physiology 2e.* attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Lymph Nodes

A **lymph node** is a small, bean-shaped organ that removes debris and pathogens from the lymph; lymph nodes are sometimes referred to as the filters of the lymph (Figure 22.3). Any bacteria that infect the interstitial fluid are taken up by the lymphatic capillaries and transported to a regional lymph node. Dendritic cells and macrophages within the nodes internalize and kill many of the pathogens that pass through, thereby removing them from the body. (This is the reason swollen lymph nodes may be a symptom of an infection.) The lymph nodes are also the site of adaptive immune responses mediated by T cells, B cells, and accessory cells of the adaptive immune system.

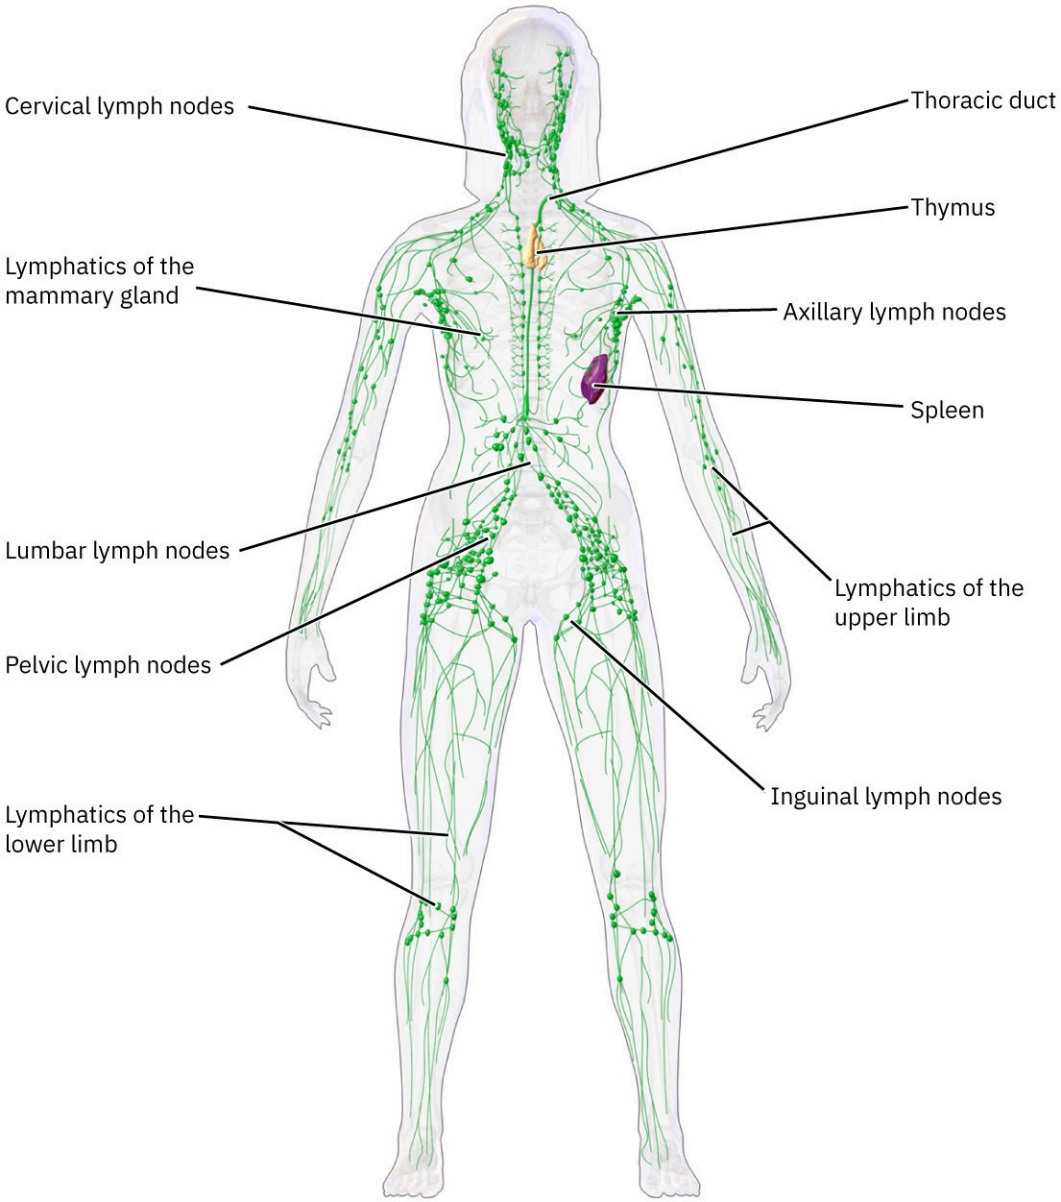

FIGURE 22.3 Lymph nodes are found throughout the body to help remove debris and pathogens from lymph. (credit: Blausen.com staff/ Wikimedia Commons, CC BY 3.0)

Spleen

The **spleen** is another important lymphoid organ (Figure 22.4). It is about 12 cm (5 in.) long and attached to the lateral border of the stomach. The spleen also is sometimes called the filter of the blood because of its extensive vascularization and the presence of macrophages and dendritic cells that remove microbes and other materials from the bloodstream. The spleen is also the location of immune responses to blood-borne pathogens. Because of its role in immune function, patients who have had their spleen surgically removed for medical reasons are at higher risk of infection.

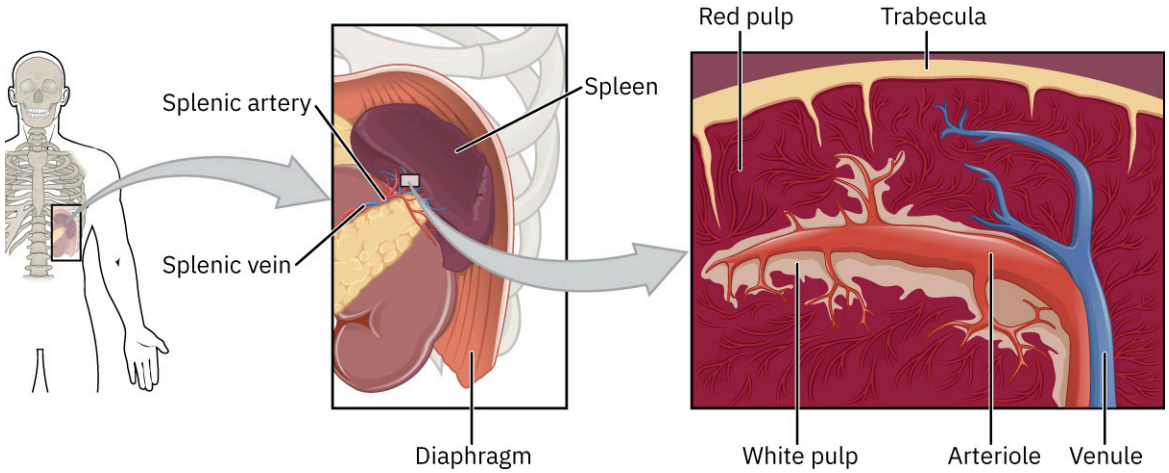

FIGURE 22.4 The spleen is located in the upper left quadrant of the abdomen, just under the diaphragm. The splenic artery carries blood to the spleen, and the splenic vein carries blood away from the spleen. (credit: modification of work from *Anatomy and Physiology 2e.* attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Bone Marrow

The soft, jelly-like tissue located inside bones is called **bone marrow** (Figure 22.5). Its main function is to produce blood cells and release them into the bloodstream once they are fully matured (Lucas, 2021). The importance of bone marrow cannot be overstated. It produces and matures red blood cells (including platelets) in addition to WBCs. Without optimal functioning of the bone marrow, the body would be unable to effectively fight infection or stop bleeding, problems that could very quickly result in a life-threatening condition such as hemorrhagic shock or sepsis (Lucas, 2021).

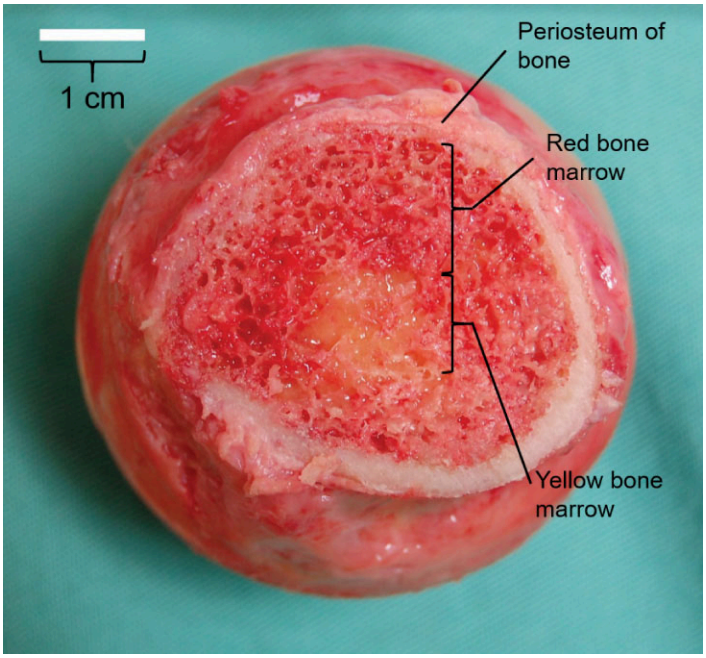

FIGURE 22.5 The bone marrow is a spongy material located inside the long bones and responsible for the production and maturation of blood cells. (credit: "Bone Marrow" by ASCCC OERI/Flickr, CC BY 2.0)

Thymus

The **thymus** is lymphatic organ whose main function is the production of a group of hormones that contribute to the development and differentiation of T lymphocytes, immune cells that contain specific receptors for antigens and play a large role in active immunity. The thymus is located in the chest cavity, between the lungs and behind the sternum (Figure 22.6).

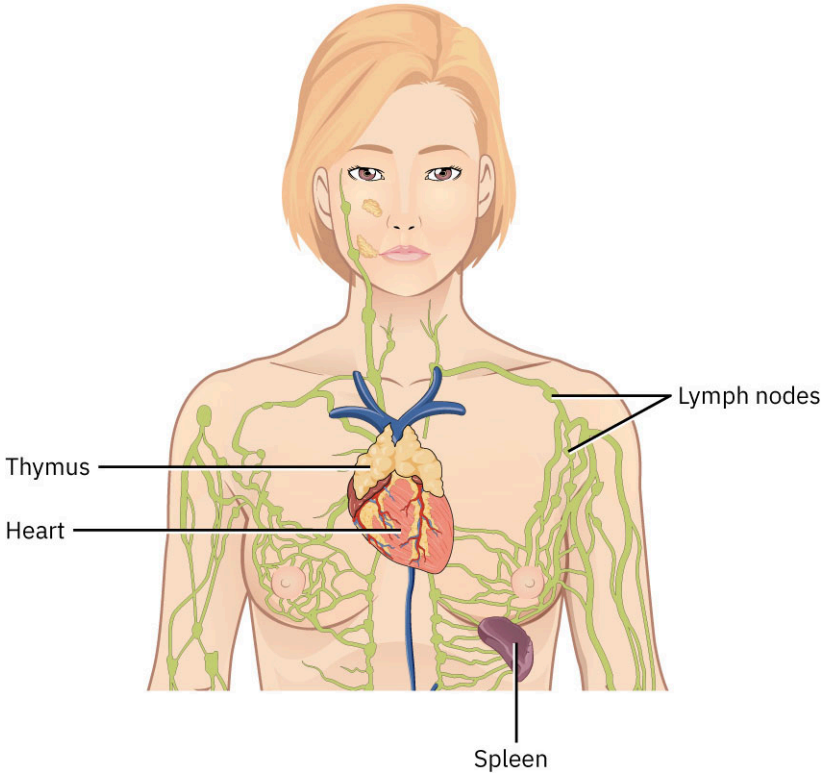

FIGURE 22.6 The thymus gland is located between the lungs, anterior to the sternum. (credit: modification of work from *Anatomy and Physiology 2e.* attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

22.2 Viral and Fungal Infections

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations for viral and fungal infections
- Describe the diagnostics and laboratory values for viral and fungal infections
- Apply nursing interventions and associated therapies in the care of the patient with viral and fungal infections
- Apply nursing interventions and associated therapies in the care of the patient with viral and fungal infections

Before 2020, you may not have thought much about viruses, except perhaps when it came time to get your annual flu shot. However, that likely all changed with the onset of the COVID-19 pandemic. The pandemic has shed light on the profound impact of viral infections on society and redefined how the world will handle outbreaks in the future.

Infection with the **human immunodeficiency virus (HIV)**, a retrovirus characterized by the destruction of certain WBCs, was nearly 100 percent fatal in the 1980s. Over the past few decades, the development of antiviral drugs has transformed HIV infection into a chronic, manageable disease—provided those with the virus learn about their infection in time to start treatment and avoid passing it to others (HIV.gov, 2023).

The hepatitis viruses are another example of pathogenic viruses. The World Health Organization (2024) estimates that more than 300 million people worldwide are currently living with chronic hepatitis infection that is either undiagnosed or untreated.

Numerous fungi live on and within the human body, but they do not usually cause disease. When they do result in an infection, the areas most often affected are the skin and nails, but it can also spread to the mouth, throat, lungs, and urinary tract.

This section takes a closer look at nursing interventions and medical therapies for various viral and fungal infections. However, we start by examining the pathophysiology of viral infections in general.

Pathophysiology of Viral Infection

A **virus** consists of a piece of genetic code, such as DNA or RNA, protected by a coating of protein; some viruses also contain an outer envelope of lipids (Kramer, 2023). Regardless of their specific characteristics and how they are classified, viruses can profoundly affect, and even kill, the organisms they infect. Figure 22.7 illustrates one type of virus.

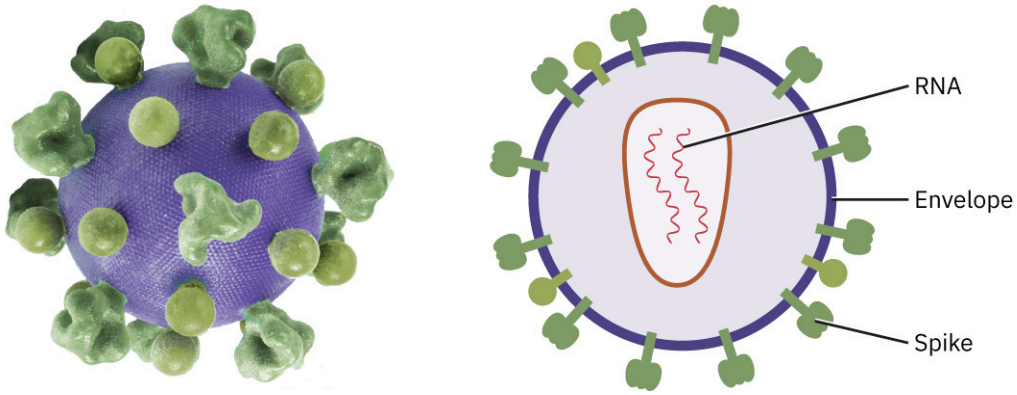

FIGURE 22.7 The virus illustrated here contains RNA, which can invade a host cell and cause infection. (credit (left): modification of "HIV Virus" by NIAID, CC BY 2.0. attribution (right): Copyright Rice University, OpenStax, under CC BY 4.0 license)

An individual whom a virus infects is called a **host**. Following the initial infection, the virus invades the host's cells, injects its genetic material, and uses the host cell's components to replicate and produce more viruses. The new viruses are then released into the body, creating a cycle of invasion, replication, and release that risks destroying the host's cells, threatening their health and, in some cases, life.

Viruses are often classified based on whether they contain DNA or RNA. Herpesvirus is an example of a DNA-containing virus, whereas SARS-CoV2 (which causes COVID-19) contains RNA. HIV is another type of virus containing RNA, but it is classified as a **retrovirus**, meaning that it is able to transcribe itself as permanent DNA inside the host cell. This ability makes retroviruses very difficult to treat. Viruses containing RNA are more likely to mutate, resulting in different strains. Medications and therapies that work on one strain may prove ineffective against a new strain with altered genetic material.

Although most viruses affect the upper airways, they can affect any body system. Humans can become infected by viruses by swallowing or inhaling them (via droplets), being stung or bitten by insects, or having sexual contact or intercourse. A mother can also transfer a virus to her fetus in utero or during birth. Viruses are difficult to treat because they are not responsive to antibiotics. Some antiviral medications are available, but they are not always effective; these are discussed in more detail later in this section.

Clinical Manifestations

Clinical manifestations will vary depending on the specific viral infection. Most viral infections cause vague general symptoms, including fatigue, muscle aches, and headache. Selected viruses and their associated clinical manifestations are listed in Table 22.2 (American Academy of Dermatology Association, n.d.; American Lung Association, 2023).

Virus	Clinical Manifestations
SARS-CoV-2 (COVID-19)	• Chills • Congestion or runny nose • Cough • Fatigue • Fever • Headache • Loss of taste or smell • Muscle aches • Nausea, vomiting, or diarrhea • Shortness of breath • Sore throat
Influenza	• Cough • Fatigue • Fever • Headache • Muscle aches • Sore throat
Respiratory syncytial virus (RSV)	• Cough • Headache • Runny nose • Sore throat
Viral meningitis	• Confusion • Fever • General rash • Headache • Nausea, vomiting • Photophobia (light sensitivity) • Stiff neck
Herpes simplex virus (HSV)	• Blisters (“cold sores”) around the mouth or lips, often with tingly or itchy skin around the mouth in the several days leading up to the outbreak • Chills • Fatigue • Fever • Muscle aches • Swollen lymph nodes
Rotavirus	• Loss of appetite • Signs of dehydration (e.g., poor skin turgor, dry mucous membranes, dizziness) • Vomiting and/or watery diarrhea lasting several days

TABLE 22.2 Clinical Manifestations for Specific Viral Infections

Assessment and Diagnostics

In many cases, viral infections can be diagnosed based on clinical manifestations alone. In other cases, blood tests and cultures may be used to determine the specific virus causing the infection. Laboratory tests are used often when

patients present with symptoms that could be indicative of multiple types of viruses. The most common example is when patients present with nonspecific symptoms such as a runny nose and fever. In this case, providers often order rapid influenza and COVID-19 tests to see if either of those infections is the cause of the symptoms, because they both present similarly.

Nursing Care of the Patient with COVID-19

COVID-19 is caused by a **coronavirus**, a type of virus characterized by a lipid envelope surrounded by proteins that jut out like spikes (Figure 22.7). Coronaviruses are often the cause of the relatively mild cluster of symptoms, including sore throat, congestion, and cough, known as the "common cold." The coronavirus that causes COVID-19 has proved especially dangerous partly because it is novel (i.e., new): our bodies had never encountered it, so they had not developed any immunity to it.

Providing nursing care for patients with COVID-19 has presented many challenges in the past few years since the onset of the pandemic (WHO, 2024b). Initially, nurses and other health-care professionals were unsure about how to care for these patients because there was not enough information available about the virus. Once there was more evidence and data collected about the virus, nursing care became more complex. However, this continuously changed as more data, trends, and treatments were discovered. COVID-19 had a significant mortality rate, requiring emotional and mental care to be provided to patients, families, and health-care staff alike (Mayo Clinic, 2023). Nurses remain on the frontlines of treating patients with COVID-19; therefore, it is critically important to be knowledgeable about the latest best practices in caring for these patients.

Recognizing and Analyzing Cues

It is imperative that nurses be able to recognize and analyze subtle changes in patients' conditions that may be indicative of the onset or progression of a COVID-19 infection. Early intervention for the infection reduces its mortality rate, so early detection is essential. Early signs include vague symptoms, such as the following (CDC, 2024c)

- congestion or runny nose
- fatigue
- fever
- headache
- muscle aches

If any of these symptoms are noted, the nurse should advocate for the patient to be tested for COVID-19 to rule out or confirm the diagnosis so treatment can be initiated quickly. Later signs and symptoms of COVID-19 include a loss of taste or smell, severe shortness of breath, cyanosis, and confusion. Emergent intervention is required once these symptoms are present, and the nurse must recognize the urgency of the situation and intervene appropriately (Administration for Strategic Preparedness & Response, n.d.).

Prioritizing Hypotheses, Generating Solutions, and Taking Action

If the patient presents with symptoms indicative of COVID-19 infection, the nurse will hypothesize that coronavirus is the cause and perform a rapid COVID-19 test. Results from rapid tests are obtained very quickly, thus the nurse can determine the next steps quickly. If the results are negative, the nurse should consider other potential causes of the symptoms and act accordingly. If the results are positive, the nurse begins to generate solutions and take actions, which include the following interventions:

- Monitoring vital signs: These can change quickly in patients with COVID-19, so the nurse should monitor them closely and frequently.
- Respiratory support: COVID-19 can cause severe lung damage, so providing respiratory support is essential. In mild cases, supplemental oxygen via nasal cannula may be sufficient, but many cases will require high-flow oxygen devices or intubation and mechanical ventilation.
- Positioning: Frequent repositioning of patients (ideally every 2 hours) helps facilitate lung expansion, which is crucial for treatment of COVID-19. The use of prone positioning also improves outcomes. Many units have specialized proning beds (Figure 35.11) for this purpose, but proning (placing patient in prone position) can also be done manually with assistance from other health-care staff.
- Infection control: Nurses caring for patients with COVID-19 must be vigilant about always wearing appropriate

personal protective equipment (PPE; e.g., gloves, gown, N95 mask). The patient should be placed on isolation precautions and visitors to the room should be limited to prevent the spread. During the pandemic, visitation regulations became stricter during the peak spread of COVID-19 and visitation was eventually not permitted.
- Psychosocial support: Offering emotional support, reassurance, and education to patients and their families is a huge aspect of nursing care for patients with COVID-19 infection. These patients are often isolated, making them anxious and afraid. The nurse should comfort them, address their concerns, and assist them to develop appropriate coping strategies while in the hospital.

Evaluation of Nursing Care for the Patient with COVID-19

Nurses play a vital role in evaluating outcomes to gauge the effectiveness of interventions. The nurse will closely monitor for changes in the patient's condition that indicate improvement or worsening of the infection.

Evaluating Outcomes

The nurse should evaluate assessment findings to determine if there has been any improvement in the patient's condition. Findings that would indicate improvement include:

- improved mobility and tolerance of activity
- increase in appetite
- negative COVID-19 test
- resolution of respiratory symptoms, as indicated by a decrease in supplemental oxygen needs and improved oxygen saturation
- stable vital signs

Medical Therapies and Related Care

For mild COVID-19 infections, specific treatment may not be required. Mild infections are usually self-limiting and improve with adequate hydration and rest. More severe cases, however, require pharmacologic intervention. With the onset of the pandemic, there was a rush to develop medications that were effective against COVID-19 infection. To date, three medications are available: nirmatrelvir/ritonavir (brand name: Paxlovid), molnupiravir (Lagevrio), and remdesivir (Veklury). Nirmatrelvir/ritonavir and molnupiravir are taken orally as pills, and remdesivir is given intravenously; remdesivir is used in more severe cases for patients who require hospitalization for symptoms. In hospitalized cases requiring supplemental oxygen, dexamethasone, a steroid, is often prescribed to reduce inflammation and improve breathing. In addition to developing medications, governments and private laboratories collaborated to develop vaccines that will prevent future outbreaks. As of early 2024, the Centers for Disease Control and Prevention (CDC, 2024f) recommends that all people over the age of 5 years get the COVID-19 vaccine and a booster. Experts also expect the COVID-19 vaccines will require annual updates to treat new and emerging strains of the virus, similar to the influenza vaccine that is recommended each year (Yale Medicine, 2023).

Some patients who did recover from COVID-19 continue to have symptoms and adverse effects for months after the infection. This is called **long COVID** or post-COVID syndrome and, in some cases, it has resulted in death (CDC, 2024e). The most common long-term symptoms following COVID-19 infection include fatigue, shortness of breath, and brain fog (Johns Hopkins Medicine, 2022). Interventions for the treatment of long COVID include:

- breathing exercises and respiratory therapy
- physical therapy
- steroid medications to reduce inflammation
- supplemental oxygen

REAL RN STORIES

Nurse: Hilary, BSN
Years in Practice: Six months
Clinical Setting: Intensive care unit
Geographic Location: Small, rural community hospital in Missouri

As I arrived for my shift, the weight of the ongoing pandemic hung heavily in the air. The halls echoed with the hustle and bustle of health-care workers, their faces obscured by masks and their eyes reflecting weariness. It was a scene that had become all too familiar in recent months. Having just graduated from nursing school 6 months ago, I never would have anticipated that my first real job as a nurse would involve so much uncertainty and so many patient deaths.

As I made my morning rounds, checking in on patients battling the virus, I couldn't shake my feelings of anxiety. Our supplies of masks, gowns, and gloves were dwindling, and administrators were unable to promise that we would get more any time soon. We had been storing our masks in brown paper sacks, wearing them for three shifts in a row. I was certain that my mask was no longer functioning effectively by the end of my third shift, but there really was no other choice. These patients needed us. We were the only people they got to interact with while in isolation, and we were the ones there holding their hand when they passed away.

Looking back on those challenging days, I am filled with gratitude for the resilience of the human spirit. Working as a frontline nurse, I may not have had enough PPE to keep me safe, but what I did have was an unwavering commitment to care for those in need, no matter the cost. And in the end, perhaps that was enough.

Nursing Care of the Patient with Influenza

Caring for patients with influenza, (more commonly called the “flu”) involves symptom management, infection control, and implementing interventions to alleviate discomfort, prevent complications, and promote recovery. Though the flu has been discussed less in recent years due to overshadowing by the COVID-19 pandemic, it is still a prevalent health concern that has led to death, and will continue to be studied in the coming years.

Recognizing and Analyzing Cues

Early detection and intervention for influenza infection is essential. Thus, the nurse is tasked with being able to recognize cues that indicate the presence of the virus. Early symptoms that may be indicative of influenza include:

- cough
- fatigue
- fever or chills
- headache
- muscle and body aches
- shortness of breath

Early symptoms of influenza are vague, making it difficult to make a definitive diagnosis based on clinical manifestations alone. The nurse must combine assessment findings with a thorough health history to recognize cues that would be consistent with influenza infection.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

If the patient presents with symptoms indicative of influenza, the nurse will first perform a rapid flu test. Likely, the nurse will also perform a rapid COVID-19 test at the same time, because both diseases present similar symptoms, at least initially. If the test is positive, the nurse begins to generate solutions and take actions, which include the following interventions:

- Symptom management: This includes administering antipyretics to decrease fever, analgesics for pain, and cough suppressants as needed.
- Respiratory support: The nurse should position the patient to facilitate breathing, apply supplemental oxygen as needed, and assist with coughing and deep breathing exercises. The nurse will monitor closely for changes such as worsening shortness of breath or dyspnea that would indicate the condition is not improving.
- Infection control: Nurses should perform adequate hand hygiene when caring for all patients, but especially patients with infections that are easily spread. The nurse should also educate all visitors about the importance of hand hygiene in preventing spread of the flu. Patients are placed on droplet precautions, and masks should be worn at all times to limit the spread of infection. Additionally, equipment and surfaces in the patient’s room should be cleaned and disinfected often.

Evaluation of Nursing Care for the Patient with Influenza

Nurses play a vital role in evaluating outcomes to gauge the effectiveness of interventions when caring for patients with influenza. The nurse will closely monitor for changes in the patient's condition that indicate improvement or worsening of the infection.

Evaluating Outcomes

The nurse should evaluate assessment findings to determine if there has been any improvement in the patient's condition. Findings that would indicate improvement include:

- adequate hydration (e.g., moist mucous membranes, adequate urine output)
- decreased fatigue
- improvement in body aches and headache
- improvement in respiratory status
- increased appetite
- resolution of fever

Medical Therapies and Related Care

Medical treatment for influenza involves a combination of medications and nonpharmacologic interventions. Most importantly, patients with the flu should be educated about the importance of rest and maintaining adequate hydration. In mild cases, this is usually enough to treat the infection, which will improve on its own over the course of days to weeks. In more severe cases, medications may be required. Oseltamivir (brand name, Tamiflu), zanamivir (Relenza), and peramivir (Rapivab) are the three antiviral medications currently available to treat influenza. It is important to note that these medications should be started within 48 hours of symptom onset for best results (CDC, 2024c). Beyond treatment, it also remains important to receive annual influenza vaccinations to decrease the risk of infection. These vaccines are altered each year to account for mutations in the virus, which is why it is important to educate patients about the need to get a vaccine every year.

Human Immunodeficiency Virus

In June 1981, the CDC, in Atlanta, Georgia, published a report of an unusual cluster of five patients in Los Angeles, California. All five were diagnosed with a rare pneumonia caused by a fungus called *Pneumocystis jirovecii* (formerly known as *P. carinii*). Why was this unusual? Although commonly found in the lungs of healthy individuals, this fungus is known to cause disease in individuals with suppressed or underdeveloped immune systems. The very young, whose immune systems have yet to mature, and older adults, whose immune systems have declined with age, are particularly susceptible. The five patients from Los Angeles, though, were between 29 and 36 years of age and should have been in the prime of their lives, immunologically speaking. What could be going on?

A few days later, eight similar cases were reported in New York City, also involving young patients, this time exhibiting a rare form of skin cancer known as Kaposi's sarcoma. This cancer of the cells that line the blood and lymphatic vessels had previously been observed as a relatively innocuous disease of older adults. The disease that doctors saw in 1981 was frighteningly more severe, with multiple, fast-growing lesions that spread to all parts of the body, including the trunk and face. Could the immune systems of these young patients have been compromised in some way? Indeed, when they were tested, they exhibited extremely low numbers of a specific type of WBC in their bloodstreams, indicating that they had somehow lost a major part of the immune system.

A new disease, called **acquired immunodeficiency syndrome (AIDS)**, was identified as caused by the previously unknown human immunodeficiency virus. Although AIDS was nearly 100 percent fatal in those early years, over the past few decades, the development of antiviral drugs has transformed HIV infection into a chronic, manageable disease—provided those with the virus learn about their infection in time to start treatment and avoid passing it to others (HIV.gov, 2023).

Pathophysiology of HIV

The underlying pathophysiology of HIV is complex because it is caused by a retrovirus (CDC, 2022c). A retrovirus is a virus that is composed of a strand of **ribonucleic acid (RNA)**, which can be turned into **deoxyribonucleic acid (DNA)** and inserted into a healthy cell permanently. HIV is dangerous mainly because it infects and destroys a specific type of WBC known as CD4. As you can see in Figure 22.8, the viral RNA strand inside of a cell infected with

HIV carries **reverse transcriptase**, which is an enzyme used to convert RNA into DNA. When an infected cell attaches to a healthy cell, it injects the enzyme into the cytoplasm of the healthy cell, where it creates strands of viral DNA. These strands are then inserted into the nucleus of the healthy cell, where they become permanently integrated into the cell's DNA. Once this happens, the newly infected cell produces more cells by using viral mRNA, all of which contain the new viral DNA. Cell replication can occur quickly, leading to an influx of infected immune cells. When this happens, the CD4 cells of the immune system can no longer function effectively, resulting in severe immunosuppression and eventually leading to the development of AIDS, the latest and most severe stage of HIV (HIV.gov, 2023a).

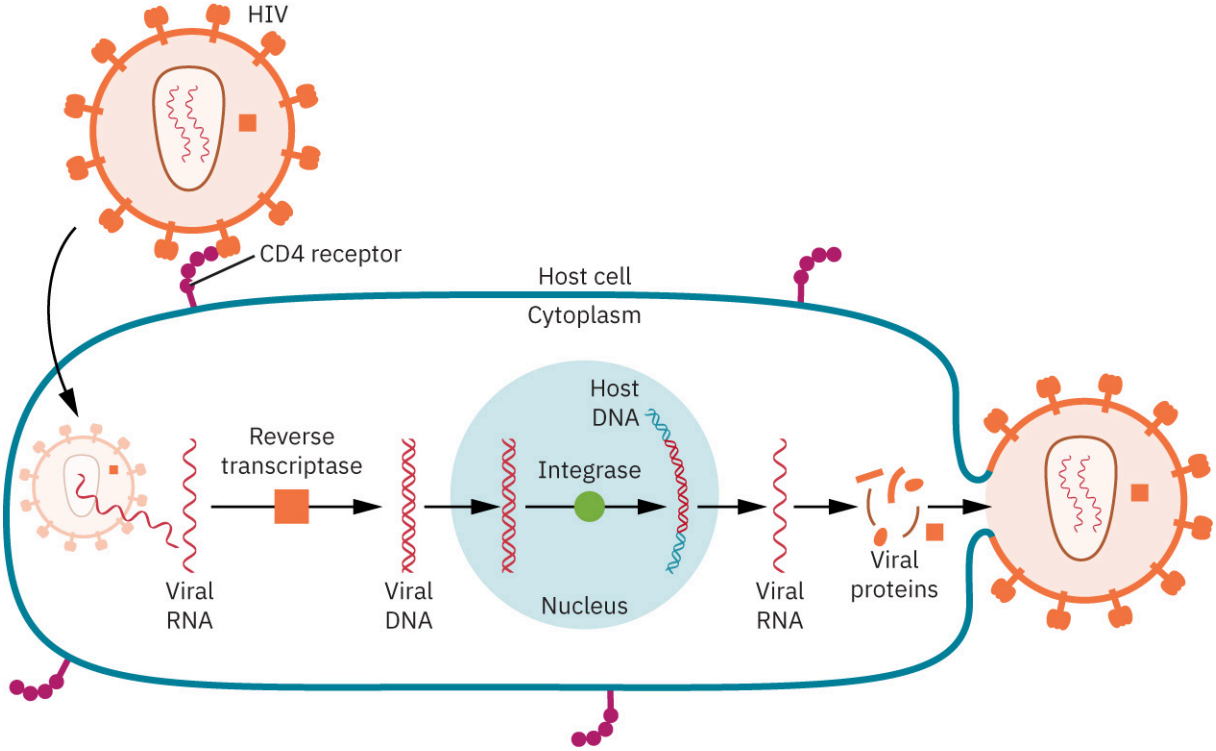

FIGURE 22.8 HIV's viral RNA is turned into DNA and integrated into a healthy host cell, which then replicates, leading to an influx of newly infected immune cells. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Watch a detailed animation of the pathophysiology of HIV and AIDS (https://openstax.org/r/77pathHIVAIDS) in this video.

Clinical Manifestations and Risk Factors

HIV is transmitted through semen, vaginal fluids, breast milk, and blood, and can be caught by having unprotected sex or sharing needles used to inject intravenous (IV) drugs; it can also be passed from an infected mother during childbirth or by breastfeeding (Justiz Vaillant, 2022). Flu-like symptoms sometimes emerge in the first 1 to 2 weeks after infection. This early period of rapid infection is known as the acute stage of HIV. The amount of virus circulating in the blood then drops to a low level. This is known as the chronic or latent stage of HIV: the person is infected but likely not carrying a large enough number of infected cells to show symptoms. This stage can last from a few months or years to decades, but eventually the immune system is overtaken by infected cells, resulting in end-stage HIV, also known as AIDS. The symptoms of AIDS include:

- diarrhea
- fever
- night sweats
- rashes
- severe weight loss (typically >10% of total body weight)

- swollen lymph nodes

In addition to these somewhat nonspecific clinical manifestations, AIDS is characterized by the development of opportunistic infections (Mayo Clinic, 2024). An **opportunistic infection** is caused by bacteria or other organisms in the body that would not typically cause an infection in a healthy individual. However, in someone with AIDS, these infections not only develop, they can also become life-threatening because the person's immune system is unable to eradicate the pathogen effectively. In some cases, patients with AIDS also develop certain cancers. Some of the common infections and cancers seen in patients with AIDS include:

- candidiasis (oral thrush)
- Kaposi's sarcoma (Figure 22.9)
- non-Hodgkin's lymphoma
- *Pneumocystis carinii* pneumonia (PCP)
- tuberculosis
- varicella-zoster virus

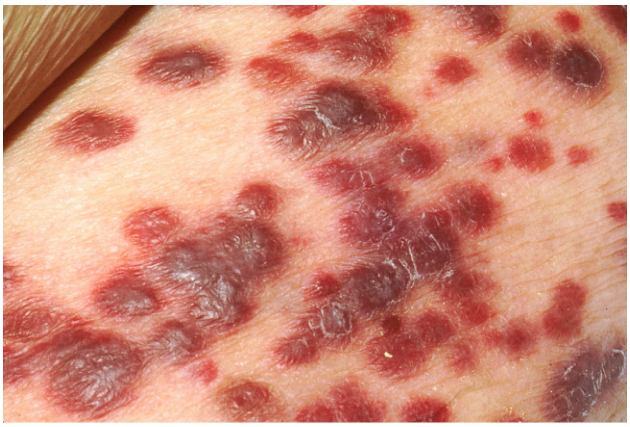

FIGURE 22.9 Kaposi's sarcoma is caused by cancer cells that manifest as nonpainful, red and purple lesions on the skin and mucous membranes. (credit: NIH: National Cancer Institute/Wikimedia Commons, Public Domain)

Assessment and Diagnostics

HIV can be difficult to detect and diagnose in the early stages because patients may be completely asymptomatic or have vague symptoms that resemble the flu. Although HIV diagnostic tests are usually fairly accurate, they cannot detect the virus immediately after infection. This highlights the need for community education about regular testing, especially for populations in which needle use for drugs or unsafe sexual practices are more common (CDC, 2022b). Table 22.3 lists the three main types of HIV tests.

Test	Description
Antibody tests	• They detect antibodies to HIV in the blood or saliva. • They can take up to 90 days after exposure to detect. • Blood tests can detect HIV sooner than an oral swab can.
Antigen/antibody tests	• They detect both antibodies to HIV and HIV antigens in the blood. • Tests of blood taken from a vein can detect HIV 18–45 days after exposure. • Tests of fingerstick blood samples can detect HIV 18–90 days after exposure.
Nucleic acid tests (NATs)	• They detect the actual virus in the blood. • They can detect HIV 10–33 days after exposure. • They are performed when exposure was recent or an individual shows early symptoms of HIV but received a negative antibody or antibody/antigen test.

TABLE 22.3 Types of HIV Tests (CDC, 2023)

Diagnostics and Laboratory Values

In addition to the diagnostic tests specific for HIV that were described in the previous section, there are several other laboratory values that are affected in patients with HIV. Because HIV is an immune disorder, the patient's WBC count will be abnormal (HIV.gov, 2023b). A normal WBC count is 5,000–10,000 cells/mm^3, whereas in patients with HIV, it is typically less than 3,000 cells/mm^3. The overall count is lower because the immune system is using up WBCs trying to fight off the virus. And because HIV specifically infects CD4 cells, their count will be exceptionally low. Consequently, CD4 count is one of the main laboratory tests used both to detect and monitor the progression of HIV. A normal CD4 count is 500–1,200 cells/mm^3, whereas in patients with HIV, it is less than 400 cells/mm^3. Once the CD4 cell count falls below 200 cells/mm^3, the patient is diagnosed with AIDS, the most advanced stage of HIV.

Another important laboratory value used to monitor the treatment and progression of HIV is the **viral load** test (CDC, 2022b). This blood test directly measures the amount of virus in the blood. A patient with high viral load has more virus in their body, indicating that treatment is not effective or the disease is progressing into more advanced stages. In contrast, an undetectable viral load indicates that treatment is effective and the patient cannot transmit the virus to others. However, it is important to note that an undetectable viral load does not mean the virus is not present in the blood. Rather, it is present in a sufficiently low amount that it cannot be detected or transmitted.

REAL RN STORIES

Nurse: Amelia, BSN
Years in Practice: Seven
Clinical Setting: Emergency department
Geographic Location: Inner city of a large metropolitan area in California

I was admitting Michael M., a 32-year-old male patient, who was being seen in the emergency department for unexplained sudden weight loss and a general feeling of illness. Michael reported that in addition to losing 10 pounds in the past month, he kept getting these "weird purple spotty rashes" on his arms and legs. He reported feeling more tired than usual and "not right."

Upon assessment, I noticed that he currently had purple pustules all over his arms and trunk. He was running a fever and looked generally unwell. While obtaining his medical and social history, he told me that he is a male having sex with another male. I began to worry that he has contracted HIV, because his sexual practices could put him at high risk. I asked him about using protection and he said that he uses condoms 90% of the time but not always. As soon as I asked about this, he said, "I have HIV, don't I? I know a lot of people who have it, and I knew it was just a matter of time for me." I reassured him that we don't know yet, but that I would relay this information to the treating clinician and get him tested immediately.

We did a rapid swab test and the results immediately came back positive for HIV. After testing his CD4 cell count, he was diagnosed with AIDS. He asked me, "How long have I been living with this?" and I didn't know how to respond at first. I ended up saying, "It's likely you have had it for awhile, but we can't be sure." Michael began to cry and asked me, "Could I have saved myself from AIDS if I had gotten treatment sooner?" I told him that we can never know for sure but the important thing is that he is getting care now. I said, "HIV treatments have come a long way in recent years, so there is hope that we can intervene and help you. We will do everything we can." The treating clinician then walked in and began to discuss the situation with him. The clinician recommended getting started on antiretroviral medications right away and taking medications to fight off the opportunistic infection Kaposi's sarcoma that Michael was currently infected with. Michael was agreeable to the plan but was distraught about the new diagnosis. I sat with him for an hour and just let him cry. Before leaving at the end of my shift, I provided him with the phone number of a support group for patients newly diagnosed with HIV and I gave him a hug and wished him well. I still think about Michael to this day and hope that he is still alive and well.

Nursing Care of the Patient with HIV

Nursing care of the patient with HIV requires knowledge of the disease, technical skills, and the ability to provide holistic care that is nonjudgmental. Patients with HIV are often scared and anxious about the diagnosis and disease

progression. Nurses not only provide medical care to these patients, they also provide emotional support and resources.

Recognizing and Analyzing Cues

Nurses should have a working knowledge of the signs and symptoms of HIV so cues can be recognized to aid with early diagnosis. This is difficult, however, because the presenting symptoms of HIV are usually vague (e.g., fever, rash, sore throat) and may be so mild that the patient does not even seek care. For patients who do seek care for presenting symptoms, the nurse must collect a thorough medical history, including assessing for risk factors for contracting HIV. If risk factors are noted, the nurse should advocate for the patient to be tested for HIV.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Patients with HIV often require a lot of nursing care, especially in the later stages of the disease. The nurse should conduct a full physical assessment and determine what symptoms are the priority. Per the CDC (2023), common nursing interventions for patients with HIV include

- alternating rest and activity periods for patients with severe fatigue
- checking laboratory values to monitor the progression of the disease and the effectiveness of treatment
- maintaining adequate nutritional status (e.g., offering high-calorie foods, administering enteral nutrition as needed)
- promoting skin integrity to prevent development of opportunistic infections
- providing regular oral care and other hygiene care to prevent infections
- providing the patient resources such as information about counseling or support groups
- relieving pain with pharmacologic and nonpharmacologic interventions

Evaluation of Nursing Care for the Patient with HIV

Patients with HIV are infected for life, so nurses will likely be continuously evaluating their health status. This is especially true in clinic settings where patients are cared for by the same provider for several years. It is important for the nurse to understand how to monitor the patient's condition and determine whether it is improving or requires a revised plan of care.

Evaluating Outcomes

First and foremost, the nurse should understand that monitoring the patient's viral load is the most accurate way to determine their health status and the effectiveness of medications. A viral load that begins to trend upward indicates that either the disease is progressing or the patient has not been taking medications as prescribed. This warrants further investigation and intervention by the nurse and care team. Outcomes that would indicate the patient's treatment is effective include a downward trending or undetectable viral load, as well as the absence of opportunistic infections, a healthy body weight, and patient demonstration of adequate coping skills.

CULTURAL CONTEXT

Providing Culturally Sensitive Care to the Patient with HIV

The Joint United Nations Program on HIV/AIDs aims to end the HIV epidemic by 2030. One of the key strategies for achieving this goal is nurse-led clinical programs. Such programs are run by nurses and involve providing home care for patients with HIV to ensure that patients adhere to antiretroviral treatments and receive adequate mental health support. Establishing trust, being nonjudgmental and compassionate, and listening have been pivotal for increasing antiviral compliance within the HIV population. Patients with HIV are at risk due to stigmatization, marginalization and having adequate access to care. Nurses have been an essential bridge connecting an at-risk population to treatment (Rouleau et al., 2019; Wood et al., 2018).

Medical Therapies and Related Care

Medical treatment of HIV focuses on decreasing viral load to slow progression of the disease, prevention and treatment of opportunistic infections, and symptom management. To decrease viral load, antiretroviral (ART) medications are used to block or slow viral replication. There are several different classes of ART medications, and most patients with HIV are prescribed at least two or three, each from a different drug class.

The various medication classes work on different parts of the HIV life cycle, so taking two different types increases the chance of slowing disease progression. It is important to note that many ART medications have unpleasant side effects, such as gastrointestinal upset or fatigue, so patients often skip medication doses or stop taking them altogether. This is dangerous not only to the patient's health but to others' because the virus is more likely to spread if it is not being controlled with medication.

When patients enter the later stages of HIV, they typically start developing frequent opportunistic infections. Patients with HIV should be counseled about the importance of maintaining good hygiene and avoiding crowds to limit their exposure to pathogens. Additionally, if they suspect they have an infection of any kind, it is important for them to seek care immediately; because their immune system is not functioning optimally, a "small" infection can quickly become life-threatening (Mayo Clinic, 2024).

Symptom management focuses on treating pain and depression, both of which are commonly seen in patients with HIV. These conditions are usually treated with pharmacologic interventions such as analgesics and antidepressants but may also be treated with nonpharmacologic options like counseling, meditation, and guided imagery. Additionally, patients with HIV often experience malnutrition and weight loss, so medical intervention may include use of appetite stimulants or administration of enteral feedings.

Hepatitis

A condition characterized by inflammation of the liver, **hepatitis** is often the result of a viral infection (WHO, 2019). There are several types, including hepatitis A, B, C, D, and E. Each of these types varies slightly regarding transmission and symptoms; types A, B, and C are the most common and, therefore, are the focus of this section. The World Health Organization (2024) estimates that more than 300 million people worldwide are currently living with chronic hepatitis that is either undiagnosed or untreated. The condition is a leading cause of **liver cirrhosis**, resulting in permanent scarring and fibrosis and in a significant number of deaths each year.

Pathophysiology of Hepatitis

Although the five hepatitis viruses differ, they can cause similar signs and symptoms because all have an affinity for a type of cell called a **hepatocyte** (liver cell) (). Hepatitis A can be contracted through ingestion, whereas types B and C are transmitted by parenteral contact (Table 22.4). It is possible for individuals to become long-term or chronic carriers of hepatitis viruses, which typically spread to the spleen, kidneys, and liver after entering the bloodstream. During viral replication, the virus infects hepatocytes. Inflammation occurs as the hepatocytes replicate and release more hepatitis virus.

Type	Transmission	Incubation Period	Prevention
Hepatitis A	Ingestion (e.g., fecal-oral route, contaminated food or water)	2–6 weeks	Vaccine is available and recommended for all children and high-risk groups (e.g., traveling to high risk area, food service workers, gay men, IV-drug users).
Hepatitis B	Parenteral, sexual contact	3–26 weeks	Vaccine is available and recommended for all children as part of standard vaccine schedule and boosters for adults, as needed, to maintain immunity.
Hepatitis C	Parenteral	2–33 weeks	No vaccine available. Prevention strategies include avoidance of using shared needles or razors and avoiding sexual contact with infected individuals.

TABLE 22.4 **Types of Hepatitis**

Hepatitis A

The hepatitis A virus is generally transmitted through the fecal-oral route, close personal contact, or exposure to contaminated water or food. Hepatitis A can develop after an incubation period of 15 to 50 days (the mean is 30 days) (CDC, 2024a). The infection is normally mild or even asymptomatic and usually self-limiting within weeks to

months. A more severe form, fulminant hepatitis, rarely occurs but has a high fatality rate of 70%–80% (CDC, 2024a). Vaccination is available and is recommended especially for children (between the ages of 1 and 2 years), those traveling to countries with higher risk, those with liver disease and certain other conditions, and drug users.

Hepatitis B

Hepatitis B has a mean incubation period of 120 days and is generally associated with exposure to infectious blood or body fluids such as semen or saliva (CDC, 2023a). Exposure to the virus can occur through skin puncture, across the placenta, or through mucosal contact, but it is not spread through casual contact such as hugging, hand holding, sneezing, or coughing, or even through breastfeeding or kissing (Tripathi & Mousa, 2023). Risk of infection is greatest for those who use IV drugs or who have sexual contact with an infected individual. Health-care workers are also at risk from needle sticks and other injuries when treating infected patients. The infection can become chronic and may progress to cirrhosis or liver failure; it is also associated with liver cancer. Vaccination is available and is recommended for children as part of the standard vaccination schedule (one dose at birth and the second by 18 months of age) and for adults at greater risk (e.g., those with certain diseases, IV-drug users, those who have sex with multiple partners). Health-care agencies are required to offer the hepatitis B vaccine to all workers who have occupational exposure to blood or other infectious materials.

Hepatitis C

Hepatitis C is often undiagnosed and, therefore, may be more widespread than is documented. It has a mean incubation period of 45 days and is transmitted through contact with infected blood (CDC, 2024b). Although some cases are asymptomatic or resolve spontaneously, 75% to 85% of infected individuals become chronic carriers (CDC, 2024b). Nearly all cases result from parenteral transmission, often associated with IV drug use or transfusions. The risk is greatest for individuals with a past or current history of IV drug use or who have had sexual contact with infected individuals.

LINK TO LEARNING

The CDC provides information about preventing needlestick injuries (https://openstax.org/r/77needleinjury) to limit the spread of hepatitis in health-care settings.

Clinical Manifestations

The clinical manifestations of each type of hepatitis vary slightly, as presented in Table 22.5. Figure 22.10 illustrates a characteristic symptom, jaundice.

Type of Hepatitis	Clinical Manifestations
Hepatitis A	• Usually asymptomatic • Vague symptoms when present (e.g., fatigue, loss of appetite, nausea)
Hepatitis B	• Abdominal pain • Clay-colored stools • Dark urine • Fatigue • Jaundice • Joint pain • Late-stage findings include confusion, coma, ascites, and GI bleeding • Loss of appetite • Nausea/vomiting
Hepatitis C	• Dark urine • Jaundice • Malaise • Nausea • Right upper-quadrant pain

TABLE 22.5 Clinical Manifestations of the Different Types of Hepatitis

FIGURE 22.10 Liver dysfunction caused by hepatitis may manifest as jaundice, a yellowing of the eyes and skin. (credit: Sheila J. Toro/ Wikimedia Commons, CC BY 4.0)

Assessment and Diagnostics

General laboratory testing for hepatitis begins with blood testing to examine liver function. When the liver is not functioning normally, the blood will contain elevated levels of alkaline phosphatase, alanine aminotransferase, aspartate aminotransferase, direct bilirubin, total bilirubin, serum albumin, serum total protein, and calculated globulin; the albumin to globulin (A/G) ratio will also be elevated. Some of these are included in a complete metabolic panel, which may first suggest a possible liver problem and indicate the need for more comprehensive testing. A hepatitis virus serological test panel can be used to detect antibodies for hepatitis viruses A, B, and C.

Nursing Care of the Patient with Hepatitis

Nursing care for patients with hepatitis will vary slightly depending on the specific type present, but care generally focuses on alleviating symptoms, preventing complications, and promoting recovery. Additionally, providing education is a major component of caring for patients with hepatitis to help prevent spread and complications (CDC,

2023a).

Recognizing and Analyzing Cues

Nurses play a vital role in recognizing and analyzing cues in patients with hepatitis to provide timely and effective care. First, nurses conduct thorough assessments, including obtaining a health history and performing a physical examination. The nurse will ascertain whether the patient is exhibiting signs and symptoms indicative of hepatitis, and if so, relay the information to the provider for further investigation. Second, the nurse will inquire about sexual practices and IV drug use to determine if the patient has any risk factors for the development of hepatitis. This should be done in a nonjudgmental manner to ensure truthfulness and allow the patient to feel comfortable talking about these sensitive subjects. Third, the nurse uses information obtained from laboratory tests to further investigate the patient's situation. Lastly, the nurse will recognize abnormalities in liver panel results and advocate for further testing, if indicated.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

After a diagnosis of hepatitis has been made, the nurse begins to generate solutions based on the type of hepatitis present. Significant nursing interventions are not likely required for hepatitis A, which is usually self-limiting. For patients with hepatitis B and C infections, some actions the nurse might take include

- administering prescribed antiviral medications
- alternating rest and activity periods to improve fatigue
- educating patients and families about hepatitis, including transmission routes, symptom management, and the importance of maintaining medication regimen and follow-up schedule, as well as vaccination education
- encouraging fluids to prevent dehydration
- providing emotional support and refer to counseling, as needed
- using proper hand hygiene, isolation precautions, and sharps (i.e., needle) safety strategies to prevent spread

Evaluation of Nursing Care for the Patient with Hepatitis

Evaluating nursing care provided to patients with hepatitis ensures that their needs are met and optimal health outcomes are being achieved. The nurse will monitor the patient over time to determine whether the current plan of care is effective or if it needs to be changed.

Evaluating Outcomes

To evaluate outcomes, the nurse will assess the patient's overall health status, monitor vital signs and laboratory values, and observe the patient's understanding of and compliance with their care plan. Assessment findings that would indicate the patient is improving include

- improved fatigue
- improvement in GI symptoms (e.g., nausea, vomiting)
- increased appetite
- normal skin tone (no jaundice)
- stable vital signs
- statements that demonstrate understanding of the disease and treatment plan

Medical Therapies and Related Care

For all types of hepatitis, supportive therapy including rest and fluids are indicated. Hepatitis A is typically self-limiting and does not require any specific treatment beyond supportive care. Hepatitis B may require specific treatment, especially if it is a chronic infection and/or the patient has a high viral load. If treatment is indicated, there are several antiviral medications that can be used, but it is important to note that there is no complete cure. For chronic cases of hepatitis C, treatment involves antiviral medications, such as sofosbuvir and daclatasvir. The goal of treatment with these medications is to completely rid the body of the virus, which can often be done by taking them for 12 weeks. In severe cases of hepatitis B or C that are refractive to treatment, a liver transplant may be necessary.

Fungal Infections

Fungal infections are caused by organisms that belong to the kingdom Fungi. A **fungus** is characterized by eukaryotic cells that contain cell walls and vacuoles but not chloroplasts and that typically grow as tubular, thread-like structures called hyphae. Fungi generally are immobile except for the spores they produce in their reproductive

stage, and they obtain energy by decomposing and then absorbing dead matter (Constantine et al., 2024). Although mushrooms may be the fungi with which we are most familiar, most fungal infections are caused by yeasts or molds.

Numerous fungi live on and within the human body, but they do not usually cause disease. When they do result in an infection, the areas most often affected are the skin and nails, but fungal infections can also spread to the mouth, throat, lungs, and urinary tract. One of the most common fungal infections is **oral thrush** (oral candidiasis), which the remainder of this section focuses on. It important to know that in patients who are immunocompromised, such as those with HIV or who are undergoing cancer treatment, fungal infections are more likely to be severe because the immune system is not functioning optimally (CDC, 2021).

Pathophysiology of Oral Thrush

Oral thrush most commonly affects young children, but it can affect all ages, especially in the presence of immunocompromise. It is caused by a fungus called *Candida albicans*, which is one of the fungi normally found in the mouth. Overgrowth of *C. albicans* leads to the clinical manifestations discussed in the next section.

Clinical Manifestations

The hallmark symptom of oral thrush is white, raised lesions in the mouth—most often on the tongue and cheeks (Figure 22.11). Other symptoms include (Cleveland Clinic, 2023a):

- difficulty or pain with swallowing
- dry mouth
- fever (if infection spreads)
- loss of taste
- mouth redness
- sore mouth and tongue

FIGURE 22.11 Oral thrush causes raised white lesions in the oral cavity. (credit: "Species identification of Candida isolates obtained from oral lesions of HIV infected patients" by V.P. Baradkar & S. Kumar/National Institutes of Health, CC BY 2.0)

Assessment and Diagnostics for Oral Thrush

Oral thrush can typically be diagnosed based on clinical manifestations alone. If the provider is unsure after visual inspection, a swab of the lesions can be done and sent to the laboratory for analysis. A swab is also recommended if medications have been started and are not working after several days. This might mean that the fungus is resistant to the medication, so a specific culture should be obtained to better tailor the medication regimen.

Diagnostics and Laboratory Values

For patients with oral thrush from an unknown cause, it is important to perform diagnostic tests for underlying

conditions such as HIV or lupus. Because oral thrush most often occurs with immunocompromise, the patient may have another underlying disorder. Additionally, blood samples can be taken to check for the presence of *Candida* in the bloodstream to aid in the diagnosis.

Nursing Care of the Patient with Oral Thrush

Oral thrush is mild and easily resolved in most cases, so it is most often treated in outpatient settings. However, some patients who are hospitalized for other problems may develop oral thrush secondary to an underlying issue, such as HIV or receiving cancer treatment, both of which suppress the immune system. Nursing care for the patient with oral thrush involves treatment of symptoms, promotion of good hygiene, and patient education. Appropriate hygiene includes brushing teeth at least twice a day, flossing at least once a day, and rinsing with warm saltwater.

Recognizing and Analyzing Cues

The nurse must be able to recognize the hallmark white lesions that occur with oral thrush and relay that information to the provider so timely intervention can be initiated. Additionally, the nurse should assess the patient for any significant symptoms or medical history that may indicate the cause of the fungal infection, such as a history of HIV or of corticosteroid use, both of which suppress the immune system, more easily allowing infection to occur.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

After determining that the patient is likely dealing with oral thrush, the nurse will begin planning care, which may include the following interventions:

- administer antifungal medications as ordered
- educate patient about importance of finishing antifungal medications as prescribed
- educate patient about oral hygiene
- encourage fluid intake to maintain hydration
- perform oral swab, if ordered by provider

Evaluation of Nursing Care for the Patient with Oral Thrush

The nurse evaluates the care provided to a patient with oral thrush through a combination of subjective and objective measures, including assessing symptoms, ensuring the patient adheres to prescribed medications, and monitoring for adverse effects.

Evaluating Outcomes

To evaluate the effectiveness of interventions, the nurse will first assess the patient's symptoms. Improvement in the oral lesions would indicate that medications and other interventions have been successful. If the lesions have not improved, a different medication may be required. The nurse should inquire about the patient's adherence to the medication regimen as well. Stopping antifungal medications too early can result in resistance of the fungus to medications, similar to what causes antibiotic resistance, as discussed in 22.3 Antibiotic Resistance. Lastly, the nurse should evaluate whether the patient is experiencing any adverse effects related to the medication or other interventions.

LIFE-STAGE CONTEXT

Dentures and Oral Thrush

Patients with dentures require extra attention to oral hygiene to prevent development of fungal infections. Management for these patients may include:

- Disinfecting dentures daily
- Removing dentures for at least 6 hours every night
- Soaking dentures in chlorhexidine and allowing to air dry
- Taking out dentures every time a topical antifungal medication is used

Medical Therapies and Related Care for Oral Thrush

The first-line therapy for mild, uncomplicated cases of oral thrush is topical antifungal medications such as nystatin, clotrimazole, or ketoconazole (Taylor, 2023). These are typically administered as a mouthwash, rinse, or lozenge.

For more severe cases, oral or IV antifungal medications may be required. In addition to pharmacologic intervention, the patient may also require dietary counseling. The patient should be educated about the importance of limiting sugar intake, because fungi tend to thrive in high-sugar environments, which may worsen the infection. It is also important to initiate treatment for the underlying cause of immunosuppression, which will decrease the risk of developing fungal infections in the future.

22.3 Antibiotic Resistance

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Describe the physiological mechanisms that contribute to antibiotic resistance
- Discuss the two most common diseases of antibiotic resistance encountered in clinical practice
- Define antibiotic stewardship
- Apply nursing interventions and associated therapies in the care of the patient with an antibiotic resistant infection

Imagine that you wake up one morning with a swollen, painful toe. You go to the clinic, where they swab your toe, diagnose a bacterial infection, and start you on an antibiotic. You take the antibiotic for the prescribed week but do not see any improvement in the infection. You go back to the clinic; after more tests, the provider determines the infection is caused by a microorganism that is not responsive to most medications, so you will have to be admitted to the hospital for administration of more potent IV antibiotics. If the infection does not improve while in the hospital, it could become life-threatening or even require invasive treatment such as amputation of the toe. What started as a simple toe infection has become potentially life-threatening because of **antibiotic resistance**. More and more, we are seeing bacterial infections that resist antibiotic treatment, highlighting the need for more education about the importance of adhering to prescribed medication regimens and other measures to prevent resistance from developing.

Pathophysiology of Antibiotic Resistance

There are several mechanisms by which bacteria can become resistant to antibiotics (CDC, 2022d). Some bacteria have outer membranes that antibiotics cannot penetrate. Others use pumps within their cell wall to remove the antibiotics after they enter the cell. Many bacteria also have their own internal enzymes that can be used to neutralize or destroy antibiotics. But the most significant driver of antibiotic resistance may be evolution. Bacteria can "remodel," meaning they can change their characteristics as they learn to evade antibiotic medications. Also, a typical dose of antibiotics does not kill every invading bacterium. Due to genetic variance, some bacteria are naturally able to withstand the drug; when these bacteria reproduce, they may pass this natural resistance to their offspring. As this process continues, subsequent generations become increasingly resistant; given enough time, a strain of the bacteria may develop that cannot be effectively treated by the antibiotic. This is why it is crucial that health-care providers maintain diligence in appropriate antibiotic prescribing. It is also important for individuals who are prescribed a course of antibiotics not to miss a dose or stop taking the medication before they complete all doses—doing so only ensures that more bacteria survive to pass on resistance to new generations.

Regardless of the specific cause or mechanism, more and more bacteria are developing resistance to the antibiotics our health-care system has come to rely on. Although new medications are becoming available, the process of researching and developing them takes years. During that time, countless generations of bacteria live, reproduce, and evolve better defenses.

Methicillin-Resistant *Staphylococcus Aureus*

A strain of bacteria that has become resistant to many antibiotics in recent years is called **methicillin-resistant *Staphylococcus aureus* (MRSA)**. MRSA infections are most commonly seen in patients who have been living in long-term care centers or have been admitted to the hospital for an extended time. MRSA typically occurs in wounds on the skin. Clinical manifestations include:

- fever
- purulent drainage
- red bumps and/or boils on the skin (Figure 22.12)
- warm skin

FIGURE 22.12 MRSA infection on the skin commonly manifests as a swollen red spot with purulent drainage. (credit: CDC/Public Health Image Library, Public Domain)

Though MRSA is usually confined to the skin, in some cases, it can spread deeper into the underlying tissues, bones, or organs, leading to severe systemic infection and sepsis if left untreated. Risk factors for the development of MRSA infection include (Mayo Clinic, 2022):

- HIV infection
- long-term hospitalization
- participation in contact sports
- residence in crowded environments (e.g., jail, dorms)
- residence in nursing home or long-term care facility
- treatment with invasive medical devices

Fortunately, there are still some combinations of antibiotics that can effectively treat MRSA, but, over time, these medications will likely become less effective.

Vancomycin-Resistant *Enterococcus*

A strain of enterococci bacteria that has become resistant to treatment with vancomycin, a common antibiotic, is called **vancomycin-resistant *Enterococcus* (VRE)**. Risk factors for infection with VRE include (Doganci et al., 2023):

- history of invasive surgical procedures or medical device placement
- long-term hospitalization
- previous use of vancomycin to treat an infection
- weak immune system (e.g., HIV, critically ill patients)

VRE can occur in many places in the body, but it is most commonly seen in the urinary tract, bloodstream, and wounds. It can be spread through contact with contaminated surfaces or from person to person, usually through contaminated hands. The best way to prevent the spread of VRE is through hand hygiene and frequent cleaning of surfaces; it is crucial to wear gloves if coming into contact with bodily fluids that may be contaminated with VRE. VRE can be treated with antibiotics other than vancomycin, but there are limited options available and, over time, the bacteria may become resistant to other antibiotics as well.

Antibiotic Stewardship

The term **antibiotic stewardship** refers to efforts to improve antibiotic prescribing strategies so infections are treated effectively without contributing to the development of antibiotic resistance. The CDC (2024) has developed a set of core elements that serve as guidelines for improving antibiotic use in practice. Some of the main takeaways from these guidelines include:

- ensuring patients take antibiotics as prescribed and finish the entire dose as ordered by the treating clinician
- not prescribing antibiotics for asymptomatic urinary tract infections
- prescribing the correct route, dose, and duration of antibiotic treatment regiments
- tailoring antibiotic therapy to specific organisms as opposed to immediately implementing broad-spectrum antibiotics

LINK TO LEARNING

For more detailed information about the CDC's guidelines, visit the Core Elements of Antibiotic Stewardship (https://openstax.org/r/77coreantibio) web page.

Medical Therapies for Antibiotic Resistance

Increases in antibiotic-resistant bacteria have highlighted an urgent need for research and development of new antibiotics. In recent years, several new antibiotics have become available, but pharmaceutical research is relatively slow to ensure safety of the medications in humans. For that reason, the development of new medications is not keeping pace with the development of antibiotic-resistant strains of bacteria. This highlights the need for strategies to improve the effectiveness of existing antibiotics. In many cases, this has involved changing the route of the antibiotic from oral to IV for quicker, more potent treatment. In other cases, this means altering the duration of therapy to eradicate the resistant bacteria more effectively. More examples to reduce antibiotic resistance include:

- Alternative antibiotics and combinations:
  - Broader-spectrum antibiotics: Use antibiotics with a broader spectrum of activity when appropriate, based on susceptibility testing.
  - Combination therapy: Use combination antibiotic therapy to enhance efficacy and prevent resistance development in cases where one antibiotic may help the other be more effective.
- Infection control measures:
  - Strict hygiene practices: Enhance infection control practices, including hand hygiene and environmental cleaning, to prevent the spread of resistant bacteria.
  - Isolation protocols: Use isolation techniques for patients with resistant infections to prevent transmission to others.
- Monitoring and surveillance:
  - Track resistance patterns: Monitor and track antibiotic resistance patterns in health-care settings to inform treatment decisions and policy adjustments.

Nursing Care to Avoid Antibiotic Resistance

One of the most important roles of the nurse in preventing antibiotic resistance is educating patients about taking their antibiotics as prescribed (National Institute of Allergy and Infectious Diseases, 2020). When patients stop a course of medication early, the bacteria are often not sufficiently treated. This allows any remaining bacteria to mutate and grow, contributing to their future resistance to antibiotic therapy. For this reason, nurses must emphasize the importance of finishing the entire course of antibiotics, even if the patient reports improved symptoms, and not sharing medications with others. Additionally, nurses can actively participate in antibiotic stewardship initiatives within their facility. This may simply mean adhering to best practices for using antibiotics and providing patient education, or it may involve active participation on a committee that is attempting to implement the initiatives on a specific unit or within the institution.

LIFE-STAGE CONTEXT

Older Adults and Antibiotics

Older adults are at a higher risk of infection because they have a less effective immune system, and they often benefit from antibiotic treatment (Soraci et al., 2023). However, older adults are also more likely to develop adverse drug events from using antibiotics because of polypharmacy (taking many other medications that may interact with the antibiotic), renal and liver dysfunction, and reduced adherence due to cognitive or functional issues. For this reason, antibiotics should be used with caution in this population, and patients prescribed antibiotics should be monitored closely for the duration of therapy.

22.4 Preventing Secondary Infections

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology of secondary infections and associated clinical manifestations
- Explain the common types of secondary infections encountered in the clinical setting
- Summarize important nursing interventions to prevent secondary infection
- Apply nursing concepts and plan associated nursing care for patients with *Clostridioides difficile* infection
- Describe the medical therapies that apply to the care of patients with *Clostridioides difficile* infection

A **secondary infection** arises after treatment of a different, primary infection (National Library of Medicine, 2023). Secondary infections (which are also called opportunistic infections) often result in a more complicated and prolonged recovery process. Most often, the pharmacologic treatment for the initial infection causes changes in the immune system that result in another infection. Two common examples of this include a person who develops a vaginal yeast infection after taking antibiotics for a bacterial infection and a person who develops bacterial pneumonia after being treated for a viral upper respiratory infection.

Clostridioides difficile Infection

One of the most common secondary infections is named for the bacterium ***Clostridioides difficile***, or *C. diff* for short (CDC, 2023b). This bacterium used to be called *Clostridium difficile*; however, it was reclassified in 2016 (Lawson et al., 2016). Normally located in the intestines, *C. diff* can cause inflammation of the colon (pseudomembranous colitis). This occurs most often after a patient takes antibiotics, which can alter the number of bacteria in the large intestine (Cleveland Clinic, 2023b). Other risk factors for the development of *C. diff* include:

- immunosuppression (e.g., HIV infection, cancer, organ transplant)
- older age (>65 years)
- previous *C. diff* infection
- recent hospitalization or residence in a long-term care facility

The hallmark clinical manifestation of *C. diff* infection is malodorous diarrhea (Mada et al., 2023). Additionally, patients may have fever, abdominal pain, and nausea.

Nursing Care of the Patient with *C. difficile* Infection

C. diff poses significant challenges in health-care settings, requiring diligent nursing care to manage symptoms, prevent transmission, and promote recovery. Nursing care for patients with *C. diff* encompasses a multifaceted approach, involving meticulous infection-control practices, symptom management, and targeted antibiotic therapy when warranted.

Recognizing and Analyzing Cues

Nurses play a key role in the initial detection of *C. diff*, especially in hospitalized patients. The nurse must be able to recognize subtle changes in the patient's condition that may be indicative of a *C. diff* infection. Specifically, the nurse should pay close attention to the patient's bowel movements, assessing for changes in consistency and signs of gradual development of diarrhea. If signs of *C. diff* are noted, the nurse should analyze the assessed cues by determining whether the patient has risk factors, such as recent antibiotic use, that increase the chance of developing *C. diff* infection.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

The nurse will recognize a recent history of antibiotic use as a major risk factor and hypothesize that the patient has developed a *C. diff* infection. Based on this information, the nurse prepares to initiate the following interventions:

- Stool sample collection: If *C. diff* is suspected, the nurse should send a stool sample to the laboratory for confirmation. While waiting for the results, the nurse should operate under the assumption that the patient has *C. diff* and use isolation precautions accordingly. If the sample comes back negative, isolation precautions can be discontinued.
- Ensure strict soap-and-water hand-hygiene regimens, not alcohol-based foams or gels, because the latter are ineffective at killing the organism. Handwashing should be completed before and after every patient encounter, not just the patient with *C. diff*. Nurses must thoroughly clean all surfaces objects with bleach

wipes.
- Implement isolation precautions: Patients with *C. diff* should be placed on contact precautions. Entering the patient's room requires gloves and a gown to prevent transmission to health-care personnel and other patients.
- Hydration and electrolyte management: Because patients with *C. diff* have a large amount of diarrhea, they are at increased risk of dehydration and electrolyte imbalances. The nurse should encourage oral fluids if tolerated and monitor the patient closely for signs that would indicate electrolyte imbalance.
- Symptom management: In some cases, the nurse may administer antidiarrheal or antiemetic medications, as ordered. For severe cases when the patient is immobile, a rectal tube may be ordered to contain the diarrhea and prevent skin breakdown.
- Educate patient and family: The nurse should educate the patient and family about measures to prevent the spread of *C. diff*. If the patient is prescribed antibiotics for *C. diff*, the nurse should educate the patient about the importance of finishing the course of medication to prevent antibiotic resistance.

Evaluation of Nursing Care for the Patient with *C. difficile* Infection

Evaluation of nursing care for the patient with *C. diff* involves assessing the patient's response to treatment, monitoring for resolution of symptoms, and preventing recurrence of infection. Examples include having the patient complete return demonstration of proper hand hygiene. Another way the nurse can evaluate the patient's and/or family's understanding and opportunity for more education is to have them explain why cleaning the home with bleach wipes is necessary.

Evaluating Outcomes

First, the nurse will assess the patient's response to treatment. If the patient has been prescribed a new antibiotic, the nurse should monitor for signs and symptoms that would indicate tolerance of the medication. If the patient reports GI distress or rash, the nurse should recognize those as potential signs of medication intolerance and alert the provider immediately. The nurse should monitor the patient's bowel movements closely, assessing for changes that would indicate the diarrhea is improving. After beginning treatment, the bowel movements should continue to become less liquid and more formed over the course of a few weeks. Lastly, the nurse should evaluate for potential risk factors for recurrence of infection. Specifically, the nurse should inquire about the patient's adherence to their antibiotic prescription to ensure the entire course was taken, which decreases their risk for developing a recurring infection.

Medical Therapies and Related Care for the Patient with *C. difficile* Infection

First and foremost, medical treatment for *C. diff* includes stopping the antibiotic that likely caused the infection. In many cases, the patient will develop *C. diff* a few days or weeks after finishing the antibiotics, so this is not possible. However, in cases where the patient is still taking an antibiotic that could have caused the infection, the antibiotic should be stopped immediately. The patient will then be prescribed different antibiotics for the *C. diff* itself: typically, metronidazole, vancomycin, or fidaxomicin. Mild cases can be treated with oral antibiotics, whereas more severe cases often require IV administration. For patients with recurring *C. diff* infections, colectomy or fecal transplant may be required. A **colectomy** is the removal of a portion of the colon, and a **fecal transplant** involves transferring medically processed stool from a healthy donor into the affected colon to restore healthy bacteria.

General Nursing Interventions for Preventing Secondary Infection

The priority intervention for preventing the development of secondary infections in general is the use of proper hand hygiene. Most secondary infections are transmitted through person-to-person contact, so washing the hands properly greatly reduces the risk of transmission. Additionally, nurses and other health-care personnel should always use gloves when caring for patients with secondary infections. This will help prevent hand contamination and subsequent transmission to other health-care workers or patients.

Although many secondary infections are related to pharmacologic interventions, some may develop secondary to placement of invasive tubes or lines. Critically ill patients often require intubation for mechanical ventilation, insertion of indwelling urinary catheters, or insertion of central lines. All these interventions involve placement of tubes in the body, increasing the risk for infection. For example, using mechanical ventilation greatly increases the risk of ventilator-associated pneumonia, and the use of urinary catheters and central lines increase the risk for catheter-associated urinary tract infection and central line–associated blood infection, respectively. Many hospitals

have started implementing committees that solely focus on the early discontinuation of these invasive tubes and lines. Extubating patients and removing indwelling lines as soon as possible greatly reduces the risk for developing secondary infections. This is significant because hospital-acquired secondary infections can negatively affect patient outcomes, increase length of hospitalization, and result in increased costs for the health-care institution.

Immunizations are another excellent strategy for prevention of secondary infections. For example, getting annual influenza and COVID-19 vaccines helps prevent initial infections that may require hospitalization, thus reducing the chance of developing a secondary infection. There are also several vaccines that prevent bacterial infections (e.g., meningococcal and pneumococcal infections). These reduce the chance of the patient requiring treatment with antibiotics, which, in turn, decreases the risk of developing secondary infections associated with antibiotic use, such as *C. diff*.

LINK TO LEARNING

Learn more about how to prevent secondary infections (https://openstax.org/r/77secondinfect) at this CDC webpage. The information focuses on opportunistic infections in the context of HIV, but many of the strategies are applicable to other kinds of secondary infection.

Summary

22.1 Infectious Process

- Infections are one of leading causes of death and disability globally. As we have learned from the COVID-19 pandemic, it is important to be prepared for outbreaks of infections.
- Nurses must remain knowledgeable about common infections, including how they spread and how best to treat them. Additionally, it is important for nurses to understand the underlying functions and mechanisms of the human immune system, so they may better care for patients with infections.
- The first step in the immune response is the body's recognition of an antigen. Infection results when a pathogen is able to evade the immune response.
- The immune response usually begins with the physical barriers that prevent pathogens from entering the body, destroy them after they enter, or flush them out before they can establish themselves as an infection. These barriers include the skin and mucus membranes.
- White blood cells, or leukocytes, are the primary cells of the immune system. They fight off pathogens to prevent infection. There are several specific types of leukocytes, including monocytes, lymphocytes, neutrophils, basophils, and eosinophils.
- The lymphatic system drains and filters various body fluids and returns them to the bloodstream. It includes organs such as lymph nodes, the spleen, and thymus, as well as bone marrow and a network of vessels and ducts.

22.2 Viral and Fungal Infections

- Viral infections are common and can be highly destructive, as evidenced by the 2020 COVID-19 pandemic. There are many kinds of viruses, but they all consist of a piece of DNA or RNA protected by a coating of protein. When a virus infects a host, it invades the host's cells, injects its genetic material, and uses the host's components to replicate and produce more viruses. This cycle risks destroying the host's cells and threatens their health and, in some cases, life.
- Humans can become infected by viruses by swallowing or inhaling them (via droplets), being stung or bitten by insects, or having sexual contact or intercourse; a mother can also transfer a virus to her fetus in utero or during birth. Most viral infections cause vague general symptoms including fatigue, muscle aches, and headache. Two of the most common viral infections today are COVID-19 (caused by the novel coronavirus) and influenza (caused by the influenza virus).
- Caring for patients with viral infections requires vigilant assessment skills, technical knowledge, and compassion. Nurses are on the frontlines of caring for these patients and must remain knowledgeable and informed about the most up-to-date clinical practices and interventions to provide care that ensures optimal patient outcomes. For serious infections, this may involve administering antiviral medications and providing respiratory support. When vaccines exist, it is also important for people to be vaccinated.
- Human immunodeficiency virus (HIV) was discovered in the 1980s. It is a retrovirus, meaning that infected cells can insert viral DNA into healthy host cells, permanently altering and infecting them.
- HIV targets specific cells of the immune system, particularly a type of WBC called CD4. As WBCs are destroyed, the immune system starts to fail. Eventually, the infected individual will no longer have a functioning immune system, putting them at risk for a variety of opportunistic infections and the development of acquired immunodeficiency syndrome (AIDS).
- HIV can be difficult to detect and diagnose in the early stages because patients may be completely asymptomatic or have vague symptoms that resemble the flu. In addition to several kinds of diagnostic tests, laboratory values such as viral load, total WBC count, and CD4 count, in particular, are key to diagnosing the disease and monitoring its progress.
- Nursing care for the patient with HIV or AIDS requires knowledge of the disease process, technical skills for monitoring viral load, and the ability to provide holistic, nonjudgmental care.
- Medical treatment for HIV is aimed at slowing the progression of the disease and controlling symptoms. Several classes of antiretroviral medications developed in recent decades have effectively turned HIV into a chronic, manageable condition rather than the death sentence it once was.
- Hepatitis is characterized by inflammation of the liver and often results from a viral infection. There are several types of hepatitis, each of which varies slightly regarding transmission and symptoms. Types A, B, and C are

the most common.

- Hepatitis A can be contracted through ingestion, whereas types B and C are transmitted by parenteral contact. Hepatitis C is often undiagnosed.
- Hepatitis A is usually asymptomatic or characterized by vague symptoms such as fatigue and nausea. Hepatitis C manifests as malaise, nausea, right upper-quadrant pain, dark urine, and jaundice. Hepatitis B has a wider range of clinical manifestations; late-stage findings include confusion, coma, ascites, and GI bleeding.
- General laboratory testing for hepatitis begins with blood testing to examine liver function. A hepatitis virus serological test panel can be used to detect antibodies to hepatitis viruses A, B, and C.
- Hepatitis remains a global health concern, highlighting the need for nurses to remain knowledgeable and prepared to care for patients with this kind of infection. Nurses must stay up to date with current research, advocate for vaccination, and promote safe practices to prevent disease transmission and limit complications.
- Collaboration with interdisciplinary teams, ongoing professional development, and a commitment to evidence-based practice are essential in nurses' efforts to mitigate the burden of hepatitis on individuals and communities worldwide.
- Fungal infections are caused by fungi. They are usually mild. However, in some cases, they can become life-threatening, especially in patients with underlying immunocompromise.
- One of the most common types of fungal infections is candidiasis, or oral thrush. Oral thrush causes white, patchy lesions in the mouth because of fungal overgrowth. It can be treated with topical antifungal medications or, in more severe cases, oral or IV antifungals.
- Nursing care for patients with oral thrush involves treatment of symptoms, promotion of adequate hygiene, and patient education.

22.3 Antibiotic Resistance

- There are several mechanisms by which bacteria can become resistant to antibiotics, including having impenetrable outer membranes, pumps that remove the medications, and the ability to remodel, or change in some way, so the medications are no longer effective.
- The two most common diseases of antibiotic resistance encountered in practice include infection by methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant *Enterococcus.*
- Antibiotic stewardship refers to efforts to improve antibiotic-prescribing strategies so that infections are treated effectively without contributing to the development of antibiotic resistance.
- One of the most important roles of the nurse in preventing antibiotic resistance is educating patients about taking their antibiotics as prescribed, because when patients stop a course of medication early, bacteria are often not sufficiently treated, which contributes to their increased risk of developing resistance to medications.

22.4 Preventing Secondary Infections

- A secondary infection arises after treatment of a different, primary infection, and often results in a more complicated and prolonged recovery process.
- One of the most common secondary infections is named for the bacterium *Clostridioides difficile* (*C. diff*).
- *C. diff* poses significant challenges in health-care settings, requiring diligent nursing care to manage symptoms, prevent transmission, and promote recovery.
- Nursing interventions for *C. diff* include stool sample collection, implementing isolation precautions, promoting hydration, managing electrolytes, and symptom management.
- Medical treatment for *C. diff* includes stopping the antibiotic that likely caused the infection and switching to a new antibiotic. In severe recurring cases, a colectomy or fecal transplant may be necessary.

Key Terms

acquired immunodeficiency syndrome (AIDS) latest and most severe stage of HIV, characterized by a low CD4 cell count and opportunistic infections

adaptive immune response relatively slow but very specific and effective immune response controlled by lymphocytes

antibiotic resistance increased ability of microorganisms to survive exposure to antibiotic medications

antibiotic stewardship efforts to improve antibiotic prescribing strategies to more effectively treat infections and

avoid the development of antibiotic resistance

antigen molecule on the cell surface of a pathogen that is recognized as an invader by the immune system

barrier defense skin, mucous membranes, and other components of the immune system that act instantaneously to prevent pathogenic invasion into body tissues

bone marrow spongy material located inside the long bones and responsible for the production and maturation of blood cells

Clostridioides difficile bacterium normally located in the intestines that can cause secondary inflammation of the colon, most often after taking antibiotics; also called *C. diff*

colectomy removal of a portion of the colon

contagious capable of spreading from one person to another

coronavirus type of virus characterized by a lipid envelope surrounded by proteins that jut out like spikes

deoxyribonucleic acid (DNA) self-replicating material that is present in all living organisms and the main constituent of chromosomes; the focus of genetics

fecal transplant transfer of medically processed stool from a healthy donor into a colon infected by *Clostridioides difficile* bacteria

fungus organism that belongs to the kingdom Fungi, characterized by eukaryotic cells that contain cell walls and vacuoles but not chloroplasts and that typically grow as tubular, thread-like structures called hyphae

hepatitis condition characterized by inflammation of the liver; often a secondary result of a viral infection

hepatocyte liver cell

host organism that has been infected by another organism or virus

human immunodeficiency virus (HIV) retrovirus characterized by the destruction of certain white blood cells, ultimately resulting in AIDS

immune system complex collection of cells and organs that destroy or neutralize pathogens that would otherwise cause disease or death

infectious disease caused by pathogenic microorganisms—agents such as bacteria, viruses, parasites, or fungi—that enter a human host, multiply, and cause infection that can spread via direct or indirect transmission

innate immune response rapid but relatively nonspecific immune response

leukocyte primary cell of the immune system that fight off pathogens to prevent infection; also called white blood cell

liver cirrhosis damage to the liver that results in permanent scarring and fibrosis

long COVID condition in which an individual has recovered from COVID-19 but continues to have symptoms and adverse effects for months after infection

lymph interstitial fluid once it has entered the lymphatic system

lymph node small, bean-shaped organs located along lymphatic vessels

lymphatic system system of vessels, cells, and organs that carries excess fluids to the bloodstream and filter pathogens from the blood

methicillin-resistant *Staphylococcus aureus* (MRSA) strain of *Staphylococcus* bacteria that has become resistant to many antibiotics

opportunistic infection infection that arises from pathogens that would not normally cause infection in a healthy individual but occur when the immune system is not functioning optimally

oral thrush infection caused by the fungus *Candida albicans*, which is found normally in the mouth but can become overgrown and pathological; also called oral candidiasis

pathogen agent such as a bacterium, virus, parasite, or fungus that enters a human host, multiplies, and causes infection

pathogenicity potential ability of a pathogen to cause disease in a susceptible host

retrovirus virus composed of a ribonucleic acid strand that can be turned into DNA and permanently inserted into a healthy cell

reverse transcriptase enzyme used to convert RNA into DNA

ribonucleic acid (RNA) nucleic acid that is present in all living cells and that carries instructions from DNA for controlling protein synthesis

secondary infection infection that arises after treatment for a different, primary infection; also called opportunistic infections

spleen secondary lymphoid organ that filters pathogens from the blood and removes damaged blood cells

thymus lymphatic organ whose main function is the production of a group of hormones that contribute to the development and differentiation of T lymphocytes

vancomycin-resistant *Enterococcus* (VRE) strain of enterococci bacteria that has become resistant to treatment with the antibiotic vancomycin

viral load amount of virus in the blood

virulence severity of an infectious disease

virus piece of genetic code, such as DNA or RNA, protected by a coating of protein and capable of self-directed movement and reproduction

Assessments

Review Questions

1. What is a common method pathogens use to evade the immune response?
    a. rapid multiplication in the bloodstream
    b. formation of antibodies
    c. continuous mutation
    d. direct attack on immune cells

2. What part of the immune system is nonspecific and acts quickly at the first sign of infection?
    a. leukocytes
    b. innate immune response
    c. adaptive immune response
    d. skin

3. What type of WBC is most involved in parasitic infections and allergies?
    a. monocyte
    b. lymphocyte
    c. eosinophil
    d. basophil

4. What acts as a barrier defense to protect the body from infection?
    a. hair follicles
    b. mucus membranes
    c. leukocytes
    d. bone marrow

5. What assessment finding would the nurse anticipate for a patient newly diagnosed with viral meningitis?
    a. constipation
    b. cough
    c. stiff neck
    d. sore throat

6. What is the most likely transmission route for hepatitis A?
    a. sexual contact
    b. hugging
    c. drinking contaminated water
    d. IV drug use

7. What laboratory value would be consistent with a diagnosis of HIV?
    a. WBC count of 5,400/uL
    b. CD4 cell count of 350 cells/mm^3
    c. red blood cell count of 5.0 cells/µL
    d. potassium level of 3.5 mEq/mL

8. The nurse is caring for a patient with oral thrush. What underlying condition should the nurse consider testing the patient for?
   a. COVID-19
   b. chronic obstructive pulmonary disease
   c. eczema
   d. lupus

9. What kind of patient would be at risk for developing a fungal infection?
   a. a patient with a history of prostate cancer
   b. a patient with HIV
   c. a patient with an indwelling urinary catheter
   d. a patient with a history of hypertension

10. How does HIV infect a cell?
   a. It injects its DNA into the cytoplasm.
   b. It injects its RNA into the nucleus.
   c. It injects its RNA into the cytoplasm, where it is converted to viral DNA.
   d. It injects its DNA into the nucleus, where it is converted to viral RNA.

11. What is an appropriate intervention for the nurse to perform when caring for a patient with oral thrush?
   a. monitoring vital signs every 30 minutes
   b. administering antibiotics as ordered
   c. encouraging fluid intake to maintain hydration
   d. providing a high-fat diet

12. What is the main rationale behind repositioning patients with lower respiratory infections every 2 hours?
   a. preventing skin breakdown
   b. minimizing virus transmission
   c. facilitating lung expansion
   d. increasing activity tolerance

13. What abnormal laboratory value would be consistent with a diagnosis of hepatitis B?
   a. decreased alkaline phosphatase level
   b. elevated alanine aminotransferase level
   c. elevated WBC count
   d. decreased direct bilirubin level

14. What is a likely treatment option for a patient newly diagnosed with HIV?
   a. a combination of antiretroviral medications
   b. surgery to remove the infected cells
   c. a course of antibiotics
   d. regular radiation and chemotherapy

15. What is the primary purpose of using personal protective equipment when providing care for patients with COVID-19?
   a. encouraging visitors to allow the patient to rest
   b. ensuring the patient remains in a clean environment
   c. providing privacy for the patient
   d. limiting spread of the virus to other patients and staff

16. What finding would indicate that interventions for treating a patient with HIV have been successful?
   a. CD4 cell count $<400/mm^3$
   b. negative for influenza

c. nondetectable viral load
d. WBC count of 14,000/mm^3

17. The nurse is caring for a patient who reports a history of IV drug use. What type of hepatitis is the patient most likely to have, given that information?
a. hepatitis A
b. hepatitis C
c. hepatitis D
d. hepatitis E

18. What assessment findings would indicate improvement in a patient's condition following interventions for COVID-19?
a. preference for prone positioning
b. increased oxygen requirements
c. decreased appetite and activity tolerance
d. stable vital signs

19. What is the role of pharmacologic interventions in treating COVID-19?
a. Paxlovid and Lagevrio are typically used for mild cases of COVID-19; Veklury is reserved for long-term management of symptoms.
b. Pharmacologic intervention is not necessary for mild cases of COVID-19, which usually resolve with rest and hydration.
c. All patients with COVID-19, regardless of severity, are prescribed Veklury intravenously as the first-line treatment.
d. The use of Paxlovid, Lagevrio, and Veklury is interchangeable and depends on patient preference.

20. What process contributes to bacteria becoming more resistant to antibiotics over time?
a. increased susceptibility to antibiotic effects
b. accelerated development of new antibiotics
c. enhanced communication between bacteria strains
d. adapting to evade or destroy antibiotics

21. What clinical manifestation is commonly associated with MRSA infection?
a. weight loss
b. new-onset cough
c. purulent drainage
d. frequent urination

22. What is a key principle emphasized in antibiotic stewardship guidelines developed by the CDC?
a. prescribing broad-spectrum antibiotics for all infections
b. administering antibiotics for all urinary tract infections
c. tailoring antibiotic therapy to specific organisms
d. allowing patients to stop antibiotic treatment when symptoms improve

23. The nurse is providing education about a newly prescribed antibiotic to a patient. What point about the prescription should the nurse emphasize in the teaching?
a. “You can stop taking your antibiotic when you feel better.”
b. “If your spouse develops the infection too, you can give them some of your medicine.”
c. “Keep any unused pills just in case you develop another infection later.”
d. “Make sure you take all the prescribed pills as directed.”

24. What is a key factor that increases the risk of adverse drug events from antibiotic use in older adults?
a. decreased susceptibility to infections

b. drug interactions due to polypharmacy
c. increased adherence to medication regimens
d. enhanced immune response to antibiotics

25. What is a factor that increases the risk for developing a *C.* diff infection?
a. consumption of probiotic-rich foods
b. regular exercise regimen
c. recent discharge from the hospital
d. history of seasonal allergies

26. What is an effective measure for preventing transmission of secondary infections in health-care settings?
a. routine use of antiviral medications
b. timely administration of broad-spectrum antibiotics
c. proper hand hygiene and glove use
d. placement of patients on airborne precautions

27. What is a priority nursing intervention when caring for a patient with suspected *C. diff* infection?
a. administering prophylactic antibiotics
b. encouraging bed rest to conserve energy
c. providing IV fluids for hydration
d. collecting a stool sample for laboratory testing

28. What is a primary consideration when implementing isolation precautions for a patient with *C. diff* infection?
a. wearing gloves and gown upon entering the patient's room
b. ensuring adequate ventilation in the patient's room
c. placing the patient in a negative-pressure isolation room
d. restricting all visitors from entering the patient's room

Check Your Understanding Questions

1. What are the main functions of the lymphatic system?
2. Identify the main parts of the lymphatic system and their respective roles in preventing or fighting infection.
3. For patients who present with vague symptoms, how can a viral infection be diagnosed?
4. What is the difference between HIV and AIDS?
5. What education should the nurse provide to a patient with dentures about preventing oral thrush?
6. Explain in your own words what an opportunistic infection is.
7. What are the main differences between how hepatitis A, B, and C are transmitted?
8. What is a primary method for preventing the spread of MRSA and VRE infections in the hospital setting?
9. What clinical manifestations should the nurse monitor for in a patient at risk for developing *C. diff* infection?

Reflection Questions

1. What do you think would happen if a patient's lymphatic system were not working optimally?
2. What do you think is the most difficult aspect of caring for patients with viral infections?
3. How would you stress the importance of getting a hepatitis vaccine to a patient who is wary of immunizations?
4. You are working with a student nurse who expresses concern about caring for a patient with HIV. The student nurse states, "I don't want to take care of this patient because I don't want to get infected." How would you respond?

5. How can nurses actively contribute to antibiotic stewardship efforts in health-care settings to promote appropriate antibiotic use and mitigate the development of antibiotic resistance?
6. What are some potential benefits that health-care institutions may experience when implementing strategies to prioritize the early discontinuation of invasive lines and tubes?

What Should the Nurse Do?

A 45-year-old male presents to the emergency department with symptoms of fever, cough, and dyspnea. He reports recent travel to an area with known cases of influenza. Upon examination, the patient's temperature is 102°F (38.9°C), respiratory rate is 24 breaths per minute, and oxygen saturation is 90% on room air. Auscultation reveals crackles in the lower lungs. The patient is tested for influenza and the result comes back positive.

1. Considering the patient's presentation and diagnosis of influenza infection, what factors may have contributed to his susceptibility to contracting the virus?
2. What are the highest priority nursing interventions at this time?
3. How might education and collaboration with other health-care professionals contribute to the management of this patient's care and the broader public health response to viral infections?

Competency-Based Assessments

1. Perform a literature search about a specific type of infection and determine how it uses mechanisms to evade the body's immune response.
2. Create an engaging handout for patients regarding the importance of obtaining annual influenza and COVID-19 vaccines.
3. Develop a patient brochure explaining risk factors and prevention strategies for the different types of hepatitis.
4. Develop a 15-minute in-service program for health-care staff about how to prevent secondary infections in the health-care setting.

CHAPTER 23

Shock and Sepsis

FIGURE 23.1 Sepsis correlates with a high hospitalization rate and requires prompt intervention. (credit: Airman 1st Class Nathan Byrnes/U.S. Air Force, Public Domain)

CHAPTER OUTLINE

INTRODUCTION A nurse is caring for a patient who has been admitted to a medical-surgical unit for evaluation of weakness and shortness of breath. Upon admission to the unit, the patient manifested the following vital signs: oral temperature 98.6°F, pulse 88 and regular, respiratory rate 16, and blood pressure 120/82 mmHg. A chest x-ray, complete blood count (CBC), basic metabolic panel (BMP), and urinalysis have been obtained, with results pending.

The nurse reassesses the patient thirty minutes later and finds the patient to be disoriented to time, place, and person. Vital signs are as follows: oral temperature of 101.3°F, pulse of 118 and regular, respiratory rate of 22, and blood pressure of 88/60 mmHg. The nurse knows that such changes in vital signs are possible manifestations of shock, a life-threatening condition that causes cells and organs not to receive adequate perfusion. The nurse notifies the health-care provider, who prescribes interventions to restore homeostasis and prevent further complications.

Early identification of the development of shock and initiation of appropriate treatment is key to full patient recovery. By conducting prompt assessments and reporting concerning changes in vital signs, such as a drop in blood pressure and an increase in heart rate, nurses can have a significant positive impact on patient outcomes. In this chapter, you will learn how to prevent, recognize, and treat one of the most life-threatening conditions a patient

can encounter: shock.

23.1 Shock Overview

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Describe the pathophysiology and clinical manifestations associated with shock
- Discuss the stages of shock
- Identify the vital sign deviations associated with each stage of shock

To maintain a healthy state of equilibrium, or homeostasis, the cells and tissues in the body must receive adequate perfusion. When this does not happen, the body may go into a state of inadequate cellular perfusion known as **shock**. There are several different types of shock—including hypovolemic, septic, and neurogenic shock—all of which will be discussed in more detail throughout this chapter.

Pathophysiology of Shock

Physiologic alterations that occur with shock are the result of inadequate tissue perfusion. An adequate quantity and quality of blood—containing plasma, platelets, and red and white cells as well as essential substances such as sugars, oxygen, and hormones—are needed to support cell life. Normal perfusion requires coordinated efforts of the neurologic, cardiovascular, respiratory, and renal systems to maintain homeostasis. The ventricles of the heart must be strong enough to propel blood through the body. In addition, blood vessels must have adequate systemic vascular tone to support the flow of blood through the vascular system (see Figure 12.29); otherwise, blood flow can stagnate, causing blood to pool in the lower extremities (legs, ankles, feet). One of the key contributors to shock is vasodilation, which occurs as the body attempts to deliver more blood rich in oxygen, white blood cells, and platelets to the area of potential damage. Vasodilation creates a drop in blood pressure, and changes in vital signs reflect the body's attempt to compensate for decreasing pressure.

In the early stages of shock, the body compensates for decreased cell perfusion by activating the sympathetic nervous system to elicit the "fight or flight" response. This releases epinephrine, cortisol, and norepinephrine, resulting in the vasoconstriction of blood vessels, an increase in blood pressure and heart rate, and increased extracellular glucose to deliver energy to the cells. When these compensatory mechanisms are exhausted, circulatory failure and tissue hypoxia occur, ultimately leading to cell death and the destruction of vital organs.

Hemodynamic Monitoring

The study of the movement of the blood as it flows through cells, tissues, and organs is called **hemodynamics**. Knowledge of this field is needed to fully comprehend the pathophysiologic implications of shock. Hemodynamic monitoring of patients provides relevant data that help nurses assess tissue oxygenation, fluid balance, and the effectiveness of fluid and drug therapies. It also provides data on cardiac output (CO), which is the volume of blood the heart can pump to the vascular system in one minute; normal CO is 5 L/minute. A drop in cardiac output occurs with shock. Cardiac function is discussed in greater detail in Chapter 12 Cardiovascular System.

Hemodynamic monitoring can be performed via invasive or noninvasive methods.

- Examples of noninvasive hemodynamic monitoring include auscultation of the apical pulse and palpating the radial artery to obtain heart rate. Providers may use a sphygmomanometer, also known as a blood pressure cuff, to obtain blood pressure; they may also assess the patient's peripheral pulses, capillary refill time, skin, and warmth and check for the presence of edema.
- Invasive methods of hemodynamic monitoring devices allow for continuous measurements and are therefore more accurate than noninvasive monitoring devices. Invasive hemodynamic monitoring devices require the insertion of a catheter into the patient's vascular system. Examples include using a central venous catheter to measure:
  - **central venous pressure (CVP)**, a measure of the adequacy of blood volume within the vascular system; normal range is 8–12 mmHg
  - **mean arterial pressure (MAP)**, a measure of the average arterial pressure through one cardiac cycle; normally 70–100 mmHg
  - **cardiopulmonary pressure**, a measure of the pressure in the pulmonary artery, the lungs, or the right

atrium and ventricle of the heart, measured by a **pulmonary artery catheter** (a central arterial device used to measure cardiopulmonary pressure); normal cardiopulmonary pressure is 11-–20 mmHg, and elevated ranges result in pulmonary hypertension

These methods are discussed in greater detail in Chapter 35 Nursing Care of the Critically Ill Patient.

Blood pressure readings can be impacted by the stimulation of the sympathetic nervous system seen in shock. Consequently, MAP obtained from an arterial line is recommended for monitoring patients experiencing shock. This method has been found to best reflect the state of cell perfusion. Normal MAP readings are 70–100 mmHg. Inadequate cell perfusion is suggested if the MAP falls below 65 mmHg. Table 23.1 lists hemodynamic readings that indicate shock.

Hemodynamic Reading	Normal Range	Effect of Shock State
Cardiac output (CO)	5–6 L/minute	Decreased CO
Mean arterial pressure (MAP)	70–100 mmHg (The goal for critically ill patients is to keep MAP above 65 mmHg.)	Decreased MAP
Central venous pressure (CVP)	8–12 mmHg	Decreased CVP

TABLE 23.1 Hemodynamic Readings Indicative of Shock

Stages of Shock

Shock has four stages: the initial stage followed by the compensatory, progressive, and refractory stages. With progression to each stage of shock, cellular perfusion is further decreased, resulting in irreversible cell changes and death. Timely detection and intervention in the early stages of shock may prevent destruction of cells and organ systems.

Initial Stage

In the **initial stage** of shock, the body responds to hypotension with stimulation of the sympathetic nervous system (SNS) and the release of epinephrine and norepinephrine. Blood vessels constrict and the heart rate increases. Though overt clinical manifestations are not apparent in the initial stage, changes are taking place at the cellular level as cell metabolism converts from aerobic metabolism to anaerobic metabolism, producing an increase in lactic acid.

More subtle changes may also be detected in this stage. Decreased perfusion to the brain can result in agitation, and decreased flow to the kidneys can result in a slight decrease in urinary output. Blood pressure is usually normal or slightly elevated due to stimulation of the sympathetic nervous system.

Vital signs in the initial stage of shock include:

- normal to slightly elevated blood pressure
- normal to slightly elevated heart rate
- normal respiratory rate
- normal temperature

Compensatory Stage

If adequate cell perfusion is not restored, shock progresses to the **compensatory stage**. In this stage, there is a noticeable drop in blood pressure; the body responds by stimulating baroreceptors of the carotid and aortic bodies (Figure 23.2). These baroreceptors respond to changes in pressure or stretch in blood vessels within the aortic arch and carotid sinus. Decreased blood pressure causes decreased signal output from the baroreceptors, leading to disinhibition of the central sympathetic control sites and decreased parasympathetic activity with the final effect of an increase in blood pressure.

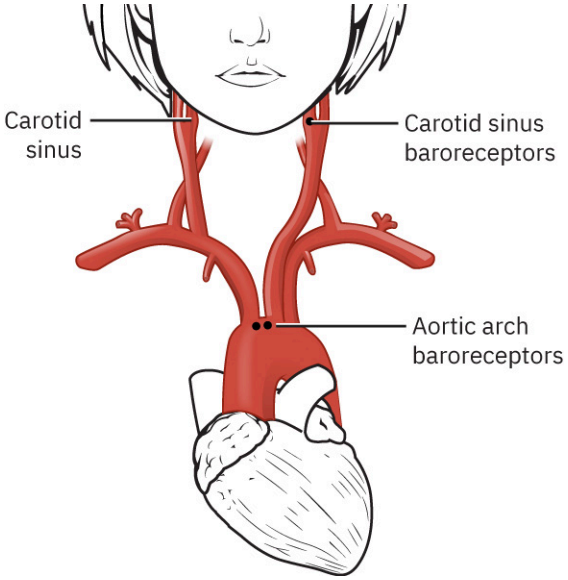

FIGURE 23.2 Carotid sinus baroreceptors and aortic arch baroreceptors respond to low blood pressure by decreasing parasympathetic activity, which increases vascular tone, heart rate, and blood pressure. (credit: modification of work from *Anatomy and Physiology 2e*. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

In the compensatory stage, norepinephrine and epinephrine are released in response to low blood pressure, resulting in constriction of blood vessels, increased heart rate, and increased cardiac output. Serum glucose elevates in the stress response. Blood flow is diverted to the vital organs—particularly the brain and heart—to preserve life. As a result, other body systems receive even less perfusion. The kidneys respond to decreased blood flow by releasing renin and activating the **renin-angiotensin-aldosterone system (RAAS)**, a critical regulator of blood volume, electrolyte balance, and blood vessel tone. As part of this system, the liver releases angiotensin and the lungs release angiotensin-converting enzyme (ACE). Renin and angiotensin combine to form angiotensin I, which combines with ACE to form angiotensin II. Angiotensin II then stimulates the adrenal gland to secrete aldosterone, which causes constriction of blood vessels and resorption of water and sodium in the kidney. The overall effect of RAAS is constriction of blood vessels and retention of fluid, increasing blood pressure.

LINK TO LEARNING

Review this web page for more information on the RAAS response (https://openstax.org/r/77RAAS) during the compensatory stage of shock.

During the compensatory stage, all body systems experience hypoxia, which initiates further disruption to each body system. Inadequate perfusion to the lungs causes disruption to the endothelial lining of the alveolar capillary membrane, increasing permeability. The result is fluid accumulation in the alveoli, leading to the development of pulmonary edema, respiratory failure, and possibly acute respiratory distress syndrome (ARDS), as shown in Figure 23.3.

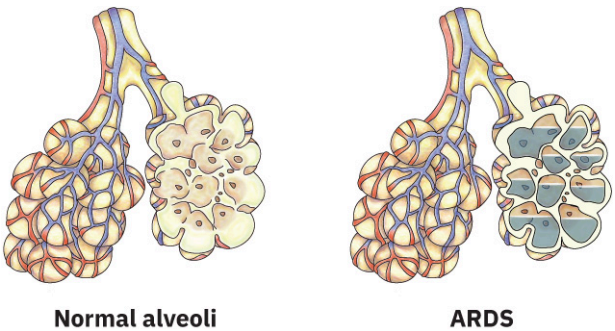

FIGURE 23.3 Shock can cause the development of acute respiratory distress syndrome (ARDS), as alveoli in the lungs fill with fluid. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Vital signs in the compensatory stage of shock include:

- low blood pressure
- high heart rate
- normal to slightly elevated respiratory rate
- normal temperature
- cool skin
- decreased urine output

If the cause of shock is identified and appropriate interventions are implemented, the situation is reversible with no permanent damage to cells and tissues. If the cause of shock is not corrected, the next stage of shock begins.

Progressive Stage

In the **progressive stage** of shock, profoundly decreased cellular perfusion results in a significant increase of capillary permeability, causing protein and fluid to leak out of the vascular system into the interstitial space. This massive shift of fluid further disrupts cell perfusion. To fully understand this process, it is helpful to review the three spaces where fluid exists in the body (Figure 23.4):

- The intracellular space consists of fluid in the cells.
- The intravascular space consists of fluid within the blood vessels.
- The interstitial space consists of fluid in the space between tissues.

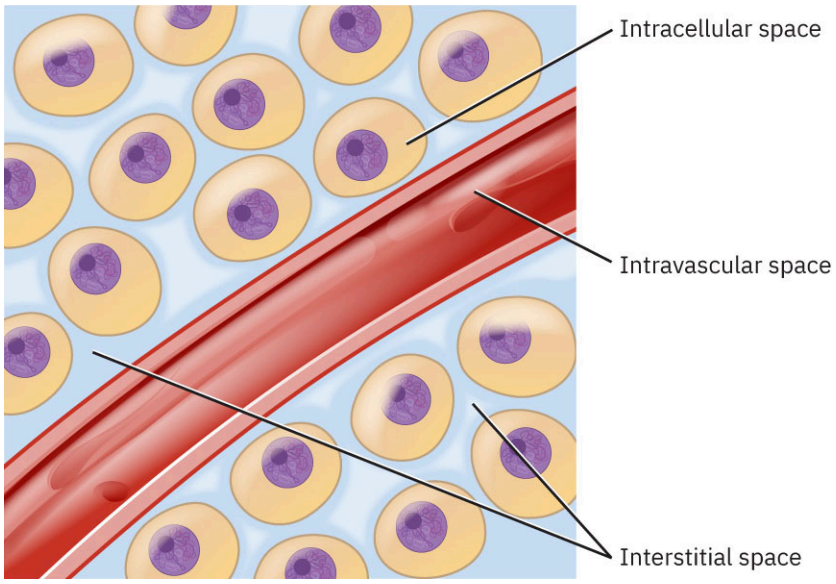

FIGURE 23.4 Fluids exist in three distinct spaces in the body. (credit: modification of work from *Anatomy and Physiology* 2e. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

A balance in these three spaces is needed for homeostasis. Loss of fluid or an overabundance of fluid in any of these spaces impairs cell function. In the progressive stage of shock, substantial capillary permeability results in dramatic shifts in fluid from the vascular space into the interstitial space, causing hypotension and electrolyte imbalance that further impair cell perfusion. All systems experience cellular hypoxia, resulting in the development of metabolic acidosis. The patient experiences pallor and cool clammy skin, as well as altered levels of consciousness because of poor perfusion to the brain. The hypoxic heart may develop irregular tachydysrhythmias, myocardial ischemia, or myocardial infarction. Complete deterioration of the cardiovascular system is possible. Additionally, the significant increase of capillary permeability results in fluid movement from the capillaries of the lung into the alveolar space, causing impaired diffusion of oxygen and carbon dioxide as well as pulmonary edema, bronchoconstriction, decreased lung capacity, tachypnea, increased crackles, increased work of breathing, respiratory acidosis, and ARDS.

Insufficient perfusion to the gastrointestinal system can result in disruption of the protective barrier of the stomach, resulting in ulceration, possible mitigation of bacteria from the gastrointestinal track, and inadequate absorption of nutrients. The renal system undergoes changes due to cellular hypoxia and further deteriorates if treatment

includes the use of nephrotoxic drugs. Urine output decreases to a rate of less than 30 mL/hour, and blood urea nitrogen (BUN) and creatinine (Cr) increase. Metabolic acidosis develops due to the buildup of waste products. Hypoperfusion of the liver results in the development of jaundice, elevated liver markers, decreased immune function, and impaired homeostasis. However, if treatment is initiated in a timely manner and the body responds, there is still a chance of recovery.

Changes by body system or organ in the progressive stage of shock are summarized in Table 23.2.

Body System	Effect
Heart	Irregular tachydysrhythmias Myocardial ischemia Myocardial infarction
Neurologic	Change in level of consciousness
Lungs	Increased alveolar capillary membrane permeability Fluid in alveolar space Impaired oxygen and carbon dioxide diffusion Respiratory acidosis Pulmonary edema Bronchoconstriction/decreased lung capacity Tachypnea Increased crackles Increased work of breathing ARDS
Gastrointestinal system	Gastric ulceration Mitigation of gastric bacteria Inadequate absorption of nutrients
Renal system	Urine output below 30mL/hour Increased BUN Increased creatinine Metabolic acidosis
Hepatic	Jaundice Elevated liver markers: ALP (alkaline phosphatase), ALT (alanine transaminase), AST (aspirate aminotransferase), GGT (gamma-glutamyl transferase) Decreased immune function Impaired homeostasis
Electrolytes	Imbalanced electrolytes
Vascular system	Significant third spacing and peripheral edema Significant vasodilation Hypotension
Skin	Pallor Cool, clammy

TABLE 23.2 Changes in Progressive Stage of Shock by Organ or Body System

Vital signs in the progressive stage of shock include:

- increased heart rate
- decreased blood pressure
- increased respiratory rate
- hypothermia
- cool skin and weak distal pulses
- decreased urine output

Refractory Stage

The **refractory stage** of shock is characterized by extreme dysfunction of cellular processes in multiple body systems. The significant increase in capillary permeability, anaerobic metabolism, lactic acid buildup, metabolic acidosis, tachycardia, and profound hypotension continues despite treatment. Cells, tissues, and organ systems shut down because of irreversible cell and organ damage, and recovery is unlikely.

Vital signs in the refractory stage of shock include mottled skin, characterized by a bluish-red lace pattern under the skin, caused by the pooling of deoxygenated blood. Other manifestations include:

- continued low blood pressure despite treatment
- increased tachycardia
- increased respiratory rate
- low to no urine output
- cool skin
- weak to absent peripheral pulses
- low temperature

Table 23.3 summarizes vital sign changes in each stage of shock.

Stage	Initial	Compensatory	Progressive	Refractory
Blood pressure	Normal	Low	Low	Low despite treatment
Heart rate	Normal	Elevated	Elevated	Elevated
Respiratory rate	Normal	Elevated	Elevated	Elevated
Urinary output	Normal	Low	Low	Low to zero
Temperature	Normal	Normal	Low	Low
Skin	Normal	Cool	Cool	Cool
Distal pulses	Normal	Normal	Weak	Weak to absent

TABLE 23.3 Clinical Manifestations of Shock Stages

Multiorgan Failure

Multiorgan dysfunction syndrome (MODS), or **multiorgan failure (MOF)**, results from prolonged cellular hypoperfusion. Figure 23.5 illustrates the organ systems that may be affected. It is most often a result of hypovolemic and septic shock. The prognosis for MOF/MODS is dependent upon the number of organs affected and the body's response to treatment. Older patients and patients with multiple comorbidities are at a higher risk for MOF/MODS.

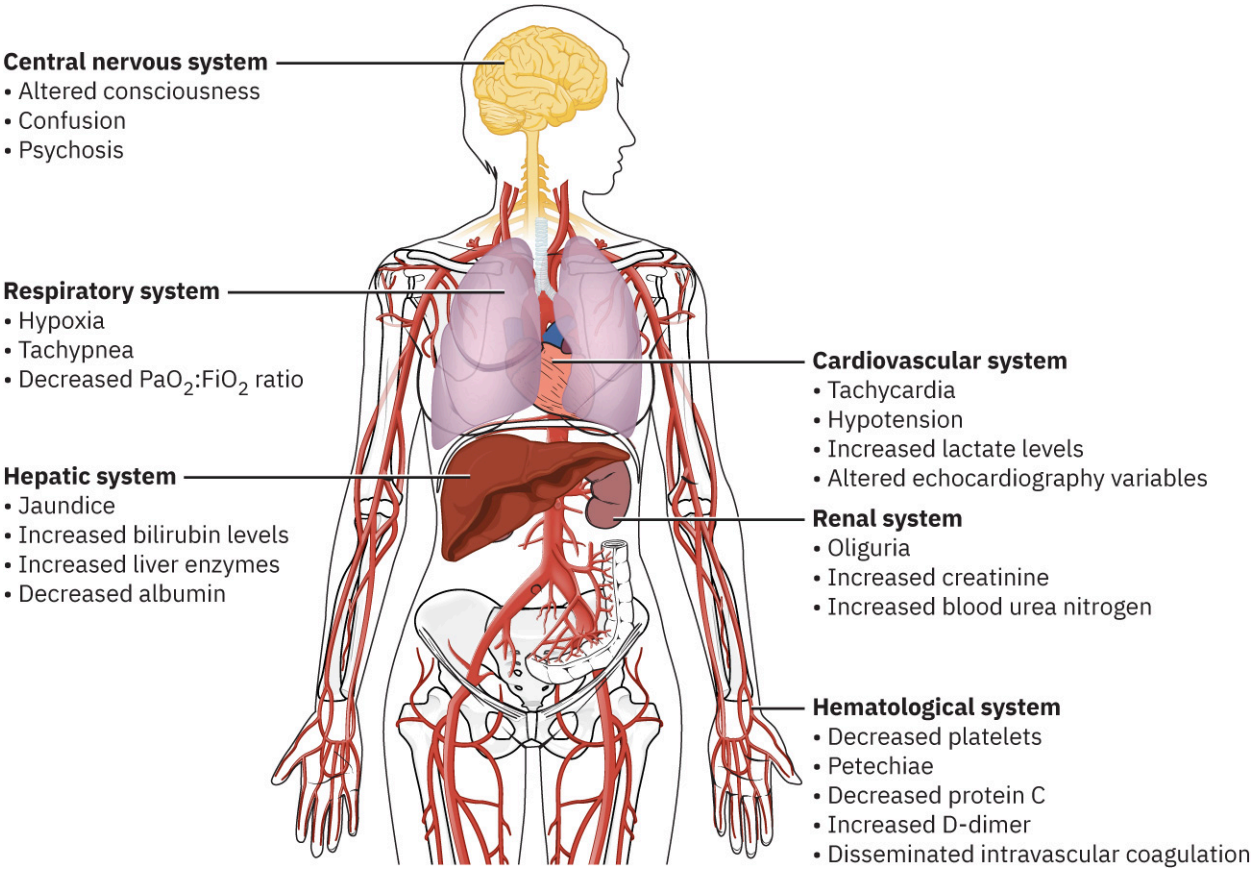

FIGURE 23.5 Multiorgan failure can manifest in many body systems. (credit: modification of work from *Anatomy and Physiology 2e*. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

A normal inflammatory response to decrease cell perfusion and cellular injury facilitates healing. Part of the normal inflammatory response includes the release of cytokines, which are protein substances that regulate the inflammatory response. MOF and MODS results when the inflammatory response extends beyond the area of injury throughout the body for a prolonged period of time. The development of MOF/MODS in sepsis has been linked to the release of cytokines. This causes an exaggerated inflammatory response throughout the body, leading to a cascade of events that can ultimately result in cell hypoxia, cell death, and organ failure.

LINK TO LEARNING

This video describes the types of shock (https://openstax.org/r/77shock) as an NCLEX review.

23.2 Hypovolemic Shock

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations of hypovolemic shock
- Describe the diagnostics and laboratory values for hypovolemic shock
- Apply nursing concepts and plan associated nursing care for patients with hypovolemic shock
- Evaluate the efficacy of nursing care for patients with hypovolemic shock
- Describe the medical therapies that apply to the care of patients with hypovolemic shock

The potentially life-threatening condition of hypovolemic shock results from a critical loss of volume in the intravascular space, which increases metabolic demand on the body. If the cause of volume loss is identified and appropriate treatment is initiated early, there is a chance of complete recovery (Taghavi, 2023). This module will review the specific pathophysiological causes of hypovolemic shock.

Pathophysiology of Hypovolemic Shock

There are two types of hypovolemic shock: absolute hypovolemia and relative hypovolemia. Commonly referred to as massive real fluid loss from the body, **absolute hypovolemia** is loss of blood that is visible. It is associated with:

- external hemorrhage
- internal hemorrhage
- gastrointestinal fluid loss from uncontrolled vomiting or diarrhea
- drainage from a fistula, an abnormal or surgically created passage between a hollow or tubular organ and the body surface
- hormonal abnormality not related to diabetes mellitus, such as diabetes insipidus, a pathologic process in which the body produces ineffective antidiuretic hormone, causing massive urinary output
- hyperglycemic induced diuresis
- diuresis

Commonly referred to as internal bleeding or third spacing of fluids rather than true loss of body fluids, **relative hypovolemia** is a volume adjustment within the body from the vascular space to the interstitial space, often called the third space. These episodes may be slow and incidental, but they can progress to hemorrhage depending on the mechanism of bleeding. Relative hypovolemia is associated with:

- bowel obstruction
- burn injury
- ascites, a condition in which fluid collects in the abdomen (Figure 23.6)
- long bone fracture
- ruptured spleen
- hemothorax, the accumulation of blood within the pleural space
- severe pancreatitis
- sepsis

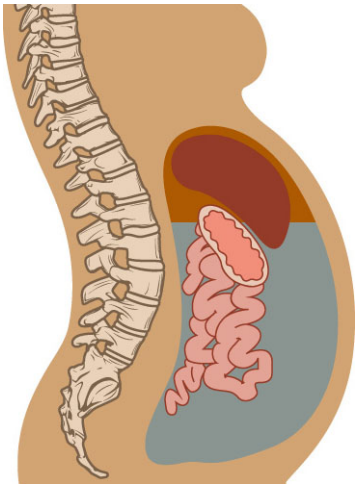

FIGURE 23.6 Ascites is a condition in which the abdominal cavity fills with fluid that shifts from the intravascular to the interstitial space, resulting in hypovolemia (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

In hypovolemic shock, lack of sufficient vascular volume causes decreased cell perfusion and hypoxia. To compensate, the sympathetic nervous system is activated to provide more blood flow to cells. Heart rate and contractility increase, as does the systemic tone of blood vessels. Blood pressure is normal to slightly elevated in the early phase of hypovolemic shock. When the body can no longer compensate, however, the patient develops hypotension and tachycardia with decrease of urinary output. The kidneys respond to decreased perfusion by retaining fluid to increase vascular volume.

The body is unable to maintain homeostasis in hypovolemic shock. In this state, the selective permeability of the cell membrane—key to maintaining optimal conditions for enzyme action and cell function, including aerobic metabolism—is lost due to hypoperfusion. Cellular metabolism converts to anaerobic metabolism because sufficient oxygen is not available at the cellular level. As a result, there is a buildup of lactic acid. In homeostasis, the liver is

able to maintain normal lactic acid levels of less than 2 mmol/L. A combination of anaerobic metabolism causing increased lactic acid and a hypoperfused liver unable to clear the substance from the body can lead to lactic acidosis.

Continued hypoperfusion of cells leads to the movement of blood to vital organs of the body, particularly the brain and heart. Other organ systems experience even greater hypoperfusion because of this. As the hypovolemic shock state progresses, acidosis does not respond to treatment, cardiac output is further decreased, cell perfusion further deteriorates, and a hypoxic state exists throughout the body. Cells and tissues die, and multiple organ failure develops. Risk factors for hypovolemic shock include recent surgery, major blood loss, open wounds, draining fistulas, diuretic use, hyperglycemia, hyperthermia, and uncontrolled vomiting or diarrhea.

Clinical Manifestations

Clinical manifestations of hypovolemic shock depend on the severity of the hypovolemia. One of the earliest manifestations is a change in mental status, most commonly anxiety caused by decreased perfusion to brain cells. Other classic manifestations of hypovolemic shock include increased heart rate, decreased blood pressure, increased respiratory rate, decreased urinary output, and cool clammy skin.

Patients experience tachycardia as their heart attempts to compensate and provide more blood flow to cells. Hypotension is the result of low vascular volume. Respiratory rate and depth increase to provide more oxygen to cells and rid the body of carbon dioxide as the cellular metabolism switches from aerobic to anaerobic. The kidneys respond to low vascular volume by retaining fluid, causing urine output to drop. The skin is cool due to the diversion of blood to the vital organs.

Assessments and Diagnostics

Symptoms of hypovolemic shock vary in severity based on the fluid volume lost. While some symptoms are sudden, others are progressive and can lead to cell death and organ destruction. Early identification and prompt treatment of hypovolemic shock can be accomplished through thorough, timely, and accurate nursing assessments.

An initial patient assessment of mental status followed by vital signs will provide the nurse with direction as to whether a more focused assessment of body systems is needed. Patients with hypovolemic shock are often confused or agitated because of the lack of blood flow to the brain. Vital signs often include decreased blood pressure, tachycardia, and tachypnea when compared with their baseline status. Orthostatic hypotension may also be present. This condition is characterized by a drop of at least 20 mmHg in systolic blood pressure and 10 mmHg in diastolic pressure within three minutes of standing up from a sitting or lying position. Patient safety is a priority when assessing orthostatic hypotension. The nurse should assist the patient in position changes, encourage the patient to gently rise to a standing position from a supine or sitting position, and encourage the patient to dangle on the side of the bed before standing.

Physical assessment may reveal classic manifestations of dehydration, including dry mucous membranes and a decrease in skin turgor. The patient may also complain of thirst and headaches. Peripheral pulses may be weak or absent and capillary refill time may be extended due to low vascular volume. It is also important to assess urine output because it is a good indicator of perfusion to the kidney. A rate of 30 mL of urine per hour is reflective of adequate kidney perfusion. The nurse should closely monitor output trending down. Lower urinary output values should be communicated to the health-care team, as adjustments to the plan of care may be necessary.

Table 23.4 reviews manifestations of early and advanced hypovolemic shock.

Type of Symptom	Early Hypovolemic Shock	Advanced Hypovolemic Shock
Blood pressure	Slightly low to normal or slightly elevated	Low blood pressure
Heart rate	Normal to slightly high	High heart rate
Respiratory rate	Normal to slightly high	High respiratory rate

TABLE 23.4 Manifestations of Hypovolemic Shock

Type of Symptom	Early Hypovolemic Shock	Advanced Hypovolemic Shock
Urine output	Normal to slightly low	Low (less than or equal to 30 mL/hour)
ABG	Normal with possible lower oxygen level	Evidence of hypoxia and metabolic acidosis
Capillary refill time	Normal to slightly long	Prolonged capillary refill time

TABLE 23.4 Manifestations of Hypovolemic Shock

Diagnostics and Laboratory Values

There is not one specific diagnostic or laboratory test to determine the presence of hypovolemic shock; however, low blood pressure is the best indicator, followed by low urinary output. A panel of blood work is drawn to serve as a baseline from which to plan appropriate care and evaluate the effectiveness of treatment. Additional diagnostic testing may include radiologic imaging, endoscopy, or exploratory surgery to identify and stop the source of volume loss.

Analysis of the complete blood count (CBC) in hemorrhagic shock may indicate low red blood cell (RBC) counts with a drop in hematocrit and hemoglobin. These values may also be low due to the dilutional effect of high-volume fluid resuscitation used to treat hypovolemic shock.

Impaired perfusion to the kidney results in an increase in the markers of renal function such as blood urea nitrogen (BUN) and creatinine (Cr). Creatinine is considered the more accurate indicator of kidney function, as BUN may be affected by muscle damage from trauma or surgery.

Activation of the sympathetic nervous system causes an increase in serum glucose. Poor perfusion to the liver may cause an increase in liver markers SGPT (serum glutamic-pyruvic transaminase) and SGOT (serum glutamic-oxaloacetic transaminase), also known as ALT (alanine transaminase) and ALP (alkaline phosphatase). Fluctuation of sodium levels occurs as the body is rehydrated. Potassium levels may increase as the nutrient is released from damaged cells. Lab findings may include lactic acidosis or metabolic acidosis due to the accumulation of waste products.

Table 23.5 reviews key findings of hypovolemic shock.

Test	Findings in Hypovolemic Shock	Rationale
Red blood cells (RBC)	High RBC hemoconcentration Low RBC hemodilution	Hemoconcentration due to loss of plasma Hemodilution due to fluid resuscitation
Hematocrit (Hct)	High hemoconcentration dehydration Low volume overload hemodilution	Hemoconcentration due to loss of plasma Hemodilution due to fluid resuscitation
Hemoglobin (Hgb)	High hemoconcentration dehydration Low volume overload hemodilution	Hemoconcentration due to loss of plasma Hemodilution due to fluid resuscitation
Blood urea nitrogen (BUN)	High	Hypoperfusion to kidney

TABLE 23.5 Findings of Hypovolemic Shock

Test	Findings in Hypovolemic Shock	Rationale
Creatinine (Cr)	High	Hypoperfusion to kidney
Liver markers	High	Damage to liver cells from hypoperfusion
Serum glucose	High	Stress response
Urine specific gravity	High urine specific gravity Low urine specific gravity	Dehydration from loss of fluids Fluid resuscitation
Sodium (Na) fluctuation	High Low	Fluctuations based on fluid status
Potassium (K)	High	As cell damage occurs, potassium migrates from inside to outside of the cell
Lactate	High	Anaerobic metabolism
Acid base status	High acidic	Accumulation of metabolic waste products

TABLE 23.5 Findings of Hypovolemic Shock

Nursing Care of the Patient with Hypovolemic Shock

Nursing care for patients with hypovolemic shock focuses on identifying the source of vascular fluid loss, stopping the fluid loss, restoring volume, and supporting all body systems as needed. If an overt hemorrhage is present, priorities of care include stopping the bleeding, which may be achieved by applying direct pressure or cold applications or elevating the site, as appropriate. In severe cases, patients may require cold saline flushed into indwelling tubes—for example, patients with presumed gastrointestinal bleeding may need a nasogastric tube. The patient may also require surgery to stop the loss of volume. Preoperative nursing interventions include providing information and emotional support for the patient and their family, ensuring that all preoperative data have been accumulated, and maintaining the patient's baseline hemodynamic status. The nurse may also need to adjust medications, schedule diagnostic tests, and complete a clinical handover and transfer of professional responsibility and accountability.

Other top nursing priorities include inserting and maintaining intravenous access devices to supply potential blood and blood products or other fluids. The type and extent of volume loss dictate the quantity and type of volume required. For example, if a patient is bleeding due to toxic effects of blood thinners, patients may require platelets or fresh frozen plasma for volume support. Some patients require the use of hemodynamic monitoring to evaluate the effectiveness of therapy.

Restoration of vascular volume is achieved by administering intravenous fluid—such as 0.9 percent normal saline or other isotonic solutions—at a rapid and high rate. This process is commonly referred to as **volume resuscitation**. These patients require frequent nursing assessments because they may not be able to tolerate rapidly administered, high-volume fluids. For example, a patient may have an underlying cardiac or renal disease that could worsen in response to fluid resuscitation. Volume resuscitation can increase the likelihood of these patients not being able to tolerate the increase of fluids, resulting in pulmonary edema. The nurse should make the provider aware of any change of respiratory status, including breath sounds to prevent the development or worsening of pulmonary edema. Hemodynamic monitoring is often needed to manage fluid resuscitation efforts.

The type and amount of solution used for volume resuscitation generally depend on the patient's fluid and electrolyte status, acid-base status, and organ function (Urden et al., 2022). Crystalloids and colloids are often used for volume replacement (Table 23.6). Crystalloids contain nonprotein substances, such as minerals, salts, and sugars, while colloids contain large molecules of proteins or starches, which help restore osmotic pressure and fluid

volume. Blood products are used when shock is caused by blood loss (Urden et al., 2022).

Intravenous Fluid	Crystalloids	Colloids
Contents	Nonproteins, minerals, salts, sugars	Large molecules or proteins or starches
Use	Maintenance of adequate fluid and electrolyte balance	Used as plasma substitutes for short-term replacement of fluid volume while the cause of the problem is being addressed
Example	Normal saline (0.9%) is a replacement solution used to increase plasma volume; it can be infused with any blood product. Ringer's lactate is a balanced salt solution containing sodium, chloride, calcium, potassium, and lactate.	Human-made (starches, dextran, or gelatins) or naturally occurring (albumin or fresh frozen plasma [FFP]) Bigger molecules stay in the blood longer before passing to other parts of the body.

TABLE 23.6 Crystalloids and Colloids

LINK TO LEARNING

Refer to this website for a review of crystalloids and colloids (https://openstax.org/r/77crystalcoll) to help nurses understand fluids and their use.

Patients experiencing hemorrhagic shock may require the administration of multiple units of blood. Nursing care should focus on safety practices for blood administration and assessment for potential complications, as the administration of multiple units of blood may cause the patient to experience several potentially dangerous conditions:

- The administration of cold or room-temperature blood can cause the core body temperature to drop, resulting in hypothermia. Blood-warming baths, warm saline, or radiant and microwave warmers are used at some institutions to warm blood and prevent hypothermia.
- Patients receiving blood transfusions are also at risk for **dilutional coagulopathy** if they do not receive sufficient clotting factors in the blood products they receive. It is important for the nurse to monitor the patient for bleeding and follow all appropriate precautions. It may be necessary to administer platelets or fresh frozen plasma.
- Citrate toxicity is another potential complication of blood transfusions. Citrate is used to keep banked blood from clotting. (Banked blood refers to units of blood products donated and available for a recipient in need.) It prevents the initiation of clotting cascade by binding to calcium. When the citrate in the transfused blood binds to calcium in the patient's system, **citrate toxicity** results. The result is hypocalcemia and hypomagnesemia. Manifestations include hypotension, arrhythmias, nervous system excitability, laryngospasm, and tetany.
- Finally, hemolysis is the destruction of red blood cells. It results from interactions of antibodies on the recipient's plasma with antigens on the donor's red blood cells. Manifestations include fever, flank pain, and red or brown urine.

Table 23.7 reviews nursing care practices for patients experiencing hypovolemic shock.

Steps for Nursing Care	Nursing Care Practices	Rationale
Assessment for hypovolemia	Trending of vital signs Dehydration assessment Hourly urine output Assessment orthostatic hypotension	Prevention of hypovolemic shock is the best treatment.
Identify source	Absolute hypovolemia Relative hypovolemia	Identifying and stopping the source of fluid loss can prevent the progression of hypovolemic shock.
Stop source	Prepare for surgery Prepare for procedures to correct intravascular volume loss	Identifying and stopping the source of fluid loss can prevent the progression of hypovolemic shock.
Intravenous access	Secure and maintain vascular access	Volume resuscitation and administration of blood and blood products can prevent the progression of hypovolemic shock.
Volume resuscitation	Frequent, accurate assessments to evaluate the patient's response to rapid high-volume, high-rate volume replacement	Complications of volume resuscitation may be prevented.
Blood transfusion and blood product administration	Follow all policies and procedures for blood and blood product infusion	Prevention of complications is key to patient recovery.
Hemodynamics	Accurate management of hemodynamic monitoring systems and accurate reporting of findings guide and evaluate the patient's response to care	Prevention of complications and evaluation of treatments are keys to decreasing morbidity and mortality.

TABLE 23.7 Nursing Care for Hypovolemic Shock

Recognizing Cues and Analyzing Cues

The nurse can recognize cues of hypovolemic shock through assessment and trending of vital signs. When determining the state of a patient's homeostasis, a series of vital signs is more representative than any one set. By recording accurate and frequent vital signs, the nurse may recognize a concerning trend. The nurse should report such a trend to the provider to prevent the full development of hypovolemic shock.

Vital signs associated with the development of hypovolemic shock include marked tachycardia over 100 beats per minute, decreased systolic blood pressure, narrowed pulse pressure, immeasurable diastolic pressure, marked decrease or no urinary output, depressed mental status, cold pale skin, cool clammy skin, delayed capillary refill time, anxiety, pallor, and increased respiratory rate. Furthermore, a change in mental status is often present. These changes—along with a history or evidence of volume loss, either absolute or relative—should cue the nurse to the potential diagnosis of hypovolemic shock.

In the early phases of hypovolemic shock, patients may complain of thirst or muscle cramps. As the condition progresses, so does the lack of perfusion to cells, causing hypoxia to cells with the conversion of aerobic to anaerobic metabolism and a buildup of waste products. All body systems may experience a decrease in perfusion during hypovolemia. The patient may experience chest pain, abdominal pain, ileus, change of mental status, dry mucous membranes, or decreased skin turgor.

Accurate and timely assessments are required to prevent long-term complications of hypovolemic shock—especially for patients experiencing excessive or prolonged diarrhea, severe burns, protracted or excessive vomiting, excessive sweating, bleeding from cuts or wounds, bleeding from traumatic accidents, internal bleeding from abdominal organs, or ectopic pregnancy. At-risk patients require frequent and accurate assessments for detection and initiation of treatment to be most effective.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Nursing care for hypovolemic shock requires a multisystem approach with input from a variety of health-care team members. The extent of volume loss can guide the level of care needed by the patient. All body systems must be supported, and any complications must be prevented. The patient and family need to be included in the development of the treatment plan, with appropriate education and emotional support provided by the nurse.

The goals of therapy include restoring intravascular circulating blood volume, preserving hemodynamic function, effecting the redistribution of circulating volume, addressing the underlying cause of fluid loss, and reversing the progression of inadequate tissue perfusion. These efforts are aimed at preventing organ damage. Priorities of care include the insertion of intravenous access devices, including central lines to restore circulating blood volume via volume resuscitation. Hemodynamic monitoring is often required to determine and evaluate the effectiveness of treatment. For the patient receiving volume resuscitation, frequent assessments should be completed in a timely and accurate manner. Any change in the patient's baseline status in general, with particular attention to the respiratory status, needs to be communicated to the provider to prevent complications of high-rate, high-volume resuscitation.

CLINICAL SAFETY AND PROCEDURES (QSEN)

Volume Resuscitation for the Patient with Hypovolemic Shock

The delivery of volume replacement for the patient with hypovolemic shock will depend on the trigger of volume loss. If volume loss is from increased elimination from diarrhea, sweat, vomiting, or high amounts of urine, the nurse will anticipate hanging crystalloid solution of 0.9 percent isotonic normal saline or lactated Ringer's solution. Hemodynamic monitoring with serial pulses, oxygen saturation, and blood pressures will gauge the patient's response to treatment. If the patient's fluid losses are from bleeding, other products such as packed red blood cells or plasma products may be considered.

Some patients may require surgery to preserve hemodynamic function. The nurse should complete all preoperative nursing interventions, including maintaining nothing-by-mouth status (NPO), ensuring completion of informed consent, determining blood type, and performing a type and cross match, as well as providing patient and family education and emotional support.

The nurse may assist with improving blood pressure by positioning the patient to increase venous return to the heart, thereby supplementing cardiac output. The preferred patient position is lying flat with the legs elevated about 12 inches. Unlike the Trendelenburg position, this position will not impair the patient's breathing ability. Some institutions recommend passive leg raises to improve the flow of blood back to the heart.

All organ systems should be supported to prevent damage. Mean arterial pressure (MAP) is often used to determine the effectiveness of organ perfusion; an acceptable minimum value is 65 mmHg or above for patients who have an arterial line. MAP levels must maintain a minimum of 65 mmHg for cells to receive the oxygen and nutrients needed to metabolize energy in amounts sufficient to sustain life Additionally, the patient should be kept warm, as a cold patient has a greater chance of developing acidosis.

Evaluation of Nursing Care for the Patient with Hypovolemic Shock

After treatment is initiated, it is important for the nurse to evaluate the patient's response to therapy and make appropriate modifications. The goal of treatment is for the patient to return to their baseline status.

An assessment of hemodynamics will be necessary to determine whether the patient has adequate cardiac output. If invasive hemodynamic measurement of cardiac output is not available, the following signs also indicate adequate cardiac output and normovolemia: a urine output of at least 30 mL/hour, the presence of peripheral pulses, systolic

blood pressure of 20 mmHg from baseline, a heart rate between 60 to 100 beats per minute, and a normal level of consciousness. Furthermore, decreased anxiety level is an important indicator of perfusion to the brain.

Medical Therapies and Related Care

The health-care team must work together in an organized manner to respond to the emergency of hypovolemic shock. The goals of treatment include identifying the source of volume loss, stopping the source of volume loss, and restoring appropriate volume. Standard treatment for volume replacement includes the insertion of large, 14- to 16-gauge intravenous catheters or the insertion of a central line for fluid administration. Fluids, blood, and blood products are administered based on the individual needs of the patient.

Identification and correction of the cause of intravascular volume loss is the first step in reversing hypovolemic shock. Some patients require the administration of medications to maintain hemodynamic stability. Medications that increase blood pressure are used to support patients in hypovolemic shock; these include epinephrine, norepinephrine, dopamine, and dobutamine. Epinephrine is the strongest vasoconstrictor of all vasopressors as it increases blood pressure, heart rate, and cardiac output. Norepinephrine increases arterial blood pressure through vasoconstriction and has little effect on heart rate. Dopamine and dobutamine are inotropes used to increase cardiac contractility.

23.3 Septic Shock

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations for septic shock
- Describe the diagnostics and laboratory values for septic shock
- Apply nursing concepts and plan associated nursing care for patients with septic shock
- Evaluate the efficacy of nursing care for patients with septic shock
- Describe the medical therapies that apply to the care of patients with septic shock

The serious medical condition that results from an overreaction of the body to the presence of harmful microorganisms in the blood or other body tissues is called **sepsis**. According to the Centers for Disease Control and Prevention (CDC, 2024), at least 1.7 million adults in the United States develop sepsis each year, and nearly 270,000 die as a result. The number of annual sepsis cases in the United States has been increasing over the past several years. There are several likely factors contributing to this rise, including the increased awareness and tracking of cases and the rise of antibiotic-resistant bacteria. Additionally, people with chronic diseases are living longer and consequently are at higher risk of developing sepsis; organ transplants are also more common, and recipients are at higher risk for developing sepsis because of their suppressed immune system (CDC, 2024).

Rapid diagnosis and early treatment of sepsis are necessary to prevent cellular hypoxia, multi-organ failure, and death. For each hour that treatment is delayed, there is a 4 to 9 percent increase in mortality (Flanagan et al., 2020).

Pathophysiology of Septic Shock and Clinical Manifestations

Sepsis is a syndrome or set of symptoms or conditions caused by an overexaggerated inflammatory response to infection throughout the body. A normal inflammatory response includes the release of histamine, bradykinin, and prostaglandins at the site of the infection. These substances increase vasodilation and capillary permeability, causing vascular fluid to migrate to the interstitial space in efforts to deliver the formed elements of blood to the infected area and promote the restoration of homeostasis.

Sepsis is most associated with bacterial infections, usually gram-negative bacteria in nature, and is one of the most severe diseases for hospitalized patients (Virzì et al., 2022). Endotoxin is the major motivator of the inflammatory process. Endotoxins are the main component of the outer membrane of gram-negative bacteria. However, sepsis can also result from viral or fungal infections. In sepsis, the infecting organism or virus secretes endotoxins that significantly increase capillary permeability and elicit an exaggerated inflammatory response throughout the body. As a result, fluids shift from the intravascular and intercellular spaces to the interstitial space, causing profound hypotension and impaired cellular function. Lack of perfusion to cells results in the conversion of cell metabolism from aerobic to anaerobic metabolism, increasing lactate levels and causing metabolic acidosis. The overall result is profound hypotension, cell hypoxia, organ and tissue damage, and failure.

There are four stages of sepsis (CDC, 2024):

1. Systemic inflammatory response syndrome (SIRS) can occur when the body is exposed to a noxious stressor, such as infection. The aim of the response is to localize the endogenous or exogenous source of the stressor.
2. Sepsis is an overreaction of the immune system to infection.
3. In **severe sepsis**, manifestations of organ malfunction are present.
4. Finally, **septic shock** is a condition of low blood pressure despite adequate intravenous fluid administration. It causes decreased blood flow to cells, formation of blood clots in vessels, organ damage, organ failure, and, ultimately, death.

To compensate for hypotension in the first stage, the sympathetic nervous system is stimulated, causing tachycardia. This attempt to increase blood supply to the body further increases the oxygen needs of the heart and decreases cardiac output. Heart function is compromised in septic shock because endotoxins cause abnormal function of heart muscle cells and myocardial depression.

Patients with septic shock are at high risk for the development of disseminated intravascular coagulation (DIC), in which microclots develop inside blood vessels, using up the clotting factors. As a result, massive bleeding occurs throughout the body. The scattering of microclots throughout the body further decreases cell perfusion, resulting in cell hypoxia and dysfunction.

Cellular hypoperfusion stimulates the endocrine and central nervous systems to elicit a **hypermetabolic state** of accelerated metabolic activity that increases the body's energy to facilitate healing. The result is an increase in cellular demand for oxygen in an already compromised state. The overall result is maldistribution of blood volume, decreased perfusion to cells, and impaired cellular metabolism.

It is important for the nurse to identify patients with the following risk factors for the development of septic shock:

- pregnancy
- over sixty-five years of age
- substance abuse
- artificial joints
- heart valve surgery or replacement
- other surgeries
- acquired immune deficiency syndrome (AIDS)
- cancer
- diabetes mellitus (DM)
- leukemia
- immunosuppression
- chronic kidney disease (CKD)
- heart failure
- malnourishment

LIFE-STAGE CONTEXT

Older Adults and Sepsis

Sepsis disproportionately affects older adults with more than 60 percent of sepsis diagnoses attributed to adults aged sixty-five years and older (Rowe & McKoy, 2017). Older adults are at high risk for the development of septic shock because aging decreases the body's immune response. Decreased immune response can allow minor infections, such as urinary tract infections (UTIs), to quickly spread bacteria throughout the body. Additionally, many older adults have other factors, such as medical comorbidities, cognitive impairment, and functional status, which all impact outcomes. Change in mental status is often one of the first clinical manifestations of sepsis in the older adult. Therefore, any older adult who experiences a change of mental status change should be screened for sepsis.

Clinical Manifestations

Clinical manifestations vary from insidious to overt presentation based on the individual response of the body and

the stage of sepsis. Eventually, all organ systems are affected.

At the onset of septic shock, common manifestations include changes in mental status, high respiratory rate, tachycardia, and hypo- or hyperthermia. Common causes of sepsis are urinary or respiratory infections. If the source of the infection is the urinary system, the patient may complain of low energy levels or urinary retention with a continual urge to void. If the source of the infection is respiratory, the patient may complain of shortness of breath or present with a cough.

As sepsis progresses and brain cells experience decreased perfusion, the patient's mental status may progress from confusion and agitation all the way to coma. The patient may experience shortness of breath as the fluid shifts into the alveolar space, and renal hypoperfusion may cause a decrease in urinary output. Loss of vascular tone and other components of the infectious process result in variations in skin and body temperature. The patient may exhibit core temperature elevations as the infection progresses and an even greater increase in core temperature as the global inflammatory response ensues. Along with fever, the patient may experience shaking and chills. The skin may be warm and clammy or sweaty with cool, pale limbs.

The terms "warm shock" and "cold shock" are sometimes used to describe where the patient is in the progression of sepsis. In the early stages, usually within the first six to seventy-two hours of sepsis, the patient is often warm as the body responds to the inflammatory process. In this state of warm shock, cardiac output is increased, and systemic vascular resistance (SVR) is decreased.

LINK TO LEARNING

This video provides a detailed review of shock (https://openstax.org/r/77shock2) and compares cold and warm shock.

The dynamic precordium causes the patient to develop tachycardia, bounding peripheral pulses, and skin that is warm to the touch, with decreased capillary refill time. As the shock progresses, the patient deteriorates to the development of cold shock, which is a hypodynamic response of the body. At this point, cardiac output is decreased and SVR is increased. Skin may have purplish discoloration from poor perfusion to the cutaneous tissue. This change, called mottled skin, is a finding associated with septic shock. Some patients exhibit a "septic skin rash," or clusters of tiny blood spots that look like pinpricks of the skin.

Assessments and Diagnostics

Nursing assessment should begin with a general review of body systems and a thorough history. If evidence suggests the possibility of sepsis, the nurse should perform a sepsis screen.

Sepsis screens play a significant role in the treatment of sepsis, as early identification of sepsis and timely implementation of treatment have been found to decrease rates of organ failure and death. An example of a sepsis screening tool is the quick Sequential [Sepsis-related] Organ Failure Assessment (qSOFA) criteria. As shown in Figure 23.7, three criteria are assessed:

- systolic blood pressure < 100 mmHg
- altered mental status
- respiratory rate > 22 breaths/minute

Each criterion has a rating of one point. If the patient has a score of two or greater, they are suspected of having sepsis and treatment is initiated.

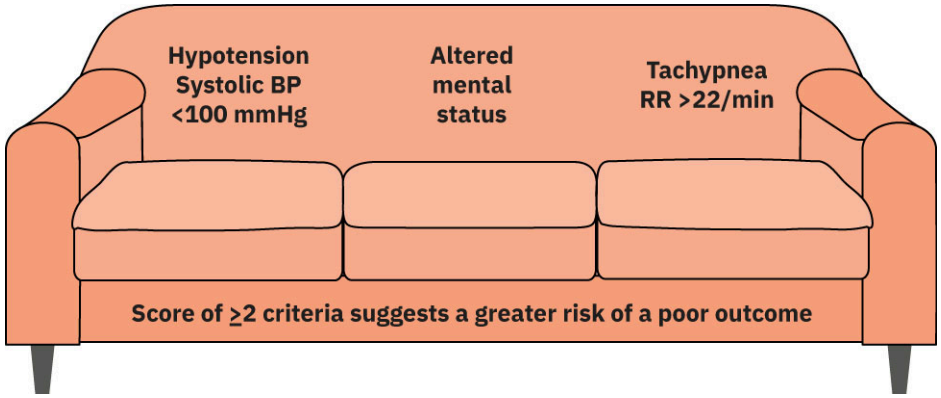

FIGURE 23.7 The qSOFA screening tool assigns one point to each of three criteria: hypotension, altered mental status, and tachypnea. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

LINK TO LEARNING

More information on rapid sepsis screening (https://openstax.org/r/77sepsisscreen) can be found on this website.

Diagnostics and Laboratory Values

A blood culture is the definitive test for sepsis. It usually takes one to three days to get the results. Consequently, some organizations incorporate the early use of a rapid sepsis screen, but the rapid results are not definitive. Most patients are treated with a broad-spectrum antibiotic if sepsis is suspected. Along with blood cultures, urine, sputum, or wound cultures are obtained to help determine the presence of infection. In some institutions, indwelling catheters such as vascular access devices and Foley catheters are removed and their tops are sent for culture and sensitivity.

Sputum culture helps providers evaluate the respiratory system. Other tools for this purpose include pulse oximetry, imaging studies of the lungs to diagnose pneumonia or other pulmonary infections, and arterial blood gas analysis to analyze the diffusion capacity of the lungs. Strep throat rapid antigen and throat culture as well as rapid influenza diagnostic tests may also be obtained.

A computerized tomography (CT) scan or magnetic resonance imaging (MRI) of the brain may be obtained if meningitis is suspected. Lumbar puncture, also called a spinal tap, may be performed to obtain cerebral spinal fluid (CSF). The provider may order a culture and sensitivity on the collected CSF to definitively diagnose meningitis.

Another test for sepsis is the presence of endotoxins. Under normal conditions, there should be no evidence of endotoxins in the blood. If gram-negative bacteria are present in the bloodstream, then endotoxins are released when the cell disintegrates. Testing for the presence of endotoxins is not a replacement for blood cultures, but it may assist in directing the immediate treatment of the patient.

Procalcitonin (PCY) levels are drawn for the patient with suspected sepsis. This substance is undetectable in patients without infection. Procalcitonin rises rapidly in response to proinflammatory stimuli, especially infection. It will not determine what type of bacteria is present, however. Another test, C-reactive protein (CRP), is sometimes obtained to assist in the diagnosis of sepsis. CRP is elevated with inflammation, which is very high in sepsis.

A complete blood count (CBC) is obtained to determine the baseline status of the patient as well as to plan and evaluate treatment. White blood cell (WBC) (leukocyte) results should be reviewed. A WBC count of 45,000 to 11,000 per microliter is considered normal. A count below 4,000 or greater than 12,000 per microliter is cause for concern. High leukocytes indicate the presence of infection, while low leukocytes indicate risk for infection.

Lactate levels are drawn to assess cellular perfusion. An elevation of lactate is indicative of cellular hypoxia. A lactate of less than 2 mmol/L is considered acceptable; however, a lactate level of greater than 4.0 mmol/L is associated with high mortality. Aggressive volume resuscitation is recommended for lactate levels of 4.0 mol/L (Lat et al., 2021).

Patients with septic shock often develop clotting abnormalities and disseminated intravascular coagulation (DIC).

Homeostasis is evaluated through analysis of prothrombin time (PT), partial thromboplastin time (PTT), and platelet count. High PT and PTT times indicate impaired clotting ability of the blood. Low platelet counts may be the result of platelet aggregation and the presence of microclots throughout the vascular system. **D-dimer** may be used as a marker of microcirculatory failure. It is the most-used fibrinogen-related marker for DIC diagnosis. Almost all patients admitted with sepsis have elevated D-dimer levels related to organ dysfunction and outcome.

Diagnostic tests for sepsis are summarized in Table 23.8.

Diagnostic Test	Normal Result	Sepsis Suspected
Blood culture	No infectious agent	Presence of infectious agent
Rapid Sepsis Screen qSOFA	Below 2	2 or higher
Endotoxin	Not present	Present
Procalcitonin	0	Greater than 2.0 µg/L
Lactate	Less than 2 mmol/L	Greater than 2 mmol/L
PT	10–13 seconds	High value
PTT	25–35 seconds	High value
Platelets	150,000 to 450,000	Low value
D-dimer	Less than 0.50	Greater than 0.50
Urinalysis	No infectious organisms	Infectious organisms detected
Sputum culture	No infectious organisms	Infectious organisms detected
Cerebral spinal fluid	No infectious organisms	Infectious organisms detected
Wound culture	No infectious organisms	Infectious organisms detected

TABLE 23.8 **Diagnostic Tests for Sepsis**

Nursing Care of the Patient with Septic Shock

Nurses should be acutely aware of subtle changes that may indicate the development of sepsis and notify the health-care team to plan and implement interventions to prevent the progression of sepsis. Due to the frequent changes in acuity, nurses must stay in regular contact with the provider once sepsis has been identified.

Recognizing Cues and Analyzing Cues

Any patient who suddenly develops hypotension, unresponsiveness, anuria, or fever is suspected of having sepsis. A sudden change in the level of consciousness is often an early manifestation of bladder infection, especially in older adults. An increase in respiratory rate is also associated with sepsis. As the body attempts to compensate for the buildup of lactic acid and metabolic acidosis, the respiratory rate increases to rid the body of carbon dioxide. As the patient decompensates, the respiratory rate will drop.

Early in the development of sepsis, blood pressure is slightly elevated from sympathetic nervous stimulation. As the shock progresses, blood pressure significantly drops. MAP is the best indicator of cell perfusion: a MAP > 65 mmHg indicates adequate blood pressure to help push life-sustaining nutrients into the cells and tissues.

When caring for patients with sepsis, nurses should also be aware of these cues:

- Hourly urine output of at least 30 mL per hour indicates adequate kidney perfusion. A drop in urine output to less than 30 mL/hour indicates poor renal perfusion.
- Lactate levels greater than 4 mmol/L indicate the need for volume resuscitation.
- Worsening manifestations of dehydration, such as decreased skin turgor and dry mucous membranes, indicate the need for fluid resuscitation.
- Assessment findings of weak to absent extremity pulses, change of skin temperature, and increased capillary refill time indicate hypoperfusion and the need for volume resuscitation.

It is imperative to recognize these cues of sepsis to prevent progression and serious complications such as respiratory failure, heart failure, kidney failure or injury, malfunction of the hematologic system, gangrene of fingers or toes, amputation of extremities, brain damage, and, ultimately, death. In the refractory stage of shock, the nurse is often present for discussions with the family to withdraw care because 30 percent of patients with severe sepsis do not survive.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Quality nursing care featuring attention to detail, close monitoring, and surveillance with prompt interventions can reduce morbidity and mortality. Any changes in the patient's status, including trends suggesting progression of the septic state, should be immediately reported for appropriate adjustment in treatment. Indications that the patient is deteriorating include an increase in respiratory rate, an elevated temperature with a quick drop, and a fast heart rate with hypotension.

Identifying and eradicating the infecting organism is essential to reversing the septic shock state. Immediate and timely administration of a first dose of broad-spectrum antibiotics is critical to the patient's prognosis. Culture and sensitivity are obtained prior to the administration of broad-spectrum antibiotics. When results are available, the antibiotic is often changed based on the identified organism. Some patients require surgical incisions and drainage of the infectious area.

When caring for the patient in sepsis, it is essential to stabilize the patient's hemodynamic status. Patients with sepsis may require massive volume resuscitation—usually between 6–10 L in the first twenty-four hours of treatment. Due to the massive input of fluid volume, an indwelling Foley catheter is often used to allow for accurate measurement of intake and output. Fluids are first administered to fill the vascular space, followed by a type of drug called a **vasopressor**, which supplies tone to the vascular system by inducing vasoconstriction and increasing blood pressure. The nurse must assess for complications of volume resuscitation such as pulmonary edema.

Patients with sepsis are at risk for developing complications to multiple organ systems; for example, poor perfusion to the lungs may cause the patient to develop ARDS. The ensuing respiratory failure may require the use of endotracheal intubation and mechanical ventilation to support the respiratory system.

There is an increase in metabolic response during the acute stage of sepsis, increasing the caloric needs of patients. Enteral nutrition may improve clinical outcomes, decrease the length of hospital stays, and reduce mortality in patients with sepsis. These feedings should be rich in protein and essential amino acids. Stress ulcer prophylaxis is also recommended.

Optimal outcomes for sepsis are influenced by regulated glycemic control. Sepsis can be associated with hyperglycemia, which can hinder the body's healing response. Hypoglycemia can also lead to a much higher mortality risk. Regulated glycemic control has been found to decrease morbidity and mortality in patients with sepsis. To stabilize and normalize serum glucose, the patient's blood glucose level should be monitored frequently and treated according to agency policy. A blood glucose level between 110 and 150 mg/dL has been associated with positive patient outcomes. Careful observation and assessment of the patient is vital, as patients with sepsis often experience variable glucose levels and insulin requirements, increasing the frequency of hypo and hyperglycemia.

Nurses should maintain urinary catheterization, calculating intake and output. Assessment of hourly urinary output is reflective of the patient's response to treatment and the status of renal perfusion. Hourly urinary output of less than 30 mL/hour should be reported to the health-care team; this reflects poor perfusion of the kidneys, which may lead to kidney failure.

Figure 23.8 illustrates equipment used to treat a patient with sepsis.

UNFOLDING CASE STUDY

COVID Complications: Part 3

Refer to COVID Complications: Part 2 for the second part of this patient's medical history.

Nursing Notes	02/23/24, 08:00 Continued low blood pressure despite treatment Increased tachycardia Increased respiratory rate Low to no urine output Cool skin Weak to absent peripheral pulses Low temperature Anuria Cold and clammy Ventricular dysrhythmias noted on monitor (increased K+ causes ventricular arrythmias) 02/23/24, 19:00 Family meeting held with the physician, nurse, and spiritual advisor. End of life was discussed with the family, including the health-care proxy. The family was in agreement to change the patient's advanced directive to a DNR and continue with comfort care. The family was offered an opportunity to seek spiritual counseling, according to their wishes.
Flow Chart	02/23/24, 08:00 BP, 74/48 HR, 120 RR, 24 Temp, 102.5 Hemodynamic values: Cardiac output, 3 L/min Mean arterial pressure, 50 mmHg Central venous pressure, 6 mmHg
Lab Results	02/23/24, 08:00 Na, 146 mEq/L K+, 5.8 mEq/L Cl, 80 mEq/L ABG: pH, 7.23 PCO_2, 60 mmHg PO_2, 65 mmHg HCO_3, 18 mEq/L BS, 180 mg/dL Lactic acid, 4.0 mmol/L
Provider's Orders	02/23/24, 11:00 Ringer's Lactate rate of 125 ml/hr Use insulin protocol for hyperglycemia Change norepinephrine to vasopressin IV drip Prothrombin time and partial thromboplastin time (PT and PTT), platelet count, and D-dimer 02/23/24, 18:00 Discuss end of life with the family.

TABLE 23.9 COVID Complications: Part 3

1. Choose the most important nursing action in caring for the septic patient.

    a. fluid replacement followed by vasopressors
    b. obtain a CXR

c. immediately insert a Swan-Ganz catheter
d. repeat ABG every hour
e. administer IV colloid fluids

2. What patient outcomes would most likely indicate the patient is in irreversible septic shock? Select all that apply.

a. anuria
b. respiratory acidosis
c. multiple organ dysfunction syndrome
d. metabolic alkalosis
e. lactic acid level of 4.5 mm/L

Evaluation of Nursing Care for the Patient with Septic Shock

Indicators of effective treatment plans for sepsis include maintenance of hemodynamic stability, treatment of the infection, and return to baseline status. The infection should show evidence of eradication based on clinical assessment and possibly repeat cultures. Some patients may need prolonged antimicrobial therapy beyond the course of their hospital stay. The patient should also demonstrate the ability to tolerate feedings and obtain adequate nutrition, leading to healthy weight gain and labs indicating nutritional adequacy.

Survivors of septic shock should be referred for counseling and provided with appropriate resources specific to their needs. Some complications of sepsis survivors include amputations and impaired lung and renal function. Other long-term effects of sepsis shock include fatigue, difficulty sleeping, decreased appetite, weakened immune system, anxiety, and depression.

LINK TO LEARNING

The Sepsis Alliance Institute (https://openstax.org/r/77SAI) has many valuable educational resources for patients with sepsis as well as their providers.

Evaluating Outcomes

Evaluation of outcomes includes determining the effectiveness of the current plan of care. Consistent monitoring of blood pressure and urinary output are key indicators of shock and recovery. Evaluation of lactate levels and electrolytes helps in determining the patient's recovery progress or continual decline. As the nurse continues to evaluate interventions, changes to the nursing care plan can be made as needed.

Medical Therapies and Related Care

Priorities of medical care for patients with sepsis include identification of the source of the infection, enhancing cell perfusion, and supporting body systems. Effective communication among health-care team members and timely implementation of protocol-based interventions for the early diagnosis and treatment of sepsis are key to patient survival. The Surviving Sepsis Campaign recommends the implementation of a one-hour bundle to obtain lactate, blood cultures, antibiotics, volume resuscitation, and possibly vasopressors within one hour of sepsis diagnosis (Lat et al., 2021).

LINK TO LEARNING

Read this article for more information about sepsis bundles (https://openstax.org/r/77sepbund) from the Indian Journal of Critical Care Medicine.

The profound hypotension seen in septic shock is the result of the massive shifting of fluid from the intravascular to the interstitial space. Fluid replacement followed by vasopressors are used to treat hypotension. After fluids are

administered, the first-line vasopressor recommended for use is norepinephrine. A target MAP of 65 mmHg is recommended. If MAP remains low to moderate with norepinephrine administration, vasopressin should be added to the treatment protocol. If blood pressure remains low, the provider will consider adding dobutamine or switching to epinephrine (Lat et al., 2021).

23.4 Neurogenic Shock

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations for neurogenic shock
- Describe the diagnostics and laboratory values for neurogenic shock
- Apply nursing concepts and plan associated nursing care for patients with neurogenic shock
- Evaluate the efficacy of nursing care for patients with neurogenic shock
- Describe the medical therapies that apply to the care of patients with neurogenic shock

The distributive type of shock that results in hypotension (low blood pressure), often with bradycardia (slowed heart rate), caused by disruption of autonomic nervous system pathways is called **neurogenic shock**. It most commonly occurs in patients who sustain a spinal cord injury (SCI) to the cervical vertebrae or the thoracic vertebrae above T7. It is found in 19.3 percent of patients with cervical spinal cord injury and 7 percent of patients who have thoracic spinal cord injury (Sager et al., 2023) (Figure 23.9). Other causes of neurogenic shock include complications from spinal anesthesia, severe head trauma, and the use of opioids and benzodiazepines.

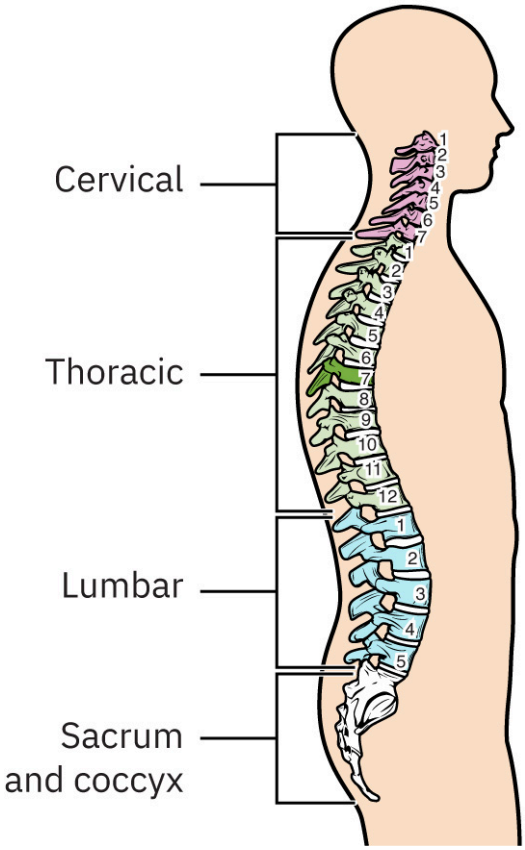

FIGURE 23.9 Injury to thoracic 7 vertebrae or above impacts the abdominal and intercostal muscles, which are essential for the expansion of the chest in the breathing process. (credit: modification of work from *Anatomy and Physiology 2e*. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Pathophysiology of Neurogenic Shock

To survive and thrive, cells and body tissues need a constant supply of oxygen and nutrients. In a state of homeostasis, the sympathetic nervous system ensures the cardiovascular system functions with adequate heart rate, cardiac output, and vascular tone to provide oxygen and nutrition to cells and body tissues. In neurogenic

shock, the sympathetic nervous system loses the ability to regulate the cardiovascular system, causing vasodilation and decreased perfusion to cells and, eventually, cellular and tissue hypoxia. Blood pressure is low because of vasodilation, not because of loss of circulating volume in the vascular system.

Neurogenic shock is a hemodynamic syndrome. When sympathetic nerve innervation is functioning properly, a drop in blood pressure is compensated for by an increase in heart rate. In this type of shock, however, sympathetic nerve innervation is lacking, and the body is not able to increase heart rate to compensate for low blood pressure caused by the dilation of vessels. Low blood pressure and low heart rate are hallmark findings in this type of shock. Additionally:

- Hypotension results from the loss of sympathetic vasomotor tone to the arteries and veins.
- Lack of sympathetic innervation to the heart results in unopposed stimulation of the vagus nerve (the main nerve of the parasympathetic nervous system), leading to bradycardia.
- Warm skin occurs initially but changes to become cool and clammy because of massive vasodilation.

Understand that **spinal shock** differs significantly from neurogenic shock. It is a transient neurologic syndrome of sensorimotor dysfunction, which can occur with injury to any part of the spinal cord. The patient experiences flaccidity and loss of reflexes in the area affected by the damage to the spinal cord. Table 23.10 contrasts these conditions.

Neurogenic Shock	Spinal Shock
Hemodynamic phenomena Loss of sympathetic stimulation Low blood pressure Low heart rate	Flaccid muscles Loss of reflexes Function may return

TABLE 23.10 Spinal Shock vs. Neurogenic Shock

It is important to realize the cause of hypotension in patients with this type of shock is lack of vascular tone, not vascular volume. Vasomotor tone plays a major role in the maintenance of blood pressure. In neurogenic shock, significant hypotension is present—usually below 70 mmHg—because the blood vessels lack vasomotor tone, limiting their ability to expand and constrict in response to perfusion changes, therefore causing hypoperfusion to the cells and organs. The hypotension of neurogenic shock is unresponsive to fluid resuscitation because sufficient volume is present already. Treatment of hypotension is therefore focused on increasing vasomotor tone and cardiac output.

Bradycardia is present in neurogenic shock because of unopposed vagus nerve stimulation (Figure 23.10). Decreased cardiac output also occurs. Treatment of bradycardia focuses on augmenting cardiac output and cardiac rate. Most patients require treatment with vasopressors and inotropes.

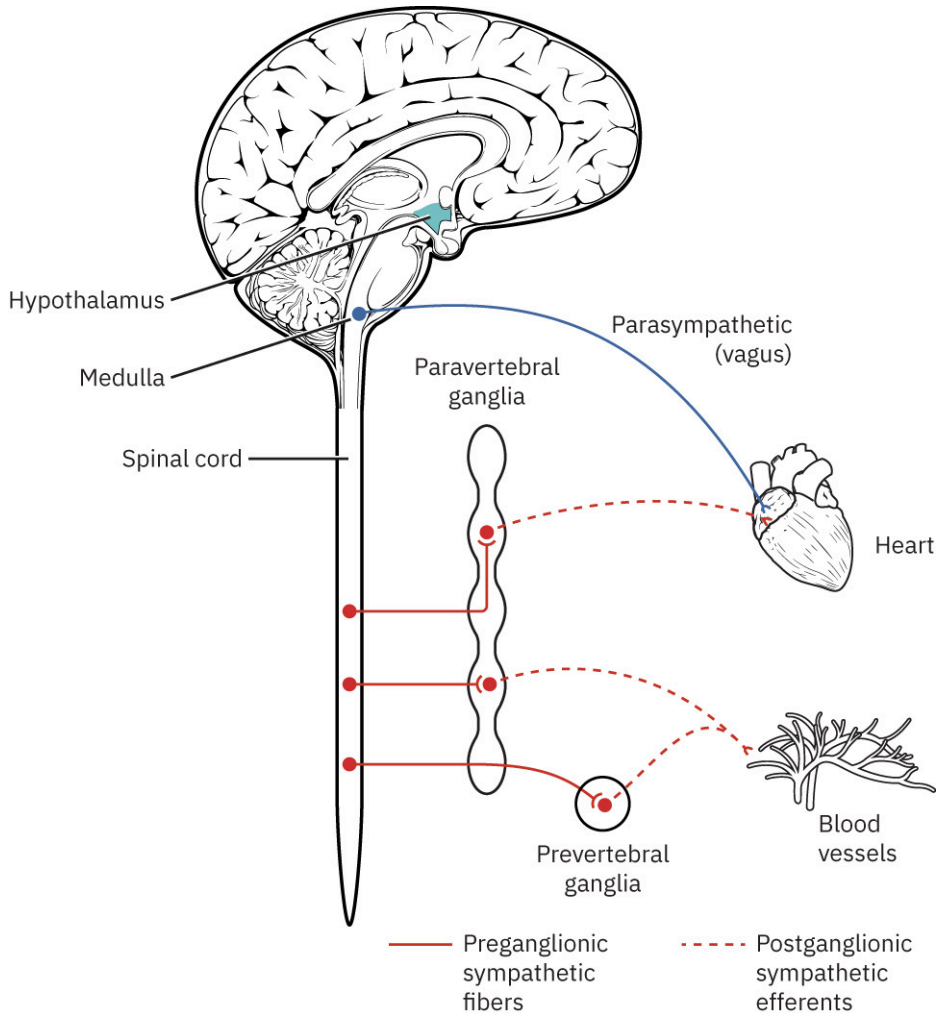

FIGURE 23.10 The image depicts the pathways of the parasympathetic nerves during neurogenic shock. Loss of sympathetic tone in neurogenic shock leads to unopposed parasympathetic response driven by the vagus nerve causing unstable blood pressure, heart rate, and temperature regulation. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Temperature regulation is altered during neurogenic shock. When sympathetic nerve stimulation is intact, the patient can maintain normal temperature by triggering their body to shiver or sweat to maintain optimal body temperature. Disruption of sympathetic stimulation results in the patient not being able to maintain normothermia. Patients in neurogenic shock may experience poikilothermia, also known as intrinsic thermoregulatory failure. The patient may go between experiences of hypothermia and hyperthermia because the body loses its ability to regulate dermal blood vessel contraction; dilation for temperature regulation is also lost due to a lack of sympathetic nerve intervention.

The massive vasodilation and decreased tissue perfusion caused by neurogenic shock affect all body systems, including the neurologic, renal, and gastrointestinal systems. Respiratory failure is also common in patients.

Clinical Manifestations

It is imperative for the nurse to assess the patient for the presence of the hallmark findings of neurogenic shock to enable the health-care team to make a rapid diagnosis and start an effective treatment. These hallmark findings include:

- low blood pressure
  - systolic less than 90 mmHg
  - diastolic less than 60 mmHg
- bradycardia
- heart rate less than 60 beats per minute
- warm skin

Other clinical manifestations of lack of vasomotor tone include absent jugular vein distention, reduced central venous pressure, altered mental status, and hypoactive bowel sounds.

Risk factors for the development of neurogenic shock include sports injuries, gunshot wounds to the spine, medications that affect the autonomic nervous system, and improper administration of anesthesia to the spinal cord.

Assessment and Diagnostics

Most patients who have neurogenic shock also have a spinal cord injury above the thoracic seven vertebrae. This creates a risk of impaired airway maintenance. The nurse should first assess that the patient has an effective airway and the ability to breathe.

The diagnosis of neurogenic shock is often a diagnosis of exclusion. When blood pressure and heart rate are low and fluids do not effectively raise blood pressure, neurogenic shock is suspected. The patient should undergo radiologic studies, including MRI, CT scan, and x-ray to assess for evidence of spinal cord injury. Routine blood work should be obtained to assess the baseline status of the patient.

Diagnostics and Laboratory Values

Patients with neurogenic shock have a variety of characteristic laboratory values, including low levels of red blood cells (RBC), hemoglobin (HGB), and hematocrit (HCT) because of the dilutional effects of volume resuscitation. Table 23.11 summarizes these findings.

Laboratory Test	Laboratory Finding	Cause
Red blood cells (RBC)	Low	Fluid resuscitation
Hemoglobin (HGB)	Low	Fluid resuscitation
Hematocrit (HCT)	Low	Fluid resuscitation
Blood urea nitrogen (BUN)	High	Decreased renal perfusion
Creatinine (Cr)	High	Decreased renal perfusion
Sodium (Na)	Vary	Volume resuscitation
Potassium (K)	High	Cell destruction
Arterial blood gas (ABG)	Abnormal findings	PH > 7.450 = early respiratory alkalosis PH < 7.350 = early metabolic acidosis
Lactic acid	Elevate	Cell death due to anaerobic metabolism
Liver markers	Elevate	Hypoperfusion to liver

TABLE 23.11 Laboratory Values Characteristic of Neurogenic Shock

Nursing Care of the Patient with Neurogenic Shock

It is important for the nurse to identify patients at risk for the development of neurogenic shock and to act in an efficient and immediate manner. Focused assessments and timely communication with the health-care team can prevent or limit long-term or fatal complications from neurogenic shock.

Prevention of neurogenic shock is the best treatment, so education plays a pivotal role in reducing risk. Because spinal cord injury is the most common cause of neurogenic shock, health-care professionals should teach the public about how to prevent spinal cord injuries: for example, by avoiding potentially dangerous activities such as diving

headfirst into a swimming pool and “heading” the ball in games such as soccer. The public should also be educated on the appropriate use of protective equipment such as seat belts and helmets.

Recognizing Cues and Analyzing Cues

The nurse can recognize cues of neurogenic shock by assessing vital signs and noting trends. Cues include low blood pressure, bradyarrhythmia, and peripheral vasodilation such as flushed warm skin that later becomes cold and clammy, and blue lips and fingertips. At-risk patients require frequent and accurate assessments to detect the onset of shock promptly and ensure treatments are most effective (Iovine et al., 2022).

- Any patient exhibiting low blood pressure and low heart rate should be suspected of having neurogenic shock.
- The level of the spinal cord from T7 to T12 helps control the abdominal muscles used for breathing and initiation of an effective cough. Therefore, any patient with a suspected spinal cord injury above T7 should be assessed for the presence of neurogenic shock. Injury of T7 to T12 also results in low lung volume, weak cough, and dyspnea. If the injury is above C3, the patient may need mechanical ventilation because impaired motor control of the respiratory muscles will result.

Nursing care of a patient with neurogenic shock in the emergent phase consists of following the ABCs of care:

- A = The patient’s airway should be assessed and maintained.
- B = The patient’s breathing status should be assessed and supplemented as needed, for example, with supplemental oxygen, endotracheal intubation, or mechanical ventilation.
- C = The patient’s circulatory status also needs to be assessed, as significant hypotension and bradycardia are often components of neurogenic shock.

The nurse should recognize these conditions and provide appropriate treatment to stabilize the patient’s hemodynamics. Figure 23.11 shows an example of a common precautionary measure to protect against neurogenic shock.

FIGURE 23.11 EMS will likely place a cervical collar on a patient with a suspected neck injury, such as this car crash victim. (credit: Szdavid/ Wikimedia Commons, CCBY 4.0)

It is important for the nurse to continually assess for volume overload when intravenous fluids are initially administered to the hypotensive patient. In addition to hemodynamic monitoring, the nurse should assess the lungs to determine the presence of adventitious breath sounds that indicate the development of pulmonary edema. It is imperative that the nurse recognize the cause of hypovolemia in patients is due to loss of blood vessel tone, not blood vessel volume.

Frequently, patients with neurogenic shock require endotracheal intubation and mechanical ventilation. The nurse should assess the patient’s response to suctioning. Insertion of a catheter into the endotracheal tube may trigger the vagus nerve, further dropping the heart rate. It is advisable to have atropine readily available for the treatment of bradycardia as needed. Some health-care providers recommend the use of pacemakers for patients with neurogenic shock who are experiencing significant bradycardia.

Hypothermia when present can be managed with a warming blanket. If the patient is hypothermic and hemodynamically unstable, slow rewarming is indicated. Studies have found that rapid rewarming may worsen the patient's unstable hemodynamic status due to further vasodilation.

The nurse should perform frequent assessments of all body systems to assess the patient's response to treatment. Along with a complete neurologic assessment, the nurse should assess for any change in the level of consciousness that might indicate decreased perfusion to the brain.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Caring for patients with neurogenic shock is complex and involves high attention to detail. The nurse must monitor the patient closely for signs and symptoms that indicate a decline in body systems. The nurse should assign patients experiencing neurogenic shock to a neurologic intensive care unit or spine center for close observation. Without prompt intervention, permanent, irreversible damage may result.

Meticulous skin care is essential. Patients with neurogenic shock are at high risk for developing pressure injuries because of poor perfusion to the skin and possible immobility related to spinal cord injury. Nursing care should also focus on preventing the development of aspiration pneumonia, foot drop, DVT, and other complications of immobility.

Some patients with spinal cord injury manifest changes in bowel and bladder function. Spinal cord injury may result in complete or partial loss of the patient's ability to control or manage excretions. The nurse should assess for urinary retention and bowel obstruction or constipation and provide appropriate care. Hourly and twenty-four-hour intake and output should be accurately assessed and documented.

Neurogenic shock also places patients at risk for the development of GI stress ulcers. The nurse needs to follow through with preventive measures to decrease the chance of gastrointestinal bleeding. Stress has also been found to increase the blood glucose level of patients. Results indicate that patients who have a blood glucose of less than 180 mg/dL experience less morbidity and mortality.

Evaluation of Nursing Care for the Patient with Neurogenic Shock

Successful management of neurogenic shock begins with early diagnosis and accurate identification of the cause. Appropriate treatments to limit low blood pressure and low heart rate have been found to decrease secondary injury to the spinal cord and restore adequate oxygenation to vital tissues, thus limiting cell damage. The effectiveness of treatment can be evaluated by the presence of baseline hemodynamic status of the patient. The optimal patient outcome for neurogenic shock is the resolution of the problem with no residual deficits.

Medical Therapies and Related Care

Medical therapies for patients with neurogenic shock focus on preventing secondary injury to the spinal cord, which starts with immobilizing the spine and completing imaging studies. The patient may require surgery for spine stabilization or decompression.

Other important therapies involve enhancing sympathetic tone to the blood vessels and heart to improve cellular and body tissue perfusion. Patients with neurogenic shock often have systolic blood pressure readings of less than 70 mmHg systolic. Treatment is geared to obtain a mean arterial pressure of 85 to 90 mmHg, as this is known to ensure adequate perfusion to cells and body tissues for patients in neurogenic shock. Hemodynamic stabilization starts with the administration of fluids followed by vasopressors. Fluid therapy is useful to compensate for the vasogenic dilation that occurs because of loss of sympathetic stimulation to the blood vessels; however, it does not result in acceptable profusion to cells and body tissues. Vasopressors are frequently required to obtain baseline hemodynamics. When administering fluids, it is imperative to assess the patient for the development of fluid overload, which often manifests as heart failure or pulmonary edema.

Pharmacotherapy for loss of vascular tone in neurogenic shock often includes the following:

- An **inotropic drug** (digoxin, dobutamine, milrinone) increases the force of cardiac contractions.
- Vasopressors (phenylephrine, norepinephrine, epinephrine, and vasopressin) constrict the blood vessels to increase blood pressure. The goal is to maintain mean arterial pressure between 85 to 90 mmHg.

Pharmacologic treatment of bradycardia in neurogenic shock includes:

- atropine, a positive chronotropic that blocks the effects of the vagus nerve on the heart
- glycopyrrolate, a positive chronotropic that blocks the enzyme that slows heart rate
- isoproterenol beta-1 and beta-2 adrenergic receptors, which reproduce a pure chronotropic effect
- Methylxanthines, which provide a positive chronotropic effect for refractory bradycardia

Summary

23.1 Shock Overview

- Shock is a state of inadequate cellular perfusion.
- Hemodynamic monitoring is the physical study of flowing blood and all solid structures where blood flows. It is useful in understanding the diagnosis and treatment of shock.
- During the initial stage of shock, clinical manifestations are not overtly apparent; however, changes occur at the cellular level.
- In the compensatory stage of shock, cell hypoperfusion causes a drop in blood pressure, tachycardia, cool skin, increased respiratory rate, and a decrease in urine output.
- In the progressive stage of shock, compensatory mechanisms fail and altered capillary permeability causes fluid to leak from the vascular system into the interstitial tissue.
- Vital signs in the progressive stage of shock include low blood pressure, increased heart rate, low urine output, increased respiratory rate, and cool skin with discoloration of peripheral extremities with weak distal pulses.
- In the refractory stage of shock, continued capillary permeability and cell hypoxia lead to cell death. Recovery is not likely from this stage of shock.
- Multiorgan failure (MOF), also referred to as multiorgan dysfunction syndrome (MODS), is a critical illness characterized by inflammation from a severe infection or simultaneous injuries to two or more organ systems.
- The direction of blood is forced to divert to the vital organs of the body, such as the heart, lungs, and brain.

23.2 Hypovolemic Shock

- An effective heart pump, sufficient blood volume, and appropriate sympathetic tone to blood vessels are needed to maintain adequate cell perfusion.
- Hypovolemic shock results when there is insufficient volume in blood vessels to maintain cell perfusion.
- Treatment of hypovolemic shock aims to identify and correct the source of volume loss.
- Absolute hypovolemia can result from overt bleeding, excessive vomiting or diarrhea, fistula drainage, diabetes insipidus, hyperglycemia, or diuresis.
- Relative hypovolemia results from fluid movement from cells and blood vessels into the interstitial space. Causes of this shift include bowel obstruction, burn injury, ascites, long bone fracture, hemothorax, severe pancreatitis, and sepsis.
- During hypovolemic shock, the body attempts to compensate for decreased vascular volume by increasing the sympathetic tone to blood vessels, increasing the sympathetic tone to the heart, increasing rate and contractility, and diverting blood to vital organs.
- Anaerobic metabolism, the accumulation of waste products, results from the hypoperfusion of cells.
- Manifestations of hypovolemic shock include increased heart rate, decreased blood pressure, increased respiratory rate, decreased urine output, and cool clammy skin.
- Treatment for hypovolemic shock focuses on identifying the source of volume loss, stopping the source of volume loss, and restoring appropriate volume. Some patients require the administration of medications to maintain hemodynamic stability.

23.3 Septic Shock

- Sepsis is a serious condition resulting from the body's overreaction to the presence of bacterial, fungal, or viral infection.
- Sepsis leads to an immediate inflammatory process throughout the body; severe sepsis results in organ malfunction, and septic shock is a cause of significant morbidity and mortality.
- MOF/MODS is a clinical syndrome characterized by the development of progressive and potentially reversible physiologic dysfunction in two or more organs or organ systems that is induced by a variety of acute insults, including sepsis.
- Early recognition and treatment of sepsis result in improved patient outcomes.
- Classic manifestations of septic shock include hypotension, tachycardia, tachypnea, low urine output, and mottled skin.
- The release of endotoxins from microorganisms causes vasodilation, maldistribution of blood flow, and

myocardial dysfunction.
- Patients require care provided in an intensive care environment.
- If profound hypotension is unresponsive to fluid therapy, vasopressors are needed.

23.4 Neurogenic Shock

- Neurogenic shock is a life-threatening medical condition caused by the sudden loss of sympathetic nerve stimulation, which is necessary to maintain normal muscle tone in the blood vessels. As a result, there is insufficient blood flow throughout the body, causing low blood pressure.
- Neurogenic shock is caused by the loss of vasomotor tone in the blood vessels, not by insufficient volume.
- Dilation of arteries and veins results in the pooling of blood and inadequate perfusion of cells and body tissues.
- The most common cause of neurogenic shock is spinal cord injury. Other causes include complications from spinal anesthesia and head trauma.
- Hallmark findings in neurogenic shock include hypotension, bradycardia, and initially warm, dry skin above the level of the injury.
- Fluid resuscitation is the first-line treatment to restore blood pressure; however, vasopressors are often needed to restore cell and tissue perfusion.
- Emergent nursing care for patients with neurogenic shock includes the ABCs, along with protecting the cervical spine and preventing secondary spinal cord injury.
- Continual assessments and interventions should be incorporated into care to prevent long-term complications.

Key Terms

absolute hypovolemia loss of blood that is visible
cardiopulmonary pressure normal range is 11–20 mmHg; elevated ranges result in pulmonary hypertension
central venous pressure (CVP) measure of the adequacy of blood volume within the vascular system; normal range is 8–12 mmHg
citrate toxicity condition caused by the accumulation of citrate, which binds to calcium in the body, causing hypocalcemia and hypomagnesemia
compensatory stage second stage of shock, characterized by a noticeable drop in blood pressure and causes stimulation of baroreceptors of the carotid and aortic bodies
D-dimer simple blood test that can help the health-care provider determine if a blood clotting condition is present
dilutional coagulopathy disruption of normal clotting mechanisms following the replacement of blood with fluids that do not contain adequate coagulation factors
hemodynamics study of blood flow and the relevant body structures
hypermetabolic state situation that occurs in response to injury and is characterized by increased blood pressure and heart rate, peripheral insulin resistance, and increased protein and lipid catabolism
initial stage first stage of shock, when the body responds to hypotension with stimulation of the sympathetic nervous system (SNS) and the release of epinephrine and norepinephrine
inotropic drug medication that increase cardiac contractility
mean arterial pressure (MAP) average arterial pressure through one cardiac cycle; normally 70–100 mmHg
multiorgan failure (MOF) failure of several organs at the same time, usually as the result of shock; also called multiple organ dysfunction syndrome (MODS)
neurogenic shock distributive type of shock resulting in hypotension (low blood pressure), often with bradycardia (slowed heart rate), caused by disruption of autonomic nervous system pathways
progressive stage third stage of shock, when profoundly decreased cellular perfusion results in a significant increase of capillary permeability, causing protein and fluid to leak out of the vascular system into the interstitial space
pulmonary artery catheter central venous catheter used to measure cardiopulmonary pressure
refractory stage final stage of shock, characterized by extreme dysfunction of cellular processes in multiple body systems
relative hypovolemia volume adjustment within the body from the vascular space to the interstitial space
renin-angiotensin-aldosterone system (RAAS) critical regulator of blood volume, electrolyte balance, and blood

vessel tone

sepsis overreaction of the immune system to infection

septic shock condition of low blood pressure (despite adequate intravenous fluid administration), decreased blood flow to cells, and formation of blood clots in vessels, leading to organ damage, organ failure, and, ultimately, death

severe sepsis sepsis that results in organ malfunction

shock state of inadequate cellular perfusion, leading to hypoxia and cell death

spinal shock altered physiologic state immediately after spinal cord injury, resulting in flaccid paralysis, anesthesia, absent bowel bladder control, and loss of reflex activity below the level of the injury; normal function may return if the spinal shock resolves

vasopressor member of a class of drugs that induces vasoconstriction and increase blood pressure

volume resuscitation administration of fluids to compensate for insufficient intravascular fluid volume

Assessments

Review Questions

1. Shock is a state of a decrease in what?
   a. heart rate
   b. urine output
   c. blood pressure
   d. cell perfusion

2. What is a hallmark finding in the progressive stage of shock?
   a. significant increase in capillary permeability
   b. activation of the sympathetic nervous system
   c. stimulation of the carotid and aortic baroreceptors
   d. arousal of the renin-angiotensin-aldosterone system (RAAS)

3. In what stage of shock are the aortic and carotid baroreceptors stimulated to regulate blood pressure?
   a. initial stage
   b. compensatory stage
   c. progressive stage
   d. refractory stage

4. What response occurs when the renin-angiotensin-aldosterone system (RAAS) is activated?
   a. Water is excreted from the kidneys.
   b. Sodium from the kidneys decreases.
   c. Blood vessels constrict.
   d. Heart rate increases.

5. What is a hallmark finding of the refractory stage of shock?
   a. low urine output
   b. low blood pressure despite treatment
   c. low respiratory rate
   d. low heart rate

6. A nurse reviews laboratory results for a patient who has had uncontrolled vomiting and diarrhea for the past thirty-six hours. What clinical manifestation is an indication that the patient may be experiencing hypovolemia?
   a. high urine specific gravity
   b. lactate level of 2 mmol/L
   c. potassium of 4.0 mEq/L
   d. urine output of 40 mL/hour

7. A patient who experienced a burn injury is receiving fluid resuscitation therapy. To prevent complications from fluid resuscitation, what is most important for the nurse to assess?
   a. breath sounds
   b. burn wound dressings
   c. pain level
   d. urine output

8. What is an example of a patient whom the nurse would identify as most at risk for the development of hypovolemic shock?
   a. an eighteen-year-old patient who sustained a neck injury while diving into a pool
   b. a forty-year-old type I diabetic with a blood sugar of 422
   c. a fifty-two-year-old patient who sustained an anterolateral myocardial infarction eight hours ago
   d. a seventy-two-year-old patient with a urinary tract infection

9. The nurse is caring for a patient who received multiple blood transfusions for treatment of hemorrhagic hypovolemic shock. The nurse is especially concerned about the patient developing citrate toxicity. To prevent this, the nurse should assess for low levels of what electrolyte?
   a. phosphate
   b. potassium
   c. sodium
   d. calcium

10. The nurse is part of the medical team caring for a patient in hypovolemic shock. The team assesses the patient and ensures that the airway, breathing, and circulation is stabilized. What next step should the team take?
   a. start epinephrine to increase the patient's heart rate
   b. start vasopressors to stabilize blood pressure
   c. start inotropes to increase the force of cardiac contraction
   d. identify the source of fluid loss

11. What laboratory finding is likely for patients who are experiencing hemoconcentration from the development of ascites?
   a. elevated hematocrit
   b. elevated BUN
   c. elevated potassium
   d. elevated lactate

12. A nurse receives orders from the provider for a post-op patient diagnosed with sepsis. What order should the nurse implement *first*?
   a. administer antibiotics
   b. change the surgical dressing
   c. insert a Foley catheter
   d. obtain a blood culture

13. A panel of blood work is drawn for a patient suspected of having septic shock. It is most important for the nurse to inform the provider of what result?
   a. lactate level: 4 mmol/L
   b. platelet count: 300,000 platelets per microliter of blood
   c. red blood cell count: 4.5 million
   d. white blood cell count: 9,000 per microliter

14. Laboratory results are reviewed by a nurse for a patient suspected of having sepsis. What value is most often associated with a diagnosis of sepsis?

a. negative endotoxin
b. high partial thromboplastin time (PTT)
c. low C-reactive protein
d. negative procalcitonin value

15. The nurse identifies what patient as being at highest risk for the development of septic shock?
a. a twenty-year-old with a closed fractured femur
b. a seventy-four-year-old who takes a diuretic for hypertension control
c. a fifty-two-year-old who had a cerebral vascular aneurysm repaired
d. a forty-year-old who had a total knee replacement

16. The nurse is caring for a patient in septic shock. What result would lead the nurse to conclude that the current treatment plan is effective?
a. urine output of 28 mL/hour
b. lactate level of 7 mmol/L
c. blood glucose of 118 mg/dL
d. mean arterial pressure of 60 mmHg

17. What is most accurate indicator of recovery from septic shock?
a. negative blood culture
b. urine output of 40 mL/hour
c. blood pressure of 118/78 mmHg
d. oral temperature of 37.2°C

18. What is a risk factor for the development of neurogenic shock?
a. myocardial infarction
b. pneumonia
c. severe burns to the chest
d. spinal cord injury

19. What drug is used in the treatment of bradycardia of neurogenic shock?
a. atropine
b. dobutamine
c. epinephrine
d. norepinephrine

20. When assessing a patient who sustained a spinal cord injury, what manifestation does the nurse identify as being most often associated with neurogenic shock?
a. bradycardia
b. hypotension
c. flaccid muscles and loss of reflex activity below the level of the injury
d. cool skin

Check Your Understanding Questions

1. What is the key contributor to the progression of shock?

2. In the early stages of shock, the body compensates for decreased cell perfusion by activating what system to elicit the “fight or flight” response?

3. In which stage of shock is blood pressure significantly low despite treatment?

4. What is the best noninvasive indicator of adequate perfusion to the kidney?

5. When a patient with hypovolemic shock is being treated with volume resuscitation, what should be the nurse’s priority concern?

6. A patient is experiencing an overreaction of the immune system. The nurse should identify the patient as being in what stage of sepsis?
7. Hypotension in neurogenic shock is primarily due to _____.
8. Patients experiencing neurogenic shock experience _____, also known as intrinsic thermoregulatory failure, which can lead to both hypothermia and hyperthermia.

Reflection Questions

1. Tissue perfusion and organ perfusion depend on mean arterial pressure (MAP), or the average pressure at which blood moves through the vasculature. Why must the MAP exceed 65 mmHg?
2. Shock progresses along a continuum and can be identified by stages. Why is it critical the nurse complete a thorough assessment and monitor the patient's signs and symptoms?
3. When administering multiple units of blood to a patient in hypovolemic shock caused by hemorrhagic bleeding from a bleeding gastric ulcer, what actions should the nurse take?
4. How can nurses evaluate the efficacy of care for patients with neurogenic shock?
5. Spinal cord injury is the number one cause of neurogenic shock. Data supports the benefits of fall prevention education for older adults. How might you incorporate fall prevention teaching into the care you provide for older patients?
6. The nurse is assessing a patient who sustained a spinal cord injury to thoracic vertebrae 5. The patient's vital signs are currently blood pressure 78/50 mmHg, heart rate 56 and regular, respiratory rate of 11 breaths per minute, and oral temperature of 36.8°C.

   Which medication should the nurse plan to administer first, and why?

7. After volume resuscitation, what medication should the nurse plan to administer next to achieve hemodynamic stabilization?

What Should the Nurse Do?

John, a thirty-five-year-old male, was involved in a motorcycle accident and sustained a spinal cord injury at the T4 level. Upon arrival at the emergency department, he presents with bradycardia, hypotension, and warm, dry skin below the level of injury. The health-care provider orders a series of diagnostics, including blood tests and imaging, to evaluate John's condition further. John's condition is confirmed as neurogenic shock. The health-care team initiates treatment protocols, and you are responsible for implementing the nursing care plan. After several hours of treatment, John's blood pressure has stabilized, and his heart rate has improved. However, he still exhibits signs of impaired perfusion. The physician orders norepinephrine and atropine to manage John's neurogenic shock.

1. What verbal and nonverbal cues should the nurse recognize that indicate John may be experiencing neurogenic shock?
2. What diagnostic tests and laboratory values should the nurse monitor to confirm the diagnosis of neurogenic shock, and how do these findings guide the next steps in care?
3. What specific nursing interventions should be prioritized for John to manage neurogenic shock, and how would these interventions be tailored to his injury?
4. How should the nurse evaluate the effectiveness of the interventions provided for John, and what indicators would suggest a need to adjust the care plan?
5. What should the nurse consider when administering norepinephrine and atropine, and how would the nurse explain the purpose and potential side effects of these therapies to John?

Competency-Based Assessments

A forty-five-year-old male is admitted to the emergency department following a motor vehicle accident. He has multiple lacerations and significant blood loss. Upon arrival, his vital signs are:

- Blood pressure: 85/55 mmHg
- Heart rate: 130 beats per minute

- Respiratory rate: 28 breaths per minute
- Skin is cold and clammy, and the patient is anxious.

1. Based on the patient's presentation, discuss the pathophysiology of hypovolemic shock and identify three risk factors and three clinical manifestations seen in this patient.
2. The same patient is undergoing diagnostics to confirm hypovolemic shock. The health-care team orders a complete blood count (CBC), blood chemistry, and arterial blood gases (ABGs). Describe the key diagnostic tests and expected laboratory findings for a patient in hypovolemic shock.
3. The patient's condition is deteriorating, and you are the nurse responsible for managing their care. Develop a nursing care plan for this patient, incorporating key nursing concepts for managing hypovolemic shock.

Jamal visits his grandmother once a week to take her grocery shopping. Today when Jamal arrives at her home, she does not answer the door. Jamal uses his key to let himself in and finds his grandmother lying on the bed. She is very confused and weak. Jamal calls 911 for assistance. She is transported to the local emergency department where you are the nurse assigned to care for the patient. Upon admission, the patient is disoriented to time, place, and person and manifests these vital signs:

- Blood pressure: 78/58 mmHg
- Heart rate: 122 beats per minute
- Respiratory rate: 26
- Temperature 39 °C

4. Using the scenario preceding, develop a plan of care identifying the patient's quick Sequential Organ Failure Assessment (qSOFA)?
5. Considering the progression for the preceding scenario, the provider orders a broad-spectrum antibiotic for the patient because sepsis is suspected. Prior to administering the antibiotic, the nurse validates that the patient has no allergies to the ordered medication. Develop a list of other steps the nurse must take prior to administering the antibiotic.
6. Early diagnosis and treatment of sepsis is key to patient survival. The nurse is aware of the recommended implementation of a one-hour bundle in the treatment of a patient who is suspected of having sepsis. Develop a presentation for your peers explaining what the one-hour bundle includes.

CHAPTER 24

Management of Patients with Allergic Disorders

FIGURE 24.1 EpiPens are hypodermic devices that deliver a dose of epinephrine for emergency treatment of acute allergic reactions and to prevent or improve anaphylaxis. (credit: New Jersey National Guard/Flickr, Public Domain)

CHAPTER OUTLINE

INTRODUCTION The human body comes in contact with many potential intruders like allergens or pathogens that can pose a threat. The body is enabled with its own defenses to combat invaders and protect itself. However, in some instances the defenses are breached, causing an interruption in the body's enzyme systems that can destroy vital tissues.

The allergic system, also known as the immune system, is a complex network of cells, tissues, and organs that work together to defend the body against harmful substances and protect it from infections. Its primary function is to recognize and respond to foreign substances, known as allergens, in order to maintain the body's overall health and well-being. At times, it may overreact creating allergic disorders, which nurses must identify and know how to treat. This chapter will explore those allergic disorders and the medical and nursing treatment.

24.1 Allergic Response

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the role of immunoglobulins in the allergic process
- Differentiate the chemical mediators and their role in the allergic process
- Discuss the pathophysiology, risk factors, and clinical manifestations for hypersensitivity
- Describe the diagnostics and laboratory values in the patient experiencing hypersensitivity
- Apply nursing concepts and plan associated nursing care for patients experiencing hypersensitivity
- Evaluate the efficacy of nursing care for patients experiencing hypersensitivity
- Describe the medical therapies that apply to the care of patients experiencing hypersensitivity

Allergic responses are the ways the body responds to a pathogen or intruder. When it overreacts, it can develop into an allergic disorder that is an inappropriate or exaggerated response of the body's immune system to a substance that is usually harmless. The response may be due to contact by inhalation, contact, or ingestion of various allergens. Common allergic responses are to seasonal allergens like various trees, ragweed, or pollens; medications; perennial allergens like dust or molds; latex; animal dander; foods; household chemicals; fragrances; and insect stings or bites, as shown in Figure 24.2. Allergic responses vary among individuals; not every person will respond in the same way to an allergen.

FIGURE 24.2 An allergic reaction to a bee sting may cause painful swelling, as seen here. (credit: " Bee Sting Gone Bad" by OakleyOriginals/Flickr, CC BY 2.0)

Physiologic Overview of an Allergic Response

An **allergy** is an inappropriate or exaggerated response of the body's immune system to a foreign substance that is usually harmless, known as an allergen. An **allergen** is a type of antigen, triggering a series of events as the body attempts to terminate and eliminate the invaders. For example, lymphocytes in the body respond to the antigens by producing antibodies. An **antibody** is a protein substance that protects against antigens. Antibodies react with antigens in a number of ways and each antibody is specific to the type of antigen present.

During an allergic response, the immune system overreacts to harmless substances, known as allergens, triggering a cascade of physiological events. Allergens can enter the body through various routes, such as inhalation, ingestion, or direct contact with the skin. Table 24.1 provides a physiologic overview of an allergic response.

Physiological Event	Description
Activation of immune cells	The allergen is captured and processed by specialized cells called antigen-presenting cells (APCs), such as dendritic cells. APCs present fragments of the allergen, known as antigens, to T cells, which are a type of lymphocyte.
T cell activation	Upon encountering the allergen, specific T cells, known as helper T cells (Th cells), are activated. Th cells release chemical signals, such as cytokines, that stimulate other immune cells, including B cells and mast cells.
B cell activation and antibody production	Activated Th cells stimulate B cells to produce antibodies, specifically immunoglobulin E (IgE) antibodies. IgE antibodies are specialized to recognize and bind to the specific allergen.
Sensitization	The produced IgE antibodies attach to receptors on the surface of mast cells and basophils, which are types of immune cells found in tissues throughout the body. This process is known as **sensitization**.
Allergen re-exposure	If the sensitized individual is re-exposed to the same allergen, the allergen binds to the IgE antibodies on the surface of mast cells or basophils.
Release of chemical mediators	The cross-linking of allergen with IgE antibodies on mast cells or basophils triggers the release of chemical mediators, including histamines, leukotrienes, and prostaglandins. Histamine, in particular, plays a significant role in producing immediate allergic symptoms.
Immediate allergic response	The released chemical mediators cause various physiological effects. They cause blood vessels to dilate, leading to increased blood flow and leakage of fluid into tissues. This results in local swelling, redness, and heat. Histamine also stimulates the nerve endings, causing itching and pain. Increased mucus production can occur in the respiratory tract, leading to nasal congestion or wheezing.
Late-phase allergic response	In some cases, an additional response, known as the late-phase response, may occur several hours after the initial allergic reaction. It is characterized by the infiltration of immune cells, including eosinophils and other inflammatory cells, into the affected tissues. This leads to prolonged inflammation and persistent symptoms.
Systemic allergic response	In severe cases, an allergic response can become systemic, affecting the entire body. This can lead to a drop in blood pressure (anaphylaxis); difficulty breathing; swelling of the face, tongue, or throat; and can be life-threatening.

TABLE 24.1 The Allergic Response

It is important to note that allergic responses can vary in severity and presentation among individuals. The specific symptoms and intensity of the allergic response depend on factors such as the type of allergen, the route of exposure, the individual's immune system, and any pre-existing allergies or sensitivities. Understanding the physiologic overview of an allergic response helps health care professionals diagnose allergies, develop treatment plans, and provide appropriate interventions to manage allergic symptoms effectively.

Immunoglobins

When the body's immune system is first exposed to an allergen, lymphocytes and plasma cells produce immunoglobulins. An **immunoglobulin** is a protein capable of acting as an antibody. Immunoglobulins can be grouped into five classes: IgG, IgA, IgM, IgD, and IgE. They are commonly found in the tonsils, appendix, lymph

nodes, and **Peyer patches** (small groupings of lymphoid follicles) of the intestinal tract; they also circulate in lymph and blood.

The IgE immunoglobulins are involved in producing an **allergic disorder**, a common pathological condition due to IgE-dependent immunological reactions to an allergen. This particular class of immunoglobulin is found in the respiratory and intestinal mucosa. IgE molecules bind together to an allergen and trigger mast cells of the tissues or white blood cells in the bloodstream, called basophils, to release chemical mediators like histamine, kinins, serotonin, slow-reacting anaphylaxis substances, and the neutrophil factor that produces allergic skin reactions, hay fever, and asthma. IgE-mediated diseases have a genetic component. The genetic tendency to develop allergic diseases such as allergic rhinitis, asthma, and atopic dermatitis is called **atopy**. It refers to a hypersensitivity response to an allergen.

Role of B Cells

A **B cell** is a regulatory cell in the immune system; they are also called B lymphocytes. B cells are designed to produce one specific antibody. When there is an encounter with a specific antigen, the B cells stimulate the production of plasma cells, resulting in a flood of antibodies that terminate and eliminate the antigen.

Role of T Cells

A **T cell** is a cell that assists B cells; they are also called T lymphocytes. T cells secrete substances that direct cell defense activity, defeat target cells, and rouse macrophages that trigger an immune response by presenting antigens to the T cells. T cells then digest the antigens; they also aid in eliminating the remains of the invading cells and other debris.

Antigens

Examples of complete protein antigens include horse serum, pollen, and animal dander. Active communication between cells is necessary in allergic reactions in order for the physiologic process involved in an allergic response to be triggered (Abbas et al., 2023). When an allergen is engulfed through the gastrointestinal tract, skin, or respiratory tract, allergen sensitization occurs. Macrophages manage the antigen and allow it access to the proper cells. These cells develop into allergen-specific secreting plasma cells that produce and secrete antigen-specific antibodies.

Chemical Mediators

A **mast cell** of the skin and mucous membranes perform a key role in IgE-mediated immediate hypersensitivity. Mast cells are specialized types of white blood cells that are found throughout the body in tissues that line the skin, blood vessels, lymph vessels, nervous tissue, lungs, and intestines and act as security guards scanning for intruders. Once they are disrupted, the mast cell releases chemicals to activate the immune response to fight off the pathogen. IgE molecules bind together to an allergen and trigger mast cells to release chemical mediators like histamine, kinins, serotonin, slow-reacting anaphylaxis substances, and the neutrophil factor that produces allergic skin reactions, hay fever, and asthma. These physiologic events that result from immediate hypersensitivity may range from mild to life-threatening symptoms.

Primary Mediators

Primary mediators include histamine, eosinophil chemotactic factor, platelet activating factor, and prostaglandins. Histamine plays a key role in immune responses; it is usually the first chemical mediator to be released in both immune and inflammatory responses. This chemical mediator is produced and kept in high concentrations in body tissues exposed to environmental substances. Effects of histamine include erythema, pruritus, localized edema (wheals), contraction of bronchial smooth muscle (resulting in bronchospasms and wheezing), and enhanced secretion of mucosal and gastric cells (diarrhea), as the role of histamine is to create vasodilation, which promotes oxygen and white blood cells to the area of attack. The histamine's effects peak 5 to 10 minutes after antigen interaction. Histamine-1 receptors are found primarily on vascular smooth and bronchiolar muscle cells. Histamine-2 receptors are found primarily on gastric parietal cells.

The eosinophil chemotactic factor of anaphylaxis impacts the movement of granular leukocytes, particularly eosinophils, to allergen sites. An **eosinophil** is a leukocyte that protects the body from parasites, allergens, and other organisms. This chemical mediator is pre-formed in the mast cells and released from disrupted mast cells.

Platelet activating factor is chemically derived from arachidonic acid and is responsible for stimulating the platelet aggregation and leukocyte permeation in immediate hypersensitivity reactions. This chemical mediator causes bronchoconstriction, increased vascular permeability, and vasodilation.

A **prostaglandin**, or an unsaturated fatty acid with a wide range of biologic activity, produces smooth muscle contraction, increased capillary permeability, and vasodilation. This chemical mediator sensitizes pain receptors and increases pain from inflammation. Prostaglandins also prompt inflammation and boost the effects of mediators in inflammatory responses. Local indications include edema, heat, and erythema.

Secondary Mediators

Secondary mediators include leukotrienes, bradykinin, and serotonin. A **leukotriene** is a chemical mediator that initiates the inflammatory response. Indications of inflammation may be in part due to leukotrienes. Leukotrienes also cause smooth muscle contraction, bronchial constriction, smooth muscle contraction, mucus airway secretions, and wheal-and-flare skin reactions. In comparison to histamine, leukotrienes are 100 to 1,000 times more powerful in triggering bronchospasm. The chemical mediator **bradykinin** is a substance that stimulates nerve fibers and causes pain. It can cause vasodilation, hypotension, increased vascular permeability, and smooth muscle contraction (for example, of the bronchi). Edema results from increased capillary permeability. The chemical mediator **serotonin** acts as a forceful vasoconstrictor and bronchoconstrictor and is formed in platelets.

Hypersensitivity

An abnormal heightened response to any type of stimulus is called **hypersensitivity**. The reaction does not normally occur after the initial exposure to an allergen. The reaction follows subsequent exposure after sensitization, or the building up of antibodies in a person who is predisposed. Hypersensitivity reactions can be broken down into four classes; types I and IV are the most common. Types I, II, and III occur within 24 hours of exposure, whereas type IV reactions occur 1 to 3 days after allergen exposure.

Pathophysiology

Type I hypersensitivity, or anaphylactic response, is facilitated by IgE antibodies produced by the immune system in response to allergens like dust mites, animal dander, and pollens. These IgE antibodies attach to mast cells and basophils that release histamine granules, which cause inflammation. This type of reaction can be seen in allergic rhinitis, allergic dermatitis, bronchial asthma, food allergy, anaphylactic shock, and conjunctivitis (Vaillant et al., 2023).

Type II hypersensitivity involves cytotoxic-mediated responses against cell surface and extracellular matrix proteins. These reactions are facilitated by IgG and IgM antibodies. The immunoglobulins damage cells by phagocytosis or by triggering the complement system. This type of reaction can be seen in autoimmune hemolytic anemia, autoimmune neutropenia, and immune thrombocytopenia (Vaillant et al., 2023).

Type III hypersensitivity, or immunocomplex reactions, are also facilitated by IgG and IgM antibodies that react with soluble antigens to create antigen-antibody complexes. The complement system is triggered and issues chemotactic agents that attract neutrophils and cause tissue damage and inflammation, as seen in glomerulonephritis and vasculitis. This type of reaction can be seen in an Arthus reaction and serum sickness (Vaillant et al., 2023). An Arthus reaction refers to an acute, localized inflammatory response that typically occurs after vaccination. It is classified as a type III hypersensitivity reaction, which is when antigen-antibody clusters, also known as immune complexes, are formed due to an abnormal immune system response.

Type IV, or delayed-type, hypersensitivity is a reaction where tissue damage is the result of T cell–dependent macrophage activation and inflammation. The pathophysiology of this type of reaction depends on the underlying cause.

- Granulomatous type reactions occur when T cells are triggered by antigen-presenting cells that are not able to terminate engulfed antigens. Macrophages are recruited to the site and accumulate intracellularly, forming a granuloma. An example is sarcoidosis.
- Drug hypersensitivity occurs when various drug particles join T cell receptors.
- Contact hypersensitivities occur when haptens invade the skin with vicinity to the cells of the epidermis and dermis and trigger an inflammatory reaction. A **hapten** is an incomplete antigen. The dendritic and Langerhans cells play a key role in antigen presentation and sensitization of these haptens to CD4 and CD8 T

cells. The T cells exude cytokines and other enzymes to enlist other immune cells to the hapten exposure sites. Keratinocytes also help in recruiting immune cells by secreting cytokines like IL-8 (Marwa & Kondamudi, 2023).

Clinical Manifestations

Clinical manifestations of type I reactions include hypotension, bronchospasm, and, in critical cases, cardiovascular collapse. This type of reaction may also include asthma, allergic rhinitis, and systemic **anaphylaxis**, which is a potentially life-threatening type I hypersensitivity response resulting from the rapid release of IgE-mediated chemicals in an attempt to eliminate a triggering allergen.

Type II reactions are characterized by tissue damage. Immune thrombocytopenia may include petechiae or bleeding of the gums, bowel, urinary tract, or bowels. Autoimmune hemolytic anemia may be characterized by jaundice. Myasthenia gravis manifestations include diplopia, extreme muscular fatigue, deconjugate eye movements, difficulty swallowing, arm weakness, and bilateral ptosis. Another common type II reaction is Goodpasture syndrome, which is characterized by lung hemorrhage and nephritis. Type III reactions are characterized by edema, hemorrhage, vasculitis, and arthritis. Clinical manifestations of type IV contact dermatitis reactions include erythema, itching, vesicles, and bullae. Other manifestations are dependent on the cause. Drug reactions may include fever, rash, wheals, or multiorgan involvement. Granulomatous-type hypersensitivity is characterized by shortness of breath, weakness, weight loss, fever, dry cough, and chest pain (Marwa & Kondamudi, 2023).

Assessment

In order to effectively manage allergic and hypersensitivity disorders, a comprehensive allergy assessment and physical examination are needed to provide sufficient data. Any reaction to an allergen should be assessed and documented, including patient symptoms or discomfort, severity, treatments (if any), and response to interventions. Assessment will include obtaining symptoms of the eyes, ears, nose, throat, chest, and skin from the patient. The nurse will also want to ask the patient about factors that precede symptoms (like food, medication, or other exposure) or that exacerbate or alleviate the symptoms, as well as how often the symptoms occur.

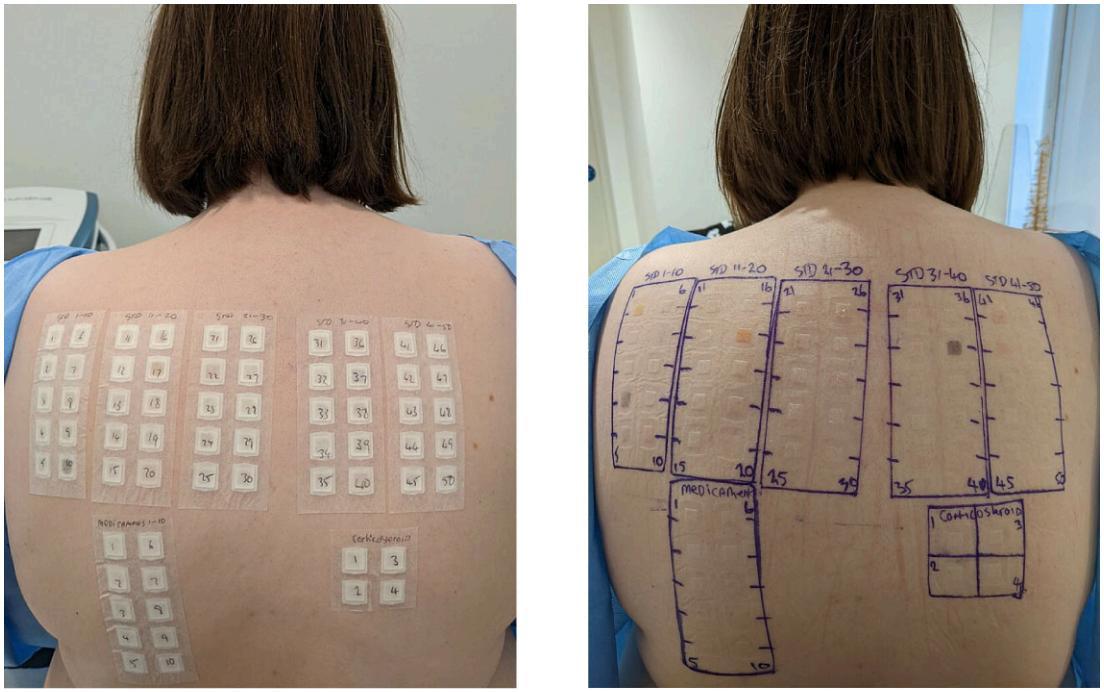
Diagnostics and Laboratory Values

Diagnostic tests for hypersensitivity include complete blood count (CBC) with differential, eosinophil count, total serum IgE, and skin tests. A complete blood count with differential frequently reveals white blood cells are elevated with infection or inflammation. Eosinophils are elevated in an allergic response and may be tested from either blood samples or smears of nasal secretions. High total serum IgE levels are indicative of an allergy disorder.

Other simple blood tests that are commonly used to detect a general state of inflammation include the C-reactive protein (CRP) and homocysteine level tests. These are commonly tested for in autoimmune conditions such as Hashimoto thyroiditis and even to detect cardiac risk for heart attacks. High levels of CRP or homocysteine have been shown to be correlated with early cardiac death.

Skin Tests

Skin tests may be performed as an intradermal injection or a superficial application of solutions at various sites (Figure 24.3). This is commonly done on a patient's back. Some allergy tests may have several solutions applied at different locations in one sitting. The solutions contain various antigens that represent an assortment of allergens known to cause reactions. Positive reactions are indicated by a wheal-and-flare reaction at the site. Depending on the severity of the reaction, some patients may also exhibit other symptoms like facial swelling or difficulty breathing.



(a) (b)

FIGURE 24.3 This patient is undergoing a skin test for allergies: (a) patches with a variety of allergens are applied to her back; (b) when the patches are removed, red marks indicate reactions to specific allergens. (credit a: modification of "Skin patch allergy test 01" by "Smirkybec"/Wikimedia Commons, CC BY 4.0; credit b: modification of "Skin patch allergy test 02" by "Smirkybec"/Wikimedia Commons, CC BY 4.0)

Skin test results should be combined with patient history, physical findings, and other lab tests like serum IgE, CBC with differential, and an eosinophil count in order for the physician to make a proper diagnosis. Not every person will react to a specific allergen. Precautions are necessary when performing skin tests. For example, avoid testing during times of bronchospasm, have emergency equipment available in the event of anaphylaxis, and perform scratch or prick tests before other methods in order to limit the risk of a systemic reaction. Other physical testing may include muscle testing, which is less invasive.

CLINICAL SAFETY AND PROCEDURES (QSEN)

QSEN Competency: Safety

Definition: "Minimizes risk of harm to patients and providers through both system effectiveness and individual performances" (Quality and Safety Education for Nurses, 2020, table 5).

Knowledge: The nurse will analyze basic safety principles, understand evidence-based practice standards, and reflect on unsafe nursing practices.

Skill: Demonstrate effective strategies to reduce the risk of harm. The nurse will:

- educate the patient (and guardian if patient is a minor) of the process and ensure consent has been obtained
- be aware of signs and symptoms related to allergic reactions
- be aware of signs and symptoms of anaphylaxis
- assess the patient is safe to proceed with testing; for example, ruling out current signs of bronchospasms or other signs of current allergic response
- remain with the patient
- have the appropriate equipment nearby in the event emergency intervention warranted
- perform scratch or prick tests before other methods in order to limit the risk of a systemic reaction

Attitude: The nurse will respect individual role in preventing errors by adhering to safe, evidence-based practice

standards.

(QSEN Institute, n.d.)

Nursing Care of Patients with Hypersensitivity

Nursing care for a patient with hypersensitivity will vary depending on the severity of the patient's reaction. In an acute care setting, if a patient is having a known or suspected reaction to a medication being administered intravenously, the medication must be immediately stopped. If the reaction is from a topical medication or solution, the patient's skin should be washed and patted dry. Removal of the offending trigger is key.

LINK TO LEARNING

Watch this video to learn more about the nursing procedure for monitoring patients receiving a blood transfusion (https://openstax.org/r/77BloodTransfus) for potential reactions.

Recognizing and Analyzing Cues

Per the Clinical Judgment Measurement Model, part of the nursing process includes recognizing and analyzing cues. When it comes to hypersensitivity reactions in an acute care setting, the nurse should assess for signs of dyspnea, anaphylaxis, rashes, fever, wheals or hives, erythema, flushing, pruritus, and edema. The nurse should also ask the patient if they are experiencing any difficulty breathing, any sudden changes in how they feel, or any other type of discomfort. The nurse should also be aware of when the symptoms started and when medication was given. The nurse should document the symptoms and onset after a medication has been administered. For patients reporting an allergy to a medication, the nurse must ask for onset, symptoms, and type of medication taken in order to assess if the patient is experiencing hypersensitivity or a side effect of the medication.

CLINICAL JUDGMENT MEASUREMENT MODEL

Recognize and Analyze Cues

Before they can recognize cues of an allergic reaction, nurses must make sure they have enough information about a patient's situation to correctly interpret the information and develop a plan of care. Suppose a patient claims to have an allergy to a certain medication. The nurse will need to assess further. For example, the nurse will need to ask what symptoms the patient experienced to determine if the patient's reaction was truly an immune response or a side effect of the medication. For example, a patient may report an allergy to hydrocodone by stating they experienced nausea after taking the medication. However, nausea is a common side effect of that medication; it is not necessarily a sign of an allergy. Only after considering all relevant information should the nurse move on to the next step of the Clinical Judgment Measurement Model: prioritizing a hypothesis and providing the appropriate education to the patient.

(National Council of State Boards of Nursing, n.d.)

Prioritizing Hypotheses, Generating Solutions, and Taking Action

If after analyzing cues the nurse determines the patient is having a reaction to a medication, the nurse must quickly prioritize interventions. Immediate interventions include discontinuing or removing the medication, managing the airway, administering oxygen as ordered, administering medications like epinephrine or diphenhydramine as ordered, and activating a rapid response in the event of anaphylaxis. The medication should also be documented as an allergy in the patient's chart, and the patient should be educated about the allergy, any related medications, and the need to report this medication at other health care facilities. For example, penicillin and amoxicillin are in the same drug category, so a patient who has an allergic reaction to one medication is likely to have a similar reaction to the other. If a patient was told they had a reaction to a medication as a child, but they are unsure of the reaction type, the nurse should err on the side of caution and document the medication as an allergy. Any interventions performed should also be documented.

Evaluation of Nursing Care for Patients with Hypersensitivity

Evaluation is an essential part of the nursing process. The nurse should compare observed outcomes against expected outcomes. This allows the nurse to evaluate for signs of improvement, decline, or no change in condition. The nurse would then use clinical judgment to assess whether the interventions were effective or if revised interventions are needed.

Evaluating Outcomes

Evaluating is not a one and done procedure; it is ongoing and multifactorial. The nurse should evaluate the effectiveness of every intervention. For example, if the patient experienced difficulty breathing, and the nursing intervention was to apply supplemental oxygen as ordered, the nurse should reassess the patient's respiratory status for improvement. The nurse should also assess whether any medications administered had the desired effect. For example, if diphenhydramine was given to aid in relieving pruritus, the nurse should ask the patient if itching has improved or gotten worse. The nurse should also watch for cues like scratching or grimacing. The nurse should document the evaluation of the interventions provided as well.

Medical Therapies and Related Care

As previously mentioned, standard interventions for an allergic reaction to a medication include immediately discontinuing the medication, assessing the airway, administering oxygen as ordered, and administering medications. The medication, along with the associated symptoms and their severity, should be documented as an allergy in the patient chart. The patient should be educated about the allergy, any related medications, and the need to report this medication at other health care facilities. Other related care would include finding alternative therapeutic medications that the patient can take to manage their health care needs.

Patients who are diagnosed with environmental allergies like pollen, various trees, plants, or grass may also be prescribed allergy injections to be given at regular intervals when those allergens are in season. Patients with allergies to insect stings or various food may also be prescribed an Epi-Pen (Figure 24.1) to keep with them in the event of an exposure to an allergen. The Epi-Pen injects a dose of epinephrine into the thigh; the medication then relaxes the muscles in the airway, stomach, intestines, and bladder. It is effective in reversing anaphylaxis that may present in allergic reactions. Some patients may be recommended to wear a medical alert bracelet to notify others of their allergies in the event of an emergency such as an extreme allergic reaction to peanuts, bee stings, or other allergens.

INTERDISCIPLINARY PLAN OF CARE

Interdisciplinary Plan of Care for Allergic Disorders

An interdisciplinary approach is important to take in response to any allergy. Various members of the health care team play key roles in maintaining patient safety and promoting optimal outcomes:

- Physician: oversee care of the allergy patient in collaboration with the interdisciplinary team
- Dietitian: evaluate nutritional status, assess food intake, advise on prevention, management, and treatment including elimination diets and long-term allergen intake
- Pharmacist: provide medication advice, check that correct medications are administered with proper technique
- Psychologist: provide in-depth psychological input and targeted interventions, apply coping strategies to support the patient and family
- Respiratory therapist: intervene when patient exhibits difficulty breathing or anaphylaxis, provide education

(Daniels et. al. 2021)

24.2 Allergic Rhinitis

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations for allergic rhinitis
- Describe the diagnostics and laboratory values in the disease of allergic rhinitis
- Apply nursing concepts and plan associated nursing care for patients with allergic rhinitis
- Evaluate the efficacy of nursing care for patients with allergic rhinitis
- Describe the medical therapies that apply to the care of allergic rhinitis

The most common type of respiratory allergy is **allergic rhinitis**, which is a localized allergic reaction in the sinuses, like hay fever or seasonal allergic rhinitis. It affects about one in eight United States adults and is among the top eleven percent of reasons for primary care encounters (Rosenfeld et al., 2015). About one-third of patients diagnosed with allergic rhinitis have correlated sinusitis, asthma, and conjunctivitis.

Pathophysiology

When antigens are inhaled or ingested, sensitization is initiated. Nasal mucosae react to re-exposure, which results in an infiltration of inflammatory cells. The primary chemical mediator with this type of allergic reaction is histamine. Vasodilation and enhanced capillary permeability lead to tissue edema and congestion.

Early diagnosis and appropriate treatment are necessary to reduce complication and alleviate symptoms. Since allergic rhinitis is provoked by airborne molds or pollens, it is distinguished by the seasonal occurrences described in (Table 24.2).

Season	Common Allergens
Early spring	Tree pollen (elm, poplar, oak)
Early summer	Grass pollen (redtop, timothy)
Early fall	Weed pollen (ragweed)

TABLE 24.2 Allergic Rhinitis by Season

Attacks typically start and end about the same time each year. Airborne mold spores require warm, moist weather; they generally appear in early spring and become more pervasive during the summer. These spores then dwindle off and fade away by the first frost in areas that experience drastic variations in seasonal temperatures. Therefore, in areas that do not endure freezing temperatures, these allergens can continue throughout the year.

Clinical Manifestations

Allergic rhinitis symptoms are persistent and vary seasonally. Rhinitis occurs as the result of an IgE-mediated immunologic response from an allergen transmitted through the respiratory tract. The number of patients with the allergic type of rhinitis rises with age and often appears with other disorders like asthma or cystic fibrosis. Allergic rhinitis can be severe and impedes a person's sleep, leisure, educational or professional success, and overall quality of life. On average, affected patients miss 1 to 2 workdays a year due to chronic rhinitis (Rosenfeld et al., 2015).

The primary symptoms of allergic rhinitis are nasal congestion, sneezing, nose and throat itching, and abundant amounts of serous nasal drainage. Other symptoms may include itching, watery eyes, hyposomnia, headache, and post-nasal drip. Chronic cases can negatively impact quality of life by interfering with sleep, causing absences from school or work, and interfering with daily activities.

Assessment and Diagnostics

An allergic rhinitis diagnosis is dependent on the patient's history, clinical examination, and diagnostic test results. Any reaction should be assessed and documented and include patient symptoms or discomfort, severity, treatments (if any), and response to interventions. Some clinics may use an intake assessment form that the patient completes that may include symptoms of the eyes, ears, nose, throat, chest, and skin that may be associated with an allergen

exposure. If a form is not used by the facility, the nurse should ask questions and assess for symptoms that may be associated with allergic rhinitis.

Diagnostics and Laboratory Values

Diagnostic tests include peripheral blood counts, total serum IgE, serum-specific IgE, nasal smears, nasal provocation tests, and **epicutaneous** (on the skin) and intradermal (just below the skin) skin testing. Nasal provocation tests are testing methods that reconstruct the upper airway response to natural exposure of irritants or allergens. Allergic causes of rhinitis will have elevated IgE and eosinophil. as well as positive allergen testing reactions. However, false-negative and false-positive skin testing results can occur and should therefore not be used alone to make a diagnosis.

Nursing Care of Patients with Allergic Rhinitis

Nurses play an important role in managing care for those with allergic rhinitis. Nursing care for this disorder includes performing an assessment to recognize and analyze cues, prioritizing hypotheses, generating solutions, taking action, and evaluating care and outcomes. If any outcomes have been deemed nonsatisfactory, then the nurse must start over, repeating the step of recognizing and analyzing cues and then following subsequent steps until a satisfactory outcome is reached.

Recognizing and Analyzing Cues

As part of recognizing and analyzing cues, the nurse should complete an assessment that includes a physical examination. The exam's findings may reveal sneezing, itching eyes and nose, lacrimation, occasional headache, or thin, watery nasal discharge. The assessment should also describe the seasonal changes in symptoms, medication history, and nature of relevant antigens. The nurse should also obtain subjective data from the patient about how they felt prior to experiencing symptoms like difficulty breathing, wheezing, tingling sensations, pruritus, hoarseness, hives, rash, erythema, and edema. Finally, the nurse should assess any emotional distress the patient may be experiencing. Stress can exacerbate allergic symptoms by causing the body to release histamines, making symptoms worse. The nurse should also document the patient's personal and family history of allergies, if any.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

After documenting the findings from the examination and patient history, the nurse should verify orders received from the provider. Interventions may be aimed at improving breathing pattern, education, managing potential complications, and promoting home-based care. Nursing interventions for improving breathing pattern may include avoiding individuals with an upper respiratory infection and modifying the patient environment to reduce or prevent allergy symptoms. For example, the nurse should ensure the patient environment is free of fragrances, such as perfumes or certain lotions, that can cause an asthma attack. The nurse should also educate the patient on the importance of maintaining their medication or treatment regimen to minimize allergy symptoms, and on the risks of nonadherence to this regimen (e.g., allergy exacerbation). The nurse can help the patient identify barriers to adherence as well as alternative solutions to overcome these barriers.

The nurse must also ensure the patient and family understand that adherence in medications and treatments are essential. Any missed medication or appointments can interfere with dosage adjustments needed to reach a therapeutic range. This also includes educating the patients and families on medications for allergy maintenance, like leukotriene modifiers, versus rescue medications for allergy exacerbation or seasonal flares, like antihistamines. This is important to avoid building up a tolerance to the medications, so that the medication is effective when flareups or allergy exacerbations are evident.

Monitoring and managing potential complications are vital roles in nursing care. Patients with allergies are at risk for anaphylaxis or experiencing any difficulty breathing due to the reaction alone or medications. The nurse should monitor the patient's respiratory rate and pattern (for example, signs of labored breathing, wheezing, shortness of breath, increased respiratory rate) and assess for abnormal lung sounds or any difficulty breathing. The patient's pulse rate and rhythm should also be monitored. Emergency medications and equipment should be readily available in the event of anaphylaxis.

Discharge planning is always part of the nursing plan of care. The patient and family should be instructed on self-care at home, including correct usage of medications, adherence to treatment schedules, and the importance of minimizing exposure to allergens. The purpose, procedure, and schedule of any prescribed regimens from the

provider should be reinforced to ensure the patient and their family members understand. Any side effects from medications or treatments should also be explained to the patient and family as well as each medication's name, dosage, frequency, and actions.

Evaluation of Nursing Care for Patients with Allergic Rhinitis

Evaluation of applied interventions is an essential part of the nursing process. The nurse should compare observed outcomes against expected outcomes, to evaluate for signs of improvement, decline, or no change in the patient's condition. The nurse would then use clinical judgment to assess whether the interventions for allergic rhinitis were effective or if revised interventions are needed.

Evaluating Outcomes

The nurse will want to evaluate expected outcomes for patients with allergic rhinitis. For example, the nurse can determine that the patient's breathing pattern is adequate if lung sounds are clear on auscultation, respiratory rate and pattern are normal, and the patient denies any symptoms of respiratory distress. The nurse can determine that the patient understands their condition by having the patient verbalize or reiterate the teachings regarding diagnosis, medications, treatment, schedule, home care, and measures to avoid allergens. The patient should also be able to demonstrate how to properly administer their medications and to describe relevant signs and symptoms such as anaphylaxis, angioedema, difficulty swallowing, wheezing, difficulty breathing, peripheral tingling, and urticaria (hives).

Medical Therapies and Related Care

There are several options when it comes to managing allergic rhinitis. Avoidance therapy may be used in an attempt to minimize an individual's exposure to allergens. Pharmacologic therapy is also used and includes adrenergic agents, antihistamines, second-generation H1 receptor antagonists, mast cell stabilizers, corticosteroids, and leukotriene modifiers. Another option is immunotherapy to treat or manage allergic rhinitis.

Avoidance Therapy

Avoidance of triggers can be effective in decreasing symptoms of allergic rhinitis. Measures and environmental controls include:

- using air conditioners, humidifiers, dehumidifiers, and air cleaners
- removing dust-collecting items like knickknacks, books, soft toys, furnishings, carpets, and window coverings
- regularly washing bedding
- regularly cleaning the house (dusting, vacuuming, mopping)
- maintaining a pet-free home or bedroom
- using pillow and mattress covers that are resistant to dust mites
- maintaining a smoke-free environment
- changing clothes when returning from outdoors
- regularly showering to remove allergens from skin and air
- using a nasal irrigation device or saline spray to limit allergens in the nasal passages

High-efficiency particulate air purifiers and vacuum cleaner filters also aid in limiting the number of allergens in an environment. The use of multiple avoidance measures can greatly reduce the severity of symptoms. It is not possible to completely avoid allergen exposure, so other therapies (pharmacologic and immunotherapy) may be needed.

LINK TO LEARNING

The American College of Allergy, Asthma, & Immunology maintains a web page on avoiding environmental allergies (https://openstax.org/r/77EnvirAllergy) that describes measures individuals can take to minimize exposure to common environmental allergens.

Pharmacologic Therapy

There are several pharmacologic options for treating allergic rhinitis. One type is an **adrenergic agent**, which is a

vasoconstrictor of mucosal vessels that may be given orally or applied topically in the nasal or ophthalmic mucosal vessels; the topical route has fewer side effects, but prolonged use can lead to rebound congestion. Examples of adrenergic agents include Afrin (nasal), Alphagen P (ophthalmic), and Sudafed or pseudoephedrine (oral). Nasal decongestants are applied topically to relieve nasal congestion. This route activates the alpha-adrenergic receptor sites of the smooth muscle of the nasal mucosal blood vessels and reduces mucosal edema, fluid exudation, and local blood flow. Eyedrops may also be an effective treatment option to relieve symptoms of eye irritation such as itching, burning, dryness, or redness. Side effects may include dysrhythmias, palpitations, hypertension, irritability, tremor, central nervous system stimulation, and tachyphylaxis, which is the acceleration of hemodynamic status.

An **antihistamine** is classified as an H1 receptor antagonist, or blocker, and is used to manage mild allergy disorders. The H1 antagonists attach to H1 receptors and prevent histamine action at those sites. They do not prohibit mast cells from releasing histamine, and they have no effect on H2 receptors.

Oral antihistamines are readily absorbed and are the most effective when given at the initial onset of symptoms, as they can prevent new symptoms from arising. These medications are effective in certain patients with hay fever, urticaria, mild asthma, and vasomotor rhinitis. The side effects include drowsiness, dry mouth, agitation, anxiety, urinary retention, anorexia, blurred vision, nausea, and vomiting. Antihistamines are contraindicated in people who are nursing, newborns, pregnant people, children, older adults, and those who experience worsening conditions or symptoms.

Unlike the first-generation H1 receptor antagonists, such as Benadryl (diphenhydramine), the second-generation—or nonsedating—H1 receptor antagonists attach to peripheral rather than central nervous system H1 receptors. This leads to less sedation. Examples include Zyrtec (cetirizine), Claritin (loratadine), and Allegra (fexofenadine).

Antihistamines may be combined with a decongestant to decrease nasal congestion. Most are available over the counter, like cetirizine/pseudoephedrine (Zyrtec-D) and loratadine/pseudoephedrine (Claritin-D). Side effects may include increased blood pressure; therefore, long-term use should be avoided in those with hypertension.

Mast cell stabilizers are as effective as antihistamines but not as effective as intranasal corticosteroids. It may take a week before benefits are noticed. This type of medication is used prior to or at the initial onset of symptoms. Intranasal cromolyn sodium (NasalCrom) acts by stabilizing the mast cell membrane, which decreases histamine and other mediators release in the allergic response. It also prevents the action of macrophages, monocytes, eosinophils, and platelets involved in immune responses. This medication is not effective in nonallergic rhinitis. Side effects are usually mild and include local burning or stinging sensations and sneezing.

Intranasal corticosteroids may be used in more severe cases of allergic and perennial rhinitis that do not respond to decongestants, antihistamines, or intranasal cromolyn. The route of administration of this medication is by meter-spray devices. Examples of corticosteroids include triamcinolone (Nasacort), beclomethasone (Beconase, Qnasl), budesonide (Rhinocort), and flunisolide (AeroSpan).

Corticosteroids have anti-inflammatory properties and are effective in controlling or inhibiting allergic rhinitis major symptoms. (A topical decongestant may be needed to clear passages prior to intranasal corticosteroid administration if there are blockages.) These medications may take several days to two weeks to take full effect and should not be used for more than 30 days. Adverse effects include drying of the nasal mucosa as well as a burning or itching sensation from the meter-spray device. Corticosteroids can suppress the immune system and should therefore not be used in those with tuberculosis or untreated bacterial lung infections, as they can worsen the infection. This suppression of host defenses also increases the risk of infection in those who use corticosteroids.

Leukotriene modifiers affect the inflammatory cycle and are designed for long-term use. Patients may take these medications daily and may have a rescue medication to treat symptom exacerbation. Examples of leukotriene modifiers include montelukast (Singulair) or zafirlukast (Accolate). These medications work by blocking leukotriene production and action and preventing asthma symptoms.

Immunotherapy

The aim of immunotherapy is to desensitize an individual from allergies by treating IgE-mediated diseases by allergen extract injections. This allergy vaccine therapy involves gradually increasing the quantity of specific allergens to a patient until a therapeutic dose is reached. The therapeutic range is one that reduces the severity of

symptoms a patient experiences with natural exposure to allergens. Immunotherapy is used as an adjunct therapy with symptomatic pharmacologic therapy and may be utilized when avoidance is not an option. The goals of this therapy include decreasing circulating levels of IgE, raising the level of blocking antibody IgG, and decreasing mediator cell sensitivity.

A positive skin test, positive allergy history, and the inability to avoid an allergen is indicative that immunotherapy is needed. This therapy may take three to five years to alter the allergic disorder. It can prevent the development or progression of allergy symptoms and asthma and is therefore considered to be a potentially preventive measure. It is essential that the patient understand immunotherapy as well as the significance of persisting with the therapy until immunocompetence is reached.

The three methods of immunotherapy include subcutaneous immunotherapy (SIT), epicutaneous immunotherapy (EPIT), and sublingual immunotherapy (SLIT). Immunotherapy should not be started during pregnancy; if a pregnant patient was already undergoing this immunotherapy prior to becoming pregnant, the dosage should not increase throughout the pregnancy. If a patient does not have a reduction in symptoms within one to two years, does not develop an increased tolerance to confirmed allergens, and is unable to reduce medication use to decrease symptoms, therapeutic failure is apparent. Failure of this therapy may be due to misdiagnosis, insufficient allergen doses, insufficient environmental controls, or newly evolved allergies.

Subcutaneous Immunotherapy

The most common method is subcutaneous immunotherapy. This therapy involves serial injections of extracts of one or more antigens that may be warranted based on an individual's allergy testing results. The treatment begins with injections of a very small amount of these extracts and gradually increases until the maximum tolerated dose is reached. Patients must be monitored for at least thirty minutes after administration due to the possibility of severe reactions like anaphylaxis. In the event of large, localized swelling at the injection site, the subsequent dose should not be increased, as this may be a sign of a possible systemic reaction. Once the maintenance dose has been reached, booster injections are given at two-to-four-week intervals over several years until the maximum benefit is reached. This timeline may vary depending on when the disease course is altered for the individual. Immunotherapy patients are monitored by a physician to determine when this therapy can be discontinued (Persaud et al., 2023).

Epicutaneous Immunotherapy

Epicutaneous immunotherapy is the delivery of an allergen to the epidermis. There is less risk of a systemic reaction with this type of immunotherapy as the area has less vascularity.

Sublingual Immunotherapy

Sublingual immunotherapy has been reported to have had therapeutic effects in as little as 16 weeks of treatment (Jacobsen et al., 2012). This therapy includes a buildup phase followed by a treatment plan of three times per week where the patient ingests a liquid containing allergen extract or a rapidly dissolving tablet. While systemic effects are rare, they have been reported in some patients who also reported a systemic effect with subcutaneous immunotherapy. Side effects may include upset stomach, nausea, irritating, and minor swelling or irritation in the mouth.

24.3 Types of Dermatitis

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors and clinical manifestations of various types of dermatitis
- Describe the diagnostics and laboratory values in diagnosing various types of dermatitis
- Apply nursing concepts and plan associated nursing care for patients with varying presentations of dermatitis
- Evaluate the efficacy of nursing care for the patient with dermatitis
- Describe the medical therapies that apply to treating various presentations of dermatitis

Inflammation of the skin, or dermatitis, encompasses several types of skin conditions with the same inflammatory reaction pattern and manifestations. Depending on the type of dermatitis, the reaction may be caused by an overactive immune system, genetics, allergies, or irritating substances. This section focuses on three types of dermatitis related to allergic disorders: contact dermatitis, atopic dermatitis (eczema), and dermatitis

medicamentosa (drug reactions).

Contact Dermatitis

Contact dermatitis is a type IV delayed hypersensitivity caused by an exogenic substance. It may be acute or chronic, and there are four types: allergic, phototoxic, irritant, and photoallergic. Most cases are due to extreme exposure to irritants like soaps, solvents, or detergents. This skin sensitivity may develop over prolonged or short periods of exposure time, and clinical manifestations may take hours or weeks to show.

Pathophysiology

Contact dermatitis begins when an allergen contacts the skin. Once the allergen has entered the stratum corneum, it is obtained by Langerhans cells. The antigens then undergo processing by these cells and are visible on their surfaces. Subsequently, the Langerhans cells move toward local lymph nodes, where the antigens encounter neighboring T lymphocytes for destruction. These lymphocytes may then migrate within the blood and into the epidermis. This process is collectively known as the sensitization phase of contact dermatitis. The elicitation phase occurs after re-exposure takes place. A cytokine-induced proliferation process is triggered when Langerhans cells that include the relevant antigen correspond with the antigen-specific T lymphocytes for that antigen. This proliferation produces a localized, inflammatory response (Murphy et al., 2022).

Clinical Manifestations of Contact Dermatitis

Clinical manifestations of contact dermatitis include erythema, pruritus, burning, edema, and skin lesions like vesicles and papules. A **vesicle** is a thin-walled sac filled with fluid, and a papule is a solid or cystic raised spot on the skin. Following these symptoms, the affected skin usually thickens, hardens, and experiences scaling. Severe cases may also have **hemorrhagic bullae**, blood-filled blisters. Bacterial infections can develop when the person rubs or scratches the affected areas, allowing pathogens to invade the skin. Systemic symptoms are unusual unless the reaction is extensive.

Atopic Dermatitis

Atopic dermatitis—also called atopic eczema or atopic dermatitis/eczema syndrome (AEDS)—is a type I immediate hypersensitivity disorder characterized by inflammation and hyperreactivity of the skin. Atopic dermatitis is often associated with a process known as the **atopic march**, which frequently leads to asthma, food allergy, or allergic rhinitis (Figure 24.4). Atopic march is the typical progression of allergic disease that begin early in life (American Academy of Allergy Asthma & Immunology, n.d.).

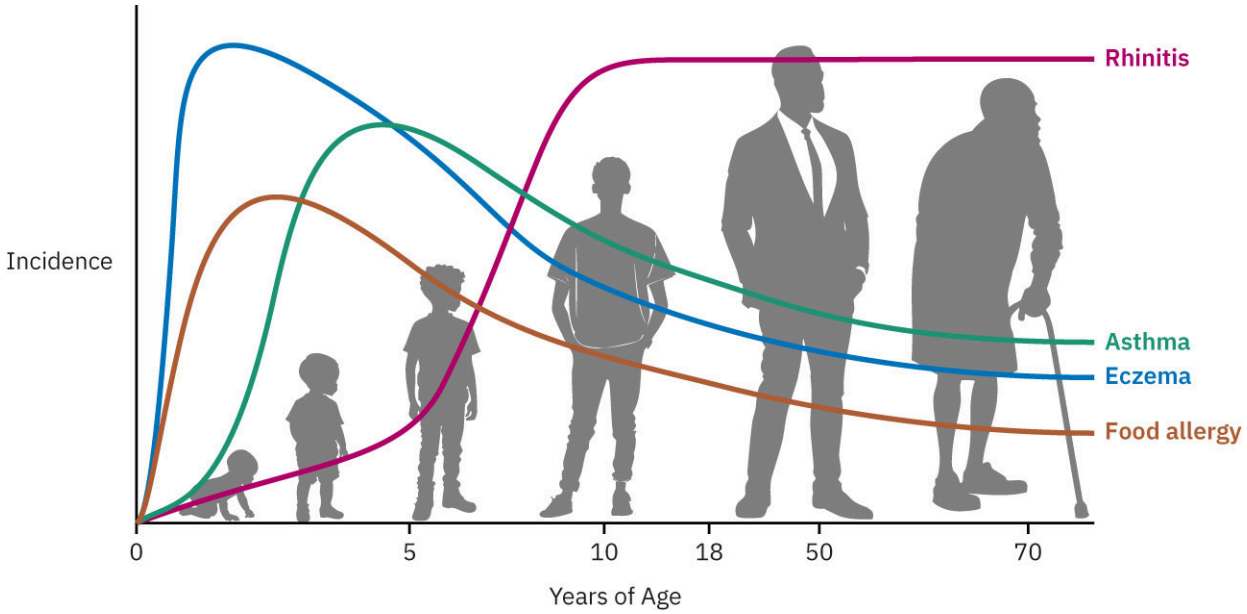


FIGURE 24.4 The atopic march is a sequence of allergic diseases that begins early in life. Eczema and food allergies peak at a young age and then diminish, while allergic rhinitis appears in later childhood and persists throughout adulthood. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Pathophysiology

Since this type of dermatitis belongs to the atopy family, there is a genetic tendency to develop allergic diseases associated with a heightened immune response, like asthma, eczema, and allergic rhinitis. The pathophysiology of this type of dermatitis is multifactorial and complex. The factors include alterations in cell-mediated immune responses, environmental factors, and IgE-mediated hypersensitivity. A key factor for atopic dermatitis is the presence of a loss-of-function mutation in the gene for the filaggrin protein. This can lead to severe atopic dermatitis due to a potential increase in trans-epidermal water loss, dehydration, and pH alterations. Those with eczema usually have a higher pH level than those that do not have eczema and can cause the skin barrier to not function as it should. Other genetic changes that may contribute to atopic dermatitis are an imbalance of Th2 to Th1 cytokines, which creates alterations in cell-mediated immune responses and can promote IgE-mediated hypersensitivity. Also, pH alterations lead to changes in enzyme activity which can trigger inflammation. In addition to loss-of-function mutations of filaggrin, harsh detergents, fragrances, and preservatives can alter pH levels of the skin (Kim et al., 2019).

Clinical Manifestations of Atopic Dermatitis

This type of eczema is characterized by itchy, chronic inflammation of the upper skin layers, as shown in Figure 24.5. In the acute phase, the rash may be red, oozing, and have crusted areas with occasional blisters present. The chronic phase may have dry, thickened areas. The rash may occur in one or more areas in adults and can spread to several areas on infants. The rash can vary in intensity, color, and location, but it is always itchy, which triggers scratching that ultimately makes the problem worse. Stress, irritation, and dry air can increase itchiness. Environmental triggers include harsh soaps, excessive bathing or hand washing, sweating, rough fabrics, wool, or *Staphylococcus aureus* present on the skin. Allergens like wheat, dairy, and eggs may also be a trigger for this reaction. Tears in the skin caused by scratching or rubbing can often lead to bacterial infections.

FIGURE 24.5 This person is using an ointment to treat their chronic eczema. (credit: "Applying steroid ointment to eczema – hand" by Kate Whitley/Welcome Collection, CC BY 4.0)

Dermatitis Medicamentosa (Drug Reactions)

Dermatitis medicamentosa is a type I hypersensitivity disorder resulting from drug reactions. Skin eruptions may not be evident until days after exposure to the antigen, but the reaction may also escalate quickly to anaphylaxis. Therefore, nurses should be sure to watch for adverse reactions when administering medications in order to provide emergent care immediately when warranted.

Pathophysiology

Dermatitis medicamentosa is a hypersensitivity manifestation of IgE-dependent (immunologic) or T cell–mediated (nonimmunologic) mechanisms initiated by topical, oral, or parenteral drug administration. Immunologic responses happen when specific antibodies or explicitly sensitized lymphocytes to a drug develop during the sensitization period, which can be up to 4 or 5 days after initial exposure.

Nonimmunologic responses may be caused by a variety of factors, including collective buildup of a drug; individual genetic predisposition; pharmacologic action of a drug; drug sensitization of the skin, producing a reaction with exposure to ultraviolet light; increased sensitivity to irritating topical solutions; and individual immune status (Knee & Sandberg-Cook, 2016).

Clinical Manifestations of Dermatitis Medicamentosa

With this disorder, skin eruptions may appear within minutes, hours, or days. The clinical manifestations are similar to the other types of dermatitis but may also include systemic symptoms like fever or difficulty breathing. Urticaria may also be present, as well as itching, burning sensations, and pain. A rash will not necessarily occur.

Assessment and Diagnostics

Dermatitis can be diagnosed by physical examination, exposure history, and patch testing. However, patch testing may not be indicated with drug reactions. The nursing assessment should include the patient's hobbies, occupation, exposure to irritants, and cosmetic use as well as the onset of symptoms. The physical examination should include the location and distribution of the lesions.

Diagnostics and Laboratory Values

Patch testing is indicated when the inflammation is not resolved with avoidance therapy. The patch test uses the Thin-layer Rapid Use Epicutaneous (T.R.U.E.) test. This test typically contains thirty-six allergens that are applied to the skin and then interpreted by a health care provider. Other patch testing options are available and may be applied using adhesive patches that contain small amounts of an allergen. The standard procedure for patch testing is to apply the patches to the skin on the back. The area is assessed for presence of edema, erythema, vesicles, crusts, and the size of the reaction in order to determine a positive or negative reaction. Patch testing is contraindicated with widespread, acute dermatitis. Other diagnostic testing may show elevated serum IgE and eosinophil levels.

Nursing Care of Patients with Dermatitis

Nurses play an important role in managing care for those with allergic dermatitis. Nursing care includes assessing the patient to recognize and analyze cues, prioritizing hypotheses, generating solutions, taking action, and evaluating care and outcomes. If any outcomes have been deemed nonsatisfactory, then the nurse must reassess. This process requires the nurse to start over with the Clinical Judgment Measurement Model with recognizing and analyzing cues and then following subsequent steps until a satisfactory outcome is reached.

Recognizing and Analyzing Cues

As part of recognizing and analyzing cues, the nurse should conduct a physical examination and complete the patient's personal and family history of allergies. Physical examination findings may reveal any of the clinical manifestations described previously. The nursing assessment should also include the patient's exposure risks in order to attempt to identify the irritant. The patient may be exposed to irritants at work, during leisure activities, or at home. Irritants may include chemical solvents, detergents, soaps, lotions, cosmetic products, or any other substance that may come in contact with the skin.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

After documenting findings from the examination and history, the nurse should verify orders received from the provider. Interventions may be aimed at improving symptoms, administering medications, educating the patient about avoidance therapy, and promoting home-based care. Nursing interventions for improving symptoms may include administering medications and eliminating identified or suspected irritants causing dermatitis. Medications may include topical corticosteroids for milder cases, oral antihistamines to relieve pruritus, system corticosteroids, topical hydrophilic creams or petrolatum to soothe the skin, and antibiotics for infection. Other interventions may include cool compresses or the application of aluminum acetate, which may be used to treat inflammation and itching. The nurse should also ensure the patient understands the importance of maintaining their medication or treatment regimen to improve and prevent symptoms. The nurse can help the patient identify barriers to adherence in order to help the patient identify alternative solutions. For example, a patient may not be able to avoid a certain chemical at their work; therefore, the nurse should help the patient identify ways to protect themselves, such as wearing personal protective equipment when handling the chemical. Discharge planning should include steps to educate the patient and family regarding self-care at home, including strategies for ensuring medications are used correctly, treatment schedules are adhered to, and exposure to irritants is minimized. The purpose, procedure, and

schedule of any prescribed regimens from the provider should be reinforced to ensure patients and family members all understand. The nurse should review the name, dosage, and frequency of all medications, as well as any side effects from medications or other treatments and actions to take in the event of side effects. Side effects may vary depending on the medication prescribed and have been covered previously in this chapter.

Other nursing interventions may be aimed at ensuring adequate coping with this diagnosis. Skin breakouts may be disturbing or embarrassing and have a negative impact on the patient's self-esteem. The nurse should ensure the patient understands the purpose of therapies aimed at treating dermatitis and measures that prevent the disorder from appearing. The nurse may also need to help the patient and family identify ways to incorporate care into their lifestyle.

REAL RN STORIES

Nurse: Rachel, BSN
Years in Practice: Ten
Clinical Setting: Family practice clinic
Geographic Location: The inner city of a large metropolitan area in Texas

A twelve-year-old girl was diagnosed with eczema at our family practice clinic. When I first walked in the room, she was quiet and withdrawn. When asking questions about when she first noticed her skin changes, she shrugged her shoulders and looked away. Her mom then stated that she had noticed her daughter went from bubbly and social to isolated and quiet. The mom expressed that felt she had been bullied at school. A part of our assessment with adolescents is to screen for depression. After I asked the screening questions, she admitted she had been having a hard time at school. She stated that kids made fun of her and said that her "rash" meant she was dirty, homeless, and poor.

I reinforced the education with her and reminded her about potential causes of dermatitis and that it is not a result of her status or being dirty. I let her know that while it is not curable, it is manageable. I asked her if she was okay with us coming up with a game plan together to manage her eczema. After she agreed, we went through a list of products she uses and identified lotions and soaps that are high in synthetic fragrances that can trigger dermatitis. We made a game plan together on how she can manage her eczema and strategized avoiding things that can trigger or worsen the eczema. We also discussed treatments that the doctor prescribed as well as managing stress as best she could, as stress is also a trigger. She looked at her mom and told her she would like to start counseling as well to learn coping skills. We also discussed exercises that aren't too strenuous to avoid worsening the eczema such as walking or swimming to help manage stress.

By the end of the conversation, she seemed hopeful and ready to take charge. I sent her home with a list of possible triggers and how to care for her eczema at home. I also provided her with a list of local counselors in the area that work with adolescents. She stated she was excited to get this managed and start wearing short sleeves to school again.

For patients with dermatitis medicamentosa, the known or suspected medication causing the reaction should immediately be discontinued. The patient should also be educated on the need to notify other providers and health-care facilities of the allergy and advised to wear a medical alert bracelet to alert providers in emergent situations when the patient is unable to speak. Since this reaction can have systemic symptoms, the nurse should be aware of the potential for anaphylaxis and have equipment readily available in case of emergency. The nurse should also monitor and treat systemic symptoms per provider orders.

Evaluation of Nursing Care for Patients with Dermatitis

Evaluation is an essential part of the nursing process. The nurse should compare observed outcomes against expected outcomes. This allows the nurse to evaluate for signs of improvement, decline, or no change in the patient's condition. The nurse should then use clinical judgment to assess whether the interventions were effective or if revised interventions are needed.

Evaluating Outcomes

The nurse will want to evaluate expected outcomes for patients with allergic dermatitis. The nurse can determine if symptoms have improved based on clinical examination as well as patient verbalization. The nurse can determine that the patient understands the education provided by having the patient verbalize or reiterate the teachings regarding diagnosis, medications, treatment, schedule, home care, and allergen avoidance measures. The patient should also be able to demonstrate how to properly administer their medications and to describe signs and symptoms to report, including anaphylaxis, angioedema, difficulty swallowing, wheezing, difficulty breathing, peripheral tingling, and urticaria.

Medical Therapies and Related Care

Medical therapies and related care should be individualized and may include identification and removal of irritants, avoidance therapy, phototherapy, aluminum acetate, cool compresses, systemic corticosteroids, topical corticosteroids, oral antihistamines like diphenhydramine, hydrophilic creams, petrolatum, antibiotics, and non-steroidal anti-inflammatory agents. Severely affected individuals may be prescribed immunosuppressants like cyclosporine or tacrolimus. Other therapies may include wearing cotton fabrics to decrease pruritus, bathing and washing with mild detergents, maintaining the room temperature from 68°F to 72°F, using humidifiers in winter, and avoiding irritants, animals, dusts, sprays, and perfumes. Patients can also manage their symptoms by keeping their skin hydrated through daily baths and using topical moisturizers that do not worsen or cause dermatitis. Patients with chronic eczema or psoriasis have also experienced relief from symptoms with ocean salt water (Peinemann et al., 2020).

24.4 Urticaria and Angioneurotic Edema

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations for urticaria and angioneurotic edema
- Describe the diagnostics and laboratory values for urticaria and angioneurotic edema
- Apply nursing concepts and plan associated nursing care for patients with urticaria and angioneurotic edema
- Evaluate the efficacy of nursing care for patients with urticaria and angioneurotic edema
- Describe the medical therapies that apply to the care of urticaria and angioneurotic edema

Hives, or **urticaria**, is a type I hypersensitivity allergic reaction involving the skin. Angioedema, or **angioneurotic edema**, is a condition that is manifested by urticaria and dispersed swelling of the deeper skin layers. Urticaria may appear anywhere on the body, while angioedema typically occurs in the face, hands, feet, or throat. These conditions often occur together, but each can appear without the presence of the other.

Urticaria

Urticaria is a common allergic disorder. This reaction is usually the result of exposure to triggers like food, medications, insect stings, physical stimuli, latex, blood transfusions, bacterial or viral infections, pet dander, plants, and pollen. Urticaria can appear anywhere on the body, including the mucous membranes, gastrointestinal tract, and the larynx.

Pathophysiology

When mast cells and basophils in the epidermis release chemical mediators, urticaria develops due to swelling from capillary and venous vasodilation. Urticaria may be immune-mediated or nonimmune-mediated. With immune-mediated mast cell activation, urticaria is caused by type I hypersensitivity reactions when the IgE antibodies attach to high-affinity mast cell and basophil cell surface receptors. With autoimmune disorders, urticaria is caused by mast cell degranulation due to IgE receptor antibodies crosslinking with IgE receptors. Nonimmune-mediated reactions may be caused by medications and by physical or emotional stimuli that activate mast cells (Benedetti, 2021).

Cold urticaria is a subtype of urticaria triggered by exposure to cold. The cold can be from water, objects, or weather. The cold stimulates mast cells to release histamine, causing capillary and venous vasodilation that results in

urticaria. Cold urticaria is either acquired or familial atypical, an autosomal dominant condition inherited from one affected parent.

Clinical Manifestations

As shown in Figure 24.6, urticaria is characterized by edematous, red or pink wheals that vary in size from 2 to 4 mm. Pruritus and angioedema may also be present with this disorder. This condition may appear within minutes and can take three weeks or longer to resolve. If the condition lasts for more than six weeks, it is considered chronic. Bradycardia or tachycardia and tachypnea may also be present. Severe cases may include wheezing, fever, fatigue, dry mouth, abdominal pain, diarrhea, tremors, night sweats, and lymphadenopathy (Benedetti, 2021). Symptoms of cold urticaria include fever, conjunctiva infection, chills, headache, sweating, and arthralgia (joint pain).

FIGURE 24.6 Urticaria is characterized by red or pink wheals that may appear on a variety of body surfaces. (credit: modification of "Urticaria" by Andy Carter/Flickr, CC BY 2.0)

Assessment and Diagnostics

The nursing assessment for urticaria should include vital signs as well as a review of the relevant body systems to identify potential causes and determine the case's severity.

- A head examination should assess for any signs of angioedema, **malar rash** (erythematous flat or raised rash across the bridge of the nose and cheeks), enlarged thyroid, dry eyes, dry mouth, or **lymphadenopathy**, and the oropharynx should be assessed for signs of infection.
- An abdominal examination should assess for any enlargement or tenderness of the kidneys or spleen as well as any masses.
- A neurological examination should assess for signs of tremor, hyporeflexia, or hyperreflexia.
- A musculoskeletal examination should assess for inflamed or deformed joints.
- A skin examination should assess for urticaria, hyperpigmentation, jaundice, cutaneous ulceration, or small papules.
- Hives should be assessed for distribution, size, frequency, and duration.

Nurses should also assess for potential triggers like exposure to medications, detergents, new foods, or recent infections, and ask if the patient has experienced prior lesions or has any complaints of pruritus, angioedema, dyspnea, or **rhinorrhea** (runny nose) (Benedetti, 2021).

Diagnostics and Laboratory Values

Diagnosis of urticaria is generally done with examination and history. In the event of persistent wheals that are not healing, a skin biopsy may need to be done to rule out **urticarial vasculitis**, inflammation of the small vessels of the skin. Patients presenting with urticaria may be referred for allergy skin testing as well as laboratory tests like complete blood count, liver tests, blood chemistries, and thyroid-stimulating hormone. Thyroid-stimulating hormone levels assessed as chronic urticaria can be associated with thyroid disease. For more severe cases or those

with abnormal laboratory results, further testing to assess kidneys, liver, intestines, and thyroid may need to be done (Benedetti, 2021). Cold urticaria may be diagnosed by applying ice cubes to the skin on the forearm for 1 to 5 minutes. A positive result is when urticaria is present at the application site. Those with cold urticaria may develop leukocytosis, increased C-reactive protein levels, or raised erythrocyte sedimentation rate (ESR).

Nursing Care of Patients with Urticaria

Nurses play an important role in managing care for patients with urticaria. The care plan should include performing an assessment to recognize and analyze cues, prioritizing hypotheses, generating solutions, taking action, and evaluating care and outcomes. If any outcomes have been deemed nonsatisfactory, then the nurse must reassess using the Clinical Judgment Measurement Model and start over with recognizing and analyzing cues and then following subsequent steps until a satisfactory outcome is reached.

Recognizing and Analyzing Cues

Recognizing and analyzing cues requires the nurse to complete a physical examination and take both a personal and family history of allergies. Physical examination findings may reveal any of the clinical manifestations described previously. A nursing assessment should include the patient's exposure risks in order to attempt to identify the triggering allergen.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

After documenting examination and history findings, the nurse should verify orders that are received from the provider. Interventions may be aimed at improving symptoms, administering medications, patient education about avoidance therapy, and promoting home-based care. Nursing interventions for improving symptoms may include administering medications and eliminating identified or suspected triggers causing urticaria. Medications may include antihistamines and system corticosteroids. Other interventions may include avoiding heat, stress, tight clothes, NSAIDs, and alcohol, as those items can further aggravate the reaction. Patients with cold urticaria should be educated to avoid cold stimuli. The nurse should also educate the patient on the importance of maintaining their medication or treatment regimen to improve and prevent symptoms. Since anaphylaxis is a risk with any allergic reaction, the nurse must assess and be ready to intervene in the event of this type of emergency.

Discharge planning includes educating the patient and family on self-care at home and the importance of adhering to the treatment plan, correctly using medications, and minimizing exposure to triggering allergens and other substances that aggravate the reaction. The purpose, procedure, and schedule of any prescribed regimens from the provider should be reinforced to ensure patient or family understanding. Any side effects from medications or treatments should also be explained to the patient and family, as well as the name, dosage, and frequency of each medication and actions to take in the event of side effects. Patients with any type of urticaria should have an EpiPen, as hives can progress to anaphylaxis. The patient and family should be educated on proper use of an EpiPen or use of inhaled epinephrine and the need to call 911 for emergency treatment and monitoring following usage.

REAL RN STORIES

Nurse: Monique
Years in Practice: Five
Clinical Setting: Postsurgical unit
Geographic Location: Central Illinois

One day, I was asked to go help start a second IV line on a patient on a post-surgical floor. When I entered the room, I introduced myself to the patient, verified patient name and date of birth, and explained that I was there to help get the second IV line started. I noticed only the patient and his wife were in the room at this time. When I got closer to the patient, I noticed urticaria and erythema on his left arm. I remembered being told in report that the patient had just been started on a Cardizem infusion 15 minutes prior. I immediately stopped the Cardizem drip, paged the assigned nurse, and asked the patient if he is having any difficulty breathing or noticed any swelling in his airway. After the patient denied the symptoms, I asked if I could look at his skin under his shirt as well. I noticed urticaria and erythema on his trunk and arms. The patient then stated that he was beginning to itch as well. The assigned nurse entered the room with normal saline and diphenhydramine. The assigned nurse then administered the

medication, and the patient stated his itching was resolved. The provider also came in the room to speak to the patient about alternative medications needed to convert his heart rhythm out of atrial fibrillation. They agreed on a new plan of care. The patient and his wife were thankful I walked in when I did and noticed the reaction, as a potentially severe reaction was avoided.

Evaluation of Nursing Care for Patients with Urticaria

Evaluation is an essential part of the nursing process. The nurse should compare observed outcomes against expected outcomes. This allows the nurse to evaluate for signs of improvement, decline, or if unchanged. The nurse should then use their judgment to assess whether the interventions were effective or if other interventions are needed.

Evaluating Outcomes

The nurse will want to evaluate expected outcomes for patients with urticaria. The nurse can determine if symptoms have improved based on clinical examination as well as patient verbalization. The nurse can determine the patient's level of comprehension by having the patient verbalize or reiterate the teachings regarding diagnosis, medications, treatment, schedule, home care, and allergen avoidance measures. The patient should also be able to demonstrate how to properly administer their medications and be able to describe signs and symptoms like anaphylaxis, angioedema, difficulty swallowing, wheezing, difficulty breathing, peripheral tingling, and urticaria that is not resolving.

Medical Therapies and Related Care

Medical therapies include avoiding the use of NSAIDs, limiting the use of items that can further aggravate the reaction, and eliminating the known or suspected allergen that caused the reaction. NSAIDs should be avoided as they can not only cause urticaria but also worsen urticaria that is present. Antihistamines may be prescribed as they suppress the release of histamine and help relieve itching and swelling associated with urticaria. Systemic corticosteroids may be prescribed for more severe cases but are not designed for long-term use. Corticosteroids inhibit histamine release by stabilizing mast cell membranes and reduce inflammatory effects of histamine. Treatments for cold urticaria include warmth, bed rest, and corticosteroids for acute cases.

Angioneurotic Edema

Angioneurotic edema is also known as angioedema. As previously stated, it can occur alongside the presence of urticaria, alone, or as a component of anaphylaxis. This disorder involves swelling of the deeper skin layers and most commonly occurs in the face (eyelids, lips, tongue, cheeks), hands, feet, genitalia or throat. Angioedema can also occur in mucous membranes of the gastrointestinal tract, bronchi, and larynx. While not as common, the reaction can also be found on the back.

Pathophysiology

Angioedema is either histamine-mediated or bradykinin-mediated. Histamine-mediated angioedema is more common; it occurs due to mast cell and basophil activation. When there is re-exposure to the causative allergen, the mast cells and basophils release histamine. Histamine contributes to an increase in vascular permeability, resulting in swelling of the deeper skin layers or mucosa (Memo & Tiwari, 2023).

Bradykinin-mediated angioedema is either due to genetics, angiotensin-converting enzyme inhibitor-associated angioedema, or acquired C1-inhibitor deficiency. Vascular permeability is increased and results in edema. Hereditary angioedema is either secondary to angiopoietin-1, F12 gene, plasminogen, or an unknown gene mutation that contributes to abnormal accumulation of C1 inhibitor or bradykinin (Memo & Tiwari, 2023).

Clinical Manifestations

Angioedema is characterized by non-pitting swelling of the dermis and subcutaneous layers. The reaction may appear suddenly, within a few seconds or minutes, or slowly over one to two hours. If the reaction occurs slowly, the patient may experience itching and burning sensations prior to the onset of swelling. This reaction generally resolves within twenty-four hours. While it is rare, a recurrence can occur at three- to four-week intervals.

Assessment and Diagnostics

A physical examination is required to assess for swelling, severity, and any resulting complications like dyspnea or anaphylaxis. Airway management is the top priority with angioedema as airway obstruction can lead to hypoxia,

brain damage, and death. The nurse should assess the head, feet, hands, airway, and back. The nurse should also ask the patient or family about onset, duration, difficulty breathing, associated symptoms such as urticaria, and any possible triggers, such as a medication or food. The use of angiotensin-converting enzyme (ACE) inhibitors should also be assessed in the event the angioedema is a result of ACE inhibitor–associated angioedema.

Diagnostics and Laboratory Values

The patient's vital signs should be measured in order to obtain a baseline and identify any potential complications. If the cause of angioedema is not clear, C1 inhibitor levels may need to be assessed to check for acquired C1-inhibitor deficiency. C1 inhibitor is a serine protease inhibitor. Low levels can result in angioedema and laryngeal edema. Additionally, complement factor C4 levels can be drawn and assessed. Low levels of C4 proteins may indicate hereditary angioedema or acquired C1-inhibitor deficiency (Frank, 2024).

Nursing Care of Patients with Angioneurotic Edema

Nurses play an important role in managing care for those with angioedema. Nursing care includes conducting an assessment to recognize and analyze cues, prioritizing hypotheses, generating solutions, taking action, and evaluating care and outcomes. If any outcomes have been deemed nonsatisfactory, then the nurse must reassess by using the Clinical Judgment Measurement Model and start over with recognizing and analyzing cues and then following subsequent steps until a satisfactory outcome is reached.

Recognizing and Analyzing Cues

As part of recognizing and analyzing cues, the nurse should conduct a physical examination and take the patient's personal and family history of allergies. Physical examination findings may reveal any of the clinical manifestations described previously. An assessment should also include the patient's exposure risks in order to attempt to identify the triggering allergen.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

After documenting findings from the examination and history, the nurse should verify orders that are received from the provider. Interventions may be aimed at improving symptoms, administering medications, educating the patient about avoidance therapy, and promoting home-based care. Nursing interventions for improving symptoms may include administering medications and eliminating identified or suspected triggers causing angioedema. If the cause is unknown, any nonessential medications should be stopped. Medications may include epinephrine in extreme cases or those causing difficulty breathing. Antihistamines or corticosteroids may also be prescribed. The nurse should also educate the patient on the importance of maintaining their medication or treatment regimen to improve and prevent symptoms. Since anaphylaxis is a risk with any allergic reaction, the nurse must assess and be ready to intervene in the event of this type of emergency.

Discharge planning includes educating the patient and family on self-care at home and on the importance of adhering to the treatment plan, correctly using medications, and minimizing exposure to the causative allergen. The purpose, procedure, and schedule of any prescribed regimens from the provider should be reinforced to ensure patient or family understanding. Any side effects from medications or treatments should also be explained to the patient and family, as well as the name, dosage, and frequency of each medication and actions to take in the event of side effects.

Evaluation of Nursing Care for Patients with Angioneurotic Edema

Evaluation is an essential part of the nursing process. The nurse should compare observed outcomes against expected outcomes. This allows the nurse to evaluate for signs of improvement, decline, or no change. The nurse would then use their judgment to assess whether the interventions were effective or if other interventions are needed.

Evaluating Outcomes

The nurse will want to evaluate expected outcomes for patients with angioedema. The nurse can determine if symptoms have improved based on clinical examination as well as patient verbalization. The nurse can determine comprehension by having the patient verbalize or reiterate what they have learned regarding diagnosis, medications, treatment, schedule, home care, and allergen avoidance measures. The patient should also be able to demonstrate how to properly administer their medications and be able to describe signs and symptoms like anaphylaxis, difficulty swallowing, wheezing, difficulty breathing, peripheral tingling, and urticaria.

Medical Therapies and Related Care

Management of angioedema may include the use of epinephrine, antihistamines, or corticosteroids. Most reactions resolve on their own within two to four days. However, the patient should be monitored for airway obstruction; a tracheostomy may be a necessary intervention should this type of emergency happen. For ACE inhibitor–associated angioedema, fresh frozen plasma and C1 inhibitor concentrate may be given.

24.5 Allergy to Food

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors and clinical manifestations for food allergies
- Describe the diagnostics and laboratory values for patients experiencing food allergies
- Apply nursing concepts and plan associated nursing care for patients with food allergies
- Evaluate the efficacy of nursing care for patients with food allergies
- Describe the medical therapies that apply to the care of patients with food allergies

Food allergies are IgE-mediated type I hypersensitivity reactions. Over 170 foods have been reported to cause allergic reactions. The most common foods known to cause food allergies are peanuts, tree nuts, seafood (lobster, crab, shrimp, clams, fish), chocolate, berries, eggs, wheat, and milk. The most severe reactions are caused by peanuts and tree nuts. Because foods may be hidden within a recipe and not obvious to those with a food allergy, the basic act of eating can pose a huge risk of escalating to anaphylaxis. For this reason, equipment used to prepare food with a particular allergen is considered contaminated and should not be used by people with an allergy to that allergen. For example, a bakery that makes desserts with peanuts in a particular mixer should use a completely different mixer to make desserts that do not contain peanuts.

LIFE-STAGE CONTEXT

Children with Food Allergies

At least six million children in the United States have reported food allergies. Children with peanut or tree nut allergies are at particular risk of a severe, even life-threatening reaction. It is extremely important that parents and caregivers report their children's allergies to the school, daycare, camp, and any other organization where the children may eat with others. Some children are extremely sensitive and can experience breathing difficulties if they only have skin contact with the allergen. Other children like to share their food and may not think to ask if something they are offered is contaminated.

Pathophysiology

Once exposed, the allergen facilitates the production of allergen-specific IgE antibodies by plasma cells. The allergen-specific IgE binds itself to the surface of mast cells and basophils. This is the process known as sensitization, when antibodies are formed. Upon re-exposure to the allergen, the allergen cross-links IgE molecules on the surface of the mast cell or basophil membrane. The mast cells and basophils then release several chemical mediators initiating the inflammatory phase, which may include pruritus and smooth muscle contraction of the respiratory tract, gastrointestinal tract, and blood vessels. Leukotrienes and prostaglandins are also released. Leukotrienes can cause smooth muscle contraction, bronchial constriction, mucus airway secretions, and wheal-and-flare skin reactions. Prostaglandins produce smooth muscle contraction, increased capillary permeability, and vasodilation. This chemical mediator sensitizes pain receptors and increases pain from inflammation. Prostaglandins also elicit inflammation and boost the effects of mediators in inflammatory responses.

LINK TO LEARNING

The Institute of Agriculture and Natural Resources at the University of Nebraska–Lincoln maintains a Food Allergy webpage (https://openstax.org/r/77FoodAllergy) with information about many kinds of food allergies. There is also a video explaining how food allergies develop.

Clinical Manifestations

Clinical manifestations of food allergies range from mild to life threatening. Reactions can occur within minutes to hours after exposure. A wide range of allergy and gastrointestinal symptoms may include urticaria, wheezing, cough, angioedema, laryngeal edema, dermatitis, diarrhea, nausea, vomiting, abdominal pain, itching, swelling (lips, tongue, palate), and cramps. Anaphylaxis may also occur with food allergies.

Assessment and Diagnostics

A thorough allergy history, physical examination, and diagnostic tests are needed for a food allergy workup. Skin testing may also be done to aid in a diagnosis. The patient may also be advised to maintain a food diary that list foods consumed and any symptoms that follow, and even to eliminate certain foods from their diet in order to monitor the effects.

Diagnostics and Laboratory Values

Skin testing may be performed to assist in identifying food allergens, though false-positive or false-negative results are possible. Serum IgE levels may also be assessed. Elevated results indicate the IgE-mediated response, confirming the allergy. If a food cannot be identified as the cause, some providers may recommend the patient follow a nonallergenic food diet, which eliminates known food allergens.

Nursing Care of Patients with a Food Allergy

Nurses play an important role in managing care for those with food allergies. Nursing care includes conducting an assessment to recognize and analyze cues, prioritizing hypotheses, generating solutions, taking action, and evaluating care and outcomes. If any outcomes have been deemed nonsatisfactory, such as patient continues to complain of itchiness, then the nurse must start over by recognizing and analyzing cues and then following subsequent steps until a satisfactory outcome is reached.

Recognizing and Analyzing Cues

As part of recognizing and analyzing cues, the nurse should complete a physical examination and take the patient's personal and family history of allergies. Findings from the physical examination may reveal any of the clinical manifestations previously. An assessment should also include the patient's onset of symptoms after exposure to the suspected or known allergen.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

After documenting the findings from the patient's examination and history, the nurse should verify orders that may be received from the provider. Interventions may be aimed at improving symptoms, administering medications, and educating the patient about avoidance therapy and emergency measures should they be necessary. Nursing interventions for improving symptoms may include administering medications and eliminating identified or suspected triggers causing a reaction. Medications may include epinephrine in extreme cases or when patients have difficulty breathing. Antihistamines or corticosteroids may also be prescribed. Since anaphylaxis is a risk with any allergic reaction, the nurse must assess and be ready to intervene in the event of this type of emergency. The nurse should also educate the patient on a variety of topics: signs and symptoms that indicate a medical emergency; instructions on how to use an EpiPen and read ingredients and food labels; and the importance of reporting their allergy to other people, including health care providers and servers at restaurants, and of asking questions before eating food they did not prepare.

Evaluation of Nursing Care for Patient with a Food Allergy

Evaluation is an essential part of the nursing process. The nurse should compare observed outcomes against expected outcomes. This allows the nurse to evaluate for signs of improvement, decline, or no change. The nurse would then use their judgment to assess whether the interventions were effective or if other interventions are needed.

Evaluating Outcomes

The nurse will want to evaluate expected outcomes for patients with food allergies. The nurse can determine if symptoms have improved based on clinical examination as well as patient verbalization. The nurse can confirm comprehension by having the patient verbalize or reiterate what they have learned regarding diagnosis, symptoms, medications, and allergen avoidance measures. The patient should also be able to demonstrate how to properly

administer their medications and be able to describe signs and symptoms such as anaphylaxis, difficulty swallowing, wheezing, difficulty breathing, peripheral tingling, and urticaria.

Medical Therapies and Related Care

The primary management for food allergies includes eliminating the allergen from the diet. Medications may be prescribed for those who cannot eliminate exposure or those who do not benefit from avoidance therapy. Medications include antihistamines, adrenergic agents, H1 blockers, corticosteroids, and cromolyn sodium. All patients with food allergies should have an EpiPen. A medical alert bracelet should also be worn. Service animals can be trained to recognize allergens that pose a threat to their owner. Service animals can scan foods and other areas for the scent of an allergen and alert their owner of the potential threat. Service animals would not be used for those with known allergies to pet dander. It is important to note that those with allergies can develop an allergy to an animal, so this option should be used with caution (US Service Animals Blog, 2022).

24.6 Allergy to Latex

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations for latex allergy
- Describe the diagnostics and laboratory values for patients with a latex allergy
- Apply nursing concepts and plan associated nursing care for patients with a latex allergy
- Evaluate the efficacy of nursing care for patients with a latex allergy
- Describe the medical therapies that apply to the care of patients with a latex allergy

The natural protein derived from the sap of the rubber tree, *Hevea brasiliensis*, is used to create **latex**. Latex allergies can cause allergic reactions including conjunctivitis, rhinitis, urticaria, asthma, contact dermatitis, and anaphylaxis. Since the introduction of latex-free and non-powdered latex gloves, the incidence of latex allergies has gradually decreased.

Latex gloves are made by converting liquid rubber into a stretchable solid form; the process uses more than 200 chemicals. The source of allergic reactions is thought to be from either the rubber proteins or the numerous chemicals used. Not all latex products have the capability to cause allergic reactions; it depends on the manufacturing method used to produce the products. Table 24.3 lists latex-free alternatives to the wide variety of home and hospital items that traditionally contain latex (Spina Bifida Association, 2009).

Category	Latex-Containing Items	Alternatives or Latex-Free Brands
Home Items	Balloons	Mylar balloons
	Condoms, diaphragms	Durex Avanti and Reality products, polyurethane products
	Diapers, incontinence pads	Always, Huggies
	Feminine hygiene products (pads, tampons)	Kimberly-Clark
	Wheelchair cushions	Sof Care or ROHO cushions
Hospital Items	Ace brown bandage	Ace white, cotton bandage
	Adhesive bandages, Telfa, Band-Aids	Cotton pads with plastic or silk tape, DuoDERM, 3M Active Strips
	Anesthesia equipment	Neoprene anesthesia equipment

TABLE 24.3 Items Containing Latex and Latex-Free Alternatives

Category	Latex-Containing Items	Alternatives or Latex-Free Brands
	Blood pressure tubing, cuff, bladder	Single-use nylon or vinyl cuffs, Clean Cuff, or use stockinette between equipment and patient clothing
	Catheters and catheter leg straps	Vinyl or all silicone IV catheters, Velcro straps for leg straps
	Crutch axillary pads, hand grips, tips	Cover silicone with tape or cloth
	EKG pads	Red Dot 3M EKG pads, Baxter
	Elastic compression stockings	Kendall SCD stockings (with stockinette)
	Enema kits that are prepackaged	Fleet Ready-to-Use, Therevac
	Gloves	Vinyl, neoprene, polymer, or Derma Prene gloves
	IV catheters	Deseret or Jelco IV catheters
	IV rubber injection ports	Cover Y-sites and ports and be careful not to puncture. Use 3 way stopcocks on plastic tubing.
	Levin tube	Salem sump tube
	Medication vials	Remove the rubber stopper
	Penrose drains	Zimmer Hemovac or Jackson-Pratt drains
	Pulse oximeters	Nonin oximeters
	Resuscitation bags	Puritan Bennett, Laerdal, and some Ambu
	Stethoscope tubing	Cover with latex-free stockinette; PVC tubing
	Suction tubing	Davol or Laerdal (PVC)
	Syringes	Abbott PCA Abboject or Terumo syringes
	Tapes	Micropore, Dermicel
	Theraband	Plastic tubing, new Theraband Exercisers
	Thermometer probes	Daitek covers
	Tourniquets	Avcor (X-Tourn) straps

TABLE 24.3 Items Containing Latex and Latex-Free Alternatives

Pathophysiology and Risk Factors

Latex allergy is a type I IgE-mediated immediate hypersensitivity due to the natural rubber proteins or other chemicals used in manufacturing. After sensitization, IgE antibodies stimulate mast cells and basophils to release histamine, prostaglandins, leukotrienes, and kinins that result in an immune response. Individuals at risk for latex allergies include patients with atopic allergies, patients with multiple surgeries, latex manufacturer workers, some health care workers, spina bifida patients, food handlers, automobile mechanics, hairdressers, and any individual in a profession that wears latex gloves. Those with latex allergies are at risk for developing an anaphylactic reaction. There have also been cross-reactions reported: some individuals with latex allergies are also allergic to bananas, avocados, kiwis, pineapples, mangoes, passionfruit, and chestnuts.

Latex exposure routes can be aerosol, parenteral, mucosal, percutaneous, or cutaneous, but allergic reactions are more likely to occur with parenteral or mucosal exposure. The most common reaction is from cutaneous contact by wearing latex gloves. The powder used in the latex gloves can also be a carrier of the rubber proteins; if the powder becomes airborne, it can lead to inhalation or settle on skin, clothing, or mucous membranes. Examples of mucosal exposure include catheters, airways, latex condoms, and nipples. Examples of parenteral exposure include hemodialysis equipment or intravenous lines.

Clinical Manifestations

There are various types of reactions to latex, including irritant contact dermatitis, allergic contact dermatitis, and latex allergy. Irritant contact dermatitis is not an allergic reaction. It is caused by skin damage due to irritation and the eventual loss of epidermoid skin. Causes include repetitive handwashing, extreme use of soaps, mechanical irritation like sweating or rubbing inside gloves, insufficient hand drying, exposure to chemicals used in the manufacturing process, and the alkaline pH of powdered gloves. Clinical manifestations may be acute (erythema, edema, burning, pruritus, or discomfort) or chronic (dry, thickened, and cracked skin).

Allergic contact dermatitis is usually the result of the chemicals used in the manufacturing process. The reaction is not life-threatening; it generally has a slow onset and occurs 18–24 hours after exposure and resolves within 3–4 days. Severe reactions may happen with re-exposure. Clinical manifestations include edema, erythema, pruritus, crusty thickened skin, blisters, and skin lesions.

Latex allergy can be due to inhalation or contact with the skin, mucosa, or internal tissues. Severe reactions are common with parenteral or mucosal exposure types. However, any individual with this type I hypersensitivity is at risk for anaphylaxis. Clinical manifestations can occur within minutes after exposure and may include localized edema, erythema, edema, pruritus, and systemic reactions such as anaphylaxis. Other clinical manifestations may include urticaria, rhinitis, flushing, laryngeal edema, bronchospasm, conjunctivitis, asthma, angioedema, extreme vasodilation, anaphylaxis, cardiovascular collapse, and even death.

Assessment and Diagnostics

Latex allergies are diagnosed by history and diagnostic test results. Laboratory tests may include serum-specific IgE, ELISA, EIA, or the level of Hevea latex–specific IgE antibodies. The preferred method for individuals with contact allergies is skin patch testing, which can detect sensitization to chemicals used in the manufacturing process. Only clinicians with expert experience with T.R.U.E. or other skin tests should perform this type of testing in the event of systemic or local allergic reactions.

Nursing Care of Patients with a Latex Allergy

Nurses play an important role in managing care for those with latex allergies. Nursing care includes completing a nursing assessment to recognize and analyze cues, prioritizing hypotheses, generating solutions, taking action, and evaluating care and outcomes. If any outcomes have been deemed nonsatisfactory, then the nurse must reassess using the Clinical Judgment Measurement Model and start over with recognizing and analyzing cues and then following subsequent steps until a satisfactory outcome is reached.

Recognizing and Analyzing Cues

As part of recognizing and analyzing cues, the nurse should conduct a physical examination and obtain the patient's personal and family history of allergies. Physical examination findings may reveal any of the clinical manifestations previously. An assessment should include the patient's onset of symptoms after exposure to the suspected or

known allergen. The nurse may use a latex allergy screening form with any new patient who may be exposed to latex.

LINK TO LEARNING

This link from Martin One Source provides a general assessment form (https://openstax.org/r/77LatexAllergy) that may be used to screen for a latex allergy.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

After documenting findings from the physical examination and patient history, the nurse should verify orders received from the provider. Interventions may be aimed at finding alternative, latex-free products for those with known or suspected latex allergies, as well as improving symptoms with reactions and educating patients about avoidance therapy and emergency measures.

Nurses working in surgery settings, emergency departments, or intensive care units should pay special attention to the possibility of patients with latex allergies. Review (Table 24.3) for alternatives to latex-containing items found within the hospital setting. Patients who have a reaction require interventions to improve symptoms, which vary depending on the reaction type. Any new latex reactions should be documented as a new allergy. Medications may include epinephrine in extreme cases or when patients have difficulty breathing. Antihistamines or corticosteroids may also be prescribed. Since anaphylaxis is a risk with any allergic reaction, the nurse must assess and be ready to intervene in the event of this type of emergency.

The nurse should educate the patient on signs and symptoms that warrant a medical emergency, instructions for using an EpiPen, and the need to report this allergy to other health care providers. The nurse should also advise the patient to be careful around foods that have been reported to be cross-linked with latex allergies, such as bananas, avocados, pineapples, and chestnuts. The nurse should identify items in the patient's home that may include latex and help identify alternatives.

Evaluation of Nursing Care for Patients with a Latex Allergy

Evaluation is an essential part of the nursing process. The nurse should compare observed outcomes against expected outcomes. This allows the nurse to evaluate for signs of improvement, decline, or if unchanged. The nurse would then use their judgment to assess whether the interventions were effective or if other interventions are needed.

Evaluating Outcomes

The nurse will want to evaluate expected outcomes for patients with latex allergies. The nurse can determine if symptoms have improved based on clinical examination as well as patient verbalization. The nurse can determine comprehension by having the patient verbalize or reiterate the teachings regarding diagnosis, symptoms, medications, and allergen avoidance measures. The patient should also be able to demonstrate how to properly administer their medications and be able to describe signs and symptoms to report like those of anaphylaxis, difficulty swallowing, wheezing, difficulty breathing, peripheral tingling, and urticaria.

Medical Therapies and Related Care

The primary management for latex allergies includes eliminating exposure. Patients with latex allergies should have a kit containing an EpiPen and antihistamines, and they should wear a medical alert bracelet. The patient should report this allergy to any health care facility where they are receiving care, local paramedic and ambulance companies, and their employer in the event of a job duty that may require exposure to latex. The patient can also get labels for their vehicle to alert paramedics or police about their allergy in the event of an emergency. The patient should also be encouraged to carry latex-free gloves with them. Those with type I latex hypersensitivity may not be able to continue their occupation if avoidance is not an option. Patients may also need to be referred to local support groups due to the significant changes that may take place with avoidance therapy or loss of occupation.

24.7 Anaphylaxis

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations for anaphylaxis
- Describe the diagnostics and laboratory values in the disease of anaphylaxis
- Apply nursing concepts and plan associated nursing care for patients with anaphylaxis
- Evaluate the efficacy of nursing care for patients with anaphylaxis
- Describe the medical therapies that apply to the care of anaphylaxis

Anaphylaxis generally occurs within minutes to hours of exposure and involves the integumentary, respiratory, cardiovascular, and gastrointestinal systems. The Allergy and Asthma Network (2023) reported that 1.5 to 5.1 percent of the American population has undergone anaphylaxis. It also found that medications are responsible for 34 percent of anaphylactic cases, food is responsible for around 31 percent, and insect stings for 20 percent. However, in infants, food is responsible for 73 percent of anaphylactic cases, while medications are responsible for only about 20 percent. The fatality rate of anaphylaxis in around 0.3 percent in the United States (Allergy and Asthma Network, 2023).

Pathophysiology

Anaphylaxis involves the rapid release of several chemical mediators from the degranulation of basophils and mast cells after subsequent exposure to a certain antigen. Common causes of anaphylaxis include foods, insect stings, latex, medications, and other pharmaceutical agents such as serums or skin testing antigens. IgE cross-linking and the resulting accumulation of high-affinity receptors induce the rapid release of stored chemical mediators. The inflammatory response is then facilitated by TNF-alpha (tumor necrosis factor) as a pre-formed and late-phase reactant (McLendon & Sternard, 2023).

The physiology of the released chemical mediators varies in the anaphylactic response. Histamine increases vasodilation and vascular permeability, resulting in reduced blood flow to the tissues. The body tries to compensate for this by increasing the heart rate and cardiac contraction. Prostaglandin D acts as a bronchoconstrictor that impacts both the cardiac and pulmonary vascular constriction. This prostaglandin also contributes to the reduction in blood flow to the tissues due to peripheral vasodilation. Leukotrienes contribute to vascular permeability and bronchoconstriction and induce alterations in the airway. Flushing, angioedema, urticaria, mucosal inflammation and edema, and hypotension may also be a result of the physiologic effects from these chemical mediators. The platelet-activating factors also function as a bronchoconstrictor and intensify vascular permeability (McLendon & Sternard, 2023).

Clinical Manifestations

Anaphylaxis reactions include multiple organ systems at once and may range from mild to moderate to severe. Generally, the faster the onset of symptoms, the more severe the reaction is. Subsequent reactions may not be as severe as the first. The severity is dependent on the degree of allergy and allergen dose exposure. Clinical manifestations of anaphylaxis are summarized in (Table 24.4).

Reaction	Clinical Manifestations
Mild	Peripheral tingling, warm sensations, and a sense of fullness in the throat and mouth. Periorbital swelling, sneezing, nasal congestion, pruritus, and tearing from the eyes may also occur. This category of symptoms typically begins within the first two hours after exposure.
Moderate	May include all of the mild symptoms, with the addition of anxiety and flushing. Some moderate reactions may be more severe and include edema of the airways or larynx, dyspnea, wheezing, cough, and bronchospasm. This category of symptoms also generally begins within the first two hours of exposure.
Severe	Also referred to as anaphylactic shock. This type of reaction has a rapid onset and includes any symptoms from the mild or moderate categories. Those symptoms rapidly progress to bronchospasm, severe dyspnea, edema of the larynx, cyanosis, and hypotension. Other symptoms include dysphagia, seizures, abdominal cramping, vomiting, and diarrhea may also occur. Untreated anaphylaxis can lead to respiratory arrest and coma.

TABLE 24.4 Anaphylaxis Reactions

Assessment

Assessment of anaphylaxis includes monitoring the patient for signs and symptoms of an anaphylactic reaction, as previously described. This assessment should include airway, breathing, circulation, level of consciousness, and exposure of the skin. Allergy testing may also be necessary to identify the allergen.

Diagnostics and Laboratory Values

Diagnostic tests to identify an allergen include skin tests, total serum IgE, complete blood count with differential, and eosinophil count. A blood test to check the amount of tryptase may also be used in the diagnosis of anaphylaxis. This enzyme is mainly found in mast cells and can be elevated up to three hours after an anaphylactic reaction. Plasma histamine levels and SC5b-9, a terminal compliment complex, may also be elevated after a severe reaction. Other diagnostics and laboratory values include vital signs, labs to assess the functionality of organs that may be impacted by the reaction, and x-rays or CT scans to assess those organs for damage or improvement.

Nursing Care of Patients with Anaphylaxis

Anaphylaxis is a life-threatening condition that occurs immediately after exposure to an allergen. Acute nursing care should be rapidly initiated to increase the patient's survival rate. Immediate treatment includes administration of any ordered medication, airway assessment and management, and circulation support.

Recognizing and Analyzing Cues

Per the Clinical Judgment Measurement Model, part of the nursing process includes recognizing and analyzing cues. When it comes to anaphylactic reactions in an acute care setting, the nurse must assess the patient for any signs and symptoms of anaphylaxis in order to quickly intervene. The nurse should assess airway, breathing, vital signs, signs of increasing edema, and respiratory distress. If the patient is able to speak, the nurse should also ask if they are experiencing any difficulty breathing, any sudden changes in how they feel, or any other type of discomfort. The nurse should also be aware of when the symptoms started and when exposure to the relevant medication, food, or other allergen happened, and document this information.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

If after analyzing cues the nurse determines the patient is in anaphylaxis, the nurse must promptly prioritize interventions. The nurse must notify the rapid response team or the provider per facility policy. Rapid interventions include intubation, emergency medication administration, intravenous line insertion, fluid administration, and oxygen administration, which may be necessary when the patient is experiencing cyanosis, wheezing, or dyspnea. Medications that may be administered during anaphylaxis include epinephrine, which should be injected as a 1:1,000 dilution subcutaneously in the thigh. A much lower concentration may be given continuously through intravenous solution following the initial subcutaneous injection. Epinephrine works quickly to improve breathing

and blood pressure by causing vasoconstriction. It also quickly reverses urticaria and reduces edema that may occur.

In addition to epinephrine, antihistamines and corticosteroids may be given. Other vasopressor agents, such as norepinephrine, dopamine, and vasopressin, and other volume expanders, such as lactated Ringer's and normal saline, may also be administered to maintain blood pressure and hemodynamic status. Patients with bronchospasms, asthma, or cardiopulmonary obstructive diseases may be given aminophylline and corticosteroids to improve airway patency and function. Other immediate interventions include discontinuing or removing the medication or other allergen. In the event of cardiac arrest, cardiopulmonary resuscitation (CPR) will need to be performed.

LINK TO LEARNING

Hamilton Health Sciences provides an excellent resource on how to use an EpiPen (https://openstax.org/r/77EpiPenUse) for patients at risk of anaphylaxis and their families. There is also a video demonstrating how to administer an EpiPen to oneself or others.

Evaluation of Nursing Care for Patients with Anaphylaxis

Evaluation is an essential part of the nursing process. The nurse should compare observed outcomes against expected outcomes. This allows the nurse to evaluate for signs of improvement, decline, or no change. The nurse would then use their judgment to assess whether the interventions were effective or if other interventions are needed. Documentation is required to include each intervention given and the patient's response.

Evaluating Outcomes

The nurse should evaluate the effectiveness of all interventions to determine if any other interventions are necessary. For example, if the patient experienced difficulty breathing, the nurse should reassess the patient's respiratory status for improvement. For example, the nurse will want to assess for improvements with wheezing or labored breathing. The nurse should check for improvements with the rate and oxygen saturation. The nurse should also assess whether any medications administered had the desired effect. If epinephrine was given, the nurse should reassess the patient's vital signs; for example, the patient should have an increase in blood pressure and heart rate.

Medical Therapies and Related Care

Patients who have experienced anaphylaxis and have received epinephrine should be taken to an emergency room if they are not already present in a hospital setting; once there, they should be monitored for four to eight hours for rebound or delayed reactions (Tupper & Visser, 2010). Patients with severe allergic reactions may be prescribed an EpiPen in the event of re-exposure to the allergen. Those individuals may also be advised to wear a medical alert bracelet.

Once the patient has recovered, the nurse should provide education to notify the patient of what happened and why they should notify their other health care facilities of the allergy. The patient and their family members should be taught how to use an immunotherapy and be able to demonstrate the proper administration. The patient and their family should also be aware of the need call 911 in order to receive care after anaphylaxis and be monitored for rebound or delayed reactions.

Summary

24.1 Allergic Response

- Allergic responses are inappropriate or exaggerated responses of the body's immune system to a substance that is usually harmless. The body has multiple defense mechanisms that recognize and eliminate antigens, or foreign proteins that invade the body.
- Hypersensitivity is an abnormal heightened response to any type of stimulus; it does not normally occur after the initial exposure to an allergen.
- Type I hypersensitivity, or anaphylactic response, is facilitated by IgE antibodies produced by the immune system in response to allergens like dust mites, animal dander, and pollens.
- Type II, or cytotoxic-mediated, responses against cell surface and extracellular matrix proteins are facilitated by IgG and IgM antibodies.
- Type III, or immunocomplex, reactions are also facilitated by IgG and IgM antibodies that react with soluble antigens to create antigen-antibody complexes.
- Type IV, or delayed-type, hypersensitivity is a reaction where tissue damage is the result of T cell–dependent macrophage activation and inflammation.

24.2 Allergic Rhinitis

- The most common type of respiratory allergy is allergic rhinitis.
- The symptoms of allergic rhinitis are nasal congestion, sneezing, nose and throat itching, abundant amounts of serous nasal drainage, itching, watery eyes, hyposomnia, headache, and post-nasal drip.
- An allergic rhinitis diagnosis is dependent on the patient's history, as well as a clinical examination and diagnostic test results.
- There are several options when it comes to managing allergic rhinitis.
- Avoidance therapy may be used to minimize an individual's exposure to allergens and thereby decrease symptoms.
- Pharmacologic therapy is also used; medications include adrenergic agents, antihistamines, second-generation H1 receptor antagonists, mast cell stabilizers, corticosteroids, and leukotriene modifiers.
- Another option to treat or manage allergic rhinitis is immunotherapy, which includes subcutaneous immunotherapy (SIT), epicutaneous immunotherapy (EPIT), and sublingual immunotherapy (SLIT).

24.3 Types of Dermatitis

- Dermatitis, or inflammation of the skin, encompasses several types of skin conditions with the same inflammatory reaction pattern and manifestations.
- The three types of dermatitis related to allergic disorders are contact dermatitis, atopic dermatitis (eczema), and dermatitis medicamentosa (drug reactions).
- Contact dermatitis is a type IV delayed hypersensitivity that may be caused by extreme exposure to irritants like soaps, solvents, and detergents.
- Atopic dermatitis, also called atopic eczema, is a type I immediate hypersensitivity disorder. Atopic dermatitis may be caused by food allergens and environmental triggers.
- Dermatitis medicamentosa is a type I hypersensitivity disorder resulting from drug reactions.
- Dermatitis can be diagnosed by physical examination, exposure history, and patch testing (except for widespread reactions and drug reactions).
- Medical therapies and related care should be individualized and may include identification and removal of irritants, avoidance therapy, phototherapy, aluminum acetate, cool compresses, systemic corticosteroids, topical corticosteroids, oral antihistamines like diphenhydramine, hydrophilic creams, petrolatum, antibiotics, and nonsteroidal anti-inflammatory agents.
- Severely affected individuals may be prescribed immunosuppressants.
- Other measures include wearing cotton fabrics to decrease pruritus, bathing and washing with mild detergents, moisturizing after bathing, maintaining the room temperature from 68°F to 72°F (20°C to 22.2°C), using humidifiers in winter, and avoiding irritants, animals, dusts, sprays, and perfumes.

24.4 Urticaria and Angioneurotic Edema

- Urticaria is a type I hypersensitivity allergic reaction involving the skin.
- Angioneurotic edema is a condition that is depicted by urticaria and dispersed swelling of the deeper skin layers.
- Urticaria may appear anywhere on the body, while angioedema typically occurs on the face, hands, feet, or throat.
- These conditions often occur together but can appear without the presence of the other.
- These conditions may be the result of exposures to allergens like food, medications, insect stings, physical stimuli, latex, blood transfusions, bacterial or viral infections, pet dander, plants, and pollen.
- Urticaria is characterized by edematous red or pink wheals that vary in size from 2–4 mm. Pruritus and angioedema may also be present with this disorder.
- The assessment should include vital signs as well as a review of the systems to identify potential causes or a severe case.
- Interventions may be aimed at improving symptoms, administering medications, educating the patient about avoidance therapy, avoiding aggravating factors, and promoting home-based care. Nursing interventions for improving symptoms may include administering medications and eliminating identified or suspected triggers. Medications may include antihistamines and system corticosteroids.
- Angioedema involves swelling of the deeper skin layers; it most commonly occurs in the face (eyelids, lips, tongue, cheeks), hands, feet, genitalia, or throat.
- Angioedema can also occur in mucous membranes of the gastrointestinal tract, bronchi, and larynx.
- Angioedema is either histamine-mediated or bradykinin-mediated and is characterized by non-pitting swelling of the dermis and subcutaneous layers.
- Interventions may be aimed at improving symptoms, administering medications, educating the patient about avoidance therapy, and promoting home-based care. Medications may include epinephrine in extreme cases or those causing difficulty breathing. Most cases resolve on their own within two to four days. Antihistamines or corticosteroids may also be prescribed.

24.5 Allergy to Food

- Food allergies are IgE-mediated type I hypersensitivity reactions.
- The most common foods known to cause food allergies are peanuts, tree nuts, seafood, chocolate, berries, eggs, wheat, and milk.
- Reactions may include smooth muscle contraction, bronchial constriction, mucus airway secretions, wheal-and-flare skin reactions, increased capillary permeability, and vasodilation.
- Symptoms of food allergies range from mild to life-threatening and include a variety of allergy and gastrointestinal problems.
- All patients with food allergies should have an EpiPen and a medical alert bracelet.

24.6 Allergy to Latex

- Latex is a natural rubber protein derived from the sap of the rubber tree.
- There are various types of reactions to latex, including irritant contact dermatitis, allergic contact dermatitis, and latex allergy, which is a type I IgE-mediated immediate hypersensitivity due to the natural rubber proteins.
- Latex allergies can cause a variety of reactions including erythema; edema; burning; pruritus; dry, thickened, and cracked skin; blisters; skin lesions; urticaria; rhinitis; flushing; laryngeal edema; bronchospasm; conjunctivitis; asthma; angioedema; extreme vasodilation; anaphylaxis; cardiovascular collapse; and even death.
- Those in settings where patients have a risk of exposure should assess the patient for latex allergies and may use a screening tool to aid in identifying if there is a risk. If there is a risk, the nurse should identify latex-free alternatives.
- Other interventions may be aimed at improving symptoms caused by reactions and educating at-risk individuals about avoidance therapy, emergency measures, and foods reported to be cross-linked with latex allergies.
- Primary management is avoiding exposure.

- Patients with latex allergy should have a medical alert bracelet and a kit containing antihistamines and EpiPen.
- The patient should also report this allergy to emergency services and health care facilities and may be advised to put a warning label on their vehicle.
- Patients may also need to seek new employment or be referred to support groups.

24.7 Anaphylaxis

- Anaphylaxis is a potentially life-threatening, type I hypersensitivity response resulting from the rapid release of IgE-mediated chemicals in an attempt to eliminate a triggering allergen.
- Anaphylaxis generally occurs withing minutes to hours of exposure and involves the integumentary, respiratory, cardiovascular, and gastrointestinal systems.
- Common causes of anaphylaxis include foods, insect stings, latex, medications, and other pharmaceutical agents like serums or skin-testing antigens.
- Clinical manifestations include bronchoconstriction, increased vascular permeability, flushing, angioedema, urticaria, mucosal inflammation and edema, and hypotension.
- Anaphylaxis reactions include multiple organ systems at once and may range from mild to moderate to severe.
- Mild reactions include peripheral tingling, warm sensations, and a sense of fullness in the throat and mouth. Periorbital swelling, sneezing, nasal congestion, pruritus, and tearing from the eyes may also occur.
- Moderate reactions include any of the mild symptoms, with the addition of anxiety and flushing. Some moderate reactions may be more severe and include edema of the airways or larynx, dyspnea, wheezing, cough, and bronchospasm.
- Severe reactions are referred to as anaphylactic shock. They have a quick onset and include any symptoms from the mild or moderate categories. Those symptoms rapidly progress to bronchospasm, severe dyspnea, edema of the larynx, cyanosis, and hypotension. Other symptoms like dysphagia, seizures, abdominal cramping, vomiting, and diarrhea may also occur.
- Assessment for anaphylaxis should include airway, breathing, circulation, level of consciousness, and exposure of the skin.
- When it comes to anaphylaxis reactions in an acute care setting, the nurse must assess the patient for any signs and symptoms of anaphylaxis in order to quickly intervene. The nurse should assess airway, breathing, vital signs, signs of increasing edema, and respiratory distress.
- Interventions include intubation, emergency medication administration, intravenous line insertion, fluid administration, and oxygen administration. CPR may be warranted in the event of cardiac arrest. Antihistamines and corticosteroids may also be given in adjunction with epinephrine.
- Patients who have experienced anaphylaxis and received epinephrine should be taken to an emergency room, if not already present in a hospital setting, as they should be monitored for rebound or delayed reactions.

Key Terms

adrenergic agent pharmacological agent that acts as a mucosal vessel vasoconstrictor
allergen foreign substance that is usually harmless
allergic disorder common pathological condition due to IgE-dependent immunological reactions to an allergen
allergic rhinitis localized allergic reaction in the sinuses
allergy inappropriate or exaggerated responses of the immune system to a foreign substance that is usually harmless
anaphylaxis potentially life-threatening, type I hypersensitivity response resulting from the rapid release of IgE-mediated chemicals in an attempt to eliminate a triggering allergen
angioneurotic edema condition that is characterized by urticaria and diffuse swelling of the deeper skin layers
antibody protein substance that protects against antigens
antihistamine H1 receptor antagonist
Arthus reaction acute, localized inflammatory response that typically occurs after vaccination
atopic march typical progression of allergic disease that begins early in life
atopy genetic tendency to develop allergic diseases
B cell regulatory cell in the immune system; also called B lymphocyte
bradykinin chemical mediator that stimulates nerve fibers and causes pain
eosinophil leukocyte that protects the body from parasites, allergens, and other organisms

epicutaneous on the skin
haptens incomplete antigens
hemorrhagic bullae blood-filled blisters
hypersensitivity abnormal heightened response to any type of stimulus
immunoglobulin protein capable of acting as an antibody
latex substance made from natural protein derived from the sap of the rubber tree
leukotriene chemical mediator that initiates the inflammatory response
malar rash butterfly rash
mast cell specialized type of white blood cells that are found throughout the body
papule solid or cystic raised spot on the skin
Peyer patches small groupings of lymphoid follicles in the small intestine
prostaglandin unsaturated fatty acid with a wide range of biologic activity
rhinorrhea runny nose
sensitization process in the allergic response where IgE antibodies attach to receptors on the surface of immune cells after an allergen has been introduced
serotonin chemical mediator that acts as a forceful vasoconstrictor and bronchoconstrictor and is formed in platelets
T cell cell that assists B cells in the immune response; also called T lymphocyte
urticaria type I hypersensitivity allergic reaction involving the skin and characterized by wheals
urticarial vasculitis inflammation of the small vessels of the skin
vesicle thin-walled sac filled with fluid

Assessments

Review Questions

1. What immunoglobulin is involved in allergic disorders?
    a. IgA
    b. IgD
    c. IgE
    d. IgM

2. What seasons are associated with allergic rhinitis? Select all that apply.
    a. Spring
    b. Summer
    c. Fall
    d. Winter

3. A patient is undergoing subcutaneous immunotherapy. If the patient exhibits localized swelling at the injection site, what conclusion should the nurse draw?
    a. This is an expected finding.
    b. This could be a sign of a possible systemic reaction.
    c. The next dose should be increased to aid in the patient reaching a therapeutic level.
    d. The injection site should be rubbed to get the swelling to go down.

4. What kind of hypersensitivity is atopic dermatitis?
    a. Type I
    b. Type II
    c. Type III
    d. Type IV

5. A nurse has provided education to a patient newly diagnosed with atopic dermatitis. What is an example of a statement by the patient that demonstrates to the nurse the patient understands the teaching?
    a. “Atopy means the reaction is on the outer area of the skin.”

b. "Atopy means there is a genetic tendency to develop allergic diseases."
c. "Atopy means the inflammation is improving."
d. "Atopy means the reaction only occurs due to contact with an allergen."

6. A nurse is caring for a patient who is experiencing angioedema. What does the nurse know is the highest priority?
a. monitoring blood pressure and heart rate
b. managing the airway and ensuring patency
c. assessing possible triggers
d. performing tests to identify the trigger

7. An experienced nurse provides education to a new nurse at an allergy and asthma clinic. What is an example of a statement by the patient that demonstrates to the experienced nurse that they understand the teaching?
a. "Urticaria is always accompanied by angioneurotic edema."
b. "Urticaria always occurs without the presence of angioneurotic edema."
c. "Angioneurotic edema only results due to urticaria."
d. "Urticaria and angioneurotic edema may occur with the other or alone."

8. A patient states they do not understand why a food they ate previously did not cause an allergic reaction but now it does. What is an example of a response the nurse should give?
a. "You did have a reaction following your first exposure, but you must not have recognized it."
b. "Your body formed antibodies during the first exposure, so the subsequent exposure resulted in an immune response."
c. "This is probably a one-time occurrence, so you can eat the food again without risk."
d. "Your symptoms were probably caused by a stomach virus rather than a food allergy."

9. A patient with a peanut allergy asks why the nurse recommends reading food labels. What is an example of a statement that demonstrates an appropriate explanation by the nurse?
a. "Some foods that you may not expect, like certain salad dressings, contain peanuts as one of the ingredients."
b. "If a patient is allergic to peanuts, then they are probably allergic to all the common food allergens like wheat, dairy, and shellfish."
c. "Some foods may be manufactured in a facility that also makes foods with peanuts in it."
d. "Foods that contain tree nuts may pose a similar reaction as peanuts."

10. What foods have been reported to have cross-reactions for those with latex allergies? Select all that apply.
a. Melons
b. Bananas
c. Avocados
d. Kiwis
e. Strawberries

11. What is an example of a vasopressor agent that may be given during anaphylaxis?
a. Normal saline
b. Dopamine
c. Aminophylline
d. Prednisone

12. A nurse has administered epinephrine to a patient in anaphylactic shock. What is an indicator to the nurse that the epinephrine is having a therapeutic response?
a. dilates the patient's airways
b. blocks histamine effects
c. increases blood pressure and heart rate

d. prevents anaphylaxis from occurring with subsequent exposures to the antigen

Check Your Understanding Questions

1. Describe the steps a nurse would take in the event of a patient experiencing an allergic response.
2. Describe how avoidance therapy may be used to manage allergic rhinitis.
3. Describe the diagnostic testing completed for allergic rhinitis.
4. Describe the pathophysiology of dermatitis medicamentosa.
5. What are techniques the nurse can use to evaluate the efficiency of provided nursing education?
6. Describe the pathophysiology of latex allergies.

Reflection Questions

1. What information should a nurse include when educating a patient or their family about a diagnosis of a new allergy disorder?
2. The nurse is caring for a patient on a medical-surgical floor, the patient is started on IV penicillin as ordered by the provider. The patient calls the nurse into the room after 20 minutes due to the presence of severe urticaria and pruritus. What should the nurse do first?
3. What information should a nurse include when educating a patient or their family about a new diagnosis of allergic rhinitis?
4. What clinical manifestations can occur with food allergies?
5. What testing may be performed with assessing for latex allergies?
6. Diagnostic tests to identify an allergen include skin tests, total serum IgE, complete blood count with differential, and eosinophil count. A blood test to check the amount of what enzyme may also be used in the diagnosis of anaphylaxis?

What Should the Nurse Do?

Ms. Stein, a 32-year-old female, presents at a local drop-in medical facility with a chief complaint of recurrent episodes of sneezing, nasal congestion, and itchy eyes for the past six months. She reports a medical history of seasonal allergies but notes an escalation in symptoms despite over-the-counter antihistamine use. Vital signs reveal a blood pressure of 120/80 mm Hg, heart rate of 78 beats per minute, respiratory rate of 16 breaths per minute, and a temperature of 98.6°F. During the assessment, Ms. Stein describes her symptoms worsening during spring and fall seasons. Her family history includes a maternal aunt with a history of severe allergies.

1. What key symptoms reported by Ms. Stein suggest the possibility of hypersensitivity, and how do they align with the objective related to the role of immunoglobulins in the allergic process?
2. What nursing interventions can be generated to address Ms. Stein's immediate symptoms, and how do they align with the application of nursing concepts in hypersensitivity care?

Mr. Pratt, a 45-year-old male, has presented to the dermatology clinic with a complaint of persistent, pruritic rash on his hands and forearms for the past month. He reports a history of occasional eczema flare-ups during the winter months but notes that the current episode is more severe and does not respond to over-the-counter creams. Mr. Pratt's vital signs are stable, with a blood pressure of 122/78 mm Hg, heart rate of 82 beats per minute, respiratory rate of 16 breaths per minute, and a temperature of 98.9°F. Physical examination reveals erythematous, scaly lesions with occasional vesicles on the dorsal aspects of both hands. He denies any recent exposure to new substances or known allergens.

3. Considering Mr. Pratt's medical history and the localized nature of his rash, what factors contribute to the analysis of potential triggers and the differentiation of various types of dermatitis.
4. What nursing interventions can be generated to address Mr. Pratt's immediate symptoms, and how do these interventions align with the application of nursing concepts in dermatitis care?
5. Based on the prioritized hypotheses, what specific actions should you as a nurse take to confirm the

diagnosis, and how do these actions correlate with the description of diagnostics and laboratory values in dermatitis?

6. A patient exhibits urticaria after taking penicillin for an infection. What should the nurse do?

Alex, a 10-year-old male, is brought to the emergency department by his mother due to a severe allergic reaction after consuming a peanut-containing snack. Alex presents with facial swelling, urticaria, and difficulty breathing. His mother reports that he has a known history of peanut allergy diagnosed in early childhood. Vital signs indicate a blood pressure of 110/70 mm Hg, heart rate of 120 beats per minute, respiratory rate of 24 breaths per minute, and oxygen saturation of 92%. Alex has no previous history of anaphylaxis, and he has not taken any medication or used an epinephrine auto-injector prior to arrival.

7. Given the urgency of the situation, what are the priority hypotheses for the nurse to consider in managing Alex's anaphylactic reaction, and how do they guide immediate nursing actions?
8. What nursing interventions can be generated to address the immediate needs of Alex, and how do they align with the application of nursing concepts in managing acute food allergies?
9. Based on the prioritized hypotheses, what specific actions should the nurse take to stabilize Alex and initiate ongoing care, and how do these actions correlate with the description of diagnostics and laboratory values for food allergies?
10. A nurse is setting up the operating room for a patient with a known latex allergy. What should the nurse do?
11. The nurse is caring for a patient on an intensive care unit. The patient has critically low hemoglobin and hematocrit levels. The nurse has begun administering a blood transfusion as ordered by the provider. The patient begins to exhibit wheezing and shortness of breath. What should the nurse do?

Competency-Based Assessments

1. Role play the appropriate procedure for performing skin testing on a patient.
2. Summarize the education a nurse would provide to a patient on managing dermatitis at home.
3. Prepare a 10-minute presentation on the clinical manifestations of urticaria.
4. Create a bullet point list of educational content for a patient recently diagnosed with food allergies.
5. Summarize education a nurse may need to provide to a patient recently diagnosed with latex allergies.
6. Prepare a 10-minute presentation on the pathophysiology of anaphylaxis.

CHAPTER 25

Preoperative Care

FIGURE 25.1 Surgical handoff, a crucial aspect in perioperative nursing, is generally performed with the patient, preoperative nurse, intraoperative nurse, and an anesthesia provider. This process ensures patient safety by verifying name, date of birth, surgery being performed and site, allergies, and any potential limb alerts. (credit: Airman 1st Class Kyle Johnson, U.S. Air Force/Joint Base Elmendorf-Richardson, Public Domain)

CHAPTER OUTLINE

INTRODUCTION Perioperative means the time around surgery. It is used to encompass the time between going to the facility, having the procedure, and then returning home afterward. This chapter will discuss the first of three phases included in perioperative nursing. There are multiple pathways a patient may take before ending up in the operating room. As health care has evolved through the years, one major advancement is the more streamlined, less invasiveness of surgery. Many procedures are now performed in outpatient settings, such as surgical clinics, allowing for a quicker return home and less downtime for the patient. Some common surgical procedures are planned, such as elective cosmetic procedures, while other surgeries are emergent and unplanned, such as for life-threatening conditions or injury. There is often overlap when it comes to the provided care between the phases of preoperative nursing, which will be discussed further in this chapter. In order to provide safe, quality, and competent patient care, the nurse must thoroughly understand the different phases of preoperative care.

25.1 Preadmission Assessment and Education

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Identify important aspects of preadmission care
- Discuss education and planning for patients scheduled for an operation

The first of the three phases included in perioperative nursing is the preoperative phase. The **preoperative phase** starts when the decision is made to proceed with a surgery or procedure and ends when the patient arrives in the operating room. Many hospitals or surgery centers have a presurgical services department to facilitate preadmission testing. The preadmission assessment and interview provide the nurse and anesthesia provider the opportunity to ensure the patient is safe to continue with the procedure or surgery. Based on the patient's health history, the nurse may identify any potential risks, as well as any further testing that may be needed as outlined by the anesthesia provider or surgical protocol. Preadmission testing also identifies any risks or interventions that may need to be addressed prior to the procedure. At this time, the nurse will also need to obtain information pertinent to the procedure, such as consent forms (as appropriate).

The preoperative phase is a crucial phase to ensure patient safety throughout the surgical process. This phase requires the nurse to utilize clear and concise communication, strong teamwork, and flawless patient assessment skills to promote the patient's best achievable outcomes and avoid errors or adverse events. The preoperative nurse should ensure the correct site and surgery are verbalized by the patient in their own words, as well as documented correctly both in the patient's chart and the surgical consent. The surgeon is responsible for marking the correct limb or surgical site. The actual marking must be verified by both the preoperative and intraoperative nurse. Omitting these crucial steps could result in surgery being performed on the wrong site. Information that the preoperative nurse obtains will be communicated to the intraoperative nurse during patient handoff (see Chapter 26 Intraoperative Care).

Preadmission Care

Preadmission care the nurse provides will vary depending on the route the patient takes to the operating room (OR). In the case of a planned procedure, there will be a scheduled appointment 7-10 days, or even up to a month, beforehand. At this time, the nurse will gather information, which includes the patient's demographics, health history, and any diagnostic and laboratory testing. This can be done via phone or in person depending on facility protocol. For example, a patient having a total joint replacement may need to come in person to the facility because the preadmission testing is extensive, as it includes several laboratory tests, an ECG, chest X-ray, and special preoperative instructions. Whereas a patient having a less invasive procedure, like a colonoscopy, is able to complete the preadmission screening over the phone.

When a patient is already in the facility (for example, admitted as an inpatient, in the ER, or in observation), the preoperative nurse is responsible for doing the interviewing and assessment at the patient's bedside. The nurse will also need to ensure that any necessary diagnostic tests have been completed, and teaching is provided prior to the procedure.

Assessment and Testing

The timing of the nurse's assessment and any preop testing may be days to weeks before a planned surgery, or day-of in the case of a more emergent surgery. The tasks are the same, whether it is happening far in advance or just hours before the procedure takes place.

The nurse should have the patient state in their own words the type of surgery they are having. This is the first safety check to see if the orders sent match the patient's description of what needs to be completed, especially when it comes to ensuring the correct site for the surgery to be performed.

A nurse's assessment needs to cover a great deal of information, including:

- Demographics (e.g., address, date of birth)
- Allergies
- Height, weight
- Current medications

- Health history
- Social history (including smoking, alcohol, and recreational drug use)
- Surgical history (including any potential problems with anesthesia—e.g., trouble waking up after surgery, nausea, vomiting, or malignant hyperthermia)
- Pertinent family history (such as diabetes, hypertension, or previous problems with anesthesia)
- History of falls
- Presence of any metal or implants in the body
- Use of corrective devices
- Advanced directive (if patient has one)

The nurse uses current, past, and family health histories obtained during the assessment to identify risks or the need for alternative medications due to an allergy. Height and weight are used to determine a person's body mass index (BMI) to decide if a transfer device or specialty bed will be needed.

Special precautions may be implemented for patients who report previous complications with anesthesia. If a patient reports having a previous lumpectomy or mastectomy, or has an AV fistula or graft in place, the nurse should assess for any restrictions with blood pressure or IV placements in either limb. If there are contraindications, the nurse will need to create a limb alert per facility protocol. Examples of a limb alert include a colored band to communicate to other care team members that the identified extremity cannot be used for blood draws or IV placement.

By gathering this information, the nurse can help confirm preventive steps are taken to ensure the patient's safety. Preadmission assessments can determine if anesthesia medications need to be adjusted from normal dosages, or if the patient may require longer monitoring in the post-anesthesia care unit (PACU) for potential reactions. The anesthesia provider may adjust the medications given during surgery for patients with a history of postoperative nausea and vomiting or trouble waking up from anesthesia, or for patients identified as those who use alcohol daily. The nurse will assess a baseline pain level acceptable to the patient, so the postoperative nurses can take that into consideration when planning a mutual, patient-centered care plan for pain management after surgery.

Preoperative tests ordered may vary, depending on the provider's orders and the nurse's assessment. Some surgeons request their own testing or simply ask the facility to follow their anesthesia protocol. Anesthesia protocols typically include:

- ECG for patients that have a cardiac history or above a certain age
- Pregnancy test for women of childbearing age
- Basic metabolic panel for those with diabetes and those with hypertension
- Fasting blood glucose for patients with diabetes the morning of surgery
- Chest X-rays for those who complain of chest pain or shortness of breath that is new or worsening
- Cardiologist clearance may be required for patients with a history of cardiac conditions or any identified dysrhythmia

Again, it's important to note that the timeline for testing may depend on the path the patient takes to the OR. If the procedure is planned, some testing may be performed prior to the date either at the patient's primary care provider or at an outpatient facility. While the patient may have some flexibility, the testing needs to be done in time for the anesthesia team or surgeon to view the results before surgery. In emergent cases or when the patient is are already admitted to a facility, testing will be done in hospital on the day of the procedure.

Education and Planning

Preoperative education includes what to expect on the day of surgery, like arrival time versus surgical start time, explaining the need for necessary tasks prior to the surgical start time. The nurse may start by helping the patient visualize what they can expect the day of their procedure. The nurse might explain that once the patient checks in at the designated area on the day of surgery, the preoperative nurse will escort them back to a preoperative room to change clothes, sign consents, place an IV, administer medications, and perform any preparation to the surgical site, such as a surgical scrub or wipe down with antimicrobial solutions.

The patient should be educated to remain **NPO**, which means to take nothing by mouth, after midnight the night before surgery. The nurse will teach that this includes not smoking, not swallowing water or toothpaste, and not

using gum or hard candies the morning of surgery. Anything eliciting extra saliva or gastric juice production will need to be avoided. The patient will need to know which medications should not be taken, and which medications can be taken. For example, a patient with diabetes may be instructed to take only half a dose of insulin the night before surgery and to take diabetic medications or insulin the morning of surgery as normally prescribed. If there are any medications the patient should take the morning of surgery, the nurse will instruct the patient to take medications with a very small sip of water. The nurse must make sure that the patient understands that it's not only prescribed medications that may need to be stopped or changed—over-the-counter medications and supplements should also be discussed. Some common over-the-counter medications like aspirin and certain herbal remedies can thin the blood, while others may interact with medications given during or after surgery. For example, a surgeon may request that a patient stop using aspirin for up to 10 days prior to the procedure to reduce the risk of bleeding, though it will depend on the reason for aspirin therapy. (Plümer et al., 2017) If the patient reports having sleep apnea, the preoperative nurse will advise the patient to bring their sleep apnea machine with them, as it will be incorporated into their plan of care.

The nurse will also need to assess the patient's psychological state, as this can impact their readiness to learn and receive preoperative education. For example, a patient who has never had a medical procedure before may be anxious and scared. Or a patient who is in a great deal of pain will likely be distracted and unable to focus. Until the patient's pain is controlled and they are in a more relaxed state, they will not be able to fully understand the information that the nurse is providing to them about their care. The nurse should determine the readiness of the patient and provide appropriate nursing interventions to each patient scenario. Patients who are cognitively or developmentally impaired will need a guardian present for education.

REAL RN STORIES

Nurse: Joseph
Years in Practice: Eleven
Clinical Setting: Outpatient surgical center
Geographic Location: Northeastern US

Joseph has been an RN for over a decade and knows the importance of talking to patients before surgery. This is not just to get key information about their health, but to make sure the patient fully understands what to expect before and after the procedure. Here, Joseph describes a thoughtful conversation with a patient, which resulted in discovering a key detail that could have had negative effects on their surgical outcomes had it remain unidentified.

It was a really busy day; I had a huge list of patients who needed to be called for preadmission assessment and interviews. I was already late because I had run into some construction on the way to work, causing a delay. The first few calls I made, I caught myself feeling rushed and tense. I was "checking off the boxes" but didn't feel like I was doing everything I could to make sure the patients had a chance to ask questions and teach-back to me what I had just educated them on. The teach-back method helps me confirm the patient understands the information I'm giving them.

The next patient I called after my reflection was a 35-year-old female named Kelly, who was planned for a cholecystectomy. Kelly was in a great mood, personable and wanted to tell me about her little daughter, who I could hear playing in the background. I tried to keep Kelly focused on the conversation, because we had a lot of information to go over.

When we got to her medications, she said she wasn't prescribed anything. I asked about over-the-counter or a supplement medication, and she said, "Well…no." I sensed a little hesitation in her response. I thought, maybe she wasn't sure about something being a supplement. I glanced at the clock and realized that the conversation was already running over the standard call time. I knew that I needed to wrap up the call, but something in my gut feeling was giving me pause. So, I circled back to the supplements and asked her more specifically if she took anything like homeopathic remedies, or was there something she took for stress, or to help her sleep? At that point, Kelly said, "Well, yeah, I take valerian root to help me sleep and, wow, does it really help!"

I was so glad that I asked, because valerian root can actually interfere with anesthesia. I explained this to Kelly, and

made sure she understood, she will need to stop taking it before her surgery. She still had a couple of weeks before her surgery, and her surgeon would be fine if she wanted to take it for a few more days to lower her dose before stopping rather than just going "cold turkey." Luckily, she didn't think it would be a big deal and said she'd just finished a bottle, so she'd just wait until after her surgery to open the new one.

Other instructions include showering with either an antibacterial soap or surgical soap per facility protocol. The patient is educated on what clothes to wear the day of surgery to accommodate the type of surgery performed. For example, loose fitting pants that will fit around a cast, boot, or immobilizer. The patient should also be instructed not to wear contact lenses, nail polish, makeup, or jewelry. The patient should be instructed to bring their own bag for personal items on the day of surgery. Also, they should be provided with information on visitor policies, and if they will need to have someone drive them home after surgery. Some facilities may require the person driving the patient home to be on campus prior to the surgery starting, as well as remaining there until the patient is ready to discharge.

At this point, advance directives are also discussed. An **advance directive** is a document that allows a patient to convey, in writing, their wishes for care if they are unable to advocate for themselves due to a medical condition. If a patient does not have an advance directive, they may be given information about the documents to help them decide if this planning is something they would like to complete before surgery. The nurse may advise patients about talking to the health information department or checking the facility's website for forms or templates that help patients create their advance directives. Patients who have an advance directive may be asked to bring it with them to their surgery so that the facility can have it on file in the event the patient is not able to make decisions for themselves.

The general recovery process for the facility can be explained prior to surgery, but most of the time, postoperative instructions are not available until after the surgeon has performed the procedure. For example, patients undergoing foot surgery may be told in the office that they will be weight-bearing as tolerated after surgery. However, if the surgery was more extensive than the surgeon originally thought, the surgeon may decide that the patient will need to be non-weight bearing. For this reason, postoperative instructions are generally given after the surgery to ensure consistency and avoid confusion. Postoperative instructions are printed and verbalized with family or a responsible adult present.

Patients who will stay overnight after surgery should be informed of this, as well as what things they may need to bring with them. Some facilities request medications either be left at home or brought into the facility in their original bottles. Patients should also be educated on approximately when they will be discharged, and that the provider will come to assess them to determine if the patient is ready to discharge.

25.2 Preoperative Nursing Priorities

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Identify documentation priorities for the preoperative nurse
- Discuss aspects of the preoperative assessment
- Analyze the preoperative physical assessment
- Explain other preoperative patient care responsibilities

Preoperative nurses have several responsibilities and priorities. They are responsible for assessing not only the physical state of a patient but also the psychological and social states. The preoperative nurse prepares patients for surgery by educating the patient on any preparation to be done at home, educating on the surgical process, and prepping the patient on the day of surgery. The appropriate nursing interventions should be implemented per facility protocol or as ordered.

Documentation

In nursing, documentation is a crucial component of the nursing process. The preadmission assessments and testing performed in the preoperative phase prior to the surgery allow for a baseline to be recorded. This baseline allows members of the health-care team caring for a patient intraoperatively or postoperatively to determine the presence of any abnormalities or unexpected versus expected findings with the type of surgery performed or medications received from anesthesia. Any intervention or education provided is also documented to communicate

that the patient has been provided with information they need to understand and make informed decisions about their care.

Verifying Consent

Informed consent is very important in the surgical setting, as the patient should not be coerced into a surgery, nor should they go into a procedure without all the information. The preoperative nurse verifies that the surgeon has given the patient all of the details regarding the procedure; that the patient understands its risks, complications, and benefits; and the patient consents to the procedure. An informed consent requires a witness signature. The preoperative nurse may witness the patient's or guardian's signature. It is the responsibility of the surgeon to provide the information needed for informed consent to the patient, as well as alternative therapies; the risk of disability or disfigurement; the removal of body parts (if necessary); what to expect postoperatively; and address any questions the patient may have. Consent must be signed prior to the patient receiving anesthesia or any medications that can alter the decision-making capacity of the patient. The nurse should also be aware of the standard requirements for what is listed on the surgical consents, which may vary by state. Obtaining consent also gives the nurse the opportunity to have the patient verbalize the surgery in their own words, which ensures patient safety and minimizes the risk of adverse events like wrong-site surgery.

Persons under age 18 may not sign their own consent unless they are an emancipated minor and have the appropriate documentation presented to the facility. Adults over age 18 who have certain neurological or cognitive impairment may be deemed incompetent and cannot sign their own consents because they lack the capacity to understand what they are signing. Instead, they will need someone with medical power of attorney to sign on their behalf. Individuals that do not understand or speak English as their native language will require a medically trained interpreter to aid with obtaining consent. The materials should be provided in their spoken language, if available. Interpreters cannot be family, friends, or other staff. To follow compliance guidelines, each medical facility has a trained medical interpreter available 24/7 via a hotline, or some facilities have one present on location. Alternative forms may be needed to ensure patient understanding, such as forms using large print if the patient has visual impairments, or a medically trained sign language interpreter for a deaf patient. The preoperative nurse must verify patient understanding in order to verify consent.

LINK TO LEARNING

The Joint Commission explains informed consent, barriers, and safety actions (https://openstax.org/r/77InformConsent) to consider. Informed consent is more than just getting the patient to sign a consent form; informed consent is the conversation a patient has with a provider that gives them enough information to decide about their care. Verifying informed consent ensures that the patient understands the risks, benefits, alternatives, and the surgery itself.

Nursing Documentation

Nursing documentation should include the patient's neurological status, confirming whether the patient is cognitively capable of giving an informed consent, including if an interpreter was used. The interpreter's ID and name should be documented on the consent form and in the chart. Documentation includes using the patient's own words to describe the surgery to be performed. Other documentation includes components of the preoperative assessment. The following list displays examples.

- Recent fluid and nutrition intake
- Current medications and when the last doses were taken for each
- Current infections that could impact healing
- Recent drug or alcohol use
- Overall mental affect or psychological state

The physical assessment findings should also be documented as further discussed in the 25.3 Preoperative Nursing Care Plan. The presence of any immobilization devices, dressings, assistive devices, corrective devices, hardware, or implants should be documented. Any nursing interventions provided in the preoperative setting should be documented, along with the patient's response to the interventions. For example, if iodine was used to prep the

patient's leg, the preoperative nurse will document if any reaction was noted.

Additional documentation includes any provided surgical preparation. This may include clipping hair from the skin or administration of a laxative regimen as a bowel preparation. The nurse will need to document whether the preparation was completed by the health-care provider or the patient, the type of prep that was used, when it was completed, and whether the patient experienced any reactions.

Education provided to the patient should also be documented. The type of education provided and how the education was performed (e.g., over the phone, in person, verbally, written, return demonstration) during preadmission should be documented in the patient chart, as well as any additional education provided in the preoperative setting. An evaluation of the patient's understanding should be included in the documentation.

When the time comes for the intraoperative nurse (discussed in Chapter 26 Intraoperative Care) to take the patient to the operating room, the preoperative nurse should perform and document a patient handoff (see 1.2 Intercollaborative Care for more information on ISBAR during a handoff). The handoff report includes verifying the patient demographics, completed consent, surgery being performed, allergies, history and physical from the surgeon within 30 days, abnormal labs, and the marking from the surgeon verifying the surgical site. Handoff report should also be performed with the patient present as an additional safety check. Documentation should include the information discussed in handoff, the date and time, who was involved in the handoff, how the patient is being transported to the OR, and who is part of the transportation to the operating room.

Preoperative Assessment

The goals of a preoperative assessment are to:

- address the state of the patient prior to the procedure
- identify any risks that can contribute to postoperative complications or delay recovery
- establish a baseline for future comparisons to assess any unexpected or expected findings after the procedure is performed.

Any risks identified allow for a plan of action to be created in order to avoid potential complications. For example, if a patient states that they have a history of postoperative nausea and vomiting, then the anesthesia protocol may allow a scopolamine patch to be ordered unless otherwise contraindicated. If the patch is contraindicated, the anesthesia provider may adjust the type of medications given in order to decrease the likelihood of postoperative nausea and vomiting.

UNFOLDING CASE STUDY

Care of the Surgical Patient: Part 1

The nurse is performing a preoperative assessment on a 45-year-old female who presents to the preoperative check at 06:00 for a 09:00 surgery for a left partial knee replacement. The patient is accompanied by her husband. The patient has left knee discomfort on admission and has been taking ibuprofen for her knee pain. She stopped taking the ibuprofen 7 days ago per her provider's orders. The patient is slightly anxious but expresses, "I can't believe I have done this to myself," "I don't have the stamina and mobility I used to have and miss running so much," and "I am so depressed." Patient is quiet and appears withdrawn at times.

PMH	**3/12/24, 0600** Patient has a history of playing high school and college sports as a track and field athlete. Patient had a left knee meniscus tear with arthroscopic repair 15 years ago and a patellofemoral arthroscopy repair 5 years ago. Patient had one miscarriage 12 years ago. Patient works full time as a grade schoolteacher. They do not have children. Patient states that she experienced a severe adverse reaction of post-op nausea and vomiting (PONV). **Family History** Father is living, has a history of a heart attack and tobacco use. Mother alive with osteoarthritis. One brother, healthy **Social History** Patient lives at home with husband. Never smoked and states she drinks only drinks 1-2 drinks/week. Patient stays physically active with a recliner air bike and walks as tolerated 5 times/week. The patient went to counseling after her second surgery 5 years ago but does not currently see a counselor. **Current Medication** Ibuprofen 800 mg every 6 hours (max dose 3200 mg/24 hr) No known allergies
Nursing Notes	**Triage Assessment, 3/12/24, 0600** The patient is alert and oriented. The patient's skin is warm and dry, easy respirations, no dyspnea noted. She arrived via wheelchair but does not use an assistive device. **3/12/24, 0630** **Physical Examination** HEENT: Pupils equal and reactive to light, mucus membranes dry, no thyroid enlargement. Lymphatic: lymphatic nodes were not swollen or enlarged Respiratory: 16, easy, good depth, no SOB noted. Lungs clear all lung fields on auscultation. Cardiovascular: NSR noted on monitor Abdomen: soft, denies pain, abdomen distended, bowel sounds present all four quadrants Musculoskeletal: Moves all extremities well with the exception of existing pain limiting the full flexion and extension of the left leg related to knee injury. Skin: Warm and dry Mental assessment**:** Patient admits to increased anxiety and depression. The patient has been NPO as of 10 pm last night. Document full assessment in the patient's EMR/chart.
Flow Chart	**Assessment, 3/12/24, 0600** Blood pressure: 110/70 Heart rate: 78 Respiratory Rate: 16 Temperature: 98.0 Oxygen Saturation: 99% room air Weight: 130 lbs Height: 5 ft 9 in Pain: 6/10

Lab Results	**Preop, 3/5/24** WBC, 8.0 × 10^3 cells/mm^3 Platelet count, 200,000 Partial thromboplastin (PTT), 30 sec Prothrombin time (PT), 11 sec Hgb, 12 g/dl Hct, 41 % INR, 1.0 BUN, 14 mg/dl Creatinine, 0.09 mg/dl Fasting glucose, 84 mg/dl Na, 138 mEq/L K+, 3.8 mEq/L Cl, 100 mEq/L Liver function tests: ALT, 25 U/L AST, 19 U/L GGT, 20 U/L Total protein, 70 g/dL Total bilirubin, 11 mg/dL eGFR, 90 Rapid PCR-Covid test, negative Pulse oximetry, 99% RA **Preop, 3/12/24** WBC, 8.0 × 10^3 cells/mm^3 Platelet count, 200,000 per microliter Partial thromboplastin (PTT), 30 sec Prothrombin time (PT), 11 sec Hgb, 12 g/dl Hct, 41% INR, 1.0 BUN, 14 mg/dl Creatinine, .09 mg/dl Fasting BS, 84 mg/dl Na, 138 mEq/L K+, 3.8 mEq/L Cl, 100 mEq/L Liver function tests ALT, 25 U/L AST, 19 U/L GGT, 20 U/L Total protein, 70 g/dL Total bilirubin, 11 mg/dL eGFR, 90 Rapid PCR-Covid test, negative Pulse oximetry, 99% RA

Diagnostic Tests/ Imaging Results	**Preop** Left knee X-ray: "repair of left knee meniscal tear with scar tissue formation, multipartite patellae as well as gross patella alta or baja," post-surgical arthroscopy surgeries. CXR: normal ECG: normal, regular sinus rhythm
Provider's Orders	**Preop, 3/5/24** Left knee x-ray, anteroposterior, lateral and axial views CXR ECG CBC with differential Electrolytes Liver function studies Coagulation profile eGFR Covid test Hold ibuprofen for 7 days preoperative Consent obtained from provider for partial left knee replacement **Preop, 3/12/24, 0600** Repeat electrolytes preop now Anesthesia provider to start IV Prep left knee for partial left knee replacement per standard preoperative orthopedic orders Confirm patient surgical consent has been obtained and patient understands what the surgeon will do during her surgery. The nurse will explain that once under anesthesia, the surgeon will inspect the left knee joint. The surgeon will make an incision at the front of the knee and explore the three compartments of the knee to verify that the cartilage damage is, in fact, limited to one compartment (unilateral), which is required for a partial knee replacement and that your ligaments are intact. If the surgeon feels that the knee is unsuitable for a partial knee replacement, the surgeon may instead perform a total knee replacement. Repeat labs in am if patient stays overnight: CBC with differential, Hgb, Hct, electrolytes, BS.

1. After assessing the patient, the nurse determines the most important patient's presentation complaint is due to [Option 1] resulting in the primary symptom of [Option 2]. Match the most likely options for the information missing from the statement by selecting from the lists of options provided.

Option 1	Option 2
Panic attack	Increased fever
Medication side effects	Pain
Educating the patient	Possible infection
Left knee injury, preop	Respiratory rate 30
Abnormal WBC	Irritability

2. Once the nurse has reviewed the relevant patient information, which assessment finding(s) are most consistent with the associated disease process?

Assessment Finding	Left knee injury repair	Depression	Anxiety
Pain in the left knee			

Lack of education for surgery			
Grieving loss of prior activity and exercise tolerance			
Emotional support from her husband			
Withdrawn			

Nutrition and Fluids

Adequate nutrition is key to aiding a body in the healing process and opposing infection or other complications. Assessing the nutritional status of a patient allows the preoperative nurse to identify any potential factors that can affect the patient's surgery and recovery process, such as malnutrition, metabolic disorders, obesity, unexpected weight loss, nutrient deficiencies, and medication effects on nutrition. Any nutrient deficiencies noted need to be addressed prior to surgery, as optimal protein is needed to aid in tissue and wound healing. Height and weight should be taken again to confirm the body mass index (BMI) of the patient, as they may have gained or lost weight (or height for pediatric patients who are still growing). Weight is needed for accurate dosage calculation for anesthesia medications.

Monitoring the fluid status of a patient is also essential because hypovolemia, dehydration, and electrolyte imbalances (see Chapter 10 Fluid, Electrolyte, and Acid-Base Imbalances) can contribute to complications in older adults or those with other chronic health conditions or comorbidities. Patients undergoing bowel preparation are at risk for dehydration and chemical imbalances due to the depletion of fluids and electrolytes and fasting. Any identified fluid or electrolyte imbalances should be corrected prior to surgery. For example, a patient may need to have IV fluids administered prior to surgery, and some surgeons may allow a patient to continue to have water or Gatorade up to two hours prior to surgery. The nurse will need to follow the Enhanced Recovery After Surgery (ERSA) protocol per facility guidelines (Sung & Yuk, 2020).

Medications

Obtaining a patient's medication history allows the preoperative nurse to identify any potential interactions or risks with any medications that may be administered during surgery. For example, patients taking blood thinners are at an increased bleeding risk associated with surgery, so these medications may need to be discontinued prior to surgery.

The patient's medication history should include any prescribed medications, herbal supplements, vitamins, and over-the-counter medications. Some medications may be taken the day of surgery, while others may need to be discontinued for a recommended period of time to avoid risks of bleeding or interactions with anesthesia. Any medication that poses a risk should be outlined by the facility and anesthesia protocol, as well as instructions to provide to the patient with regards to stopping the medication. Some medications may require a clearance from the prescribing provider to stop. For example, a cardiac patient may be on aspirin or another blood thinner. The cardiologist (or prescribing physician) should clear the patient for surgery, giving approval for the patient to stop the medication and specifying how many days the patient should remain off the medication. Table 25.1 provides examples of common medications and treatments that are contraindicated before surgery because they increase the risk of bleeding (Sung & Yuk, 2020).

Type of Medication	Examples
Anticoagulants	Warfarin, coumadin, heparin
Antiplatelet medications	Dipyridamole
Antibiotics	Flagyl, doxycycline

TABLE 25.1 Medications Contraindicated before Surgery

Type of Medication	Examples
Antipsychotics	Thioridazine, thorazine
Corticosteroids	Hydrocortisone, prednisone
Herbal supplements	Gingko biloba, ginseng, St. John's wort
Hormonal contraceptives or hormone replacement therapy	Oral birth control pills, estrogen creams/patches
Nonsteroidal anti-inflammatory medications	Aspirin, ibuprofen, naproxen
Tricyclic antidepressants	Anafranil, clomipramine, Elavil

TABLE 25.1 Medications Contraindicated before Surgery

Many patients leave out the use of vitamins or herbal supplements during the medication assessment, so it is imperative the preoperative nurse specifically ask about their use. Common herbal supplements include garlic, ginger, St. John's wort, echinacea, ginseng, ginkgo biloba, valerian root, and licorice extract. Many of these supplements can cause interactions with anesthesia or increase a patient's risk of bleeding, so it is imperative that the preadmission testing nurse assess the patient's use, as they may require discontinuation of one to two weeks prior to surgery.

Immune System

The function of the immune system is an important component to assess to determine if the patient has any allergies that may cause complications during or after surgery (e.g., medications, latex), as well as checking for the presence of an active infection. Infections may postpone a surgery and are usually detected by a urinalysis or obtaining a white blood cell count. Any allergies identified may alter the course of routine medications given during the surgical course. Allergies must be documented in the patient's electronic medical record or paper chart, and a wrist band noting the allergy should be placed on the patient on a limb that does not interfere with the surgery. Allergies to medications, latex, foods, blood transfusions, and contrast should be assessed and identified, as well as the signs and symptoms associated with the reaction.

A special consideration with the immune system is if the patient is on or undergoing immunosuppressive drugs or therapies like corticosteroids, chemotherapy, radiation therapy, or if the patient has any immune system deficiencies. Examples of disorders that impact the immune system include HIV, AIDS, and leukemia. When the vital signs are obtained, any mild symptoms or temperature elevations must be reviewed in order to determine if surgery is a safe option for the patient at that time.

Alcohol and Drug Use

The use of alcohol and illicit drugs can greatly affect the anesthesia process. This can be a sensitive subject for patients to discuss, and they may not be honest. It is essential that the preoperative nurse ask direct questions about alcohol use in a nonjudgmental, caring, and patient manner. Those who consume larger amounts of alcohol respond differently to anesthesia and may require stronger medications or higher amounts of anesthesia. Any patient reporting daily drinking should be reported to anesthesia in order to determine if a change in the plan of care is warranted. Excessive alcohol use often leads to malnutrition and metabolic imbalances that can pose risks with surgery. Research has shown that patients who use substances, including alcohol and tobacco, have a higher risk of poor surgery outcomes, readmission, and reoperation. (Fernandez et al., 2022). Complications can include increased bleeding, cardiac events, vomiting, aspiration, sepsis, medication interactions, delayed recovery, stroke, and death.

Illicit or illegal drugs may increase the sedative effects of anesthesia and can lead to respiratory failure. Some drugs may also be associated with cardiac risks or other interactions when mixed with anesthesia. If a person presents for surgery under the influence or suspected under the influence of illicit or illegal drugs, the surgery will be cancelled to avoid complications or injury. In the event of emergency surgery, special precautions are implemented for those under the influence, such as using a local, regional, or spinal block. A nasogastric tube is inserted before general

anesthesia in emergency cases to prevent vomiting and aspiration.

The use of alcohol and drugs can weaken a person's immune system, which can deter healing, as well as increase the chances of postoperative complications. If the patient is admitted to the facility (inpatient) after surgery, they could experience symptoms of withdrawal from a substance, or **detoxification**. This situation will require special monitoring in the postsurgical unit. Signs of withdrawal from suddenly stopping alcohol include seizures, delirium, or death. A Clinical Institute Withdrawal Assessment (CIWA) scale should be used for patients experiencing detoxification (Canver et al., 2024).

LINK TO LEARNING

Review the Clinical Institute Withdrawal Assessment of Alcohol Scale – Revised (https://openstax.org/r/77Withdrawal) from the *British Journal of Addiction*, which is used for assessing a patient's withdrawal status.

Psychosocial Status

Surgery may trigger many emotions for some patients. Some people may experience fear or anxiety due to the unknown. Some may be anxious over the lack of control they have over the situation. Other people may be expecting the worst outcome, and the anticipation of pain is too much to handle. The nurse can relieve these symptoms by providing education related to each step of the procedure.

The preoperative nurse should assess the patient's psychosocial state prior to surgery by asking questions and observing the patient's behavior. Some patients may cry, be withdrawn, bite fingernails, talk excessively, avoid eye contact, or exhibit other types of behavior typical of someone experiencing anxiety. The nurse should remain empathetic, address concerns the patient may have, or ensure the patient has a support person nearby, when allowed. Some patients may be more relaxed when their loved one waits with them in their room before their surgery; some might prefer not to have family or a friend with them.

CULTURAL CONTEXT

Spiritual Surgical Care

Patient-centered care is culturally competent and spiritually aware care. The preoperative nurse should inquire about and honor any spiritual or cultural beliefs the patient has. If these beliefs are unable to be honored due to possible harm, the nurse should provide an explanation and offer an alternative, if possible. For example, a patient may request that a clergy come visit the patient before surgery.

A nurse who is culturally competent understands that in some cultures, it is more polite to avoid eye contact. When the nurse understands the cultural practice, they knowe that not making eye contact is not a sign of anxiety or fear in the patient but a sign of respect. Another example of cultural competence is in some Thai cultures, the top of the head is considered sacred. In this case, the nurse would allow the patient to put their own surgical cap on to avoid offending the patient by touching their head.

Preoperative Physical Assessment

An adequate preoperative physical assessment includes the assessing of all the systems of the body for optimal functioning. The baseline assessment data that are collected ensures the patient is stable for surgery and allows the postoperative nurse to compare their data to the baseline. Any abnormalities or unexpected findings in the preoperative physical assessment should be investigated further prior to surgery. If those findings are found postoperatively, the postoperative nurse will have a protocol to follow to investigate further.

Respiratory

The respiratory system is assessed prior to surgery and includes breathing pattern, respiratory rate, breath sounds, work of breathing, and oxygen saturation. Elective surgeries may be postponed for patients who have poor or weak vitals, or present with a respiratory infection. Patient history is also obtained to identify patients with respiratory disorders as well as those with any recent changes in their respiratory status. A chest X-ray may be ordered prior to

surgery depending on the type of surgery or if the patient has had new or worsening respiratory symptoms.

Patients who smoke should be educated to stop smoking 30 days prior to surgery to aid wound healing and reduce pulmonary complications. Those who smoke are at higher risk for delayed wound healing, surgical site infection, pneumonia, and venous thromboembolism (Fernandez et al., 2022). Smoking cessation education and materials should be provided to the patient.

When needed, patients will be educated about the use of an **incentive spirometer** or tool used for breathing exercises to promote lung function postsurgery. This education is important to be performed prior to the administration of any anesthesia medications, so that the patient is able to fully inhale and exhale in order to set the appropriate goals. This is important to the patient's ability to fully inflate the lungs when breathing after surgery to prevent pneumonia or atelectasis.

LINK TO LEARNING

Watch this video to learn how a patient can use an incentive spirometer (https://openstax.org/r/77Spirometer) to fully inflate the lungs, taking slow, deep breaths.

Cardiovascular

Assessment of the cardiovascular system prior to surgery includes obtaining baseline blood pressure and heart rate; assessing capillary refill time; obtaining peripheral or radial pulses (as appropriate); and obtaining the patient's history and verifying medications. An ECG may also be performed prior to surgery. Surgery may be postponed for patients with uncontrolled dysrhythmias or uncontrolled heart rate until the condition is resolved or the patient has been cleared by a cardiologist.

Renal and Hepatic

The kidneys and liver metabolize and filter out wastes, toxins, and medications. It is essential to ensure that the renal and hepatic systems function optimally before, during, and after surgery, as these systems are integral to the clearance of medication (including anesthesia) and waste from the body. The following blood tests may be ordered to assess their functionality: liver function tests (ALT, AST, GGT, total protein, bilirubin, LDH), CMP, PT/INR, eGFR, BUN, and creatinine. A urinalysis may also be performed to check for color, cloudiness, odor, the presence of acid, albumin, bacteria, glucose, or specific gravity for urine concentration.

Patients with poor liver function are at higher risk for surgical mortality due to the inability to effectively metabolize anesthesia medications. Elective or non-emergent surgeries may be postponed, allowing time for interventions that will increase liver function. Surgery may be contraindicated in those with acute renal insufficiency, oliguria, anuria, or acute nephritis. However, exceptions include life-saving surgeries, procedures aimed at improving renal function, or surgeries to provide dialysis access.

Endocrine

Endocrine disorders that impact surgery include diabetes, thyroid disorders, and Addison's disease. Poorly controlled diabetes and hyperglycemia increase the risk of slowed surgical site healing and infection. The patient's blood glucose should be monitored preoperatively, intraoperatively, and postoperatively. Facility protocols should be implemented if the fasting blood glucose is too high or low. Patients with hyperthyroidism are at risk for thyrotoxicosis, while patients with hypothyroidism are at risk for respiratory failure. Patients should be educated on the importance of continuing with their thyroid medications prior to surgery to ensure their thyroid levels remain controlled. Patients taking corticosteroids are at risk for surgical complications. Corticosteroids can have a negative impact on adrenal function. The use of corticosteroids within the last year should be reported to the anesthesia provider or surgeon as soon as possible. The patient will need to be monitored for signs of adrenal insufficiency. Close monitoring is also paramount for patients with Addison's disease, in which an adrenal crisis may be triggered by fasting, the stress of surgery, or medications.

Preoperative Patient Care

Patient care in the preoperative setting may include skin preparation, bowel preparation, and education. Some preparation may be performed at home by the patient or by the preoperative or intraoperative nurse on the day of

surgery. Skin preparation and bowel preparation should be followed per surgeon order or per facility protocol if there is no surgeon specification.

Skin Preparation

Skin preparation is essential to prevent infection. Some surgeons may request the patient's hair be clipped if the hair interferes with the procedure or the surgeon's field of vision. For example, if the surgeon is using a microscope, hair can interfere with the surgeon's ability to see. Patients should be educated to not shave at home to reduce risk of skin injury or infection. If hair removal is necessary, the nurse will perform it prior to the procedure. Other skin care may include the patient's use of a surgical or antibacterial soap prior to coming to the facility. The preoperative nurse may also use a type of skin preparation such as iodine or chlorhexidine gluconate the day of surgery.

An important component of skin preparation is for the surgeon to mark the site where surgery is to be performed prior to surgery. The surgery site should be verified by the preoperative and intraoperative team as part of a safety handoff prior to the patient transferring to the operating room.

Bowel Preparation

Bowel preparation is only warranted for procedures where the patient is undergoing an abdominal or pelvic procedure. Laxatives or enemas may be prescribed for the patient to perform at home or by the preoperative nurse if the patient is admitted prior to surgery. Complete bowel elimination allows the surgeon to see inside the intestines clearly and reduces the potential for infection from fecal matter, if an accidental perforation happens during surgery.

REAL RN STORIES

Nurse: Cory
Years in Practice: Six
Clinical Setting: Surgery center
Geographic Location: Utah

Cory is a nurse at a surgery center. Here, Cory recalls an occasion early in his nursing career when he thought his actions were compassionate toward a patient who needed to complete a bowel prep before a procedure. Only afterwards did Cory realize his actions were not as helpful as he thought.

I was a fairly new nurse, still less than a year out of school. This was definitely one of those formative experiences I had early on as a nurse that I've never forgotten, and I use it as a teaching example for student nurses now!

I had a patient, 65-year-old named Barbara, who was scheduled for a colonoscopy. She'd had some blood in her stool, and her primary care provider wanted her to have a GI consult to help get to the bottom of it. I called her to go over all the preop information and made sure she understood the bowel prep protocol—and she was so nervous about it. I tried to reassure her that while it's no fun, most people get through it just fine. I even gave her a tip I'd picked up from other patients, which is that chilling the beverage tends to help it taste better. She was receptive to doing her best, and I encouraged her.

The night before her procedure, she called the surgeon's office to talk to the on-call—she was having a terrible time with the prep. They told her how important it was that she keep going and get through it, and she said she'd try. The next morning, she called again right after I came in and since I'd done her preop education, I said I'd be happy to talk to her. Well, she was just about in tears. She'd been "sick all night" from the prep and said she absolutely could not finish the rest of it. I gently told her that she needed to do the whole prep, but she just couldn't continue on, and she promised me "there wasn't anything left to come out" at that point. I just felt for her, really I did. And she was full-on crying. So, I told her it was fine, she could stop the prep. She was so relieved, thanked me. I told her we'd see her in a few hours for her procedure.

Well, she came in on time, and got through preop fine. She looked pretty exhausted, though, and she thanked me again for not making her "suffer any more" with the rest of the prep.

Now, I thought I'd done the nice, compassionate thing...but in reality, I had made her situation so much worse. See, when the surgeon went in with the scope, she couldn't see anything. The bowel hadn't been cleared, and the whole

procedure had to be stopped. And when the patient woke up, I was the one who had to break it to her that they couldn't do the procedure because she hadn't finished the prep...and now she'd have to start all over again.

25.3 Preoperative Nursing Care Plan

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Describe the nursing care plan to ensure patient safety during the preoperative phase
- Describe the nursing care plan to initiate the prevention of complications during the preoperative phase
- Discuss the role of the nurse in providing education and psychosocial support to the patient and their family

The preoperative nursing care plan includes interventions aimed at preparing the patient both physically and psychologically for the procedure while prioritizing patient safety. The nurse must be familiar with the patient's history, preadmission assessment and diagnostic results, surgeon orders and preferences, type of procedure, any special positioning required during the surgery, and type of anesthesia being used to adequately prepare the patient for surgery. The preoperative phase affects the entire surgical and recovery process, so it is crucial that the nurse effectively prepares the patient for surgery and documents nursing interventions.

Nursing Care Plan for the Preoperative Patient

The nursing care plan for the preoperative patient encompasses a variety of nursing interventions aimed at maintaining the safety of the patient and preventing complications. It's important for the nurse to remember that every patient is at risk for becoming overwhelmed, confused, and anxious, or developing infections and complications like fluid and electrolyte imbalances and blood loss. While there will be patients who will be at a higher risk, the nurse should still take care to prepare all patients for their procedures.

Ensuring Patient Safety

Patients undergoing a procedure may experience anesthesia complications, physiological stress on the body, and the invasiveness of the procedure itself. To ensure patient safety in the preoperative phase, the nurse must ensure that the patient is stable enough to undergo the procedure by obtaining vital signs, obtaining any laboratory tests that were not done during the preoperative testing or need to be repeated, verifying medications taken or held for surgery, and taking steps to prevent a wrong-site surgery. The nurse must perform a proper preoperative assessment and surgical preparation, such as administering medications as ordered and hair clipping around the surgical site, if necessary. They will also monitor and manage the patient throughout the preoperative phase. Jewelry should not be worn into the operating room due to the risk of injury.

INTERDISCIPLINARY PLAN OF CARE

Preoperative Team

Interdisciplinary care is vital to patient outcomes and patient safety. Each member of this team has their own role in the plan of care for a surgical patient. The following members play a vital role in the preoperative stage:

Surgeon**:** the provider who orders and performs the surgery, provides patient with vital information for informed consent, typically sees patient for a preoperative and postoperative appointment.

Anesthesia provider: the provider who provides anesthesia for the surgery, performs assessment prior to surgery, develops and explains anesthesia care plan to patient, oversees anesthesia care if a certified registered nurse anesthetist is present for surgery. A **certified registered nurse anesthetist (CRNA)** is an advanced practice RN who has received special training to administer anesthesia.

Preoperative nurse: the nurse who analyzes patient history, verifies surgery and informed consent, reviews medication, performs assessment, preps patient for surgery, reports any findings that may impact surgery or patient safety.

Other members may include:

- A social worker in the event the patient is in need of financial assistance
- A radiologist may be needed for any preoperative scans or X-rays
- A dietician to assist the patient with nutrition after surgery
- Medical interpreters may be needed when the patient does not read, speak, or understand English

Patient Identification

Patient identification is an important component of patient safety. The nurse must verify the patient's name and date of birth and ensure that the patient has an ID wrist band. The nurse should also have the patient verify that the spelling of their name is correct. Any time the nurse is part of a patient handoff, the receiving nurse and transferring nurse should both verify patient name and date of birth comparing the wrist band to the patient chart and orders. This is especially important if the patient has received anesthetic agents and is not able to speak coherently.

Preventing Wrong-Site Surgery

Preventing wrong-site surgery is crucial to patient safety. Wrong-site surgeries are considered a **sentinel event**, or any unexpected event that causes serious harm to a patient or leads to death. Multiple steps are followed leading up to the surgery to prevent this from happening. As mentioned in 25.1 Preadmission Assessment and Education, the preoperative testing process is the first chance to ensure that the surgery the patient states they are having matches the surgical orders and consent. On the day of surgery, the preoperative nurse should ask the patient again to state in their own words the surgery they are having, including having them state the location of the surgery site without any coaching. For example, a patient having a joint replacement would be asked not only what surgery they are having, but also to identify the extremity and joint that is being replaced. The preoperative nurse should check the patient's statements against the orders and consent. If they do not match, the nurse should contact the surgeon to correct the surgical orders and consent. The nurse should ensure any prep is being performed on the correct site and that the surgeon has marked the site correctly (Figure 25.2). Once the patient is ready to transfer to the operating room, a safety handoff is performed between the preoperative and intraoperative nurse to confirm the surgery and laterality with the patient and confirm with the orders, consent, and site the surgeon has marked.

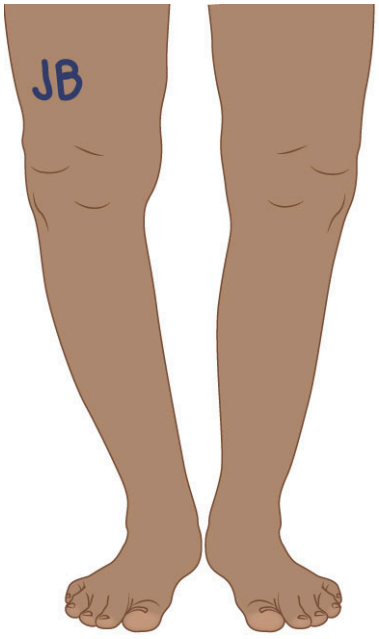

FIGURE 25.2 The surgeon marks the surgical site in preop after providing informed consent to the patient. This site is verified during handoff between the preoperative and intraoperative nurse as well as during handoff in the operating room with the surgeon, intraoperative nurse, CRNA, and other members of the surgical team that may be present. REAL RN STORIES

Nurse: Ashley, BSN

Years in Practice: Ten
Clinical Setting: Preop department
Geographic Location: The inner city of a large metropolitan area in Texas

We are a surgical hospital that has the capacity to do inpatient or outpatient procedures. We have a freestanding emergency room as well and can receive emergency and urgent cases. Most surgeries at our facility at this time are podiatry, spine, orthopedic, gynecologic, and general.

One day, I was preparing to bring a patient back to preop to prep for surgery. I had reviewed the patient chart prior to going into the room to learn patient history and preoperative assessment, medication list, surgeon orders, and consents. The preop nurse wrote down the patient was having a left total knee arthroplasty. The orders and consents were also marked for the left knee.

When I brought the patient back to the preop room, I verified everything was correct. I asked the patient to tell me in his own words what procedure he was having done. The patient stated, "I am having my right knee replaced." I responded to let the patient know that the surgeon had marked the left knee on his orders. The patient stated he had the left knee done two years ago and pulled his pant leg up to show me his scar. I advised the patient I would get this updated and resolved.

I walked to the nurse's station to call the surgeon; however, he had just arrived. I let him know what had happened. The surgeon pulled the patient's history and physical out, and in the surgeon's notes, he states the patient is to have the right knee replaced. The surgeon apologized for the error. My charge nurse reprinted the consents to state the correct laterality while the surgeon and I walked into the patient's preop room together. The surgeon and patient agreed the right knee was the correct laterality. I had the surgeon correct his orders, and the surgeon went ahead and explained the surgery, risks, and benefits to the patient for informed consent. During that time, my charge nurse also had our surgery scheduler update the surgery details in the computer to reflect the correct surgery. I notified the operating room charge nurse as well.

After the patient changed clothes, I continued with surgical preparation, completed an assessment, prepped the right knee for surgery, placed compression stocking on the left leg to promote blood return, started an IV with fluids, and administered preop medications per the surgeon's order. Once respiratory therapy and anesthesia had completed their tasks, the intraoperative nurse was ready to take the patient to surgery. We verified in handoff, with the patient, the patient's name, date of birth, allergies, family member present, and surgery type with laterality. I checked on the patient after surgery, and the right knee was replaced. This is one of those examples that makes you glad you verified to avoid a wrong-site surgery.

Preoperative Laboratory Tests

While many tests can be performed during preadmission testing, some laboratory tests are not performed until the day of surgery for accuracy. For example, a pregnancy test performed the day of the surgery is more current than days prior to the surgery to confirm whether a patient is pregnant. A blood test may be done the day of the surgery for accuracy (Wechter, 2024). Fasting blood glucose should be assessed the day of the surgery to ensure that the patient has a stable blood glucose before undergoing the procedure.

Blood type screening for AB antibodies, in case of an emergency and blood transfusions are needed, can be done prior to the surgery date as well. However, most facilities have a policy that a blood identification wrist band is good for a certain period of time. The nurse will need to follow facility protocol on the timing of blood typing. The preoperative nurse should review the results prior to the patient going into surgery to ensure any lab or diagnostics are within range to not cause harm to the patient. Any critical or abnormal values should be reported to the surgeon and anesthesia provider.

Medication Safety

Another way to ensure patient safety is to verify the patient's medication list and when the last dose of each medication was taken. Some medications can interact with anesthetic agents and have major complications or risks, and some medications can pose a risk of heavy bleeding. The preoperative nurse should be familiar with the medications that pose risks and make sure that the surgeon is aware of any medications that were taken that could cause harm to the patient during the procedure. The nurse should also verify allergies, ensure that the patient has

an allergy band if they do have an allergy, and ensure that the allergy is documented in the patient's chart. The nurse should also confirm with the patient the symptoms associated with the allergy and ensure that the intraoperative and anesthesia teams are aware.

Prevention of Complications

The preoperative nurse is typically the first health-care professional to meet the patient the day of surgery. They are in the position to assess for risks, verify patient information, obtain a baseline of vital signs, confirm that surgery site and laterality are correct, and get the patient's consent. The nurse will also ask the patient questions, such as:

- When they last ate or drank
- Medication history and last doses
- Last shower
- Wounds or rashes
- Metal or implants in the body
- Use of corrective devices
- Previous problems with anesthesia
- Allergies and associated symptoms
- Who will take them home after the procedure

While the preoperative nurse is not in the operating room with the patient, there are interventions they can implement to help prevent complications during surgery. Patients having surgery are at risk for a variety of complications, including anesthesia complications, aspiration, injury, blood clots, and infection. Diligent care by the preoperative nurse helps minimize these risks. Ensuring a thorough and accurate assessment and history of the patient is crucial for their safety. The preoperative nurse should review the patient's chart and be familiar with the patient's history and ask any questions that need clarification. For example, a patient's medications must be reviewed in case they have started any new medications between their preoperative appointment and the surgery, and any that could pose a risk must be reported to the surgeon in case the procedure needs to be delayed to avoid harm.

CLINICAL SAFETY AND PROCEDURES (QSEN)

QSEN Competency: Safety

Definition: "Minimize risk of harm to patients and providers through both system effectiveness and individual performances" (Quality and Safety Education for Nurses, 2020, Table 5).

Knowledge: The nurse will analyze basic safety principles, understand evidence-based practice standards, be familiar with facility and anesthesia protocols as well as state regulations, and reflect on unsafe nursing practices (for instance, stating the surgery rather than the patient stating the surgery and laterality in their own words).

Skill: Demonstrate effective use of strategies to reduce risk of harm to self or others, the nurse will:

- Describe factors that facilitate a culture of safety in surgery, such as time outs (see 26.3 Intraoperative Nursing Management), obtaining health history, performing assessments, medication reconciliation
- Value personal role in error prevention (verifying surgical sites, medications)
- Value the contribution of reliability for safety (preventing patient harm or near-miss events)
- Use national patient safety resources for own professional development (National Patient Safety Goals from The Joint Commission)
- Communicate observations or concerns related to hazards and errors to patients, health-care team members, and families (for example, if the patient states a different laterality than the surgeon, then the nurse should clarify and correct to ensure the correct site surgery is performed)
- Examine human factors and other basic safety design principles
- Examine commonly used unsafe practices (not verifying laterality, not reading over patient health history, not verifying medications)
- Value continuous improvement of own conflict resolution and communication skills

Attitude: Nurses caring for those undergoing surgery must prioritize patient safety and exhibit the practices listed precedingly. Surgery is a special instance where patients are not always able to advocate for themselves due to anesthetic agents, pain medications, mental state, health status, or the type of injury. The nurse must be aware of the vulnerability of the patient, be prepared to intervene when necessary, stopping immediately if something that threatens patient safety is suspected or apparent. The nurse possesses the knowledge and skills needed to promote optimal patient outcomes and uses clinical judgment to maintain patient safety.

(QSEN Institute, n.d.)

Decreasing Complications with Anesthesia

Some complications that may arise with anesthesia include:

- Anaphylaxis or allergic reaction
- Malignant hyperthermia
- Tooth damage
- Nausea and vomiting
- Aspiration
- Nerve injury
- Stroke
- Respiratory depression
- Cardiac events
- Awareness under anesthesia
- Embolisms

The anesthesia provider or CRNA will be monitoring the patient throughout the procedure to prevent complications and be able to intervene quickly if necessary. The preoperative nurse should ensure an adequate history of allergies and anesthesia and report any previous problems with anesthesia that the patient or a blood-related family member has experienced. The patient's teeth should be examined prior to surgery to identify any loose teeth or potential for damage due to intubation. Patients with a history of nausea and vomiting are at risk for aspiration. The anesthesia provider may request the preoperative nurse apply a scopolamine patch to the patient, or they may opt to adjust the anesthesia medications through the IV to aid with preventing nausea and vomiting. Special precautions are implemented for patients with a personal or family history of **malignant hyperthermia**, a serious genetic condition that causes a life-threatening elevation of body temperature and muscle spasms, among other severe symptoms. The preoperative nurse must follow the facility and anesthesia protocol.

Decreasing Aspiration Risk

To prevent aspiration, the preoperative nurse must assess when the patient last had anything to eat or drink. If the patient ate breakfast or had a large amount of something to drink prior to coming into a procedure, they are at risk for vomiting during surgery. If the patient vomits, they are at risk for aspiration. If the nurse suspects the patient is not being truthful, they should educate the patient about the risks of aspiration. A patient who experienced nausea and vomiting with a past surgery is also at risk for aspiration.

Decreasing Injury Risk

The preoperative nurse can aid in decreasing injury risk by assessing the patient and ensuring a thorough history has been obtained. The preoperative nurse should be aware of the patient's position during the surgery, as this aids in the decision of where to place an IV line that is not in the way or poses a risk of injury to the patient. Swelling could also occur due to positioning and pose injury risk or impaired circulation. The preoperative nurse assesses for any metal or jewelry on the patient, which can pose a burn risk in the operating room. Metal such as jewelry can cause sparks and is a fire hazard. Patients may be able to leave on various clothing items as long as there is no metal present. To avoid pressure injuries, the intraoperative nurse is generally the one to implement those interventions, as the patient will transfer to an operating room bed in the operating room.

Decreasing Clot Risk

Depending on the surgery, the surgeon may order compression stockings or thromboembolic deterrent (TED) hose for the patient to be worn on either both legs or a specific leg. These garments help stimulate blood flow to help reduce the risk of clots after surgery, particularly in patients who will be spending time immobile or in bed. While the

preoperative nurse is applying the TED hose, they should explain to the patient how to appropriately put them on and to ensure they are not up walking without socks or shoes that provide traction to avoid slipping. The surgeon may also order sequential compression devices to be used on a patient during a surgery, or the facility may have protocols in place for surgeries over a certain length of time. The patient should be educated on how to prevent blood clots postoperatively. Interventions include frequent position changes, walking as soon as possible (unless contraindicated), and the use of compression stockings or hose.

Decreasing Infection Risk

One of the main goals of a preoperative nurse is to prevent infection. Surgical site prevention is crucial, as the number of identified infections continues to increase. The burden of surgical site infections (SSIs) has been shown to be increasing over the last 10 years (Utzolino et al., 2021). This is due to the increasing number of comorbidities patients are presenting with and the number of surgical procedures being performed continuing to rise. According to the CDC, over half of SSIs are deemed preventable using evidence-based strategies (Utzolino et al., 2021).

The patient's vital signs and bloodwork should be analyzed for potential signs of infection, and any abnormalities should be reported to the provider. The patient's skin is assessed for any wounds or rashes. The preoperative nurse must take special care in performing skin preparation to the surgical site per facility or surgeon order and explain to the patient that the intraoperative nurse will repeat the skin preparation in the operating room as well.

LINK TO LEARNING

The CDC defines surgical site infections (https://openstax.org/r/77SurgSiteInfct) as well as provides guidelines on how to prevent the infections. Many of these guidelines are tools that have been adapted by facility protocols and surgeon orders to aid in preventing surgical site infections. However, the patient must understand their role at home in preventing infection as well.

Patient and Family-Centered Care

Patient and family-centered care can have a positive impact on the surgical experience, as fear or anxiety is common among people undergoing surgery and their families. Preoperative nurses provide patient and family-centered care by focusing on education, reducing anxiety and fear, and providing emotional support.

Education

Some fear and anxiety associated with surgery can be due to the patient or family being unaware of what to expect. The preoperative nurse should explain what to expect on the day of surgery. For example, the patient should be informed of all the steps that will be taken in preop, what transferring to the operating room looks like, where the patient will recover, and about how long the patient will be in recovery as long as there are no complications. The nurse should educate the family about where they will wait while their loved one is in surgery and that they will be reunited with the patient once the surgery is completed and the patient is stable in the recovery room.

Education should also include any preparation performed in preop. If compression devices such as TED hose are required, the patient and family should be instructed on how to put them on, the need to smooth out wrinkles, and not to walk around without assistance or nonslip socks to avoid falling. Any skin preparation should also be explained, as well as any signs of intolerance or allergies. For example, if iodine was used, the patient should be educated to contact the surgeon's office if any rashes, hives, itching, or other symptoms appear. The preoperative nurse should also educate on any medications given in preop, side effects, and why they are being given.

The preoperative nurse should ask if the patient or family has any questions. If it is anything related to the surgery, its risks and benefits, or alternatives, the nurse should direct those questions to the surgeon to ensure the patient has informed consent of the procedure. Most postoperative education is given in the PACU by the postoperative nurse unless the physician has already outlined their instructions. If the surgeon has prepared postoperative instructions, the preoperative nurse can provide those as well.

Reducing Anxiety and Fear

If the patient or family is still experiencing anxiety or fear after the nurse has provided education, the preoperative nurse should ask if there is anything specific that they are nervous about. The nurse can address those concerns if it

is something that the nurse knows the answer to. If the nurse is unsure of the answer, they should inform the patient they will find out and come back with an answer. Some resources may be available if it is a financial concern, such as contacting a social worker. If a patient requests prayer or a visit from a spiritual advisor, the nurse should make accommodations.

Most facilities have a way for the family to monitor the patient while they are in surgery. The preoperative nurse should ensure that the family is aware of how to track their loved one throughout surgery. Some patients and families may be concerned about the length of the surgery or how long the patient has been in the operating room. The nurse should assure them that the length of time has no bearing on the severity of an operation. The length of time is determined by preparation that needs to be performed by anesthesia and the intraoperative team prior to the surgeon starting the case. In addition, some patients are taken to the preop holding area in advance of the surgery starting, and the surgeon could still be in a previous surgery, causing a delay in the surgical start time of their family member.

Providing Emotional Support

Preoperative nurses can provide emotional support by active listening and remaining empathetic. The nurse should encourage the patient to be a part of the care plan in order to provide person-centered care. There is usually a waiting area with amenities (drinks, snacks, television) for the family while their loved one is undergoing surgery. Some facilities even have resources available to visitors, such as notary services, in the case legal documents like advance directives need to be signed. A staff member should also provide frequent updates on the progress throughout the procedure.

CLINICAL JUDGMENT MEASUREMENT MODEL

Applying the CJMM to the Preoperative Patient

Recognize and Analyze Cues

Before recognizing cues, nurses must make sure they have enough information about a patient's situation before interpreting the information and developing a plan of care. For example, the preadmission testing nurse completes a health history prior to the patient's arrival at surgery. On the day of surgery, the preoperative nurse reviews the patient's health history, performs an assessment, and verifies the patient's medication list is up to date and accurate.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

When the nurse considers the patient's history and assessment, they can then move on to the next step of the CJMM to prioritize a hypothesis and take action. During this step in the preoperative phase, the nurse will need to use their knowledge and skill to determine the patient's safety. For example, any unexpected wounds or rashes that could interfere with the surgery or pose risk of infection or any medications taken that were not supposed to be taken day of surgery need to be addressed with the surgeon and anesthesia provider to ensure the patient is safe to undergo the procedure. If the patent is safe to undergo the procedure, the nurse can continue with any surgeon orders or preferences per facility protocol like skin preparation, starting an IV, administering fluids, administering medications, drawing labs for diagnostic testing, and notifying respiratory therapy to come in for any incentive spirometer education or ECG testing. The nurse will also assess and care for the patient's psychosocial status as well.

Evaluation of Nursing Care/Evaluating Outcomes

After the surgical preparation has been performed, the nurse should verify the patient's tolerance. For example, the nurse should verify that the patient did not have any signs of allergic reaction with any medications or skin preparation. The nurse should also verify the results of any testing performed. Any abnormal or critical values should be reported to the surgeon. Some values may warrant the surgery to be postponed or warrant intervention, like a medication to be administered prior to surgery. Any education given to the patient in preop should be assessed for patient understanding. The nurse should document any interventions performed, patient tolerance, education given, and patient understanding (return demonstration, verbalized). In the event of any undesirable outcome, the nurse may have to start over with the Clinical Judgment Measurement Model in order

to reach an optimal outcome. However, with surgery, if the patient is unable to have surgery on that day, the Clinical Judgment Measurement Model will start over when the patient comes back in for surgery.

(National Council of State Boards of Nursing, n.d.)

25.4 Special Preoperative Considerations

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Identify measures to improve preoperative safety
- Discuss preoperative care changes of a patient requiring emergency surgery
- Identify how to adjust preoperative care to meet the needs of special populations

As with any specialty in nursing, the preoperative nurse must be aware of special considerations. Preoperative nursing requires special attention to promote safety. Many surgeries may be done on an elective or preplanned basis. However, there are instances where there may be an urgent or emergency surgery. There are also instances that require extra care or accommodation. The preoperative nurse must be aware of these special considerations to effectively care for various patient populations undergoing a variety of surgery types.

National Patient Safety Goals

The National Patient Safety Goals aim to promote patient safety. When it comes to surgery, these goals include (The Joint Commission, 2022):

- Identifying patients correctly
- Improving staff communication
- Using medicines safely
- Using alarms safely
- Preventing infection
- Identifying patient safety risks
- Preventing mistakes in surgery

Many interventions that support these goals have been discussed. The preoperative nurse plays a major role in performing or verifying that the proper steps are taken to promote patient safety. For example, the nurse verifies the medication record and implements interventions that promote the prevention of blood clots and surgical site infections.

LINK TO LEARNING

The Joint Commission's Hospital National Patient Safety Goals (https://openstax.org/r/77HospSftyGoal) aim to improve patient safety. This outlines safety goals for surgery and how to meet those goals.

Emergency Surgery Cases

Most surgeries are planned; however, there are instances where an emergency arises, leaving little time for surgical preparation. For example, a patient with a gunshot or stab wound requires immediate surgical intervention. When situations like this arise, there is generally not a preadmission testing appointment, and time is limited. Therefore, the patient does not receive presurgical instructions. These instances require the preoperative nurse to obtain as thorough a history as possible from either the patient or family member to verify medical history, medications, and allergies to try to prevent complications. The preoperative nurse must communicate these findings to other members of the surgical team. A quick assessment should also be performed to identify any possible signs of injury when trauma cases present. In emergent cases, skin preparation is often done in the OR to prevent delay of getting the patient into the OR.

Special Populations

Surgery is not a "one size fits all" procedure. Considerations are required for special populations like older adults, bariatric patients, and patients with disabilities. The preoperative nurse should remain knowledgeable of special populations to promote safety across each phase of surgery. The nurse should strive to be a lifelong learner and seek out opportunities for professional development related to their desired nursing specialty. The National League for Nurses (NLN), the American Nurses Association (ANA), and the Association of Operating Room Nurses (AORN) are a few examples of recognized organizations within the field of surgical nursing. Each hosts webinars, training, and workshops across the nation allowing OR nurses to remain up to date with best practice standards.

Older Adults

The older adult population is considered special because they have unique needs and require knowledge of the requirements to provide tailored care. People 65 and older not only have age-related changes that can impact the surgical process, but often they present multiple comorbidities that can impact surgical recovery outcomes. When a person reaches an advanced age, the organ systems tend to have lower reserves for recovery and may take longer to "bounce back" to the patient's baseline after surgery. Cardiac and respiratory complications are common causes of postoperative morbidity and mortality in older adults. The prevalence or incidence of an illness within a population is called **morbidity**. The death of a population measured and expressed as a ratio is called its **mortality**. Changes in kidney function, body composition, and gastrointestinal physiology lead to variations correlated with pharmacokinetics and pharmacodynamics of most drugs (Maanen et al., 2020). This means that the older adult does not recover as quickly as the younger adult and metabolizes anesthetic agents and pain medications more slowly or are generally more sensitive to those drugs.

Advancing age is also associated with skin changes like dry, itchy skin that is more fragile. This requires careful precautions when moving older adults from one bed to another. Older adults are also more likely to experience temperature changes due to a reduction in adipose tissue. Maintaining as warm an environment as possible, applying a warming blanket or temperature monitoring system, if available, and asking if the patient feels warm enough are appropriate interventions. The patient's subjective report of temperature may not reflect their actual body temperature; therefore, the nurse will also need to continue to monitor temperature to ensure not just comfort, but safety. Patients with decreased body temperatures are at risk for surgical site infections, blood loss, altered medication metabolism, increased pain, and cardiac arrythmias (Brooks & Bosserman, 2022).

LIFE-STAGE CONTEXT

Older Adults and Surgical Procedures

Older adult patients are more at risk for surgical complications than younger adults. Therefore, the preoperative nurse must ensure they have performed a comprehensive preoperative exam. Postoperative and post-anesthesia care must also be thorough and skillful to promote optimal patient outcomes (Salzman et al., 2022). Postoperative care must also focus on effective communication to educate the patient about postsurgical care and pain management. Older adults may need more time to cover the education with multiple explanations to appropriately understand the information (Kumar et al., 2021).

Bariatric Patients

This special patient population requires meticulous care as there are a number of complications that may arise with surgery as shown in Table 25.2 (Rakhlin, n.d.).

Possible Complication	Reasoning
Surgical site infections or delayed wound healing	Reduced blood flow to the area; diabetes or uncontrolled blood glucose; malnutrition
Blood clots	Higher amounts of estrogen in the body; more difficult to ambulate after surgery
Hypoventilation, atelectasis, pneumonia, or other pulmonary complications	Shallow breathing in supine position; sleep apnea
Wound dehiscence or hernia	Increased tissue weight exerting forced on dependent tissue
Increased cardiac demand	1 mile of capillaries must be created to perfuse 1 pound of excess weight; risk for poor oxygenation
Anesthesia complications	High blood pressure may affect perfusion; airway obstruction from excess fat; high cholesterol and lipid metabolism may alter anesthesia effects (Ramírez-Reyes-Reyes et al., 2021; Seyni-Boureima et al., 2022)

TABLE 25.2 Surgical Complications in Bariatric Patients

If a patient with obesity also smokes, they are at an increased risk of wound infections due to the reduction of oxygen available to the tissues. Excess adipose tissue can lead to impaired circulation. Decreased oxygenation and reduced circulation are directly related to impaired healing. Reduced oxygenation can cause impaired immune function (de Frel et al., 2020). Due to the potential complications associated with surgery, the preoperative nurse will want to ensure a thorough and accurate assessment has been obtained.

Pregnant Patients

Pregnant patients may need surgery that is related or unrelated to their pregnancy. In either case, the health and safety of both the patient and the fetus are addressed during preoperative care. Even if the patient is having a non-obstetric procedure, their pregnancy care provider will be an important collaborator during planning.

While a pregnant patient will receive much of the same preoperative care, counseling, and education as a non-pregnant patient, they will likely have some specific concerns about the well-being of the fetus that the nurse will need to address. For example, a patient may worry that the anesthesia during the surgery could harm the fetus, or that the procedure itself could be harmful. The nurse will want to address the patient's concerns fully and make sure they understand the risks and benefits of having the procedure.

While an elective procedure can often be postponed until after delivery, surgery cannot always be delayed. In the case when a procedure is medically necessary for a pregnant patient, coordination between care team members is key to ensuring the health and safety of both the patient and the fetus. This involves close monitoring of both the mother and baby and taking proactive steps to prevent complications like preterm labor and thrombosis. Ideally, the procedure would be done at a facility with a neonatologist or pediatric specialist who can be present during the procedure (ACOG, 2022).

Patients with Disability

The preoperative nurse will care for patients with both physical and mental disabilities. The nurse may need to make accommodations for the use of any needed assistive devices, modify patient education, or ensure additional assistance is available to aid with transferring or positioning. The preoperative nurse should verify the needs of the patient, as well as document what type of assistive devices the patient brought with them to the facility and where those items were placed prior to surgery. This allows the postoperative personnel to ensure the patient receives their belongings after surgery.

Patients with mental disabilities may be accompanied by a caretaker or advocate who can help facilitate clear communication. While the person overseeing their care does need to be made aware of the details, that does not mean a patient with a mental disability can simply be "talked over" or ignored during the preoperative assessment. A patient's capacity to fully understand the reasons for the procedure and what will happen during it will depend on their intellectual function, so the nurse will need to meet the patient where they are in terms of understanding. The education should be aligned with the patient's level of comprehension, and other forms of media (such as graphics or videos) may also be helpful.

Generally, patients are asked to move from the stretcher to the operating room bed at the start of the surgery and back after the surgery. Patients that are either unable to hear or understand instructions or unable to move independently will require assistance in the operating room. Therefore, it is important that the preoperative nurse communicate those needs to the intraoperative nurse when transferring care.

Cultural Considerations

Cultural considerations the preoperative nurse must consider include but are not limited to language, eye contact, gender, touch, and spirituality. Patients who speak and understand another language require a medically trained interpreter for consent and education. Materials should be provided in the language that the patient reads and understands. The medical protocols seen as common to some are not allowed in certain cultures or communities. For example, the administration of blood products is not allowed in the Jehovah's Witnesses community (Cummins & Nicoli, 2018).

Other cultures may have preferences when it comes to gender. For example, some Chinese cultures view the husband's role as protector of his wife. The husband may answer questions on behalf of his wife, or act as a buffer to provide protection (Badanta et al., 2022). Another example is touch. Touching a person can be a sign of comfort or compassion to some people, while others may consider touch to be greatly offensive or inappropriate. Providing culturally competent care means the nurse should ask the patient and their family what their preferences are regarding care.

Summary

25.1 Preadmission Assessment and Education

- The perioperative surgical experience includes the preoperative phase, intraoperative phase, and the postoperative phase.
- The preoperative phase starts when the decision is made to proceed with a surgery or procedure and ends upon transfer to the operating room and is crucial to ensure patient safety.
- The preoperative phase requires a nurse to possess strong communication, teamwork, and patient assessments skills to promote optimal outcomes and avoid errors or adverse events.
- Preadmission care provides the nurse and anesthesia provider the opportunity to ensure that the patient is safe and in a stable condition prior to a procedure or surgery.
- Preadmission assessment includes obtaining many variables, such as the patient's demographics, allergies, height, weight, medications, health history, surgical history, any potential problems with anesthesia, pertinent family history, history of falls, any metal or implants in the body, and social history of smoking, as well as alcohol or recreational drug use.
- Preadmission testing may vary and is dependent on surgeon orders or anesthesia protocol.
- Preoperative education includes arrival time, surgery start time, clothing, showering, medications, corrective devices that cannot be worn in surgery, transportation, advanced directives, and that the postoperative nurse will provide recovery education prior to discharge from the facility.

25.2 Preoperative Nursing Priorities

- Preoperative nurses have several responsibilities and priorities, including documentation, preoperative assessment, physical assessment, and preoperative patient care.
- Documentation should include any assessments, testing, education, and interventions. Informed consent should be verified and documented prior to surgery in order to ensure that the patient is willingly undergoing the procedure and was given all the information regarding the procedure, alternatives, risks, and benefits.
- The preoperative physical assessment ensures that the patient is stable enough for surgery and identifies any issues that should be addressed prior to surgery. The preoperative physical assessment evaluates the respiratory, cardiovascular, renal and hepatic, and endocrine systems and should consider fluid and nutritional status, medications, immune system function, drug and alcohol use, and psychosocial status.
- Patient care in the preoperative setting may include skin and bowel preparation. Any preparations should be followed as ordered by the surgeon or per facility protocol.

25.3 Preoperative Nursing Care Plan

- The preoperative nursing care plan includes interventions aimed at preparing the patient both physically and psychologically for the procedure while prioritizing patient safety.
- The preoperative nurse ensures patient safety by verifying the patient's identity, performing assessments, evaluating the stability of the patient, obtaining vital signs, obtaining any laboratory tests that were not done preoperatively or need to be repeated, verifying medications taken or held for surgery, and taking steps to prevent a wrong-site surgery.
- The preoperative nurse completes interventions to aid in preventing surgical complications.
- Examples include following established protocols and taking steps to decrease complications such as risk for aspiration, injury, and SSI.
- Not only does the preoperative nurse care for the patient, but also for the family. Patient and family-centered care focuses on providing education, reducing anxiety and fear, and providing emotional support.

25.4 Special Preoperative Considerations

- The National Patient Safety Goals aim to promote patient safety and include identifying patients correctly, improving staff communication, using medicines safely, using alarms safely, preventing infection, identifying patient safety risks, and preventing mistakes in surgery.
- Special considerations are required for unplanned or emergency surgeries when immediate intervention is warranted. A quicker, but thorough, assessment should be performed with the patient or their family.
- Older adults not only have age-related changes that can impact the course of their surgical process, but they

often also have comorbidities that affect the surgical course and outcomes.
- Meticulous care is warranted with bariatric surgeries due to the complications or risks associated with obesity.
- Patients with mental and physical disabilities may need accommodations for the use of needed assistive devices, modified education, or additional assistance with transferring or positioning.
- Cultural considerations the preoperative nurse must remember including language, eye contact, gender, touch, and spirituality. It is essential that the nurse be culturally competent to avoid cultural bias or insensitivity.

Key Terms

advance directive document that allows a patient to convey, in writing, their wishes for care if they are unable to advocate for themselves due to a medical condition
certified registered nurse anesthetist (CRNA) advanced practice RN who has received special training to administer anesthesia
detoxification withdrawal from substance
incentive spirometer tool used for breathing exercises to promote lung function
malignant hyperthermia serious genetic condition that causes a life-threatening elevation of body temperature and muscle spasms, among other severe symptoms
morbidity illness measured in prevalence or incidence within a population
mortality death measured within a population expressed as a ratio
NPO nothing by mouth
preoperative phase begins when the decision is made to proceed with a surgery or procedure and ends when the patient arrives in the operating room
sentinel event unexpected event that leads to serious patient harm or death

Assessments

Review Questions

1. What phase starts when the patient determines to have a surgical procedure?
   a. Perioperative phase
   b. Preoperative phase
   c. Intraoperative phase
   d. Postoperative phase

2. What is a component of preadmission nursing care? Select all that apply.
   a. Verifying patient surgical history
   b. Verifying patient medications
   c. Performing ordered tests
   d. Marking the surgical site

3. The preadmission nurse has explained what to expect the day of surgery to a patient having an outpatient procedure to remove cataracts. What patient statement lets the nurse know that they need to reinforce education to ensure safety after the procedure?
   a. “I will be able to drive myself home.”
   b. “I will bring my glasses case for my glasses.”
   c. “I will leave jewelry at home.”
   d. “I should hold my metformin the morning of surgery.”

4. The nurse is reviewing a consent form with a patient whose native language is not English. What action should the nurse take?
   a. Have the patient’s English-speaking family member to go over the consent form and document the family member’s name as the interpreter.
   b. Ask a nurse coworker who speaks the patient’s language to verify the consent form with the patient and document their name as the interpreter.

c. Call a medically trained interpreter to verify the consent form either over the phone or in person and obtain the interpreter's name and ID for the consent form and chart.
d. Reschedule the surgery until a medically trained interpreter can be present for the day of surgery.

5. The preoperative nurse brings the patient to the preop room to begin an assessment and prepare for surgery. The patient appears fearful and is crying and tugging on the sleeves of their jacket. What intervention should the nurse implement? Select all that apply.
a. Let the patient's family come back with them.
b. Keep the interview going, as nervousness is a normal part of surgery.
c. Ask the patient if there is anything in particular they are nervous about.
d. Ask about any spiritual or cultural beliefs or practices the patient may have.

6. The nurse provides a patient with preoperative instructions. The nurse understands the need to reinforce education when the patient makes what statement?
a. "I should hold all my vitamins and supplements until after surgery."
b. "I can take my baby aspirin the day of surgery."
c. "I should not have anything to eat or drink after midnight."
d. "My husband will need to drive me home after the procedure."

7. A 25-year-old female presents to the facility for a right knee arthroscopy. The preoperative nurse advises the patient that a urine sample is needed. The patient states that "If this is for pregnancy, I just took a test last week, and it was negative." How should the preoperative nurse best respond?
a. "Okay, if you took a test last week, then we will skip the test today."
b. "I understand, but it is protocol to test the day of surgery."
c. "I'm sorry, I cannot trust your previous test was accurate."
d. "It doesn't matter. We have to test all patients prior to surgery."

8. The preoperative nurse brings a patient to the preop room to begin an assessment and prepare for surgery. What steps will the nurse take to prevent complications? Select all that apply.
a. Have the patient remove any jewelry.
b. Verifying the last doses of medications.
c. Allow the patient to put the hospital gown over their clothing.
d. Prep the skin and verify there are no open wounds near the surgical site.

9. The preoperative nurse has provided the patient and family with education related to the events of the surgery day. The nurse knows that education needs to be reinforced when the patient's partner makes what statement?
a. "I can go into the operating room with my partner."
b. "I can watch the screen in the lobby for updates with my partner's case number."
c. "I will be the one to drive us home."
d. "The provider will come talk to us before my partner goes back to the operating room."

10. What is a goal of the National Patient Safety Goals? Select all that apply.
a. Identifying patients correctly
b. Preventing infection
c. Improving patient communication
d. Improving staff communication

11. The preoperative nurse is reviewing a chart for a next day surgery patient who has a BMI of 47. What complications should the nurse recognize? Select all that apply.
a. Wound dehiscence
b. Pulmonary complications
c. Surgical site infections

d. Blood loss

Check Your Understanding Questions

1. The preadmission nurse has performed an assessment on a patient. The patient denies being diabetic but states they take metformin. What should the nurse do?
2. Describe how a patient's drug and alcohol use may impact surgery.
3. The preoperative nurse is reviewing the consent with the patient. The patient states the surgeon has not explained the procedure nor its risks and benefits. The patient asks the nurse to explain it. What should the nurse do?
4. Describe the patient safety measures the preoperative nurse can take.
5. Describe how the preoperative nurse's workflow will be different for emergency surgery compared to elective procedures.

Reflection Questions

1. What information should the nurse obtain when performing a preadmission assessment for a surgical patient?
2. What interventions should a preoperative nurse perform to prevent complications?
3. The preoperative nurse is verifying the surgery with the patient. The orders and consent are written for a left total knee arthroplasty, but the patient states the surgery is supposed to be on his right hip. What should the nurse do?
4. What special considerations should the preoperative nurse remember with older adults?
5. The preoperative nurse is preparing the surgical chart for a deaf patient. What interventions should the nurse implement?

Critical-Thinking Questions about Case Studies

1. Why is it important to ensure the patient has not taken any ibuprofen for 7 days prior to the knee replacement surgery?
2. Explain why it is important to ensure a surgical consent form was signed and placed in the medical record?

Competency-Based Assessments

1. Prepare a Do and Do Not education handout to provide to a surgical patient during the preoperative assessment and interview.
2. Prepare a checklist that the nurse could use to perform a physical assessment of a preoperative patient.
3. Prepare a handout with a checklist that covers education for a patient and family on the day of surgery.
4. Complete an internet search for best practice standards. Prepare a checklist of cultural considerations that the preoperative nurse should be aware of that are specific to surgery patients.

CHAPTER 26
Intraoperative Care

FIGURE 26.1 The nurse's role is pivotal for the patient's care during surgery. The nurse must collaborate with other providers on the surgical team to ensure the patient's safety before, during, and after the procedure. (credit: "Aviano's surgical team" by Airman 1st Class Ryan Conroy/U.S. Air Force, Public Domain)

CHAPTER OUTLINE

INTRODUCTION The surgical experience is a multifaceted journey that encompasses a range of emotions, preparations, and procedures. From the initial consultation with a health-care provider to the postoperative recovery period, patients navigate a series of critical steps designed to ensure their safety and the success of the operation. This journey often begins with a detailed evaluation and diagnosis, followed by meticulous planning and coordination among a team of medical professionals. The actual surgery, whether elective or emergency, marks a significant event, demanding both physical and emotional resilience from the patient. Post surgery, the recovery phase involves continuous care and monitoring, aiming to restore the patient's health and well-being. Understanding the comprehensive nature of the surgical experience is essential for patients and their families, as it helps in setting realistic expectations and fostering a sense of preparedness and confidence. *Perioperative* describes the time frame surrounding surgery. It is used to encompass the time between going to the facility, having the procedure, and then returning home afterward. This chapter will discuss the second of the three phases included in perioperative nursing.

26.1 Overview of the Surgical Experience

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Describe the various surgical settings
- Differentiate the three surgical categories
- Compare the common types of surgery by their suffixes
- Distinguish the members of the surgical team

The intraoperative phase is the second of three phases of perioperative care. The **intraoperative phase** begins when the patient is transferred to the operating room bed and ends when the patient is transferred to the post-anesthesia care unit (PACU). Just like the previous phase, the intraoperative phase is also broken down into distinctive responsibilities and tasks for all team members. In recent years, emphasis has been placed on adhering to strict protocols and developing best practice standards throughout the surgical procedure, ensuring the highest level of safety for each procedure. This chapter will explore the complexities involved with intraoperative care, roles of the surgical team, safety and infection prevention, and nursing management.

Surgical Settings

Surgical settings can vary based on the type of procedure, the medical facility, and the complexity of the patient's individual scenario. There are several primary surgical settings:

- An **inpatient hospital operating room** is the most common surgical setting for patients (Figure 26.2). Hospitals have dedicated operating rooms with specialized equipment, surgical tools, anesthesia, and monitoring devices to perform safe and effective surgery. Inpatient facilities have strict sterilization protocols and are staffed by surgeons, anesthesiologists, nurses, and other support members of the interprofessional team. This setting can also be used for robotic-assisted surgical procedures.
- An **ambulatory surgical center (ASC)** is a facility designed for outpatient procedures that do not require the patient to be monitored overnight. They offer a more convenient and cost-effective alternative to the inpatient operating room setting. ASCs are equipped to perform minor and minimally invasive surgeries, such as cataract surgery, minor cosmetic surgery, colonoscopies, and minor orthopedic procedures, such arthroscopy of the knee.
- Clinics or specialty provider offices host minor surgeries such as wisdom teeth extraction, skin lesion removals, and biopsies. The types of procedures that can be done in a clinic or provider's office are minimally invasive and require no long-term observations of the patient. These settings are equipped with the essential surgical equipment for minor surgical procedures. This type of practice promotes cost-effective care by only requiring local anesthetic, and no admission or discharge to a facility resulting in low costs to the patient.

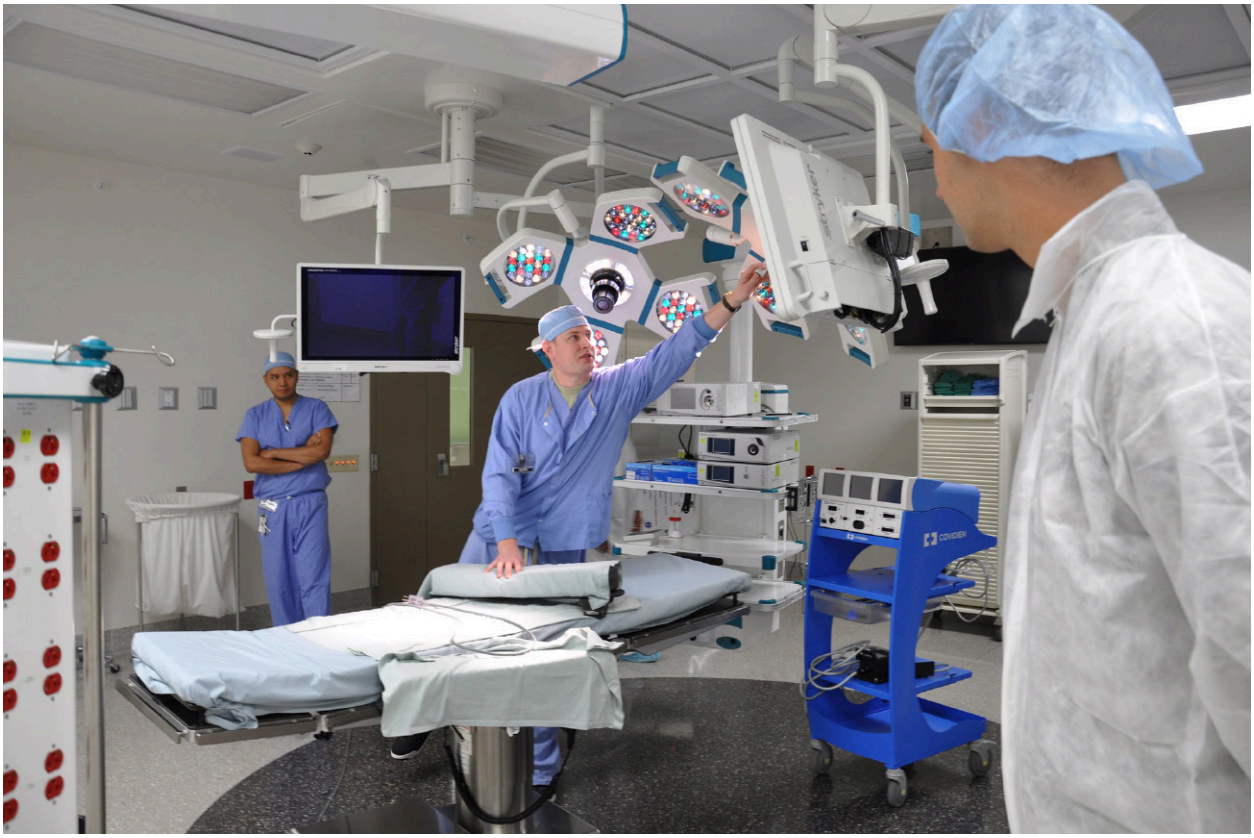

FIGURE 26.2 A standard operating room contains specialized equipment, tools, and monitoring devices. (credit: "New operating rooms at WPAFB Medical Center Complex" by LouisvilleUSACE/Flickr, CC BY 2.0)

Surgical Categories

Surgical procedures are categorized based on the timing and necessity of the operation deemed by the surgical team. Using a system to categorize surgeries can help the medical and surgical teams prioritize and manage the care needed for patients. There are three primary categories used to organize surgical procedures: elective, urgent, and emergent.

An **elective surgery** is defined as a non-emergent, planned procedure that is scheduled in advance based on the patient's preference, surgical procedure, location of procedure, and surgeon's availability. These surgeries are performed to improve a patient's quality of life, address chronic illnesses, or address non–life-threatening medical issues. They can be scheduled in advance, giving patients time to prepare for the surgery. Procedures like joint replacements, cosmetic surgeries, cataract removal, hernia repairs, and some tumor removals may fall under this category.

An **urgent surgery** is a necessary procedure that must be performed promptly, usually within twenty-four to forty-eight hours. While they are not considered life-threatening, these surgeries address conditions that could worsen without intervention by the surgical team. Delaying these surgeries can lead to complications, causing the patient's condition to turn into a life-threatening problem. Procedures such as long bone fractures, infections that require drainage devices, or acute gallstones are often considered urgent.

An **emergency surgery** is an immediate, unplanned procedure performed to save a patient's life or prevent severe disability. Emergent surgeries are necessitated by acute, life-threatening conditions or injuries that require immediate intervention. Examples of emergency surgeries include perforation to the bowel or bladder, rupture of an organ like spleen or appendix, severe trauma, burns, active bleeding, or organ damage.

Surgical Procedures

Surgical procedures are often named for the location, body part, condition, and specific technique that is used. The suffix provides insight into the nature of the surgery. (Table 26.1) lists common surgical suffixes and their meanings.

Suffix	Meaning	Examples
-graphy	Imaging or recording	Mammography (imaging of the breast tissue) Angiography (imaging of blood vessels)
-ectomy	Excision or surgical removal	Lobectomy (removal of a lung lobe) Hysterectomy (removal of the uterus)
-otomy	Cutting into or incision	Tracheotomy (incision into the trachea/windpipe) Craniotomy (surgical opening of the skull bone) Laparotomy (abdominal incision to access the abdominal cavity)
-ostomy	Artificial opening or creating an opening	Colostomy (creation of an artificial opening in the colon to the outside of the abdomen) Urostomy (surgical opening for urine diversion)
-plasty	Surgical repair or reshaping	Mammoplasty (augmentation or reduction of the breast tissue) Rhinoplasty (surgical reconstruction of the nose)
-scopy	Examination or visualization	Thoracoscopy (minimally invasive visualization inside the thoracic cavity) Endoscopy (examination of internal organs using an endoscope)

TABLE 26.1 Common Surgical Suffixes

Understanding the suffix at the end of the words can give an idea of the type of procedure being performed. This can help surgeons, nurses, and other medical professionals prepare the proper equipment for a safe and effective surgical procedure.

The Surgical Team

In the intricate realm of health care, the surgical team stands as a collaborative force at the forefront of medical intervention. This section explores the dynamic and multifaceted world of the surgical team, shedding light on the diverse roles, responsibilities, and expertise that each member brings to the operating room.

The Patient

First and foremost, the most important team member is the patient. The role of the patient in the operating room is fundamentally passive but essential to the success of the surgical process. As the individual undergoing surgery, the patient plays a critical role in entrusting their well-being to the surgical team. Before the procedure, the patient collaborates with health-care professionals to provide a thorough medical history, disclose any allergies, and offer pertinent information to ensure safe surgery. The surgical team trusts the patient to perform all presurgical instructions, such as washing with surgical soap the night before, not eating or drinking per instructions, and taking medications as ordered.

While in the operating room, the patient is prepared for the procedure by the anesthesia team, to induce a state of unconsciousness or sedation. While sedated the patient is relying on the surgical team to treat their body with dignity and respect, such as only exposing areas needed for the procedure, and maintaining professionalism throughout the surgery. The patient relies on the expertise of the surgical team to perform any necessary interventions if anything unexpected happens.

Following the surgery, the patient's role shifts to more active participation in their recovery. Compliance with postoperative instructions, medication schedules, and follow-up appointments is crucial for a successful recovery. The patient's trust, cooperation, and adherence to medical advice contribute significantly to the overall efficacy of the surgical process and the achievement of positive health outcomes.

Nursing Roles

The surgical team is comprised of several nursing roles, each with their own set of responsibilities during the surgery. This section will discuss the three main roles of a nurse within the surgical team. The **RN circulator**, also known as a circulating nurse**,** is responsible for coordinating and managing various aspects of the operating room before, during, and after surgery, which is critical in ensuring the smooth and safe functioning of surgical procedures. Before the procedure, the circulating nurse prepares the operating room by ensuring all necessary equipment, supplies, and instruments are available and in working order. During surgery, they maintain a sterile environment, monitor the team's compliance with aseptic techniques, and manage the flow of communication and materials. The circulating nurse also advocates for patient safety and liaises between the surgical team and other health-care professionals. Post-surgery, they assist in transferring the patient to the recovery area and document the procedure for the patient's medical records. The role demands excellent organizational skills, attention to detail, and the ability to handle high-pressure situations to ensure optimal patient outcomes and a well-coordinated surgical experience.

LINK TO LEARNING

The Association for Operating Room Nurses (AORN) has created evidence-based best practice guidelines for perioperative practice (https://openstax.org/r/77PeriOpBPGuide) to help nurses care for surgical patients safely and effectively and to ensure workplace safety.

The role of a scrub nurse in the operating room is indispensable, contributing significantly to the efficiency and safety of surgical procedures (Russell, 2022). The **scrub nurse** is tasked with maintaining the sterility of the surgical environment. They play a pivotal role in preparing and organizing the sterile instruments and supplies needed for the surgery. Before the procedure, they collaborate closely with the surgical team to ensure all necessary equipment is available, sterilized, and organized. During the surgery, the scrub nurse passes instruments to the surgeon, anticipates the surgeons' needs, and remains vigilant to preserve the sterile field. They also assist in counting surgical instruments and supplies to prevent any items from being left inside the patient. Additionally, the scrub nurse collaborates with the circulating nurse in managing the overall flow of the surgery, ensuring seamless communication and coordination among the team members. Their meticulous attention to detail, knowledge of surgical procedures, and ability to work effectively under pressure contribute significantly to the success of surgical interventions and the well-being of patients.

The last of the three main nursing roles in the operating room is the RN first assist. The **registered nurse first assist (RNFA)** controls bleeding during surgery, sutures incisions and wounds, and assists in stabilizing patients when necessary. RNFAs must earn additional education and credentials that certify their ability to perform in this expanded role. To become an RNFA, students must take advanced coursework, earn certifications, and undergo an extensive training process. According to the Association of Perioperative Registered Nurses (AORN). RNFAs practice intraoperatively at a surgeon's direction while not concurrently functioning as scrub nurses (Croke, 2020).

Medical Providers

The operating team has two types of medical providers. The first type, and the lead of the surgical team, is the surgeon. The **surgeon** is a medical doctor with extensive training in performing surgical procedures. The role of the surgeon in the operating room is central to the success of any surgical procedure. Surgeons are highly trained medical professionals with the expertise to diagnose, plan, and execute a variety of surgical interventions. In the operating room, the surgeon is responsible for leading the surgical team, providing guidance, and making critical decisions throughout the procedure. They are tasked with performing the surgery which requires skill, precision, and knowledge to address the patient's medical condition. Surgeons work collaboratively with the other surgical team members to ensure a smooth and coordinated process. Communication is crucial, as the surgeon directs the team, communicates with the patient when necessary, and collaborates with colleagues to optimize patient outcomes.

Beyond the operating room, surgeons are involved in preoperative and postoperative care, obtaining informed consent, discussing treatment plans, and monitoring the patient's recovery. The surgeon's role demands a combination of technical proficiency, decision-making skills, and effective communication to navigate the complexities of surgery and provide the best possible care to patients.

The second type of provider on the surgical team is the anesthesiologist. The role of anesthesiologists in the operating room is paramount in ensuring the comfort, safety, and maintenance of the patient's airway throughout the surgical process. An **anesthesiologist** is a highly trained professional responsible for administering anesthesia, monitoring the patient's vital signs and airway, and managing the patient's pain during surgery. Before the procedure, the anesthesia provider evaluates the patient's medical history, assesses the patient's overall health, and develops an anesthesia plan tailored to the individual's needs. During the surgery, they administer the appropriate type and amount of anesthesia, ensuring the patient is in a controlled state of unconsciousness or sedation. Anesthesia providers continually monitor vital signs, such as heart rate, blood pressure, and oxygen levels, adjusting the anesthesia to maintain stability. Their expertise extends to managing potential complications and responding to emergencies, contributing significantly to patient safety.

Another anesthesia provider that works directly under the guidance of the anesthesiologists includes the certified registered nurse anesthetist (CRNA), who is a master prepared and board-certified advanced practice nurse in the specialty of anesthesia. Additional roles include anesthesia assistants, and resident physicians. Postoperatively, anesthesia providers oversee patients' recovery from anesthesia and manage pain control. Their crucial role in optimizing the patient's experience in the operating room underscores the importance of their skill, knowledge, and vigilance in ensuring a successful and comfortable surgical outcome.

Other Personnel

In addition to the core members of the surgical team, the intraoperative phase involves the collaboration of various other personnel who play crucial roles in ensuring the smooth progression and success of surgical procedures. These include surgical assistants, who provide invaluable support to the surgical team and contribute to the seamless execution of surgical procedures. Their responsibilities encompass a wide range of tasks, from ensuring the sterility of instruments and supplies to actively participating in the surgical procedure. Surgical assistants collaborate closely with the surgeon, anticipating needs, providing instruments, and aiding in complex aspects of the surgery. With a keen understanding of anatomy, instrumentation, and aseptic techniques, they contribute to the precision and efficiency of the surgical process. Beyond technical proficiency, surgical assistants serve as liaisons between team members, fostering effective communication and maintaining a harmonious workflow. Their role is dynamic, adapting to the specific demands of each procedure, and their contributions significantly enhance the overall success and safety of the intraoperative experience for both the surgical team and the patient. Their comprehensive nursing knowledge and attention to detail ensure that patients receive optimal care from preoperative preparation to postoperative recovery. Collectively, these dedicated personnel form an integral part of the intraoperative team, working collaboratively to uphold the highest standards of patient care and safety in the operating room.

26.2 Intraoperative Considerations

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Describe the surgical environment in relation to the intraoperative phase
- Discuss the use of sterile technique to maintain surgical asepsis
- Explain the importance of the time-out during a surgical procedure
- Explore patient positioning used in the surgical setting
- Define airway management during the surgery
- Differentiate types of anesthesia and sedation used during the surgical experience

The intraoperative phase is uniquely situated at the heart of surgical interventions, which can pose unique challenges and opportunities for health-care professionals dedicated to providing optimal care. The surgical team must create and maintain a secure environment to ensure patient safety and the prevention of post-surgical infection. From the implementation of rigorous aseptic techniques to vigilant monitoring and communication, the pursuit of excellence in intraoperative safety and infection prevention is integral to fostering successful surgical

outcomes and safeguarding the well-being of those entrusted to the surgical team's care.

The Surgical Environment

The environment for surgical procedures serves as the stage for the delicate interplay of medical expertise and technological advancements through a strictly controlled workspace. The **surgical environment** is a controlled and sterile setting in which surgical procedures are performed, including the operating room, associated equipment, and related practices and protocols designed to maintain asepsis. The operating room, often referred to as the "surgical suite," is meticulously designed to facilitate optimal conditions for surgical procedures. Characterized by its spotless surfaces, advanced equipment, and an array of specialized tools, the environment prioritizes the prevention of infection and the maintenance of patient safety. Controlled temperature, humidity, and airflow contribute to asepsis, reducing the risk of postoperative complications. Lighting and ergonomic considerations are paramount, providing surgeons with optimal visibility and comfort during intricate procedures. Beyond the physical attributes, the surgical environment thrives on collaboration and communication among the diverse members of the surgical team. The collective commitment to maintaining sterility, adhering to safety protocols, and working as a team within this environment underscores its pivotal role in ensuring the success of surgical interventions and, ultimately, the well-being of the patient.

Principles of Surgical Asepsis and Sterile Technique

Principles of surgical asepsis and sterile technique form the bedrock of infection prevention in the operating room, safeguarding patients from potential complications and promoting successful surgical outcomes (Table 26.2). The set of practices designed to maintain a sterile field and prevent the introduction of microorganisms into the surgical environment is called **surgical asepsis**. This includes rigorous hand hygiene (Figure 26.3), the use of sterile attire, and the meticulous preparation and handling of surgical instruments and supplies. The **sterile technique** extends to the creation of a sterile field around the surgical site, ensuring that only sterile items come into contact with the patient and the surgical wound. Adherence to these principles is critical in mitigating the risk of surgical site infections and other complications. Aseptic and sterile techniques are both crucial in preventing contamination and infection in medical and operating room settings.

FIGURE 26.3 Hand hygiene is one critical step in ensuring asepsis during surgery. (credit: "Magicians behind the curtain: 88th Surgical Operations Squadron" by Matthew Fink/U.S. Air Force, Public Domain)

Technique	Definition	Objective	Applications	Key Practices
Aseptic technique	Involves practices and procedures that help reduce the risk of infection by minimizing the presence of pathogenic microorganisms	To prevent contamination and maintain asepsis by reducing the number of pathogens to a safe level	Applied during the handling of sterile instruments, dressing wounds, and administering injections	Hand washing, wearing gloves, masks, gowns, sterilizing instruments and surfaces, and using barriers such as sterile drapes
Sterile technique	Involves procedures that eliminate all microorganisms, including spores, from an area or object	To achieve and maintain sterility, ensuring an environment free from all microorganisms	Surgical environments and compounding pharmacy	Sterilization of instruments and supplies, creation of a sterile field where only sterile items are used, and using sterile gloves, gowns, and drapes

TABLE 26.2 Comparison of Aseptic and Sterile Techniques

Surgical attire plays a crucial role in infection prevention. Surgeons, nurses, and other members of the surgical team don specialized attire, including gowns and gloves, to maintain a barrier between their own microbiota and the sterile field (Table 26.3). The attire is designed to be impermeable and covers the entire body, minimizing the risk of microbial contamination. Proper donning and doffing procedures are followed to maintain the integrity of the sterile environment. Surgical attire not only serves as a protective measure for health-care professionals but also reflects the dedication to patient safety, ensuring that the surgical team operates within the highest standards of cleanliness and sterility throughout the perioperative process.

Attire	Description
Scrub suit	Top and pants (scrubs) are laundered by the hospital that are lightweight and breathable; usually in the color of blue or green
Surgical Cap/ bouffant	Covers scalp hair to prevent contamination, both disposable or reusable
Surgical mask	Covers mouth and nose and beard hair to prevent the spread of microorganisms; disposable
Protective eyewear	Protects eyes from splashes and droplets; can be goggles or a full face shield
Shoe covers	Covers shoes to prevent contamination; disposable

TABLE 26.3 Surgical Attire Requirements for the Operating Room

Time-Out

The surgical **time-out** represents a critical moment in the perioperative process designed to enhance patient safety and reduce the risk of errors. This best practice standard involves a brief pause in the operating room immediately before the start of a surgical procedure. During this intentional break, the entire surgical team comes together to confirm essential details. Including verifying patient identity (name and date of birth), surgical site, surgical procedure, and verified consent. After the verification of the correct patient, correct procedure, and correct surgical team, the surgical area of the patient is clearly marked with marker by the surgeon, and all labs and tests are reviewed. This time serves as the last break to discuss anything of concern before the start of the procedure.

CLINICAL SAFETY AND PROCEDURES (QSEN)

Teamwork and Collaboration: Surgical Time-Out

Disclaimer: Always follow the agency's policy for surgical time-out procedures.

Definition: Function as an effective and efficient team member utilizing clear, concise communication, professionalism and respect, and an overall shared goal for optimal patient care outcomes.

Knowledge: The intraoperative nurse will have a strong knowledge of surgical concepts and surgical best practices. The nurse will stay current in learning new knowledge as discoveries are made for best practice standards.

Skill: The nurse will:

- avoid distractions during the surgical time-out to minimize mistakes.
- instruct each team member to introduce themself and their role in the surgical setting.
- verbalize all concerns relating to the patient (allergies or other pertinent information for the procedure).
- read the procedure directly from the consent form.

Attitude: The nurse will place value on the knowledge and experience of each team member.

(QSEN Institute, n.d.)

The primary goals of the time-out include the prevention of wrong-site surgeries, identification of potential errors, and reinforcement of effective communication within the team. The World Health Organization (WHO) and various health-care accreditation bodies endorse the implementation of the time-out as a standard safety measure for all procedures, and in all surgical settings (Figure 26.4).

FIGURE 26.4 A surgical time-out allows the surgical team to confirm key details about the patient and procedure. This review helps prevent errors and improves patient safety and, ultimately, patient outcomes. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

This brief yet pivotal pause fosters a culture of collaboration, safety, and accountability among the surgical team. It underscores the commitment to patient safety and serves as a final checkpoint to catch any discrepancies or oversights before the surgical intervention commences. The surgical pause is a testament to the proactive approach taken in modern health-care settings to minimize the occurrence of preventable errors and ensure the highest standards of care for every patient undergoing surgery.

Patient Positioning

The surgical experience is not merely a physical event; it is an emotional and often transformative passage for patients facing medical challenges. This patient is in a mental state where it is important for the interdisciplinary team to take care of the patient holistically, not just their condition. The surgical team's commitment to patient-centered care and the pursuit of excellence becomes the guiding force that ensures not only the success of the procedure but also the patient's overall outcome and satisfaction.

Intraoperative patient positioning is a crucial aspect of surgical care, designed to optimize exposure, accessibility, and patient comfort during a procedure. The proper positioning of the patient is a collaborative effort between the

members of the surgical team, to ensure the safety of the patient and promote the best outcome.

Accurate and careful positioning is essential to avoid complications such as pressure injuries, nerve damage, and circulatory issues. The surgical team considers the patient's anatomy, any pre-existing medical conditions, and the requirements of the surgical procedure when determining the most suitable position. Intraoperative positioning must allow the surgical team optimal access to the operative site while accommodating the use of equipment and ensuring proper alignment of the patient's body. Proper padding and support and vigilant monitoring of the patient's vital signs and neurovascular status are maintained throughout the surgery to identify and address any issues promptly.

Common Intraoperative Positions

In the operating room, various patient positions are used based on the surgical procedure's requirements, the surgeon's preferences, and the patient's medical condition. Each positioning serves specific purposes to optimize exposure, accessibility, and safety during surgery. The following table identifies common positions based on surgical procedures (Table 26.4). Proper training and adherence to established protocols are crucial to ensure the effective and safe use of these devices in the operating room.

Position	Description	Illustration
Supine	Patient lies on their back with arms either tucked at their sides or positioned on arm boards. Commonly used for abdominal, chest, cardiac, and many other procedures.	 (modification of work from *Clinical Nursing Skills*. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)
Fowler's	Patient lies supine but with the head of the bed raised. Commonly used for cranial surgeries, ophthalmic procedures, and some neck surgeries.	 (modification of work from *Clinical Nursing Skills*. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)
Orthopneic (tripod)	The patient is in a sitting position, leaning on an overbed table. Commonly used for intraspinal procedures such as placement of an epidural.	 (modification of work from *Clinical Nursing Skills*. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)
Prone	Patient lies face down, often with supports under the chest and pelvis. Commonly used for spinal surgeries, posterior cranial surgeries.	 (modification of work from *Clinical Nursing Skills*. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

TABLE 26.4 Common Patient Positions

Position	Description	Illustration
Lateral (side-lying)	Patient lies on their side with the operative side facing up or down. Commonly used for hip surgeries, kidney surgeries, thoracic procedures.	 (modification of work from *Clinical Nursing Skills*. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)
Sims (semiprone)	Patient lies in a position between prone and lateral positions.	 (modification of work from *Clinical Nursing Skills*. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)
Lithotomy	Patient lies on their back with legs elevated and positioned in stirrups. Commonly used for gynecological and urological procedures.	 (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)
Trendelenburg	Patient lies on their back with arms at their sides and is positioned with the head down and feet up. Commonly used for pelvic and abdominal surgeries requiring better visualization.	 (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)
Reverse Trendelenburg	Patient lies on their back with arms at their sides and is positioned with the head up and the feet down. Commonly used for neurosurgical procedures, upper abdominal surgeries.	 (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)
Knee-chest	Patient lies on side with torso positioned diagonally across table and with hips and knees flexed; can also be with patient in prone position, on their knees with chest and face on the table.	 (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

TABLE 26.4 Common Patient Positions

Position	Description	Illustration
Jackknife	Also called Kraske; patient lies prone on the table, and the table is split to lift the hips and lower the head and legs.	 (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)
Kidney	Patient lies in a modified lateral position; the table is split, lowering the head and legs.	 (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

TABLE 26.4 Common Patient Positions

Positioning Devices

Operating room positioning devices are essential tools designed to support and maintain the proper positioning of patients during surgical procedures. These devices, when used appropriately, contribute to the precision and safety of surgical procedures and can help prevent complications related to poor positioning. Devices optimize exposure and accessibility for the surgeon while ensuring the safety and comfort of the patient. Various types of positioning devices are used based on the surgical procedure and the desired patient position (Table 26.5).

Positioning Device	Description	Features
Surgical table	Adjustable tables are designed to support the patient in different positions.	The tabletop can be tilted, raised, lowered, and rotated to accommodate various surgical positions.
Headrests and skull clamps	Devices to secure and support the patient's head during head and neck surgeries.	May include gel pads or foam cushions for comfort and stability.
Armboards	Extensions attached to the side of the surgical table to support the patient's arms.	Adjustable height and angle to ensure proper arm positioning without compromising blood circulation.
Stirrups	Devices attached to the end of the surgical table to support the patient's legs in lithotomy position.	Adjustable to provide proper leg elevation and abduction.
Body supports and bolsters	Cushions or pads placed under specific body parts to maintain proper alignment.	Different shapes and sizes to support areas such as the spine, shoulders, or pelvis.

TABLE 26.5 Common Positioning Devices

Positioning Device	Description	Features
Gel pads and positioning pillows	Soft pads or pillows used to provide additional support and pressure distribution.	Conform to the body's contours, helping to prevent pressure injuries.
Bean bags	Soft, moldable bags filled with small beads that conform to the patient's body shape.	They are used for positioning in various surgical procedures, providing stability and support.
Vacuum bean bags	Similar to traditional bean bags but with a vacuum system to remove air, creating a firm and moldable surface.	Offers enhanced stability and immobilization during surgery.
Shoulder chairs	Chairs designed for shoulder surgeries, allowing the patient to be positioned in a seated or semi-seated position.	Adjustable to accommodate different patient sizes and surgical approaches.
Traction devices	Devices used for limb traction during orthopedic procedures.	Provide controlled and adjustable traction to the limb being operated on.

TABLE 26.5 Common Positioning Devices

Positioning Complications

While proper positioning is essential for the success of surgical procedures, there are potential complications associated with patient positioning in the operating room (Table 26.6). These complications can arise due to inadequate support, prolonged immobility, pressure on vulnerable areas, or interference with blood circulation. To mitigate these complications, the surgical team should follow established protocols, communicate effectively, and regularly reassess the patient's positioning throughout the procedure. Proper padding, positioning devices, and vigilance are essential to ensure patient safety and to prevent adverse events related to positioning in the operating room.

Positioning Complication	Cause	Prevention
Pressure injuries (pressure ulcers)	Prolonged pressure on a specific area, particularly over bony prominences.	Regular repositioning, adequate padding, and using pressure-relieving devices.
Nerve injuries	Compression or stretching of nerves during positioning, leading to neurologic deficits.	Careful padding, avoiding excessive stretching or compression of nerves, and monitoring for signs of nerve injury.
Musculoskeletal injuries	Improper positioning leading to strains, sprains, or joint injuries.	Careful handling during positioning, using appropriate supports and padding.
Compartment syndrome	Increased pressure within a muscle compartment, often due to improper limb positioning.	Monitor for signs of swelling, maintain proper limb alignment, and avoid excessive pressure.

TABLE 26.6 Common Positioning Complications

Positioning Complication	Cause	Prevention
Peripheral nerve palsies	Pressure on blood vessels leading to compromised blood flow.	Monitor vascular status, avoid excessive compression, and ensure proper positioning to maintain blood circulation.
Eye injuries	Pressure, compression, or excessive stretching of the eyes during surgeries involving head positioning.	Use appropriate eye protection and ensure careful positioning.
Airway complications	Inadequate airway management during positioning leading to respiratory distress.	Proper placement of airway devices, ensuring adequate ventilation, and monitoring respiratory status.
Patient falls	Improper securing or instability of the patient on the operating table.	Adequate restraints, secure positioning, and careful handling during transfers.
Positioning-related infections	Compromised skin integrity or breaches in aseptic technique during positioning.	Strict adherence to sterile techniques, proper skin preparation, and maintaining a clean environment.

TABLE 26.6 Common Positioning Complications

Airway Management

Airway management during the intraoperative phase is a critical component of anesthesia care, ensuring the patient's respiratory function and oxygenation are adequately maintained throughout the surgical procedure. Anesthesia providers employ a range of techniques to secure and manage the airway, including endotracheal intubation or the use of supraglottic airway devices. The selection of the appropriate method depends on various factors: the type and duration of surgery, patient characteristics, and the preferences and expertise of the anesthesia team. As patients under general anesthesia are completely unconscious, their vital functions are supported by mechanical ventilation. Continuous monitoring of the patient's airway pressure, oxygen saturation, and end-tidal carbon dioxide levels is imperative to promptly detect and address any complications or deviations from normal respiratory parameters. The anesthesia provider's expertise in airway management is crucial in navigating potential challenges, ensuring proper ventilation, and safeguarding the patient's respiratory well-being throughout the intraoperative phase.

LINK TO LEARNING

Watch these videos that explain respiratory anatomy and physiology (https://openstax.org/r/77RespAnatPhys) in depth.

Anesthesia Awareness

Also known as intraoperative awareness, **anesthesia awareness** is a rare but potentially distressing phenomenon where a patient becomes partially or fully aware of their surroundings during surgery despite being under general anesthesia. This condition occurs when the depth of anesthesia is insufficient to block consciousness, leading to the patient experiencing sensory perceptions, sounds, or even the awareness of the ongoing surgical procedure. While the exact incidence of anesthesia awareness is low, its potential psychological impact on patients is considerable. Patients who experience awareness may recall sensations, conversations, or even feelings of paralysis, creating lasting emotional distress. In cases where awareness does occur, postoperative support and counseling are essential to address the patient's emotional well-being. Anesthesia awareness underscores the delicate balance in achieving optimal depth of anesthesia to ensure patient comfort and safety, highlighting the ongoing efforts within

the anesthesia community to refine monitoring techniques and prevent this rare but significant occurrence.

Types of Anesthesia and Sedation

Anesthesia and sedation are critical components of modern medical procedures, ensuring patient comfort and pain management during surgeries and other interventions. Anesthesia can be classified into several types, including general anesthesia, regional anesthesia, and local anesthesia, each serving different purposes and levels of patient sedation. These techniques are chosen based on the type of procedure, patient health, and desired outcomes, ensuring safety and comfort throughout the medical process. Table 26.7 provides a brief overview of the types of commonly used anesthesia.

Type of Anesthesia	Use of Anesthesia	Forms of Administration	Commonly used Medications
General anesthesia	Induces a reversible state of unconsciousness	Combination of intravenous and inhalation medications	IV: Propofol, benzodiazepines and opioids Inhaled: sevoflurane, isoflurane, and desflurane
Multimodal anesthesia	Employs a diverse array of strategies, including regional anesthesia, non-opioid analgesics, and adjunct medications	Combination of intravenous and PO (by mouth) medications	Nonopioid medications (e.g., acetaminophen, nonsteroidal anti-inflammatory drugs, and gabapentinoids alongside regional techniques like spinal, epidural, or nerve blocks
Regional anesthesia	Encompasses a diverse set of techniques aimed at providing targeted pain relief to specific regions of the body	Spinal, epidural, and peripheral nerve blocks	Short acting: lidocaine and mepivacaine Long-acting ones are bupivacaine and ropivacaine
Moderate sedation (conscious sedation)	A controlled state of reduced consciousness that allows patients to undergo medical procedures while remaining responsive and able to maintain their own airways	Intravenous utilized for procedures such as endoscopies, dental treatments, and minor surgeries	Propofol, benzodiazepines, and opioids

TABLE 26.7 **Commonly Used Anesthesia**

General Anesthesia

The sophisticated medical technique that induces a reversible state of unconsciousness, allowing patients to undergo surgical procedures without experiencing pain, awareness, or discomfort is called **general anesthesia**. It involves a combination of intravenous medications and inhaled anesthetics. The intravenous drugs, often including an induction agent and muscle relaxants, initiate unconsciousness, while inhaled anesthetics maintain the state of general anesthesia throughout the surgery. Anesthesia providers carefully monitor the patient's vital signs, including heart rate, blood pressure, and oxygen levels, to ensure the patient's safety and well-being. General anesthesia allows for a controlled and pain-free surgical experience, making it suitable for a broad range of procedures, from minor surgeries to complex interventions. The advancements in anesthetic agents and monitoring technologies have contributed to the safety and precision of general anesthesia, making it an essential and integral component of modern surgical care.

General anesthesia involves a combination of inhaled and intravenous administration of medication. This combination is a cornerstone of modern anesthetic practice, offering a rapid and efficient means of inducing and maintaining a controlled state of unconsciousness during surgical procedures. Anesthesia providers administer intravenous (IV) anesthetics directly into the bloodstream, facilitating a quick onset of anesthesia and allowing for precise titration to achieve the desired depth of unconsciousness.

Intravenous medication in combination with inhaled medication offers advantages such as a smoother emergence from anesthesia, reduced risk of postoperative nausea and vomiting, and a faster recovery compared to inhaled anesthetics. However, meticulous attention to dosage, continuous monitoring of vital signs, and consideration of individual patient factors are imperative to ensure patient safety during the perioperative period. The intravenous route of administration remains a critical component in anesthesia administration, allowing for precise control and customization of anesthesia to meet the unique needs of each patient and each surgical procedure.

Multimodal Anesthesia

An evolving approach in perioperative care that seeks to optimize pain management by combining various techniques and medications to achieve a balanced and comprehensive analgesic effect is called **multimodal anesthesia**. Unlike traditional methods relying solely on opioids, multimodal anesthesia employs a diverse array of strategies, including regional anesthesia, nonopioid analgesics, and adjunct medications. By targeting pain from different angles, this approach aims to reduce reliance on opioids and to minimize the associated side effects such as respiratory depression and nausea. Incorporating nonopioid medications (e.g., acetaminophen, nonsteroidal anti-inflammatory drugs [NSAIDs], gabapentinoids) alongside regional techniques like epidurals or nerve blocks, provides a synergistic effect in pain control. The continual refinement of this approach underscores its growing importance in optimizing pain relief while minimizing the potential adverse effects associated with traditional opioid-centric analgesia. Multimodal anesthesia reflects a patient-centered paradigm in modern perioperative medicine, tailoring pain management strategies to individual needs and promoting a holistic approach to surgical care.

Regional Anesthesia

The diverse set of techniques aimed at providing targeted pain relief to specific regions of the body is called **regional anesthesia**. By interrupting nerve signals, regional anesthesia effectively blocks sensation to a localized area, allowing patients to undergo various surgical procedures without the need for general anesthesia. Common forms of regional anesthesia include spinal anesthesia, epidural anesthesia, and a peripheral nerve block. These techniques offer several advantages: reduced systemic exposure to anesthetic agents, decreased postoperative pain, faster patient recovery, and improved patient outcomes. Regional anesthesia is particularly well-suited for surgeries involving the extremities, abdominal, pelvic, and thoracic regions. The application of ultrasound guidance has enhanced the precision and safety of regional anesthesia, allowing for more accurate placement of needles and catheters. The versatility and efficacy of regional anesthesia make it an integral component of contemporary anesthesia practice, contributing to enhanced patient satisfaction and improved perioperative care.

Epidural Anesthesia

The widely employed technique in regional anesthesia, providing effective pain relief for various surgical procedures and obstetric interventions is called **epidural anesthesia**. It involves the injection of local anesthetic agents into the epidural space surrounding the spinal cord, providing a controlled and prolonged analgesic effect. Commonly used in obstetrics for pain management during labor and delivery and in the postoperative period, epidural anesthesia allows patients to remain conscious while experiencing reduced sensation in the lower half of the body. The insertion of a catheter into the epidural space permits continuous or intermittent administration of local anesthetics or opioids, tailoring the pain relief to individual needs.

Epidural anesthesia is favored for its versatility, providing targeted analgesia for abdominal, pelvic, and lower extremity surgeries. While generally considered safe, meticulous attention to sterile technique, proper dosage calculation, and continuous monitoring are essential to minimize potential complications. Potential problems include low blood pressure, headaches, temporary changes in bladder control nerve damage, and infection. The widespread use of epidural anesthesia underscores its efficacy in enhancing patient comfort and satisfaction across a spectrum of medical procedures.

Spinal Anesthesia

The well-established and widely utilized form of regional anesthesia that involves the injection of local anesthetic agents (e.g., bupivacaine, lidocaine) into the cerebrospinal fluid surrounding the spinal cord is called **spinal anesthesia**. This results in a temporary loss of sensation and motor function in the lower half of the body, facilitating various surgical procedures without the need for general anesthesia. Administered through a lumbar puncture, spinal anesthesia offers rapid onset and reliable anesthesia, making it particularly suitable for lower abdominal, pelvic, and lower extremity surgeries. Its advantages include a quicker recovery, reduced postoperative pain, and minimized systemic effects compared to general anesthesia. While spinal anesthesia is generally safe, careful patient selection, proper dosage calculation, and meticulous attention to sterile technique are essential for its successful administration. Patients are at an increased fall risk and due to the half-life of this type of anesthesia, pain can reappear quicker than other types. The technique's effectiveness and widespread applicability make spinal anesthesia a valuable option in modern anesthesia practice, contributing to improved patient outcomes and satisfaction in a variety of surgical settings.

Peripheral Nerve Blocks

A specialized form of regional anesthesia that involve the precise injection of local anesthetic agents near specific nerves to block sensation in a targeted region of the body is called a **peripheral nerve block**. This technique provides effective pain relief for surgical procedures or chronic pain management without the need for general anesthesia. By temporarily interrupting nerve signals, peripheral nerve blocks can result in complete or partial anesthesia, depending on the location and extent of the nerve block. Commonly used local anesthetics for peripheral nerve blocks include lidocaine, bupivacaine, and ropivacaine. The advantages of peripheral nerve blocks include reduced systemic drug exposure, decreased postoperative pain, and potentially faster recovery times. These blocks can be administered for various purposes, including orthopedic surgery, limb surgeries, and certain outpatient procedures. While the procedure is generally well-tolerated, careful consideration of the patient's medical history, and potential complications are crucial for the safe and effective administration of peripheral nerve blocks. The use of ultrasound guidance has enhanced the precision of these blocks, contributing to their growing popularity as an integral component of multimodal pain management strategies in contemporary medical practice.

Moderate Sedation

Also known as conscious sedation, **moderate sedation** is a controlled state of reduced consciousness that allows patients to undergo medical procedures while remaining responsive and able to maintain their own airways. During moderate sedation, patients are in a state of relaxed wakefulness, experiencing diminished anxiety and discomfort. This type of sedation is commonly administered by anesthesia providers or trained health-care professionals using medications such as benzodiazepines and opioids, which induce a calming effect and provide pain relief. It is important for the nurse to know what medication was used and how long its effectiveness will last. Pain will return immediately. If the nurse is aware of when the medication will possibly wear off, they can proactively administer pain medication to help with a smooth transition. While under moderate sedation, patients can respond to verbal commands and tactile stimulation but may have impaired memory of the procedure. The level of sedation is carefully titrated to achieve the desired effect while ensuring patient safety.

Moderate sedation is frequently utilized for procedures such as endoscopies, dental treatments, and minor surgeries, offering a balance between patient comfort and the ability to maintain vital functions independently. Close monitoring of the patient's respiratory status, cardiovascular function, and level of sedation is essential throughout the procedure to prevent complications and ensure a smooth recovery. Overall, moderate sedation plays a valuable role in facilitating a wide range of medical interventions while optimizing patient comfort and cooperation.

Monitored Anesthesia Care

The specialized approach to anesthesia that combines elements of local anesthesia and sedation to provide a controlled and comfortable experience for patients undergoing certain procedures is called **monitored anesthesia care (MAC)**. Unlike general anesthesia, MAC allows patients to remain conscious and maintain protective reflexes while alleviating pain and discomfort. During MAC, anesthesia providers administer sedative medications intravenously, tailoring the dosage to achieve the desired level of conscious sedation. Simultaneously, providers closely monitor vital signs, including heart rate, blood pressure, and oxygen saturation, to ensure the patient's safety and comfort. This form of anesthesia is commonly employed for minimally invasive procedures, such as

endoscopies, certain diagnostic tests, or minor surgical interventions. The key advantage of MAC lies in its ability to balance patient comfort and cooperation with the need for pain control, all while maintaining the flexibility for rapid conversion to general anesthesia if necessary. The vigilant oversight and personalized care provided during monitored anesthesia care contribute to its effectiveness in enhancing the overall patient experience during various medical interventions.

26.3 Intraoperative Nursing Management

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Explain appropriate application of the clinical judgment medical model (CJMM) for a patient during surgery
- Identify appropriate education for the patient during surgery
- Discuss potential complications and corresponding interventions during the surgical experience

Nurses play a pivotal role in ensuring the safety, comfort, and well-being of patients throughout the surgical journey. In the dynamic and intricate environment of the operating room, intraoperative nurses serve as crucial members of the surgical team, with responsibilities that range from patient advocacy and communication to aseptic technique and surgical site care. As advocates for patient safety and guardians of infection prevention protocols, intraoperative nurses contribute significantly to the seamless execution of surgical procedures.

The Clinical Judgment Measurement Model: The Patient During Surgery

The clinical judgment measurement model (CJMM) is a systematic and patient-centered approach aimed at ensuring the delivery of safe and effective care. For a patient who is having surgery, this includes the pre-operative, perioperative, and postoperative periods. The process typically begins with a thorough pre-operative assessment, where the nurse collects comprehensive information about the patient's health history, medications, allergies, and psychological status. This assessment lays the foundation for individualized care planning, addressing the unique needs and potential risks of the patient. During the intraoperative phase, nurses are actively involved in patient positioning, maintaining a sterile environment, and collaborating with the surgical team to ensure optimal conditions for the procedure. Continuous monitoring of vital signs, administering medications as prescribed, and addressing any emergent issues are crucial components of nursing care.

Nursing Care

In the intraoperative phase, nursing care plays a critical role in ensuring the safety, comfort, and well-being of the patient undergoing surgery. The intraoperative phase encompasses the time from when the patient enters the operating room until their transfer to the post-anesthesia care unit. Nursing care during this phase involves a range of responsibilities that contribute to the overall success of surgical interventions. Pre-operative assessments should encompass a thorough review of the patient's medical history, including chronic conditions, medications, and any potential age-related impairments. Monitoring vital signs becomes even more crucial in the older adult population, considering the heightened risk of cardiovascular and respiratory complications. Maintaining a normal body temperature is essential, as older adults may be more susceptible to temperature fluctuations. Particular attention should be given to preventing postoperative delirium, a common concern in older adults, through strategies like minimizing anesthesia exposure and ensuring a quiet, familiar environment during recovery. Additionally, collaboration with the patient's family or caregivers is vital, as they often play a significant role in providing support and ensuring continuity of care during the perioperative period. Communication strategies should be adjusted to accommodate potential sensory deficits or cognitive impairments.

LIFE-STAGE CONTEXT

Gerontological Considerations

When caring for older adults in the intraoperative phase, nurses must consider various gerontologic considerations to ensure optimal outcomes. Age-related changes, such as altered pharmacokinetics, need to be considered when caring for older adults. For example, older adults metabolize mediations at a slower rate and dosage should include renal considerations. They may have a more increased effect of medication due to decreased metabolism. Older

adults also have a reduced physiological reserve, meaning they often have multiple comorbidities that prevent "bouncing back" from anesthesia as fast as they could when younger and in a healthier state. Older adults tend to have blood pressures in the lower range after administration of anesthesia for longer periods of time than a younger, healthier people. Older adults are also at increased susceptibility to complications, such as airway complications and increased risk of infection, due to lower immunity thresholds, all of which necessitate a tailored approach.

Cultural competence is imperative in intraoperative nursing care to provide patient-centered and respectful treatment. Cultural considerations encompass a range of factors, including beliefs, values, practices, and preferences. Understanding a patient's cultural background enhances communication, builds trust, and contributes to positive patient outcomes. Language barriers may arise, requiring the use of professional interpreters to ensure accurate communication with the patient and their family. Respect for cultural norms regarding modesty and privacy is crucial when positioning and draping patients in the operating room. Moreover, dietary restrictions, religious practices, and rituals should be considered during pre-operative preparations and postoperative care. Cultural competence extends beyond the patient to the entire surgical team. Sensitivity to diverse cultural perspectives within the team fosters effective collaboration and enhances the overall quality of care.

CULTURAL CONTEXT

Religious and Spiritual Practices in the Operating Room

A cultural consideration in the intraoperative phase revolves around the use of human-derived products. For example, many Jehovah's Witnesses do not accept any human-derived product, such as blood, for medical treatment, as it is against their beliefs. Because surgical procedures can cause a need for blood transfusions, alternative medical approaches should be considered. Some Jehovah's Witnessess may be willing donate their own blood for use during the procedure, but this may not be an option for all. It is important to note that Jehovah's Witnesses' beliefs may vary, but health-care providers should plan for no use of human-derived products for these patient populations during surgery

(Cho et al., 2019)

Postoperatively, nursing care extends to the recovery phase, including monitoring for complications, managing pain, and facilitating the patient's transition to a stable condition. Effective communication with the patient, their family, and other health-care team members is important for fostering trust and ensuring the delivery of holistic care that aligns with the patient's unique needs and preferences.

READ THE ELECTRONIC HEALTH RECORD

Intraoperative EHR Information Verification

Patient Information
Name: Mrs. Joan Smith
Date of Birth: 03.04.1954
Medical Record Number: 290879999
Procedure: Emergency laparotomy for acute bowel obstruction confirmed by X-ray and CT scan
Allergies: Latex
Pre-operative Assessment:

- Vital Signs: Stable
- PMH: HTN, DM
- Medication: Metformin, lisinopril
- Social History: Lives alone, no one with her
- Surgical History: The appendix was removed when the patient was 7 years old.
- Surgical Consent: Signed and completed appropriately.
- Blood Consent: Declined due to religious beliefs.

- Advance Directives: Not available

2. What information is the *most* concerning?
3. What is an expected finding?
4. What information should you question?

Recognizing Cues

The assessment phase of the nursing process during surgery is a foundational step in providing individualized and comprehensive care to the patient. This critical stage involves a thorough and systematic gathering of information about the patient's health status, medical history, and psychosocial factors. Pre-operative assessments include evaluating the patient's baseline physiological parameters, identifying potential risks and allergies, and obtaining a detailed medication history. Additionally, the nurse assesses the patient's emotional and psychological well-being, addressing any concerns or anxieties related to the impending surgical procedure. This holistic approach ensures that the nursing care plan is tailored to the unique needs of the individual. During the intraoperative phase, ongoing assessments involve monitoring vital signs, ensuring proper positioning, and promptly addressing any emergent issues. The assessment continues postoperatively, focusing on the patient's response to the surgical intervention, pain management, and the detection of potential complications. A comprehensive and diligent assessment is the cornerstone of effective nursing care during surgery, guiding subsequent interventions and contributing to the overall well-being and safety of the patient throughout the perioperative period.

REAL RN STORIES

Nurse: Elizabeth, MSN, RN, CNOR
Years in Practice: Six
Clinical Setting: Operating room in a large hospital
Geographic Location: Metropolitan area of Columbus, Ohio

We serve a diverse patient population in the inner city. This hospital is a Level II trauma center and is ranked the nation's top leader for oncology care. On average, this hospital completes a thousand or more intraoperative procedures monthly. This story reflects why the patient interview prior to the surgical procedure can make a difference in safety concerns in the intraoperative phase of care.

Just like any other workday, I came in to work and verified I was on the designated surgical team. I went to the nurse's station to familiarize myself with the first surgical procedure of the day. My patient, a 67-year-old woman, was scheduled for 7:30 a.m. for an above-the-knee amputation (AKA) on the right leg, due to the metastasizing of renal cell carcinoma to her bones. As I read through the patient chart, I noticed some red flags in the documentation and provider notes from her clinic visits the week prior. On her current medications list, it was noted she takes Plavix by mouth daily. There were also notes indicating uncertainty and hesitation about this procedure based on her anticoagulant medication, as noted by the surgical team in the clinic setting.

Prior to all surgical procedures, part of role as the intraoperative nurse is to pre-operatively assess and interview the patient before surgery. I ask important questions that can plan care in the intraoperative phase. As I walked into the pre-operative room, I quickly recognized cues that my patient was exhibiting anxiety and fear. I even noticed anxiety from her family members standing around her bed.

My first action was to introduce myself and ask her to tell me how she was feeling. As nurses, we sometimes forget to ask our patients how they are doing mentally because of our fast, repetitive routine checking boxes. She stated that she was still concerned about this procedure and was not sure she understood what was really going to happen. I read the consent form to her that she signed at the surgical clinic, and she stated she did not realize they would remove her entire leg above the knee. She thought they were just taking out the tumor on her tibia bone. I called the surgeon to come explain the procedure to her again for understanding.

After she agreed to the procedure, I asked if she stopped her Plavix for seven days for surgery. She replied that she taken her Plavix on her way to the hospital this morning and had not stopped it. She started to cry and stated that she didn't know she was supposed to stop it.

At this point I called the surgeon to come back to the patient's bedside, as there was now a safety risk for bleeding: first, because we are doing surgery very shortly, and second, because renal cell carcinomas tend to bleed uncontrollably. The surgeon explained to the patient the need to stop the medication for the next seven days and the procedure was canceled for today. I went over all the patient education related to pre-surgery instruction with the family at the bedside to make sure everyone understood the importance of following the plan of care. The intraoperative assessment and interview were crucial in identifying a safety risk. I was able to prevent the patient from unnecessary blood loss, and other potential complications during her surgical procedure.

Analyzing Cues and Prioritizing Hypotheses

In the nursing process for the patient during surgery, the diagnosis and identification of collaborative problems are integral steps aimed at formulating a precise and patient-centered care plan. Following the comprehensive assessment, nurses analyze the collected data to identify actual and potential health issues. Diagnosing involves synthesizing information to recognize the patient's responses to the surgical experience, potential complications, and any pre-existing conditions. Common nursing diagnoses during surgery may include impaired gas exchange, risk for infection, anxiety, and altered comfort. Collaborative problems, which require joint efforts with other health-care team members, are also identified. This collaborative aspect is crucial, involving effective communication and teamwork to address issues that fall beyond the scope of independent nursing interventions. The nurse collaborates with surgeons, anesthesiologists, and other health-care professionals to manage complex situations and ensure a seamless continuum of care. Accurate diagnosis and collaborative problem identification lay the groundwork for an effective nursing care plan, allowing the health-care team to anticipate, prevent, and address potential challenges, thereby promoting positive surgical outcomes and enhancing the overall well-being of the patient.

Generating Solutions

The planning phase of the nursing process for the patient during surgery is a meticulous and patient-centered endeavor that involves formulating a comprehensive care plan tailored to the individual's needs. Building upon the earlier stages, the nurse collaborates with the health-care team to establish clear and achievable goals and interventions. Planning encompasses a range of considerations, including the type of surgery, the patient's health status, and any potential complications. Strategies for maintaining aseptic technique, ensuring proper patient positioning, and managing pain are integrated into the plan. Attention is given to preventive measures, such as infection control protocols and risk reduction strategies. In collaboration with the patient, the nurse discusses the plan, sets expectations, and addresses any concerns. Flexibility is key, as the plan may need adjustments based on the evolving dynamics of the surgical process. Through effective planning, nurses strive to optimize patient outcomes, enhance recovery, and contribute to a positive and safe surgical experience for the patient.

Taking Action

The intervention phase of the nursing process during surgery involves the execution of a carefully devised care plan to ensure the safety, comfort, and well-being of the patient. Intraoperatively, nurses play a vital role in implementing aseptic techniques to maintain a sterile environment, assisting with patient positioning to optimize surgical access, and monitoring vital signs to address any deviations from normal parameters promptly. Medication administration, including anesthesia and other prescribed drugs, is carried out with precision. The nurse collaborates closely with the surgical team, providing essential information, anticipating needs, and addressing any emergent issues. Pain management interventions are initiated to ensure the patient's comfort postoperatively. Moreover, the nurse acts as an advocate, consistently communicating with the patient, their family, and other health-care team members to uphold the highest standards of care and keep all parties informed and reassured throughout the surgical process. The implementation of these interventions demands a blend of clinical expertise, compassion, and effective communication, reflecting the commitment of nurses to optimizing patient outcomes during the intricate phases of surgery.

Evaluating Outcomes

The evaluation phase of the nursing process for the patient during surgery is a critical step in assessing the effectiveness of the care plan and interventions. Nurses systematically review the patient's response to the surgical

experience, monitoring for expected outcomes and identifying any unanticipated complications. Parameters such as vital signs, pain levels, and the patient's overall well-being are continually assessed to gauge the success of the implemented interventions. The nurse collaborates with the health-care team, including surgeons and anesthesia providers, to ensure a holistic perspective on the patient's condition. Any deviations from the expected outcomes prompt a reassessment of the care plan, allowing for necessary adjustments to enhance patient recovery and address any unforeseen challenges. Continuous communication with the patient is maintained to gather feedback and address concerns. Successful evaluation of the nursing process not only contributes to positive patient outcomes but also provides valuable insights for refining perioperative care practices and promoting continuous improvement within the surgical setting.

UNFOLDING CASE STUDY

Care of the Surgical Patient: Part 2

See Care of the Surgical Patient: Part 1 for previous information on this patient.

Nursing Notes	**3/12/24, 9:30 a.m.** **Assessment** Patient is escorted to the OR suite with the surgical nurse. The patient is planned for general anesthesia. Education provided by intraoperative nurse regarding time frame a typical partial knee replacement operation typically lasts.
Flow Chart	**Intraoperative Patient Education** The nurse reinforced teachings from the surgeon, asking the patient if they have any follow-up questions. The nurse explains, we will start with inspection of the left knee joint. The surgeon will make an incision at the front of the knee. They will then explore the three compartments of the knee to verify that the cartilage damage is, in fact, limited to one compartment and that the ligaments are intact. If the surgeon feels that the knee is unsuitable for a partial knee replacement, they may instead perform a total knee replacement. The surgeon will have discussed this contingency plan with the patient before the operation to make sure they agree with this strategy. The intraoperative nurse explains a partial knee replacement operation typically lasts between 1 and 2 hours and explains the equipment and monitoring devices in the surgical suite and general anesthesia administration by the anesthesiologist. **3/12/24, 9:00 a.m.** Pre-intubation Blood pressure: 126/80 mm Hg Heart rate: 96 bpm Respiratory rate: 20 breaths per min Temperature: 98.1°F / 36.7°C Oxygen saturation: 98% on room air Physical examination: Head, eyes, ears, nose, and throat (HEENT): pupils equal and reactive to light, mucus membranes dry, no thyroid enlargement Lymphatic: lymphatic nodes were not swollen or enlarged Respiratory: respirations easy and unlabored, without dyspnea or shortness of breath, lungs clear with auscultation Cardiovascular: cardiac monitor displays normal sinus rhythm (NSR) with a rate of 96 bpm Abdomen: soft, denies pain, abdomen not distended, bowel sounds present all four quadrants Musculoskeletal: No weakness or numbness in all four extremities, moves all extremities with limited mobility of her left knee Skin: Warm and dry

Flow Chart	**3/12/24 10:00–13:00** Intraoperative phase: As the surgery begins, Mrs. Johnson was induced with general anesthesia, with the surgical team administering the medications. The anesthesiologist also administers antiemetics during the intraoperative phase to prevent her from hyperemesis postoperatively. The patient has several risk factors for hyperemesis postoperatively. These include female sex, history of prior reaction to anesthesia medications immediately postoperative, motion sickness, and a nonsmoker. The patient experienced very minimal estimated blood loss (EBL). Patient tolerated the procedure well. Patient had intermittent hypotensive readings with blood pressure ranging from 88/58 mm Hg, 90/60 mm Hg, 87/48 mm Hg during the surgery and received two 1,000 ml IV fluid over 3 hours. O_2 saturation remained 97–100%. Heart rate was 88 bpm to 112 bpm and sinus rhythm was borderline sinus tachycardia. Hypotension can be the result of significant blood loss, fluid shift, third spacing losses, lack of oral intake or changes in vascular permeability as a result of the anesthesia. **Assessment Post-Intubation** Blood pressure: 120/76 mm Hg Heart rate: 88 bpm Respiratory rate: 20 breaths per min Temperature: 96.0°F / 35.5°C Oxygen saturation: 100%
Diagnostic Tests/ Imaging Results	**Intraoperative pre-discharge to post-anesthesia unit (PACU)** **Intraoperative diagnosis: L knee x-ray of total left knee replacement.** The postoperative radiographic impression confirmed the left total knee replacement prostheses and their specific indications along with a detailed review of the patient post-surgical anatomic and critical angles, alignment, and correct positioning of femoral and tibial components was successful.

1. Which of the following choice(s) is/are based on the individualized plan of care when identifying the risks during surgery?

   Word Choices

   Fever
   Dysrhythmias
   Aspiration
   Seizures
   Bleeding

2. After the nurse prioritizes the patient's clinical problems and needs, identify the correct solutions from Option 2 with the correct complication, from the choices provided in Option 1.

Options for 1	Options for 2
Hypovolemia	Provide appropriate IV fluid management per provider order.
Emesis, PONV	Administer an antiemetic per provider order.
Hypertension	Administer antihypertensive as per provider order.

Options for 1	Options for 2
Depression, pre-operative	Prepare the postoperative team. The patient will require support and empathy when learning of the total knee replacement due to admitted depression.
Blood loss	Transfuse 1 unit red blood cells prior to discharge from the surgical suite.

Patient Education

Patient education is a pivotal component of nursing care during surgery, aiming to empower individuals with the knowledge and understanding necessary to participate actively in their care and recovery. Pre-operative education involves providing information about the surgical procedure, potential risks, and expected outcomes. This helps alleviate anxiety and fosters a sense of preparedness. Clear instructions regarding pre-operative fasting, medication management, and postoperative expectations contribute to a smoother perioperative experience. Intraoperatively, nurses educate patients about the monitoring devices, anesthesia administration, and any specific aspects of the procedure. Postoperatively, comprehensive education covers topics such as pain management, wound care, and activity restrictions. The nurse tailors information to the individual's learning preferences, ensuring comprehension and addressing any concerns. A well-informed patient is better equipped to collaborate in their care, make informed decisions, and actively participate in the recovery process. Patient education not only enhances the patient's experience but also plays a crucial role in promoting positive outcomes and preventing complications throughout the surgical journey.

Potential Complications During the Intraoperative Phase

The goal of any surgical procedure is to achieve optimal outcomes and promote patient well-being. However, the complexity of surgery inherently introduces the potential for intraoperative complications. Any complications can create challenges that require swift identification and management. From unforeseen changes in a patient's physiological status to technical difficulties within the operating room, understanding and addressing these potential complications are crucial for the surgical team.

Nausea and Vomiting

Nausea and vomiting are recognized as potential intraoperative complications that can significantly impact the well-being of patients undergoing surgical procedures. Referred to as PONV, this complication is multifactorial, influenced by patient-related factors, surgical characteristics, and the type of anesthesia administered. PONV can be distressing for patients, affecting their immediate postoperative recovery experience. Risk factors for PONV include female sex, a history of motion sickness or previous PONV, nonsmoking status, and the use of certain anesthetic agents. Anesthesia providers employ proactive strategies to minimize the risk of PONV, including the administration of antiemetic medications, appropriate fluid management, and the avoidance of volatile anesthetics or opioids when possible. As part of comprehensive perioperative care, anesthesiologists remain attentive to patient risk factors, continually refining strategies to reduce the incidence of PONV and improve the overall surgical experience.

Anaphylaxis

Anaphylaxis is a rare but critical intraoperative complication that demands immediate attention and intervention. It can occur in response to various substances, including medications administered during surgery (e.g., antibiotics, muscle relaxants) or latex-based products used for the procedure. Anaphylaxis manifests rapidly; patients may exhibit difficulty breathing, swelling, hypotension, and cardiovascular collapse. Anesthesia providers are trained to recognize the signs of anaphylaxis swiftly and respond with prompt and targeted interventions. These may include stopping the administration of the suspected allergen, administering epinephrine, providing supportive measures such as intravenous fluids, and ensuring adequate ventilation.

Preventive measures involve thorough pre-operative assessments to identify potential allergies and employing

alternative medications when needed. The unpredictability of allergic reactions necessitates constant vigilance and preparedness within the operating room, emphasizing the importance of comprehensive allergy histories and ongoing education for the entire surgical team. Prompt and effective management of anaphylaxis is paramount to ensure patient safety and mitigate the potentially severe consequences of this rare intraoperative complication.

Hypoxia and Other Respiratory Complications

A condition characterized by low oxygen levels in the body, **hypoxia** can result from factors such as airway obstruction, respiratory depression, or inadequate ventilation. Other respiratory complications may include bronchospasm, atelectasis, or pulmonary aspiration. Anesthesia providers use various measures to prevent these complications, including proper airway management, administration of supplemental oxygen, and vigilant monitoring of respiratory parameters. Endotracheal intubation and mechanical ventilation may be employed to secure and maintain the airway during certain procedures.

Timely recognition of these complications allows for immediate corrective actions, such as adjusting ventilation parameters, administering bronchodilators, or addressing airway concerns. The goal is to ensure optimal oxygenation and ventilation to prevent hypoxia and minimize the risk of adverse respiratory events during the intraoperative phase. Continuous assessment and proactive measures underscore the commitment of anesthesia providers to maintaining patient safety in the complex and dynamic environment of the operating room.

Hypotension/Hypertension and Other Cardiac Complications

Hypotension (low blood pressure) may result from factors such as excessive vasodilation, blood loss, or inadequate fluid replacement, potentially leading to compromised organ perfusion. Conversely, hypertension (high blood pressure) can be triggered by factors such as pain, anxiety, or a heightened sympathetic response to surgery. Anesthesia providers employ various strategies to maintain hemodynamic stability, including fluid administration, vasopressor or inotropic support, and careful titration of anesthetic agents. Continuous blood pressure, heart rate, and electrocardiogram monitoring is fundamental in the early detection of cardiac complications. Additionally, patients with pre-existing cardiac conditions may need clearance from their cardiologist before any surgical procedure.

Fluid and Electrolyte Imbalances

Fluid and electrolyte imbalances are potential intraoperative complications that require anesthesia providers to maintain physiological equilibrium and support optimal organ function. Surgical procedures can lead to shifts in fluid balance due to factors such as blood loss, third-space losses, or changes in vascular permeability. Anesthesia providers carefully monitor and manage fluid administration to prevent hypovolemia or fluid overload. Electrolyte imbalances, including disturbances in sodium, potassium, and calcium levels, may arise during surgery and impact cardiac, neuromuscular, and renal function. Regular assessment and correction of electrolyte levels are essential components of anesthesia care. Strategies such as intravenous fluid therapy, blood product transfusions, and the administration of electrolyte solutions are employed to address imbalances promptly. Advanced monitoring technologies, including arterial blood gas analysis and laboratory tests, aid in the real-time assessment of fluid and electrolyte status.

Residual Muscle Paralysis

Residual muscle paralysis, also known as postoperative residual neuromuscular blockade, is a potential intraoperative complication associated with the use of neuromuscular blocking agents (NMBAs) during surgery. These drugs induce muscle relaxation, facilitate intubation, and improve surgical conditions. However, incomplete reversal or prolonged effects of NMBAs can lead to residual muscle weakness and compromise respiratory function in the postoperative period, resulting in hypoxia or difficulties in spontaneous respiration. Anesthesia providers utilize neuromuscular monitoring techniques, such as train-of-four (TOF) monitoring (Figure 26.5), to assess the degree of muscle blockade and guide the administration of reversal agents like neostigmine or sugammadex. Ensuring complete recovery of neuromuscular function is crucial for patient safety and is part of the comprehensive approach to preventing postoperative respiratory issues.

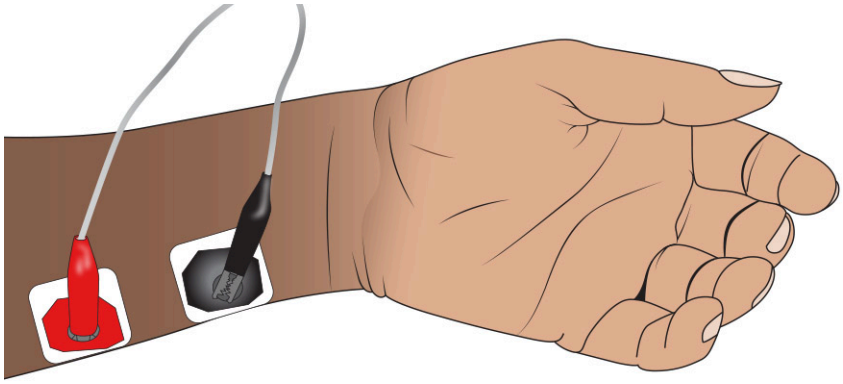

FIGURE 26.5 The train-of-four monitoring technique uses electromyography to determine the level of paralysis induced by medication. When the ulnar nerve is stimulated, if the fingers twitch four times, then the paralysis is less than 75 percent effective. When the fingers do not twitch, the paralysis is 100 percent effective. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Hypothermia

A patient's core body temperature dropping below the normal range, called **hypothermia**, is a potential intraoperative complication. Hypothermia can adversely affect metabolic processes, coagulation, and immune function, potentially leading to complications such as surgical site infections and delayed recovery. Surgical procedures, especially those involving prolonged exposure or open body cavities, can cause heat loss. Anesthesia providers mitigate the risk of hypothermia through the use of warming blankets, forced-air warming systems, and heated intravenous fluids. Maintaining normothermia is a key aspect of perioperative care, as it not only supports optimal physiological function but also enhances patient comfort and facilitates a smoother recovery.

Malignant Hyperthermia

The rare but potentially life-threatening intraoperative complication characterized by a hypermetabolic response to certain drugs, most notably volatile anesthetics and succinylcholine is called malignant hyperthermia (MH). MH manifests as a rapid and uncontrolled increase in body temperature, muscle rigidity, and a cascade of metabolic changes. The condition is primarily triggered by a genetic predisposition and affected individuals may not be aware of their susceptibility. Anesthesia teams undergo rigorous training to respond effectively to MH and must maintain a high level of vigilance to recognize the early signs. Common signs and symptoms include:

- Cardiac dysrhythmias
- Changes in CO_2 absorbance (temperature, color)
- Hypercarbia (excessive amounts of carbon dioxide in the blood)
- Hyperkalemia, hypercalcemia, lactic acidemia
- Hypoxia and dark (desaturated) blood in the operative field
- Metabolic and respiratory acidosis
- Muscle stiffness or rigidity
- Myoglobinuria (presence of myoglobin in the urine indicating muscle hypoxia)
- Peripheral mottling, cyanosis, or sweating
- Rising body temperature (1°C–2°C every 5 minutes)
- Pronounced elevation in creatine kinase level
- Tachycardia
- Tachypnea (may not be seen in a paralyzed patient)
- Unstable or elevated blood pressure

Immediate cessation of triggering agents, administration of dantrolene to mitigate the hypermetabolic state, and supportive measures such as cooling interventions are crucial in managing MH. Early detection and swift intervention are needed to prevent severe complications, including organ failure and death.

Neurological Problems

Neurological problems pose potential intraoperative challenges requiring careful management by anesthesia providers. Patients with pre-existing cognitive conditions, such as dementia, may experience heightened vulnerability during surgery, necessitating a tailored approach to minimize perioperative cognitive decline. Other

potential complications include prolonged awakening and paresthesia.

Prolonged awakening, although rare, can be attributed to various factors, including drug interactions, individual patient response, or incomplete metabolism of anesthetic agents. Anesthesia providers diligently monitor patients during the emergence phase to ensure timely recovery and address any issues contributing to delayed awakening. Physical signs include:

- Delayed responsiveness: the patient takes longer than expected to respond to verbal commands or physical stimuli
- Reduced consciousness: the patient remains in a stuporous or semi-conscious state for an extended period
- Slowed reflexes: the patient exhibits decreased or sluggish reflexes that persist longer than usual
- Impaired breathing: the patient exhibits shallow, irregular, or weaker than normal breathing patterns for an extended duration
- Low blood pressure: the patient exhibits low blood pressure longer than anticipated post-anesthesia
- Prolonged muscle weakness: the patient exhibits muscle relaxation and/or the inability to move or respond appropriately
- Paresthesia: the patient complains of abnormal sensations such as tingling or numbness; may occur due to nerve compression, positioning, or other factors related to the surgical procedure

Nurses must have a comprehensive understanding of each patient's medical history, and employ vigilant monitoring and proactive measures to optimize the overall safety and well-being of patients undergoing surgery.

Summary

26.1 Overview of the Surgical Experience

- Surgery can take place in various facilities. The most common is an inpatient hospital operating room. Others include ambulatory surgical centers, and specialty providers offices or clinics.
- Surgical procedures can be organized into three categories: elective, urgent, and emergency. Each requires the same type of diligent attention to detail, with the difference being how fast the procedure is scheduled.
- Suffixes in the name of the procedure signal the type of surgery to the health-care team members. For instance, -*ostomy* means artificial opening or creating an opening; -*plasty* means surgical repair or reshaping; -*scopy* means examination or visualization.
- To be a competent and safe nurse within the surgical team, one must fully understand the roles and responsibilities assigned to each team member. Team members consist of medical providers like surgeons and anesthesiologists, and specialized nursing roles like circulating nurse, scrub nurse, and RNFA. The team is also comprised of support staff who play a vital role in creating a seamless continuum of care.
- The surgical team functions as a cohesive unit, using a variety of skills and expertise to deliver comprehensive and patient-centered care throughout the perioperative process.
- Collaboration and communication among the surgical team members are pivotal, emphasizing the importance of a harmonious working relationship.
- The continuous commitment to excellence and collaboration underscores the significance of the surgical team in navigating the complexities of the operating room and ensuring a positive surgical experience for the patient.

26.2 Intraoperative Considerations

- The surgical environment is one that is strictly controlled to maintain best patient outcomes and reduce safety errors. Maintaining a secure and aseptic environment during surgical procedures is critical.
- Implementation of principles of surgical asepsis, sterile technique, and appropriate surgical attire minimizes the risk of infections.
- Surgical time-out is an evidence-based standard practice paramount for maintaining patient safety and reducing any errors during the surgical procedure.
- Meticulous planning and execution of patient positioning, tailored to the specific requirements of each surgical procedure, contribute to optimal exposure and accessibility while prioritizing patient safety.
- There are many types of anesthesia each with their own unique purpose. General anesthesia refers to a complete state of reversible unconsciousness. Moderate sedation means the patient remains conscious but has no pain or memory of the procedure.
- Airway management, a cornerstone in ensuring adequate ventilation and oxygenation, requires careful assessment and intervention by anesthesia providers to mitigate potential complications.
- The administration of anesthesia demands precision, and takes into account patient factors, type of surgery, and monitoring to achieve the delicate balance of inducing and maintaining a controlled state of unconsciousness.

26.3 Intraoperative Nursing Management

- The intraoperative nurse utilizes the clinical judgment medical model (CJMM) as a critical thinking tool to recognize and analyze cues for risks or complications related to the surgical procedure. Then, the nurse will prioritize the cues and develop a hypothesis for implementation of care. After the nurse acts through a seamless integration of aseptic techniques, vigilant patient monitoring, and collaboration with the surgical team, they will evaluate the outcomes to allow for real-time adjustments, ensuring the effectiveness of interventions.
- Patient education is a foundational aspect of nursing care. Education empowers patients with knowledge about the surgical process, monitoring devices, and postoperative care, allowing the patient to play a role as a vital team member.
- The nurse must use critical thinking and clinical judgement skills to prevent complications related to the surgical process. Examples of complications include blood loss, impaired airway, anaphylaxis, and impaired thermoregulation such as hyper- or hypothermia.

Key Terms

ambulatory surgical center (ASC) facility designed for outpatient procedures that do not require the patient to be monitored overnight

anesthesia awareness (also: *intraoperative awareness*) rare but potentially distressing phenomenon where a patient becomes partially or fully aware of their surroundings during surgery despite being under general anesthesia

anesthesiologist highly trained medical professional responsible for administering anesthesia, monitoring the patient's vital signs, airway, and managing the patient's pain during surgery

elective surgery non-emergent, planned procedure that is scheduled in advance based on the patient's preference, surgical procedure, location of procedure, and surgeon's availability

emergency surgery immediate, unplanned procedure performed to save a patient's life or prevent severe disability

epidural anesthesia injection of local anesthetic agents into the epidural space surrounding the spinal cord, providing a controlled and prolonged analgesic effect

general anesthesia involves a combination of intravenous medications and inhaled anesthetics

hypothermia body temperature below the normal range

hypoxia inadequate oxygen levels in the body's tissues

inpatient hospital operating room most common surgical setting for patients

intraoperative phase begins when the patient is transferred to the operating room bed and ends when the patient is transferred to the post-anesthesia care unit (PACU)

moderate sedation controlled state of reduced consciousness that allows patients to undergo medical procedures while remaining responsive and able to maintain their own airways; also known as conscious sedation

monitored anesthesia care (MAC) specialized approach to anesthesia that combines elements of local anesthesia and sedation to provide a controlled and comfortable experience for patients undergoing certain procedures

multimodal anesthesia combines various techniques and medications to achieve a balanced and comprehensive analgesic effect

peripheral nerve block specialized form of regional anesthesia that involves the precise injection of local anesthetic agents near specific nerves to block sensation in a targeted region of the body

regional anesthesia blocks sensation to a localized area, allowing patients to undergo various surgical procedures without the need for general anesthesia

registered nurse first assist (RNFA) controls bleeding during surgery, sutures incisions and wounds, and assists in stabilizing patients when necessary

RN circulator responsible for coordinating and managing various aspects of the operating room before, during, and after surgery; also known as a circulating nurse

scrub nurse tasked with maintaining the sterility of the surgical environment

spinal anesthesia well-established and widely utilized form of regional anesthesia, involves the injection of local anesthetic agents (e.g., bupivacaine, lidocaine) into the cerebrospinal fluid surrounding the spinal cord

sterile technique extends to the creation of a sterile field around the surgical site, ensuring that only sterile items come into contact with the patient and the surgical wound

surgeon medical doctor with extensive training in performing surgical procedures

surgical asepsis involves a set of practices designed to maintain a sterile field and prevent the introduction of microorganisms into the surgical environment

surgical environment controlled and sterile setting in which surgical procedures are performed, including the operating room, associated equipment, and related practices and protocols designed to maintain asepsis

time-out critical moment in the perioperative process designed to enhance patient safety and reduce the risk of errors

urgent surgery necessary procedure that must be performed promptly, usually within twenty-four to forty-eight hours

Assessments

Review Questions

1. A nursing student is reviewing information about the roles within the surgical team. What statement

demonstrates an accurate understanding of the role of the surgeon in the operating room?

a. The surgeon primarily manages the sterile field and passes instruments to the scrub nurse.
b. The surgeon is responsible for coordinating activities, obtaining necessary supplies, and ensuring aseptic conditions in the operating room.
c. The surgeon leads the surgical team, makes decisions during the surgery, and is responsible for the overall success of the procedure.
d. The surgeon administers anesthesia to the patient, monitors vital signs, and ensures the patient's comfort and safety.

2. A nursing student is studying communication within the operating room (OR) team. What statement best reflects the importance of effective communication among the surgical team members during a procedure?

a. Communication in the OR is optional, as everyone knows their role and responsibilities.
b. Effective communication in the OR is essential to ensure a positive work environment but has minimal impact on patient outcomes.
c. Communication in the OR is critical for ensuring patient safety, coordinating activities, and responding promptly to changes in the surgical environment.
d. Communication among the surgical team is primarily the responsibility of the circulating nurse, as they coordinate activities in the operating room.

3. During the intraoperative phase, what is the primary responsibility of the circulating nurse?

a. assisting the surgeon with the surgical procedure
b. monitoring the patient's vital signs and anesthesia administration
c. managing the sterile field and passing instruments to the surgeon
d. advocating for the patient's safety and coordinating activities in the operating room

4. A patient is scheduled for a surgical procedure to remove their gallbladder due to the presence of gallstones. What suffix would be the proper ending for surgical removal?

a. -otomy
b. -ectomy
c. -plasty
d. -scopy

5. What surgical setting would be appropriate for a patient needing a tonsillectomy?

a. inpatient
b. ambulatory
c. clinic
d. trauma hospital

6. The nurse is caring for a patient who has been diagnosed with acute appendicitis, with potential rupture. What surgical category would this patient fall under?

a. emergency
b. urgent
c. elective
d. none of the above

7. A nurse is preparing to participate in a surgical time-out procedure before a scheduled surgery. What is an example of a statement that accurately reflects the purpose and components of a surgical time-out?

a. The surgical time-out is an optional break for the surgical team to relax before the procedure.
b. It is a moment for the circulating nurse to review the patient's medical history with the team.
c. The time-out involves a review of important details by the surgical team to ensure patient safety before the surgery begins.
d. It is a mandatory waiting period for the patient to reconsider and provide consent for the surgery.

8. A nurse is preparing a patient for surgery and is reviewing the plan of anesthesia with the anesthesiologist. The nurse knows that what type of anesthesia involves the injection of a local anesthetic into the subarachnoid space, resulting in a reversible loss of sensation and motor function below the level of injection?
   a. local anesthesia
   b. general anesthesia
   c. epidural anesthesia
   d. spinal anesthesia

9. A nurse is preparing a patient for surgery and is responsible for ensuring appropriate positioning in the operating room. Why is proper patient positioning crucial during surgery? Select all that apply.
   a. to make the patient more comfortable
   b. to facilitate communication with the surgical team
   c. to optimize exposure of the surgical site and access for the surgical team
   d. to prevent the patient from seeing the surgical instruments

10. A nurse is monitoring a patient in the operating room who is positioned for surgery. What potential complications could be linked to improper positioning?
   a. enhanced surgical exposure
   b. facilitated communication with the surgical team
   c. increased risk of nerve damage or pressure injuries
   d. improved visual access for the anesthesia provider

11. An intraoperative nurse is caring for a patient who exhibits signs of malignant hyperthermia, including increased temperature and muscle rigidity. What is the priority nursing intervention in managing malignant hyperthermia? Select all that apply.
   a. administer antipyretic medications
   b. provide a cooling blanket and monitor vital signs
   c. continue airway management and administer dantrolene
   d. discontinue triggering agents

12. A nurse is caring for a patient with a history of cardiac complications who is scheduled for surgery requiring anesthesia. What is the nurse's primary role in collaborating with the anesthesia care team for this patient?
   a. administer prescribed anticoagulants to prevent clot formation
   b. monitor the patient's blood pressure and heart rate during the surgery
   c. educate the patient on the risks and benefits of anesthesia
   d. communicate the patient's history and relevant information to the anesthesia team

13. Utilizing the *analyze* step of the CJMM, what is a medical treatment that would be avoided for a patient who is a Jehovah's Witness?
   a. blood or blood products
   b. antinausea medications
   c. male surgical team members
   d. surgery performed on sabbath

14. During your intraoperative interview and assessment, you discover new information. What is a situation that would be contraindicated and indicate the need to contact the surgeon?
   a. Patient is anxious and fearful about the procedure.
   b. Patient did not use the entire bottle of surgical wash the night before.
   c. Patient did not stop taking anticoagulants seven days prior as instructed.
   d. Patient's wife forgot to pack additional contact lenses.

Check Your Understanding Questions

1. Describe the meaning of emergency/emergent surgical procedures.
2. The circulating nurse is coordinating the time-out and is feeling pressure from other members of the surgical team to skip or abbreviate the time-out. Why is the time-out necessary?
3. As a nurse, how would you prioritize the patient's surgical experience, and prep the surgical environment to ensure optimal care and support throughout the perioperative journey?
4. Describe sterile technique and its relation to surgical asepsis.
5. Explain three key points a nurse should include in the patient education for a patient scheduled for surgery regarding the intraoperative phase.
6. Describe the most important aspects of the *taking action* step when using the CJMM as a critical thinking tool for a patient in the intraoperative phase.

Reflection Questions

1. What communication skills should the nurse use to work with a large interdisciplinary team?
2. Describe the difference between general anesthesia and conscious sedation.
3. You are a nurse caring for a patient in the intraoperative phase. Identify an experience where you would apply the CJMM. Describe how you would utilize each step to ensure optimal care and safety for the patient during this critical phase of their surgical journey.
4. As a nurse caring for a patient undergoing anesthesia, consider the patient who has experienced hypoxia during past surgical procedures. What aspects must be assessed?

Critical-Thinking Questions about Case Studies

1. Refer to Care of the Surgical Patient: Part 2.
   The nurse is planning next actions for this patient. Select the cues the nurse should be aware of that are individualized for this patient during the intraoperative phase. Choose the appropriate cues from the choices provided in Option 1 that correlate to rationales in Option 2.

Options for 1	Options for 2
Routine use of ibuprofen	Bleeding
Prior history of hyperemesis as a related to anesthesia	Prevent aspiration and immediate post-extubation emesis
Depression	Unstable vital signs during surgery, drop in O_2 saturation
Increased anxiety	Patient will under anesthesia and unable to experience anxiety
Inability of surgeon to perform a partial knee replacement	Total knee replacement

Competency-Based Assessments

1. Conduct an internet search to find articles for best practices standards for airway management while providing intraoperative nursing care. Develop a presentation for your peers outlining what steps should be taken.

2. Draw a chart outlining the different positions used during surgery and provide one example of each procedure used for the identified position.
3. Develop a patient care education pamphlet for instructions prior to a knee arthroscopy. Share with your peers.
4. Develop a presentation to share with your peers about nursing care for a patient experiencing malignant hyperthermia.

CHAPTER 27

Postoperative Care

FIGURE 27.1 Postoperative nursing care transitions the patient from surgery to recovery. (credit: Airman 1st Class Kyle Johnson/Joint Base Elmendorf-Richardson, Public Domain)

CHAPTER OUTLINE

INTRODUCTION Today, as the number and intricacy of surgical procedures performed increases, the nurse must remain up-to-date with best practice standards to achieve quality patient care. The perioperative specialization was recognized in nursing prior to 1889; however, the first documented reference is found in the appendix of the text *Notes on Nursing* by Florence Nightingale, which states, "The surgical nurse must always be alert, always on guard, against the lack of cleanliness, musty air, lack of light" (Salazar Maya, 2022, para. 2). Perioperative describes the time frame surrounding surgery encompassing the time between going to the facility, having the procedure, and then returning home afterward. This chapter discusses the last phase of perioperative nursing: postoperative care.

27.1 Postanesthesia Recovery and Care

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the admission and nursing priorities of a patient in the PACU
- Identify ways to manage postoperative nausea and vomiting
- Differentiate patient discharge to home versus patient transfer to another hospital unit from the PACU

Precision and compassion combine to help each patient through the path to successful recovery. Understanding and

meeting the unique needs of each postoperative patient is at the core of effective postoperative nursing. The transition of a patient from surgery to a **postanesthesia care unit (PACU)**, the hospital unit where patients are temporarily admitted after a surgery, requires different nursing duties and responsibilities, such as airway management and assisting a patient with postoperative nausea and vomiting. Understanding and effectively treating common postoperative complications are important in order to maximize patient comfort while mitigating potential complication risks. Nurses also face complex decisions when distinguishing between discharging patients to home or transferring patients to another unit from PACU.

Postanesthesia Care Unit Admission and Care

A smooth transition from a surgical operating room where the patient's vitals and airway are supported and monitored throughout the surgery into the PACU is a key element to a successful outcome for the patient. The **postoperative phase** begins when the patient is transferred to the PACU and ends when the patient is transferred to another unit or discharged home.

PACU nurses serve a bridge between a surgical procedure and the recovery process by acting as intermediaries that facilitate safe transitioning of the patient. Communication between the surgical team and the PACU nurse is important, as nurses relay relevant details regarding patient health status or unexpected findings to anesthesiologists and surgeons for immediate attention as well as plan ahead for what lies next in the patient's journey of care.

In many hospitals, there are two phases within the PACU: Phase I and Phase II. Each phase provides different levels of care and resources to the patient during the immediate postoperative recovery. A **phase I PACU**, often referred to as main or primary PACU, usually accommodates surgical procedures of higher severity as well as higher acuity patients. This unit is staffed with highly experienced nurses capable of overseeing complex cases requiring major surgeries or patients who present with significant comorbidities. Phase I PACUs offer advanced monitoring capabilities, sophisticated life-support systems, and an assortment of medications designed to address postoperative needs. Phase I PACUs focus on providing intensive postoperative care that ensures prompt intervention. Most patients who receive an endotracheal tube (ETT), or artificial airway, during surgery will have it removed during the phase I PACU stay. Patients are monitored for confirmation that the ETT is no longer required. Patients who have had serious and extensive surgery such as an open heart or thoracic surgery may retain the ETT and be transferred to an intensive care unit (ICU).

The **phase II PACU**, or an extended care unit, offers treatment for patients who need less acute support after surgery. Patients requiring less complicated surgeries or less immediate postoperative needs tend to visit phase II PACUs as the nursing assignment includes multiple patients, whereas phase I units may have fewer patients per nurse due to the higher acuity compared with phase II units. Patients do not transition from a phase I PACU to a phase II PACU as this is only a category of the acuity setting. A phase II PACU is common in same-day surgery and monitoring equipment and resources can be tailored specifically for less acute cases. Patients admitted to a phase II PACU still receive vigilant care, yet the surgeries are not as complex and a quicker PACU recovery is expected (Glick, 2024).

Assessment

As patients emerge from anesthesia, they move from the controlled environment of an operating room into the PACU where attention shifts to postoperative care immediately afterward. Once a patient is admitted into PACU care, the primary nursing priority is to assess the patient's physiological stability to facilitate a smooth recovery following anesthesia. Ensuring a stable airway for oxygen delivery is the priority of care. Monitoring vital signs such as heart rate, blood pressure, respiratory rate, and oxygen saturation levels are key nursing tasks. The standard for interval frequency of checking vital signs begins at every five minutes for the first fifteen minutes, and then every fifteen minutes after that if stable (Thran, 2018). In addition to the basic vital signs, nurses should assess heart rhythm as dysrhythmias may occur due to changes in fluids and electrolytes.

REAL RN STORIES

Nurse: Ezechiel, RN

Years in Practice: Thirteen
Clinical Setting: PACU
Geographic Location: Inner-city metropolitan hospital, MD

I was working on a busy phase II PACU. One of my patients was an older person who had undergone a left hip replacement (ORIF). The surgical procedure went smoothly with no noted complications or extenuating circumstances.

As I entered the patient's room to do a set of vital signs, I noticed he was alert and able to answer my questions. However, I did notice the patient breathing rather fast, at twenty-eight breaths per minute. He was taking quick shallow breaths, which I knew was an ineffective breathing pattern. The patient's temperature was 98.8 F, and pain level was 8 on a 0–10 scale. The patient's heart rate was 114 bpm, and his blood pressure was 136/88 mmHg.

I asked the patient's wife at the bedside, "Has he been breathing like this for a while?" Using my years of experience and critical thinking skills, I was able to immediately identify ineffective breathing. I grabbed a pulse oximeter and collected the patients SPO_2 at 88 percent. I immediately placed the patient on 3 L of oxygen per our facility's post-op protocol and notified the surgeon. Now that I was getting a closer assessment of the patient, I recognized his skin was pale and he was using his accessory muscles to breathe. This meant not only was his breathing ineffective, but he was working hard just to maintain this level of oxygenation. The surgeon arrived at the bedside and ordered the patient to be transferred to the intensive care unit (ICU) for closer monitoring, and more extensive oxygen therapy.

Close observation of a patient's level of consciousness, airway patency, and response to stimuli are vital to identify any signs of complications or adverse reactions from anesthesia. At the same time, nurses conduct surgical site assessments for bleeding, swelling, signs of infection, or other postoperative concerns that require immediate action. Additionally, nurses provide pain management, which is vital for patient comfort and healing (see Chapter 7 Pain Assessment and Management). Nurses also assess patient consciousness levels using standard scales while monitoring pain levels to ensure maximum comfort levels are reached.

The ABCs

In a PACU, a nursing assessment focuses on the ABCs—airway, breathing, and circulation—to maintain both immediate and ongoing physiological stability for those recovering from anesthesia and surgery.

Airway assessment by nurses involves:

- carefully evaluating airway patency
- looking out for obstructions or signs of compromise (e.g., secretions, swelling)

Promptly acting upon any concerns is needed through nursing actions, such as repositioning or using airway adjuncts (e.g., an oral airway, nasopharyngeal airway, or bag valve mask) (see Chapter 11 Gas Exchange, Airway Management, and Respiratory System Disorders).

Breathing assessment involves:

- monitoring respiratory rate and depth
- assessing breath sounds
- capnography
- assessing the need for supplemental O_2
- using pulse oximetry to measure oxygen saturation levels

LINK TO LEARNING

This video provides different examples of abnormal breath sounds (https://openstax.org/r/77AbnrmlBreath) most commonly heard.

Circulation assessments focus on:

- heart rate
- blood pressure
- temperature
- color, temperature of skin
- ECG
- peripheral pulses
- capillary refill

Patients who are not recovering well after surgery may show signs of dehydration, which may present as tachycardia, hypotension, weak pulses, and slow capillary refill. Patients may also exhibit signs of respiratory complications manifested by tachypnea, gurgling secretions in the airway, or irregular breathing. Comprehensive ABC assessments are performed regularly and consistently every fifteen minutes to detect any deviations from normal parameters early; prompt actions can ensure patient safety and recovery within PACU units.

UNFOLDING CASE STUDY

Care of the Surgical Patient: Part 3

See Care of the Surgical Patient: Part 2 for previous information on this patient.

Nursing Notes	**3/12/24, 13:15** **PACU Triage Assessment** The patient's postoperative diagnosis: Total left knee replacement. Patient received from surgery to Phase I PACU by the use of the ISBAR format of a handoff report. Patient is attended by the anesthesiologist and surgical nurse. Patient was extubated in surgery, is sedated, but arousable. Can open eyes and nods appropriately to simple questions, however continues to be very sleepy. Pallor color, cool, and dry to touch. Airway open and patent with minimal secretions. Patient suctioned orally with scant whitish color secretions. Lungs are clear on auscultation. Respirations 16 and easy, unlabored with adequate depth on inspirations. Heart rhythm: normal sinus rhythm (NRS) Respiration: 16 breaths per min BP: 100/68 mmHg Heart rate: 88 Temperature: 97.0 F Capillary refill of nailbeds < 2 sec Pulse oximetry 99% on 2 LPM nasal cannula Left knee dressing clean, dry, and intact. No drainage noted. Patient able to move lower extremities, including legs and feet on command. Left foot pale, cool to touch, able to move. Palpable bilateral pedal pulses both posterior tibial and dorsalis pedis. Patient moaning and grimacing whispering "pain." Patient had emesis after moving and settling on cart. **Physical Examination** HEENT: Pupils equal and reactive to light, mucous membranes dry, no thyroid enlargement. Lymphatic: Lymphatic nodes were not swollen or enlarged Respiratory: 16, easy, and unlabored Cardiovascular: HR 88, RSR on monitor, capillary refill good, < 2 sec. Abdomen: Soft, denies pain, not distended. No bowel sounds present all four quadrants. Musculoskeletal: Patient able to help roll side to side in bed to reposition. Patient able to move lower extremities, including legs and feet on command. Left foot pale, cool to touch, able to move. Palpable bilateral pedal pulses both posterior tibial and dorsalis pedis. Skin: Cool and dry **3/12/24 13:30** Patient vomiting yellowish bile-like liquid. Ondansetron 4 mg IV given per anesthesiologist order. Patient c/o pain, number 9 on pain scale. Hydromorphone 1 mg IV given Post pain reassessment with moderate relief reporting a pain score of 6. **3/12/24 18:15** Patient had a restless night, short periods of sleep. Continues with severe pain lasting 2 hours of relief after hydromorphone 1 mg IV administered. Continues with nausea and emesis. Ordered antiemetic provided throughout the night with relief of N/V. Voiding through the night, walking with walker and assist of one to the bathroom. Voiding measured at 300 ml during the shift. **3/13/24 06:00** Ambulate with walker and assist of one to bathroom Only tolerated liquids and few bites of dry toast for breakfast Pt N/V- Ondansetron 4 mg po every 4 hours for nausea or vomiting Ketorolac 30 mg IV every 6 hours (NSAID-anti-inflammatory) Psychological support and resources for depression and panic attacks provided by licensed

	social worker (LSW). Chaplin in to see patient per request. Advanced diet to regular per patient's preferences for lunch. Pain is controlled on hydrocodone 7.5 mg every 3 hours PO for a post pain assessment level of 5–6. IV changed to 0.9% at a rate of 125 ml/hour. K+ IV bolus of 20 meq in 100 ml 0.9% NS over 1 hour.
Flow Chart	**3/12/24 18:00** Transferred to observation bed Vital signs: BP: 106/72 mmHg Respiration: 20 breaths per minute HR: 90 bpm T: 97.9 F O_2 saturation on room air: 98% on room air **3/13/24 06:00** Vital signs: B/P: 108/72 mmHg HR: 76 bpm Respirations: 20 breaths per minute T: 98.1 Pulse oximetry on room air: 99% on room air
Lab Results	**3/13/24 06:00** WBC: 6.2×10^3 cells/mm^3 CBC with differential: pending Hgb: 14 g/dl Hct: 41% BUN: 14 mg/dl Creatinine: 0.09 mg/dl Na: 133 mEq/L K+: 3.2 mEq/L Cl: 94 mEq/L

Provider's Orders	**3/12/24 1315** Ondansetron 2 mg IV stat per anesthesiologist. **Labs stat:** CBC Electrolytes Hct Hgb Continuous IV Lactated Ringer's at the rate of 125 ml/hr Hydromorphone 0.5mg IV push every 30 min × 2. Hold if B/P < 90/50 Then hydromorphone 1mg IV push every 4 hours for moderate pain (4–6 on pain scale) Hydromorphone 1 mg IV every 3 hours for severe pain (7–10 on pain scale) When tolerating fluids: Switch to hydrocodone 7.5 mg po every 4 hours for moderate pain (4–6 on pain scale) Hydromorphone 7.5 mg every 3 hours for severe pain (7–10 on pain scale) Ondansetron 4 mg IV push slowly, over 30–60 seconds every 4 hours for nausea or vomiting Ketorolac 30 mg IV every 6 hours Ice chips, advance to clear liquids as tolerated Physical therapist to teach ambulation with assistive device when transferred to observation unit Discontinue O2. Maintain O2 saturation > 92%, if pulse O_2 drops below 91%, place O_2 2 LPM NC Transfer to observation unit once awake and VS, Pulse oximetry > 92%. Repeat labs in a.m.: CBC, electrolytes, Hct, Hgb **3/13/24 11:00** Discharge to home after dinner Discontinue IV Provide discharge instructions and review education for postoperative care of a total knee replacement. Begin home care physical therapy 3 × week for 2 weeks. Then continue with outpatient PT rehabilitation. Prescriptions sent to patient's pharmacy. Follow-up appointment made with surgeon in 2 weeks.
Diagnostic Tests/ Imaging Results	Total left knee x-ray: Unchanged from the last x-ray The postoperative radiographic impression confirmed the left total knee replacement prostheses and their specific indications alongside a comprehensive review of the assessment of important angles, alignment, and correct positioning of femoral and tibial components was successful.

1. Based on the patient's assessments and labs at 6:00 on 3/12/24, what are the most important nursing actions in caring for this patient? Select all that apply.

    a. IV fluid replacement of 0.9% NS
    b. obtain a CXR
    c. administer antiemetics as ordered
    d. ABT every 4 hours
    e. administer pain medication as ordered, observing for a BP of > 90
    f. do not administer ketorolac if administering hydromorphone for pain

2. What patient outcomes would most likely indicate the patient is improving and ready for discharge? Select all that apply.

a. The patient is eating regular solid food as tolerated.
b. The patient has metabolic acidosis.
c. The patient has multiple organ dysfunction syndrome.
d. The patient has K+ level of 4.0 mEq/L.
e. The pain is controlled with taking hydrocodone 7.5 mg every 3 hours po with a pain level of 5–6 post pain assessment.

Postoperative Nausea and Vomiting

Nurses play an invaluable role in postoperative care by managing **postoperative nausea and vomiting (PONV)**, or the excessive nausea and vomiting associated with administration of anesthesia. The nurse's role is to enhance patient comfort and avoid complications. Nursing approaches for managing PONV begin with conducting a comprehensive evaluation to detect early signs and symptoms, with open patient communication to better understand the nature and severity of nausea. Nurses consider contributing factors like pain or anxiety as part of the evaluation. Nurses administer antiemetic medications per provider order for each patient according to their medical history and type of surgery.

Maintaining proper fluid balance through intravenous therapy is essential to prevent dehydration in patients with compromised oral intake, especially due to vomiting (Siparsky, 2024). Encouraging good oral hygiene practices and providing oral care items to minimize nausea can be helpful. With a provider's order, patients usually start with clear liquids before progressing to regular foods as tolerated after an abdominal surgery. Patients recovering from short-term surgeries or those not requiring general anesthesia may begin on a regular diet as tolerated. Many same-day surgeries offer a full diet as tolerated (Ho et al., 2022).

CLINICAL SAFETY AND PROCEDURES (QSEN)

Volume Resuscitation for the Patient with PONV

The delivery of volume replacement for the patient with PONV will depend on the volume of fluids being lost. If volume loss is high, the nurse will anticipate hanging a crystalloid solution of 0.9 percent isotonic normal saline or lactated Ringer's solution. Hemodynamic monitoring with serial pulses, oxygen saturation, and blood pressures will gauge the patient's response to treatment. If the patient's fluid losses are low, other medications such as antiemetics may be considered to reduce the symptoms. Patients who have recently undergone any type of surgical procedure should be monitored closely for fluid volume loss.

Education is an integral component of nursing care for PONV management, and nurses should provide patients with vital information regarding potential triggers of nausea and vomiting. Continuously monitoring vital signs and evaluating patient responses to actions are also integral aspects of PONV treatment management duties performed by nurses. Collaboration among health-care team members, such as providers and anesthesiologists, ensures an integrated, holistic approach that tailors treatment according to the needs of each patient, and making adjustments to treatment plans as needed. Table 27.1 lists common medications used to treat PONV.

Medication	Class	Route of Administration	Typical Dosage	Common Side Effects
Ondansetron	5-HT3 Receptor Antagonist	Oral, IV, IM	4–8 mg	Headache, constipation, dizziness
Metoclopramide	Dopamine Antagonist	Oral, IV, IM	10–20 mg	Drowsiness, fatigue, restlessness

TABLE 27.1 Medications Used to Treat PONV

Medication	Class	Route of Administration	Typical Dosage	Common Side Effects
Promethazine	Antihistamine	Oral, IV, IM, Rectal	12.5–25 mg	Drowsiness, dry mouth, blurred vision
Prochlorperazine	Dopamine Antagonist	Oral, IV, IM, Rectal	5–10 mg	Drowsiness, orthostatic hypotension
Dimenhydrinate	Antihistamine	Oral, IV, IM	50–100 mg	Drowsiness, dry mouth, dizziness

TABLE 27.1 Medications Used to Treat PONV

Discharge or Transfer from the PACU

In the critical phase of patient discharge and transfer from the PACU, nurses take great care and attention in making sure each patient is prepared to continue into the next stage of recovery. Nurses play an instrumental role in patient transfers between hospital units by overseeing and communicating any pertinent information to a receiving unit. Nursing duties consist of conducting a detailed evaluation to confirm that patients fulfill all established discharge criteria, such as stable vital signs within acceptable ranges, effective pain management, and recovery from anesthesia without loss of baseline alertness and orientation. Additionally, nurses confirm the voiding and safe ambulation status of the patient, which is reported to the receiving nurse. Nursing responsibilities often extend to providing emotional support, addressing patient concerns, and helping with patient anxiety during this transitional phase. Patient and family education is important to help with the transition from one unit to the next.

INTERDISCIPLINARY PLAN OF CARE

Interdisciplinary Approach to Discharge Readiness

Nurses work within an interdisciplinary team and coordinate care for patients in the postoperative phase of recovery. The following professionals may be part of the team to determine discharge readiness:

- Postoperative nurse: Assesses subjective symptoms and objective data for recovery, and determines the patient's level for postoperative compliance.
- Surgeon: Assesses patients for stabilized vital signs and no signs of postoperative complications before implementing discharge orders.
- Pulmonologist and critical care intensivist: May be necessary if the patient was transferred to critical care unit after surgery. Sometimes complications are immediately resolved, and other times they are so severe that the patient requires sedation and intubation to maintain their airway.
- Case manager: Coordinates follow-up discharge appointments and referrals to any needed rehabilitation care or other community services such as arranging for home delivery of durable medical equipment.

Any time a patient is discharged from one unit and transferred into another unit, a formal system of communication known as ISBAR (introduction, situation, background, assessment, and recommendation) is used. All health-care personnel should follow this system when moving a patient from one unit to another to share information in a consistent manner. Using the ISBAR format meets the Quality Safety and Education for Nurses criteria (Rotolo et al., n.d.).

Table 27.2 gives an example of a discharge nurse, Marcus, preparing to transfer a patient, Ms. Johnson, from the PACU to an inpatient surgical unit, using ISBAR. Marcus contacts Lina, the receiving nurse on the medical-surgical unit. Lina acknowledges the information, reassuring Marcus that Ms. Johnson will be welcome at the surgical ward and her room is ready. Using ISBAR facilitates clear and structured communications exchange, encouraging a smooth transition of care while upholding patient safety during the transfer processes.

Stage	Information
I	Hello, Lina! This is Marcus RN from the PACU calling to give you a report for Kathy Johnson.
S	Kathy Johnson is a fifty-eight-year-old female postoperative patient who underwent a laparoscopic cholecystectomy at 0700. She is ready for transfer into your surgical unit now that it's 1015.
B	Ms. Johnson underwent an uncomplicated surgical procedure and is recovering well in our PACU. She's been here for approximately two hours, is awake, vital signs are stable, ondansetron 8mg was given at 0930 for nausea and 2 mg Morphine Sulfate IV was given at 1000 and is currently providing effective pain control from a previous rating of 8/10 down to 3/10.
A	Vital signs for this patient remain stable: heart rate is 80, blood pressure 120/70, and respiratory rate is 16, while oxygen saturation on room air is 98%. She is alert and oriented, moving all extremities well, reporting pain at 3/10 after morphine was given by IV. Her surgical dressings remain dry and intact without signs of bleeding or other complications.
R	I recommend transferring Ms. Johnson to your unit for ongoing recovery and monitoring, as she has started on a clear liquid diet of apple juice and is tolerating it well. She is ambulating with assistance and requires routine postoperative care. Please continue her pain management plan as prescribed while being mindful to any signs or complications. I will accompany her for a smooth transfer and provide detailed handover instructions as per postoperative instructions provided prior to surgery. Do you have any questions?

TABLE 27.2 Example of ISBAR Communication

Preparation for Discharge

Communication of postoperative instructions pertaining to wound care, medication administration, activity restrictions, and potential signs of complications are essential to a successful postdischarge for both patients and their caregivers (Figure 27.2). According to the National Institutes of Health, most patient medication errors and complications occur during these periods of transition (Flatman, 2021; Wheeler et al., 2018). Documenting patient conditions, nursing actions, and instructions accurately in their medical record ensures continuity of care and ensures effective collaboration among health-care providers. Collaboration among interdisciplinary team members such as anesthesiologists, surgeons, physical therapists, and occupational therapists is imperative to facilitate an uninterrupted transfer of care.

FIGURE 27.2 Nurses help prepare patients for discharge after surgery. (credit: Jacob Sippel, Naval Hospital Jacksonville Public Affairs/All Hands Magazine of the U.S. Navy, Public Domain)

LINK TO LEARNING

The Agency for Healthcare Quality and Research developed an evidence-based tool to simplify discharge planning called the IDEAL tool. Go to the AHRQ website to see an overview and printable checklist (https://openstax.org/r/77IDEALPlanning) for incorporating the IDEAL discharge planning tool.

Going Home after Surgery

When a patient is ready for discharge to their home, nursing responsibilities encompass making any follow-up arrangements, so the patient has all their appointments or home care instructions on hand. Depending on the patient's needs, nurses may also need to consult with the social worker to order **durable medical equipment (DME)** such as elevated toilet seats, walkers, or ambulatory devices in preparation for a discharge to home after surgery. By being diligent with these duties, health-care providers ensure a seamless experience for patients as they transition out from PACUs, postrecovery surgical units, and back to their homes.

27.2 Postoperative Pain Management

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Define how to assess the patient's postoperative pain
- Describe how to manage the patient's postoperative pain
- Discuss the nurse's responses when pain interferes with healing

Pain assessment and management are essential nursing duties to ensure patient comfort during the postoperative recovery phase. As patients wake from anesthesia, they frequently experience various degrees of discomfort caused by surgery, necessitating an extensive and tailored postoperative pain management plan developed in collaboration with the patient's health-care providers. To create a baseline for developing a successful plan, the nurse must understand key information about a patient's pain experience, including the location and quality of the pain and any aggravating or alleviating factors. Depending on the patient's pain, nurses can implement various therapies to alleviate discomfort and aid recovery, including administering analgesic drugs as prescribed or encouraging nonpharmacological techniques such as positioning, relaxation techniques, or distraction methods to promote patient comfort.

Assessment of Acute Postoperative Pain

Postoperative pain assessment is at the core of comprehensive nursing care during the postoperative recovery phase. As soon as a patient transfers from an operating room to the PACU, nurses take on the responsibility of evaluating postoperative pain severity. The first tasks of the pain assessment entail developing effective communication with patients and ascertaining their subjective experience of pain. An important consideration is that the expression of pain is subjective and should not be judged by the nurse to be different than what the patient claims it is.

Pain Scale Consideration

Nurses play an invaluable role in early recognition and management of acute postoperative pain, aiding patient comfort while speeding recovery time. Their attentive observation skills, effective communication, and use of assessment tools makes a substantial contribution toward early pain recognition and management, ultimately optimizing recovery process and recovery outcomes. The numeric pain scale is used most often, having the patient rate their current pain on a scale of 0–10 with zero being no pain and ten being the worst pain they have ever felt. Nurses must carefully consider specifics of the surgical procedure when assessing a patient's pain, while examining surgical sites for signs of inflammation or swelling that could worsen postoperative pain. Furthermore, nurses investigate potential factors that exacerbate or relieve postoperative pain such as patient movement or changes to body position. This continuous assessment allows for the development of personalized pain management plans tailored to each patient's unique needs and responses in the recovery phase.

As discussed in Chapter 7 Pain Assessment and Management, culture plays an essential role in shaping individual perception, expression, and management of pain, affecting patient experiences with the health-care system. Culture shapes how individuals communicate and display pain and may also affect health-care providers' assessments and interpretations of patients' pain, affecting the accuracy of pain assessments and decision-making regarding treatment decisions. Patients may also use complementary or alternative therapies alongside mainstream medical interventions, as dictated by their culture.

REAL RN STORIES

Nurse: Sarah, RN
Years in Practice: Four
Clinical Setting: PACU
Geographic Location: Central New Jersey

In the busy PACU, I welcomed Juan, a male patient after his appendectomy surgery. Initially uneasy and wincing occasionally in discomfort, Juan showed signs of distress during recovery, and I realized he spoke very little English. I recognized the necessity of effective pain assessment and chose the FACES pain scale, an international tool that transcends language barriers. While waiting for the charge nurse to call the medical interpreter, I explained this universal tool using facial expressions from no pain (smiling face) to severe suffering (tearful/crying face). I gestured toward the faces on the scale to convey their correlation to different pain levels, encouraging Juan to select a face that reflected his current discomfort. Despite his limited proficiency in English, Juan comprehended the visual scale and indicated moderate discomfort. At this time, the charge nurse brought in the cell phone with the medical interpreter on the line. The interpreter explained the pain scale to Juan, and then stated that Juan said his pain was moderate, a 6 out of 10 on the scale. By using the correct type of assessment scale, and a medical interpreter to address the communication barrier, I helped to ensure that Juan's pain was accurately evaluated and that his pain medication was adjusted accordingly.

Methods of Pain Management

Postoperative pain management is an integral aspect of patient care, comprising various strategies designed to mitigate discomfort and promote recovery. Pharmacological interventions are a primary approach, employing various analgesic medications such as opioids and nonopioids. Medication choices depend upon several factors, including type of surgery performed and patient medical history. Regional anesthesia techniques like epidural analgesia and peripheral nerve blocks offer targeted pain relief by temporarily impeding pain signals at specific

spinal sites. During the PACU phase, IV narcotic analgesics are very effective for acute pain. Typical opioids used in PACU settings include fentanyl, hydromorphone, morphine, oxycodone, oxymorphone, and tramadol (Mayo Clinic, 2024). An important concept for patients to understand is that postsurgical use of narcotics for acute pain will not lead to narcotic substance use disorder as it is meant to be short-term. An important note, however, is that for those who have a substance use disorder, higher doses to control postsurgical pain may be needed (Pashkova, 2020). Nonpharmacological interventions for postoperative pain management that can be used outside of the PACU may include physical therapy, heat and cold therapy, acupuncture and acupressure, rest, distraction, and position changes, which also provide a holistic approach for managing postoperative pain beyond the PACU setting.

Patient education and counseling play an essential part in providing pain management while encouraging active involvement in the recovery processes. Psychological interventions such as cognitive behavioral therapy and relaxation techniques aim to address psychological aspects of pain perception, while innovative techniques like virtual reality and distraction techniques may offer alternate forms of relief from postoperative discomfort. Health-care providers strive for comprehensive yet personalized management of postsurgical pain, tailoring interventions according to each patient's specific needs and the nature of the surgical procedure to optimize postoperative pain control management and achieve comfort for their patients.

Pharmacological Pain Management

In hospital settings, various pharmacological interventions are utilized to effectively manage postoperative pain and increase patient comfort. The provider may prescribe opioid analgesics such as morphine, oxycodone, and hydromorphone, which can provide effective pain management after surgery for moderate to severe discomfort. These medications work by acting on the central nervous system to relieve pain. Depending on the provider's order, the nurse will administer these medications intravenously, orally, or via a patient-controlled analgesia system. A patient-controlled analgesia (PCA) system is a method of pain management that allows the patient to push a button that administers the prescribed medication via an IV site. The nurse is responsible for regularly monitoring the PCA for proper functioning.

Nonopioid analgesics such as acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen or ketorolac, play an integral part in pain management strategies. Acetaminophen has long been recognized for its analgesic and antipyretic effects in postsurgical settings. Meanwhile, nonsteroidal anti-inflammatory drugs (NSAIDs) provide relief in muscle-skeletal surgeries. Local anesthetics may be administered using epidural catheters or nerve blocks in specific surgical locations to provide targeted pain management. Adjuvant medications, such as gabapentin or pregabalin, also known as anticonvulsants, have increasingly become part of postoperative pain management plans to enhance the effectiveness of analgesic medications and provide enhanced analgesia relief. Adjuvant medications work by modulating nerve signals, making them effective treatments for neuropathies like neuropathic pain conditions. By employing a multimodal approach, health-care providers hope to maximize pain relief while simultaneously minimizing any potential adverse side effects linked with any single class of medication.

These same medication classes may be given at discharge for the patient; however, they are transitioned from IV route with a fast onset, to the oral route, which has a more extended release. IV pain medication should not be administered prior to discharge because the patient must be monitored for signs of respiratory depression. Manageable pain control is a criterion for discharge (Certain et al., 2022).

Nonpharmacological Pain Management

Nonpharmacological pain management strategies form an integral component of holistic health care both within hospital settings and as self-care practices in daily life at home. While in the hospital, a provider's order needs to be obtained before these modalities may be applied. Table 27.3 outlines nonpharmacological methods that can be used in both the hospital and home setting (Skelly et al., 2020).

Method	Mechanism of Action for Pain Management
Physical therapy	Muscle relaxation helps to relieve pain by releasing endorphins. Muscle strength and endurance training help prevent pain.
Heat/cold therapy	Vasoconstriction and vasodilation are known to relieve pain at the nerve endings.
Massage, acupuncture, acupressure	Increase circulation, which encourages oxygenated blood flow to the muscle area.
Transcutaneous electrical nerve stimulation (TENS) units	Stimulation of the nerve cells blocks pain signals to the brain. Electrical pulses also release endorphins, a natural pain chemical.
Cognitive behavioral therapy (CBT)	Pain is managed by altering one's thought processes and repetition of behaviors to reduce pain.
Guided imagery, deep breathing exercises, and progressive muscle relaxation	Relaxation techniques are used to distract the pain sensation and redirect the pain gate signals.
Art, music, and pet therapy	Activities stimulate an increase in oxytocin, which induces relaxation and diversion from pain process.

TABLE 27.3 Nonpharmacological Approaches for Postoperative Pain Management

CULTURAL CONTEXT

Culture and Expressions of Pain

Varying cultures have diverse beliefs about the expression of pain. Some cultures encourage stoicism and may view the outward expression of pain as weakness, whereas other cultures embrace the expression of pain through crying loudly. Communication styles also impact how patients describe their pain, including language and euphemisms, making it important for the nurse to clarify what the patient means. Gender roles influence expressions of pain such as men downplaying their pain to be perceived as strong, whereas women may be more vocal about their pain. Family dynamics can also impact expressions of pain as some may rely on the patriarch or matriarch of the family to verbalize the pain of the patient.

When Pain Interferes with Healing

Painful events can greatly disrupt the natural healing process and present difficulty for patients recovering from surgeries or injuries. Compromised immunity can slow healing while increasing the risk for infections or any related ailments. Painful experiences often elicit physiological responses such as release of cortisol hormone; in excess, cortisol may impair immunity function, increase blood glucose levels, and hinder the overall healing process. Persistent pain may increase inflammation levels and contribute to a prolonged delay in tissue repair and an increase in scar formation, which can exacerbate existing conditions and cause greater scar formation. Painful conditions may restrict mobility and discourage patients from engaging in necessary physical activities and rehabilitation exercises that would support restoration of function and strength, further impeding healing efforts.

27.3 Hospitalized Postoperative Patient

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Explain the process of receiving a transfer from the PACU
- Discuss care of the postoperative patient in relation to differentiating normal versus concerning findings
- Describe interventions for the postoperative patient to promote healing

After a patient has undergone a surgery that requires a hospital stay, there will be a time of recovery from anesthesia in the PACU until a transfer to a recovery unit. The PACU stay will be for several hours until the patient is stable.

Accepting the PACU Transfer

The nurse who is accepting the PACU transfer should plan to receive pertinent info in ISBAR format. The receiving nurse should confirm there is a room ready to receive the patient. The nurse who is receiving a patient from PACU should expect to receive the following information about the patient:

- Patient information: full name, date of birth, and medical ID number, allergies, code status, previous medical history
- Surgery details: type of surgery, duration, and any complications that occurred, patient response to anesthesia
- Postsurgical drains: any drains, locations, and or dressings
- Vital signs: current and any significant patterns
- Fluid status: IV and blood products received, and current urine output
- Medications: medications and pain management
- Postoperative complications: focused assessment on respiratory status and hemodynamics such as bleeding
- Level of consciousness: orientation to person, place and time—current and baseline prior to surgical procedure
- Special needs: wound care, allergies, limitations to mobility, bariatric needs, language, special preferences postoperatively, names and relations of any family present
- Procedures: pending tests or procedures to be done after transfer

Care of the Postoperative Patient

Postoperative patient nursing care can be divided into various components that begin immediately in the PACU, continuing throughout the recovery period and beyond. The following is a list of nursing actions to care for a postoperative patient:

- Patient complete assessment: physical, mental, and vital signs
- Pain management
- Monitoring: vital signs, pulse oximetry, changes from baseline
- Fluid balance: provide fluid resuscitation as ordered, monitor imbalances between input and output (I&Os), noting a minimum of 30 ml/hr of urine production
- Surgical site/wound care
- Nutritional support
- Mobility and ADL assistance
- Patient and family education
- Preparation for discharge

INTERDISCIPLINARY PLAN OF CARE

Interdisciplinary Care for Patient Transfer

Nurses work with an interdisciplinary team and coordinate care for patients transferring from PACU to another unit within the facility, such as the intensive care unit (ICU). The following are examples of these team members:

- PACU nurse: provides handoff and transfer of care

- ICU nurse: receives handoff reports and accepts patient care
- Respiratory therapist: sets up any cardiopulmonary equipment such as a ventilator, or sleep apnea machine; provides the patient with education on pulmonary exercises such as incentive spirometer and breathing treatments.
- Surgeon: orders the transfer of the patient to an alternative unit, provides the receiving provider a handoff report, and orders any specialty referrals needed to manage patient care
- Case manager: coordinates ancillary departments needed for the patient's plan of care and coordinates resources for the family once the patient is able to be discharged

Postoperative Priorities

Care of postoperative patients requires acute clinical observation in order to distinguish normal recovery from potential complications. After surgery, it is common for patients to experience some discomfort, pain, and fatigue as part of postoperative recovery. Vital sign monitoring is a key part of general nursing duties and nurses need to be watchful for changes within normal ranges in vital sign readings. Initial heart rate and blood pressure spikes due to stress or pain may occur; however, any persistent abnormalities or substantial deviations from baseline warrant further examination. Monitoring surgical sites for potential signs of inflammation such as mild redness and swelling is also necessary for successful surgery outcomes. Drainage or minimal oozing may occur postoperatively, but any signs of excessive bleeding or an abnormal color change should prompt medical intervention and further evaluation.

While mild postoperative nausea is normal, persistent or severe nausea that leads to vomiting should be addressed quickly. Health-care providers should administer antiemetics and/or adequate fluid replacement as treatment measures, and nurses must remain alert for signs of dehydration or electrolyte imbalance that might require other intervention strategies. Dehydration may present with tachycardia, hypotension, poor capillary refill, disorientation, thirst, headache, and dizziness.

As postoperative patients are susceptible to atelectasis and pneumonia, routine use of an incentive spirometer as well as monitoring oxygen saturation levels can assist in early identification of potential respiratory complications (Figure 27.3). Persistent respiratory distress, increased oxygen requirements, or diminished breath sounds could signal more critical health concerns requiring immediate action to address. Mild confusion or disorientation immediately following surgery could be the result of residual anesthesia effects; however, persistent changes to consciousness or neurological deficits could signal complications like cerebral hypoxia or adverse reactions that require further evaluation. Thorough and frequent neurological assessments, including evaluation of orientation, strength, and sensory function, are crucial. Overall, keen observation, prompt intervention, and effective collaboration within health-care teams can help ensure optimal postoperative patient care.

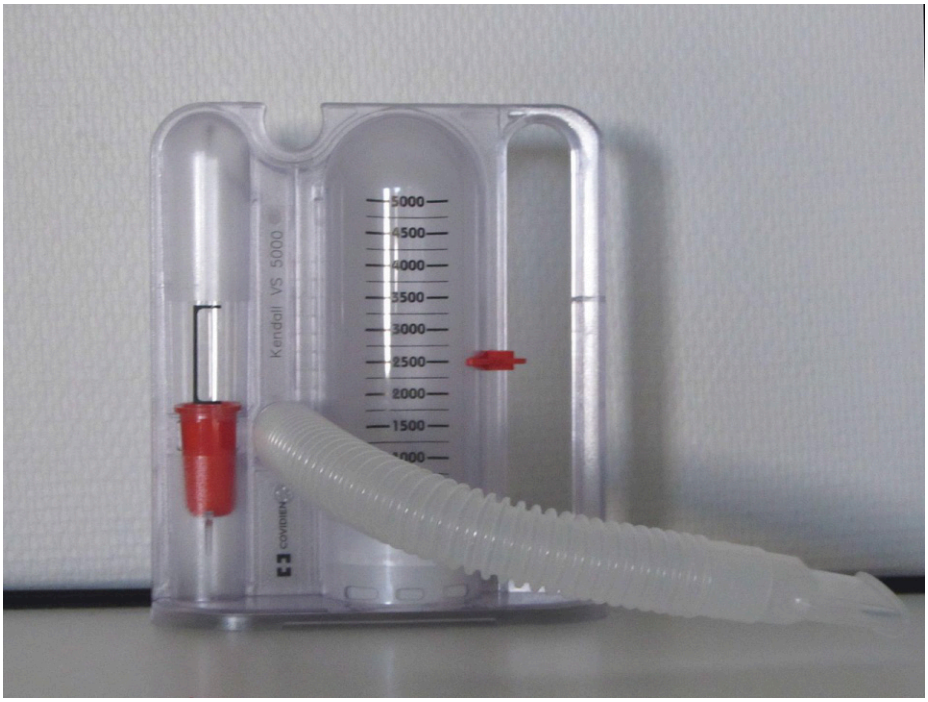

FIGURE 27.3 Patient use of incentive spirometry can decrease postoperative respiratory complications. (credit: "Incentive spirometer2" by Stefan Bellini/Wikimedia Commons, CC0 1.0)

Identifying Normal versus Concerning Findings

In postoperative care, nurses must be able to distinguish normal from abnormal findings to protect patient safety and ensure a successful recovery. Monitoring vital signs with an awareness of acceptable ranges is crucial to recognizing trends and concerning changes that need immediate attention. Adherence to pain control standards while remaining aware of signs that indicate complications or inadequate relief is a key component to effective pain management. Regular inspection of surgical sites is necessary to detect infections or any issues with wound healing, while respiratory and cardiovascular assessments help detect distress signs or complications, necessitating rapid intervention. Fluid balance, electrolyte status, and neurological assessments are essential in early identification of imbalances or deficits. Furthermore, monitoring of both digestive and urinary functions aids in the prevention of complications like ileus or urinary retention. Wound care and patient education on how to identify symptoms and adhere to postoperative instructions is important to promote positive patient outcomes. Effective communication with the interdisciplinary team as well as prompt reporting of concerns ensures comprehensive care that contributes to overall well-being of the postoperative patient (Bendowska, 2023).

REAL RN STORIES

Nurse: Alex
Years in Practice: Four
Clinical Setting: Medical-surgical unit
Geographic Location: New York

In a bustling surgical ward, I found myself facing a challenging shift. Amidst the flurry of patient care tasks, I received a call from the recovery room about a patient, Mrs. Martinez, who had developed a fever shortly after undergoing abdominal surgery. The patient appeared flushed and uncomfortable, with a temperature reading of 101.5°F. Sensing Mrs. Martinez's distress, I introduced myself and began a systematic assessment. I checked Mrs. Martinez's vital signs, noting her elevated heart rate and respiratory rate. I carefully inspected the surgical incision site for signs of infection, but it appeared clean and without new blood. I also inquired about Mrs. Martinez's pain level and any other symptoms she might be experiencing. I explained the possible causes of postoperative fever, including inflammation from surgery, atelectasis, or infection. With gentle reassurance, I assured Mrs. Martinez that we would work together to address her fever and ensure her comfort.

Drawing upon my nursing knowledge, I collaborated with the interdisciplinary team to develop a tailored plan of care. I initiated a fever-reducing medication and encouraged Mrs. Martinez to increase her fluid intake to prevent dehydration. I also collaborated with the physician to order blood tests and a chest x-ray to rule out underlying infection or pulmonary complications.

Over the next few hours, I diligently monitored Mrs. Martinez's condition, documenting vital signs and responses to treatment. As the fever began to subside, Mrs. Martinez's symptoms improved. My commitment to providing rapid, patient-centered care made all the difference. My proactive approach to assessing and treating postoperative fever exemplified the impact of nurses on positive patient outcomes.

Postoperative complications related to deep vein thrombosis (DVT) and pulmonary embolism (PE) require intensive nursing intervention to identify them quickly and initiate treatment. A thrombus is a clot, but when it moves to a different location such as the lungs or the head, it is known as an embolism. A clot to the legs generally lodges in the lungs, whereas a clot in the heart can lodge in the head (Bui et al., 2019). Postoperative patients are a risk for DVT and PE due to factors like immobility, surgery-related trauma, and altered blood clotting factors. DVT occurs when blood clots form in deep veins of the legs. Left untreated, DVT may develop into PE, which occurs when one or more blood clots break loose from their original location and travel directly into one or more pulmonary arteries, blocking these passages and preventing adequate airflow to tissues. Many nursing actions for the postoperative patient are to aid in prevention of these two complications. Early and frequent ambulation is key to stimulating blood flow and avoiding stasis as immobility increases circulatory stagnation. Leg exercises and ankle pumps can be used to promote circulation, and compression stockings, or sequential compression devices (SCDs) may be recommended to reduce the risk of blood clot formation in lower extremities. Health-care providers may prescribe prophylactic anticoagulant medication based on patient risk factors.

Even with preventive measures in place, nurses must recognize signs and symptoms of DVT, including swelling, tenderness, and discoloration of an affected limb, in order to recognize potential concerns about DVT promptly and report any concerning findings immediately. Symptoms of PE include sudden chest pain, shortness of breath, and increased heart rate, which should all be immediately treated as indicators of a problem. Proper patient education on reporting any unusual signs as soon as they occur as well as adhering to prescribed preventive measures are crucial. Any deteriorating respiratory problems require that the nurse sit the patient up in bed with pillow support, measure vital signs, including oxygen saturation, and call the provider immediately for further instructions. Possible postoperative complications are summarized in Table 27.4.

Complication	Clinical Presentation	Nursing Actions
Atelectasis	Decreased breath sounds, low oxygen saturation, dyspnea, tachypnea	Encourage deep breathing, coughing exercises, use of incentive spirometer, early ambulation and frequent repositioning of the patient, as well as monitor oxygen saturation
Dehiscence	Separation of wound edges, increased drainage, visible underlying tissues	Apply sterile dressings, notify the surgeon immediately, keep the patient calm, avoid strain on the wound, apply an abdominal binder if indicated
Deep vein thrombosis (DVT)	Swelling, pain, warmth, redness in one leg, positive Homans sign	Encourage early ambulation and leg exercises, apply compression stockings or SCDs, administer anticoagulants as ordered, monitor for signs of PE
Fever	Temperature > 101	Administer antipyretics, apply cool washcloths to forehead or feet, remove layers of sheets or clothing to cool patient

TABLE 27.4 Postoperative Complications (Stephenson et al., 2020)

Complication	Clinical Presentation	Nursing Actions
Hemorrhage	Hypotension, tachycardia, excessive bleeding at surgical site, decreased hemoglobin and hematocrit	Apply pressure to the bleeding site, notify the surgeon immediately, do not leave the patient, prepare for possible return to surgery, administer IV fluids and blood products as ordered
Infection	Redness, swelling, warmth, pain at surgical site, fever, purulent drainage	Maintain sterile technique during wound care, maintain strict adherence to hand hygiene practices, administer antibiotics as prescribed, monitor temperature and white blood cell count, educate patient on signs of infection
Nausea and vomiting	Nausea, vomiting, retching, abdominal discomfort	Administer antiemetics as prescribed, encourage slow and small sips of clear fluids, monitor for dehydration, maintain a clean and calm environment
Paralytic ileus	Abdominal distension, absence of bowel sounds, nausea, vomiting, constipation	Encourage ambulation, administer IV fluids, insert and manage nasogastric tube if ordered, monitor bowel sounds and abdominal girth
Pneumonia	Cough, fever, purulent sputum, chest pain, crackles on auscultation, dyspnea	Encourage coughing and deep breathing, use incentive spirometer, administer antibiotics as prescribed, monitor respiratory status, elevate the head of the bed
Pulmonary embolism	Cough, absent or diminished breath sounds, shortness of breath, chest pain, tachypnea, tachycardia, hemoptysis, cyanosis	Activate the hospital's alert system for medical rapid response team, provide oxygen at high flow mask for SaO_2 > 90%, administer anticoagulant low molecular weight heparin or thrombolytic therapy (alteplase)
Urinary retention	Inability to void, bladder distension, lower abdominal or back pain	Assess for urinary retention with bladder scan, catheterize if necessary and ordered
Wound infection	Redness, warmth, swelling, increased surgical site pain, purulent drainage	Clean wound with sterile technique and dressings, administer antibiotics

TABLE 27.4 Postoperative Complications (Stephenson et al., 2020)

Interventions to Promote Healing

Early mobilization and ambulation are encouraged as an essential way of avoiding postoperative complications and improving overall recovery. Respiratory care is of utmost importance, including deep breathing exercises, incentive spirometry use, and supplemental oxygen administration when necessary. Monitoring for signs of inflammation and regular dressing changes according to surgical protocol are integral parts of care management. Nutritional support should be tailored specifically to each patient; nutrient intake and feeding requirements should be taken into consideration.

Whenever a patient presents with symptoms of shortness of breath and increased respiratory rates, nurses should quickly identify and address potential sources of respiratory distress. At first, a nurse should ensure the immediate safety of the patient by offering a comfortable and upright position to facilitate maximum lung expansion. At the same time, nurses should measure oxygen saturation using a pulse oximeter and administer additional oxygen as necessary to ensure adequate levels. A comprehensive respiratory examination should then take place, including auscultation to identify any abnormal lung sounds such as wheezing, crackles, or decreased breathing patterns.

Assessing skin color and mucous membrane status of patients can give additional clues regarding oxygenation. Vital signs, including heart rate and blood pressure measurements, should be regularly assessed to detect signs of respiratory distress or impending respiratory failure. Based on assessment findings, nurses should promptly contact health-care providers to report patient symptoms as soon as possible and receive further advice for interventions or diagnostic evaluations. Other interventions could involve conducting arterial blood gas analysis to evaluate their respiratory status and initiating treatments such as bronchodilators as needed. Depending on the severity and underlying cause, additional diagnostic tests such as chest x-rays or CT scans may also be needed to pinpoint its source and find relief for respiratory distress.

Patient Education

Patient education plays a pivotal role in postoperative care as the patient is the center of care and needs to be involved in the care plan. Nurses should provide the patient with details regarding surgery procedures, recovery processes, and discharge instructions. For example, a patient may need to know how to correctly use an incentive spirometer, and the nurse should follow up on the patient's progress with the spirometer throughout the hospital stay to ensure adequate expansion of the lungs to prevent respiratory complications. In addition to clinical care, psychosocial support is integrated through the postoperative care plan to meet the patient's emotional needs: screen for anxiety or depression symptoms and encourage open dialogue among the patient, their family members, and the interdisciplinary team. Furthermore, nurses collaborate with interdisciplinary team members to plan discharge with assessments of self-care abilities as well as follow-up care plans designed to ease back into daily living.

27.4 Postoperative Nursing Care Plan

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Relate interventions for the postoperative patient to common postoperative concerns
- Describe the nursing plan of care to prevent complications during the postoperative period
- Discuss the role of the nurse in providing education and psychosocial support to the postoperative patient and their family

Establishing a postoperative care plan is an integral aspect of nursing practice and must include everything a patient needs for optimal recovery while mitigating potential complications. An effective care plan should be customized to the needs of the individual patient. The process begins with an evaluation of a patient's health status as well as any preexisting health issues or concerns they have. From this information gathered during an assessment, a nurse can identify specific nursing diagnoses, such as reduced mobility, knowledge deficit, risk of infection, or altered comfort that will serve to guide goal setting and intervention strategies (Rao et al., 2021).

Goals set during postoperative care plans aim at meeting both physiological and psychological needs for each patient during recovery, including preventive measures, monitoring protocols, and interventions to address potential complications. Communication is at the center of creating care plans. Communicating key details regarding patient conditions, goals, and interventions between health-care team members, including dietitians and physical therapists, can promote collaborative and cohesive care delivery. Furthermore, postoperative care plans often extend well beyond postsurgical recovery to incorporate education and discharge planning. Nurses provide guidance to both their patient and the patient's support system about postoperative care, potential complications to monitor for at home, and follow-up appointments. This proactive approach allows and encourages active participation from everyone involved during recovery.

Common Postoperative Concerns

Ongoing assessment includes vital signs, pain levels, respiratory and cardiovascular status, surgical site condition as well as the emotional well-being of a patient. Regular assessments allow the nurse to adapt the care plan as required, keeping up with evolving patient needs and recovery progress. The most serious postoperative complications, as previously discussed, include a DVT or PE. Additionally, hemorrhage from a surgical site can cause hypotension, changes in hemodynamics, and shock. The most common postoperative concerns are typically postoperative nausea and vomiting (PONV), pain, hemodynamic changes, and urinary retention.

Postoperative Nausea and Vomiting

Assessing and treating PONV are integral components of nursing care for surgical recovery patients. Nurse assessments begin by reviewing each patient's medical history and symptoms to identify potential risk factors of PONV, such as previous episodes of motion sickness or recent surgical procedures that increase PONV risk. After surgery, nurses monitor patients closely for any signs and symptoms of PONV, including patient reports, facial expressions, and physiological indicators like increased salivation or pallor (Jin et al., 2020). There are pharmacological and nonpharmacological interventions the nurse can use to help decrease PONV.

Pain Management

Effective postoperative pain management is key for optimizing patient comfort and supporting recovery. Combining both pharmacological and nonpharmacological interventions tailored to an individual patient's specific needs and the nature of surgical procedure should be used. Pharmaceutical interventions might include taking analgesics. Nurses carefully assess a patient's level of pain using validated pain scales and administer analgesics as recommended by health-care providers. As discussed earlier, there are pharmacological and nonpharmacological interventions the nurse can use to help decrease postsurgical pain.

Hemodynamics

Managing postoperative hemodynamics requires vigilant observation and intervention by the nurse to protect the patient's cardiovascular function and to avoid potential complications. Hemodynamics deals with the flow of blood and the body's ability to perfuse tissues, which is measured by blood pressure and pulse. Nurses frequently monitor vital signs following surgery to evaluate a patient's overall hemodynamic status. Continuous electrocardiogram (ECG) monitoring provides real-time information regarding cardiac rhythm, allowing early identification of any arrhythmias or abnormalities that might develop. Hemodynamics reflect tissue perfusion and adequate oxygenation. Central venous pressure or pulmonary artery pressure monitoring may be utilized to assess fluid status and cardiac function more accurately. Nurses may need to administer intravenous fluids and medications to support hemodynamic stability. Fluid management should consider each patient's individualized needs, surgical factors, and potential comorbidities to avoid both hypovolemia and fluid overload.

Nurses monitor and are prepared to respond to changes of cardiac function, specifically hypotension or hypertension. For hypotension, nurses may give a **bolus** (a single large dose of fluid) to increase blood pressure per the provider's order. When electrolytes are increased and blood pressure is low, often a simple bolus of normal saline can restore normal hemodynamics and balance the electrolytes. For hypertension, nurses need to evaluate the cause, which may be from pain, emotional stress or fear, or cardiac overload of fluids. With a provider's order, interventions may include diuretics to help the body rid excess fluid and avoid peripheral edema and respiratory congestion.

As indicated, **inotropic** (medications that impact the speed of cardiac contraction) or vasopressor medications may be administered to optimize cardiac output and blood pressure. Assessing peripheral perfusion is important, and nurses need to monitor skin color, temperature, capillary refill time, and peripheral pulses closely in order to spot indicators of inadequate tissue perfusion. Recognizing and taking prompt corrective action upon any deviations from baseline hemodynamic parameters is of vital importance. Nursing interventions for postoperative hemodynamics management may include changing a patient's position, providing oxygen therapy, or initiating fluid resuscitation/vasopressor support as directed by the health-care provider. Nurses should communicate any concerning findings to the provider immediately to facilitate prompt interventions and modifications of a patient's care plan. Patient education is important, especially focusing on discharge planning, to help the patient understand the impact of the surgery on their circulatory system and when to call their provider.

If a nurse detects a postoperative patient is experiencing low blood pressure or tachypnea after surgery, immediate action must be taken. Nurses should immediately conduct an ABC assessment to pinpoint potential sources of hemodynamic instability and identify any possible solutions. When there are signs of compromised airway or breathing conditions, interventions such as repositioning, administering additional oxygen therapy, or calling for respiratory support should be implemented immediately. Concurrently, a nurse should assess the surgical site for signs of bleeding or hematoma that might explain any observed decreases in blood pressure. Communication between the nurse and the health-care provider is of utmost importance at this point in order to report findings, discuss possible causes, and get guidance regarding further interventions. Based on the severity of a situation, additional actions could include administering intravenous fluids or medications or prepping for advanced

monitoring or interventions. Close monitoring, ongoing assessment, and effective communication with the health-care team are all integral parts of responding effectively to postoperative hemodynamic instability as a nurse.

Urinary Retention

Nursing management of postoperative urinary retention includes proactive assessment, monitoring, and intervention to address potential complications related to impaired urinary elimination. The inability to urinate after surgery even when the bladder is full is called **postoperative urinary retention (POUR)** (Pomajzl & Siref, 2023). After surgery, nurses regularly assess a patient's urinary status by tracking intake and output as well as asking the patient about any difficulty or discomfort experienced while urinating. Patients at risk of postoperative urinary retention include those who have undergone lower abdominal or pelvic surgeries, have received epidural anesthesia, or have an established history of urinary issues. Nurses ensure the patient has access to a bedside commode or urinal and should encourage frequent attempts at voiding. When a patient reports difficulty or inability in passing urine postoperatively, nurses can implement various strategies for managing urine retention. These may include providing privacy and an unhurried environment in which to void, aiding with positioning that promotes relaxation of pelvic floor muscles, and providing ample hydration to promote urine production. In certain circumstances, nurses may utilize bladder scanning technology to assess urine volume in the bladder and ascertain the need for intervention.

If noninvasive measures prove ineffective, catheterization might become necessary under medical guidance and the provider's order. Intermittent straight catheterization may help relieve urine retention and avoid complications such as urinary tract infections or bladder distension. Catheterization should be used only as a last resort due to associated risks with infection. Generally, if an indwelling urinary catheter was placed during surgery, it is removed within six hours postoperatively. Research indicates the quicker a urinary catheter is removed after surgery, the less risks the patient has for long-term infections (Gad & AbdelAziz, 2021).

Patient education plays a vital part in nursing management for POUR. Patients should immediately be assessed if they report any difficulty with voiding and practice strategies to support normal urinary function. Routine evaluation of urinary output, assessment of signs and symptoms of bladder distention, and ongoing communication with patients contribute to effective nursing management of POUR. In many facilities, it is a requirement for the patient to urinate once before being allowed to return home after a same-day surgery.

Prevention of Complications

Prevention of complications is an essential aspect of nursing care for postoperative patients. Nurses need to monitor, assess, and intervene quickly to handle potential complications such as infections, respiratory ailments, or thromboembolic events. Implementation of evidence-based practices like proper wound care, administration of prescribed medications, and early patient ambulation has proven highly successful in mitigating adverse events and improving recovery times. Patient education on warning signs, postoperative care instructions, and follow-up appointments empower individuals to actively take part in their recovery while seeking timely assistance when needed. Nurses' expertise in anticipating, identifying, and responding to potential complications benefits both patients and health-care delivery systems by decreasing hospital readmission rates, hospital-acquired infections, and their associated costs.

Decreasing Aspiration Risk

Aspiration can pose serious danger, particularly to postoperative individuals who may experience altered consciousness or compromised protective airway reflexes. Preventing aspiration in postoperative patients is of vital importance, and nurses play a pivotal role in ensuring patient safety during recovery phase. Nurses assess risk factors associated with the effects of anesthesia as well as the presence of comorbidities and employ positioning techniques (e.g., keeping the head of the bed ≥30 degrees) that lower regurgitation risks. Patients must adhere to preoperative fasting guidelines and tolerate the gradual return to oral intake postoperatively, to prevent aspiration during recovery. Nurses should actively watch for any signs of aspiration, such as coughing, choking, or respiratory distress, to identify patients who require emergency intervention such as withholding oral intake until the patient's protective reflexes and swallowing ability has fully returned.

Decreasing Respiratory Impairment Risk

Nurses bear a responsibility to safeguard postoperative patients' respiratory function as compromised breathing

poses significant health risks during recovery. As part of postoperative patient care, nurses monitor respiratory status by measuring oxygen saturation levels, respiratory rates, and chest movement. Early mobilization, incentive spirometry, and deep breathing exercises are integral parts of nursing interventions to maintain lung expansion and avoid atelectasis. Patients with obstructive sleep apnea are also at risk for postoperative complications. They should be monitored for adequate oxygenation after surgery. Pain management strategies must also be strategically applied in order to provide patient comfort without suppressing respiratory function. Prompt assessment and interventions such as improved positioning, administration of additional oxygen therapy, or collaboration between medical services providers and respiratory therapy services promotes positive patient outcomes. Effective patient education on the significance of good respiratory hygiene practices and early ambulation allows individuals to actively take part in their respiratory health care, reducing the risks of postoperative complications while hastening recovery.

Decreasing Clot Risk

Preventing blood clot formation, particularly DVT and its potentially life-threatening complication of a pulmonary embolism (PE), is an integral component of nursing care for postoperative patients. Nurses play a pivotal role in providing effective thromboprophylaxis strategies such as early mobilization, use of sequential compression devices (SCDs) (Figure 27.4), compression stockings, and anticoagulant medications as part of evidence-based protocols for prevention.

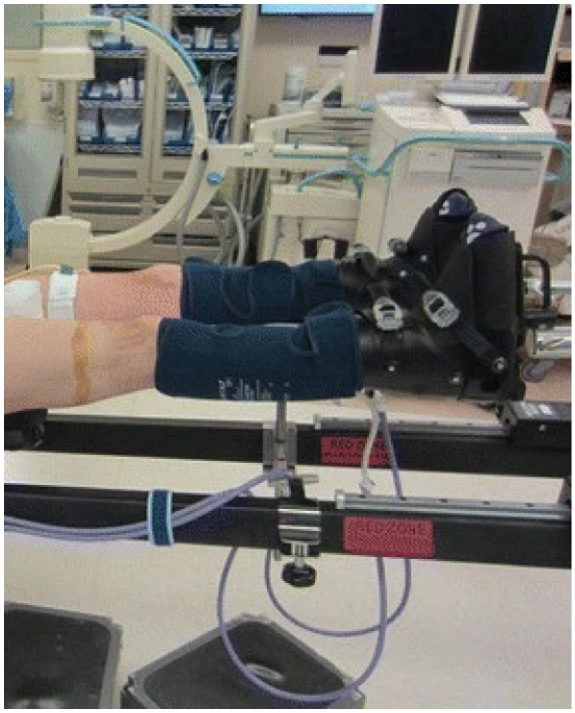

FIGURE 27.4 Use of SCDs or compression stockings can reduce the risk of DVT complications. (credit: modification of "Figure 1" by Ziran, N.M., Sherif, S.M. & Matta, J.M./ Patient Safety in Surgery Journal, CC BY 4.0)

Regular assessments of risk factors associated with blood clot formation such as immobility, type of surgery performed, and any coexisting diseases inform an individualized prevention plan tailored specifically for each patient. With thorough education on the symptoms and prevention measures associated with thromboembolic events, nurses can empower patients to actively take an active part in ensuring their own safety. Nurse work closely with interdisciplinary team members to ensure that prevention plans can be customized as required to minimize risk and enhance postoperative patient well-being.

Decreasing Infection Risk

SSIs or surgical site infections are a quality assurance risk that all members of the health-care team must diligently reduce. Surgical wounds are susceptible to bacterial contamination that can result in life-threatening complications. Preventing infection should always be a priority when caring for postoperative patients. As preventive measures, nurses utilize aseptic practices, and ensure proper hand hygiene, sterile dressing changes, and meticulous wound

care. Monitoring for signs of infection at surgical sites, such as redness, swelling, warmth, or drainage, allows for early identification and intervention (Figure 27.5). Administering prescribed antibiotics and promptly removing drains and catheters also help to combat infection. Patient education on wound care, hygiene practices, and reporting any signs of infection helps individuals take an active part in their own recovery while aiding early detection.

FIGURE 27.5 Redness and swelling are signs of infection. (credit: "Figure 1. Examples on the different types of infection" by Bjerknes S, Skogseid IM, Sæhle T, Dietrichs E, Toft M/PLOS Journals, CC BY 4.0)

CLINICAL SAFETY AND PROCEDURES (QSEN)

Preventing Postoperative Complications

Preventing postoperative complications is a critical aspect where QSEN competencies are directly applicable. Here's how nurses observe QSEN competencies to prevent postoperative complications:

1. Patient-centered care
   Involving patients and families: Nurses involve patients and their families in the care plan, ensuring they understand postoperative care instructions, potential complications, and when to seek help.
   Respecting patient preferences: Tailoring pain management and care plans according to the patient's needs, cultural backgrounds, and preferences enhances recovery and reduces the risk of complications.
2. Teamwork and collaboration
   Effective communication: Nurses communicate clearly and regularly with the surgical team, anesthesiologists, and other health-care providers to ensure a seamless transition of care and address any issues promptly.
   Interdisciplinary collaboration: Collaborating with physical therapists, dietitians, and other specialists helps in creating a comprehensive care plan that addresses all aspects of patient recovery and reduces the risk of complications such as deep vein thrombosis (DVT) and pneumonia.
3. Evidence-based practice
   Implementing best practices: Nurses stay informed about the latest evidence-based guidelines for postoperative care, including infection control, pain management, and early mobilization strategies.
   Continuous education: Engaging in lifelong learning ensures that nurses are up-to-date with the latest research and techniques to prevent postoperative complications effectively.
4. Quality improvement
   Monitoring outcomes: Nurses participate in quality improvement initiatives by tracking postoperative outcomes, identifying trends, and contributing to the development of strategies to improve patient care.
   Feedback and reflection: Regularly reflecting on care practices and outcomes allows nurses to identify areas for improvement and implement changes to prevent future complications.
5. Safety
   Preventing infections: Adhering to strict aseptic techniques and protocols for wound care, catheter care, and

hand hygiene minimizes the risk of postoperative infections.
Medication safety: Carefully managing and administering medications, including anticoagulants and antibiotics, to prevent complications such as DVT and surgical site infections.
Fall prevention: Implementing safety measures such as ensuring the patient's environment is free of hazards and assisting with ambulation to prevent falls during the postoperative period.

6. Informatics
Electronic health records (EHR): Utilizing EHRs to document and track patient information accurately, ensuring that all members of the health-care team have access to up-to-date patient data.
Decision support systems: Using clinical decision support systems to identify potential risks and alert health-care providers to implement preventive measures promptly.
By integrating QSEN competencies into daily practice, nurses play a crucial role in preventing postoperative complications and ensuring high-quality, safe patient care. This holistic approach not only improves patient outcomes but also enhances overall health-care quality and safety.

Decreasing Hemorrhage Risk

Nurses caring for postoperative patients must prioritize preventing hemorrhage as an essential goal, given that surgical procedures carry inherent risks of bleeding complications. Nurses monitor vital signs closely, assess surgical sites for signs of excessive bleeding, and educate patients to recognize abnormal blood loss or hemorrhage symptoms. Administration of prescribed hemostatic medications on an optimal schedule and close monitoring of drainage and blood loss help prevent hemorrhages. Furthermore, early intervention when abnormal bleeding occurs is also essential to preventing complications. Patient education on activity restrictions, adhering to postoperative care guidelines, and being alert for signs of bleeding help facilitate active patient participation in their healing journey. Nurses play an invaluable role in mitigating hemorrhagic risks and encouraging safe postoperative recovery for their patients through vigilant monitoring, effective communication with the interdisciplinary team, and proactive patient education.

Patient and Family-Centered Care

The focus of all health practice is patient-centered care. Including the patient's family and support network is paramount to successful outcomes. Family members and close friends provide emotional support, comfort, and encouragement that contribute significantly to the patient's overall well-being and mental health during recovery periods. Their involvement can also improve continuity of care by knowing and reinforcing the patient's postoperative instructions, medication schedules, and rehabilitation exercises. Family members can provide invaluable advocacy on behalf of their loved one by communicating any changes or concerns with health-care staff. Encouraging open dialogue and collaboration between nurses and the families of patients generates an atmosphere of support that enhances the recovery journey, provides a sense of safety, and creates more positive postoperative experiences.

Patient Education

Patient education after surgical treatment involves many crucial elements to ensure successful healing and a good recovery. Nurses should offer the patient guidance in pain management strategies, emphasizing the need to quickly report a change in pain levels to enable timely interventions that meet the patient's needs. Wound care instructions, including signs of infection and proper dressing changes, are provided to the patient to minimize complications at surgical sites. Mobility exercises and ambulation techniques, medication education, and respiratory exercises are all included as part of a postoperative education plan, along with instructions regarding potential complications. Educating patients and family members about the importance of follow-up appointments and when to notify their health-care provider if concerns or complications develop, along with the rest of the postoperative plan, create an informed and empowered patient who experiences a smoother postoperative recovery process.

Providing Emotional Support

Nurses can offer postoperative patients emotional and spiritual support by cultivating open communication and showing genuine care and empathy. Acknowledging any worries, fears, or anxiety around surgical experiences and recovery processes as soon as they arise is helpful for proper healing and wellness. Nurses should strive to create an atmosphere in which a patient feels free to express themselves without the fear of judgment. This is key to building trusting and therapeutic relationships with patients. Nurses can offer assurance and realistic expectations

regarding recovery processes while clearing up any misconceptions or uncertainties patients may have. Providing information to the patient about their progress, including the patient in decision making where applicable, and encouraging the patient to express their feelings all foster an atmosphere of control and empowerment. Nurses work collaboratively with other interdisciplinary team members, such as social workers or counselors, to provide additional emotional support as needed, further strengthening postoperative patients' overall well-being and resilience during recovery.

Summary

27.1 Postanesthesia Recovery and Care

- Perioperative refers to the entire surgical experience from preoperative to surgery to postoperative within the postanesthesia care unit (PACU). Postoperative refers to the time after surgery and includes the monitoring and interventions from the interdisciplinary team.
- PACU duties include stabilizing the airway and monitoring vital signs.
- Nurses must intervene to manage PONV for patient comfort by administering medications, maintaining proper fluid balance through intravenous therapy, and educating patients.
- From the PACU, patients can be discharged to their home or transferred to another hospital unit.
- Nurses use the ISBAR communication strategy when communicating about patients, especially during transitions of care.

27.2 Postoperative Pain Management

- Pain is a subjective experience and not to be judged by the nurse's interpretation of pain.
- Pain management is a key task in the PACU, and nurses need to use a variety of tools to complete an effective pain assessment.
- Pharmacological and nonpharmacological methods are available for nurses to manage postoperative pain.
- Nurses educate patients about the relationship between pain management and the healing processes, encouraging adherence to prescribed medications and engagement in rehabilitation activities.

27.3 Hospitalized Postoperative Patient

- Transfer from the PACU to an inpatient unit such as an ICU, should focus on airway management and stabilization of vital signs.
- ISBAR is the best practice standard for reporting or handing off from one health-care team member to another.
- A key nursing activity for a postoperative patient is to differentiate between normal and abnormal physical findings.
- Nursing duties beyond the PACU include activities to prevent complications and promote healing, such as providing hydration, nutrition, promoting mobility, and patient education.

27.4 Postoperative Nursing Care Plan

- Nursing care of the postoperative patient involves monitoring vital signs and surgical wound sites to quickly identify any complications.
- Nursing care can help prevent many common complications, such as thromboembolic events (DVT and PE).
- Nurses create a plan of care to prevent complications during the postoperative period.
- By providing patient education, the nurse can support the patient and family's psychosocial needs in the postoperative period. Collaborating with interdisciplinary team members helps strengthen the resources the patient has for best outcomes. Involving the family members and the patient's support network in the postoperative care can be an emotional strength to a patient during recovery.

Key Terms

bolus single large dose of fluid or medication
durable medical equipment (DME) equipment such as elevated toilet seats, walkers, or ambulatory, mobility devices
inotropic medications that impact the speed of cardiac contraction
phase I PACU accommodates complex surgical and high-acuity patients; also known as main or primary PACU
phase II PACU extended care units for patients who need less acute support after their surgery
postanesthesia care unit (PACU) hospital unit where patients are temporarily admitted after a surgery
postoperative nausea and vomiting (PONV) excessive nausea and vomiting that occurs as a result of anesthesia
postoperative phase begins when the patient is transferred to the PACU and ends when the patient is transferred to another unit or discharged home
postoperative urinary retention (POUR) inability to urinate after surgery even when the bladder is full

Assessments

Review Questions

1. In the immediate postoperative period in a PACU setting, what nursing task is most essential?
    a. administering postoperative medications
    b. discussing discharge instructions with the patient and family
    c. assessing vital signs and airway status
    d. giving an ISBAR to the receiving medical surgical unit nurse for future transfer

2. To help address PONV, what key aspects of nursing care will the nurse implement for postanesthetic recovery in PACUs?
    a. administering narcotics to help with pain control
    b. encouraging early ambulation
    c. advancing from a liquid diet to regular diet to decrease nausea
    d. assessing nausea and vomiting regularly and treating it promptly

3. What nursing duty is key when preparing patients to leave the PACU?
    a. administering antiemetic drugs at prescribed times
    b. assessing wound healing every hour
    c. sending patients to their next unit with an incentive spirometer
    d. communicating clear postoperative instructions to the patient and caregivers

4. What action by the nurse demonstrates competency in the assessment of postoperative pain management?
    a. employing a pain assessment tool regularly to evaluate both pain intensity and response to interventions
    b. administering pain medications on a fixed schedule without assessing patient pain level
    c. relying solely on self-report of pain without considering objective indicators
    d. asking the family member if the patient is in pain

5. What nursing intervention is appropriate when treating postoperative pain for patients who have shown prior opioid sensitivity?
    a. administering the same opioid dosage prescribed to other patients
    b. employing only nonpharmacological interventions
    c. conducting a thorough pain evaluation in conjunction with health-care team to devise alternative analgesic strategies
    d. performing a pain assessment and consulting with health-care team for alternative analgesic approaches

6. What action is appropriate for a nurse to take when managing a patient's postoperative pain that considers the patient's cultural background?
    a. administering the maximum of the doctor's pain medication available regardless of the patient's expression of pain
    b. encouraging the patient to only use a numerical scale as it's the most objective
    c. considering both verbal and nonverbal expressions of pain
    d. relying on family members to describe the patient's pain level

7. A postoperative patient is hesitant to report their pain and frequently states, "I can handle it," despite grimacing and wincing. What should the nurse do next?
    a. Respect the patient's wishes and withhold pain medication.
    b. Educate the patient about the importance of pain management for healing and encourage open communication about their pain.
    c. Increase the dosage of pain medication without informing the patient.
    d. Wait until the patient has severe pain and is willing to express it.

8. A nurse is caring for a postoperative patient who reports severe pain that rates as an 8 out of 10 and requests additional pain relief after receiving an opioid only one hour ago. What should the nurse do?
   a. Administer the additional dose as ordered even if before the scheduled time.
   b. Call the health-care provider to request earlier administration of the next dose.
   c. Inform the patient no additional can be administered due to the patient's risk for substance use disorder.
   d. Explain to the patient the importance of adhering to the doctor's prescribed medication schedule and offer nonpharmacological options to help control pain in between doses.

9. You are the nurse caring for a postoperative patient who complains of increasing pain despite receiving the prescribed analgesics. What is the best action?
   a. Administer an additional dose of the ordered pain medication.
   b. Assess the patient's vital signs and surgical site and report findings to provider with pain issues.
   c. Educate the patient that postoperative pain is expected and teach nonpharmacological methods to deal with the pain.
   d. Document the pain and assess vital signs per routine on the unit.

10. After completing a physical assessment, the nurse notes that the breath sounds on one side are diminished and the patient reports difficulty breathing. What is the priority action of the nurse?
   a. Administer a bronchodilator of your choice to improve respiratory function.
   b. Encourage the patient to use an incentive spirometer.
   c. Document the findings and continue with the routine nursing care.
   d. Sit the patient up in bed and notify the health-care provider immediately.

11. What intervention should the nurse prioritize to prevent a deep vein thrombosis for a postoperative patient?
   a. Encourage early safe ambulation and mobility.
   b. Administer acetaminophen to decrease inflammation.
   c. Limit fluid intake to avoid overloading the heart.
   d. Apply heat packs to the lower calves to promote circulation.

12. A nurse is preparing to ambulate a postoperative patient for the first time. What interdisciplinary team member should the nurse collaborate with to ensure the patient's safety?
   a. pharmacist
   b. dietitian
   c. physical therapist
   d. social worker

13. To prevent postoperative respiratory complications such as atelectasis and pneumonia, the nurse educates the patient on the use of an incentive spirometer. What QSEN competency is the nurse demonstrating?
   a. informatics
   b. safety
   c. quality improvement
   d. patient-centered care

14. What nursing intervention is essential for preventing a postoperative deep vein thrombosis (DVT) and involves the interdisciplinary team?
   a. administering antibiotics
   b. encouraging early ambulation and leg exercises
   c. providing high-protein diet recommendations
   d. teaching wound care techniques

15. A postoperative patient is at risk for infection. The nurse collaborates with the interdisciplinary team to monitor and manage this risk. What specific role does the pharmacist play in this process?

a. developing a mobility plan
b. managing antibiotic therapy
c. teaching wound care
d. assessing nutritional needs

16. To ensure a patient understands the signs of postoperative complications and how to manage them at home, the nurse provides detailed discharge instructions. What QSEN competency does this action best represent?
    a. evidence-based practice
    b. teamwork and collaboration
    c. patient-centered care
    d. safety

Check Your Understanding Questions

1. Explain the process of giving an ISBAR to report the status of a patient during transitions of care.
2. Depending on the patient's needs, nurses may also need to consult with the social worker to order durable medical equipment (DME). What are some examples of DME?
3. Education is an integral component of nursing care for PONV management. What should the nurse include in the education for a patient with PONV?

Mr. Thompson, a fifty-four-year-old male, has been admitted to PACU following a laparoscopic cholecystectomy. He is currently awake and alert but appears restless and uncomfortable. His vital signs are: blood pressure 135/85 mmHg; heart rate 90 bpm; respiratory rate 18 breaths per minute; and oxygen saturation 97 percent on room air. Mr. Thompson states, "I'm in quite a bit of pain, about 7 out of 10." He is grimacing, holding his abdomen, and shifting frequently in bed. The provider has ordered postoperative pain medication as needed.

4. Using the preceding data, how would you assess the patient's postoperative pain?
5. After analyzing the given cues, how would you manage the patient's postoperative pain?
6. The nurse notices the patient's pain is preventing him from completing the postoperative deep breathing exercises, which could impact his healing. What should the nurse do?
7. Explain the process of receiving a transfer from the PACU.
8. Describe two concerning findings of a postoperative assessment.

Reflection Questions

1. Describe to a friend the interventions for the postoperative patient to prevent common postoperative complications.

Critical-Thinking Questions about Case Studies

1. Describe ways the postoperative nurse can manage nausea and vomiting during the recovery phase.
2. What are the priorities when caring for a patient admitted to the PACU?
3. Referring back to the case study in this section, how would the nurse know the patient is meeting criteria for discharge?

Competency-Based Assessments

1. Develop a presentation for your peers differentiating the interventions needed for home discharge versus discharge to another inpatient unit such as the intensive care unit (ICU).
2. Using the pain scale, practice assessing the pain levels of your peers or family members.
3. Develop an educational pamphlet outlining tasks the patient can do to promote postoperative healing.
4. Develop a five-minute presentation outlining psychosocial support interventions for the postoperative patient and their family.

CHAPTER 28
Inflammation and Healing

FIGURE 28.1 Welcome to where the art and science of nursing meet: caring for wounds with compassion. Providing wound care requires a knowledge base of healing pathophysiology, wound etiology, patient factors, and appropriate treatment selection. (credit: Dr. Steven Galvan/Joint Base San Antonio, Public Domain)

CHAPTER OUTLINE

INTRODUCTION For nurses, wound care exemplifies the union of the art of compassion and the science of care. To best meet patient needs and provide optimal wound care, it is important to understand what is occurring beyond the surface. How does a wound heal? How do you select the best dressing or treatment among the hundreds of products? How do you know if the treatment is working? This chapter will explore inflammation in the context of healing wounds of all kinds—from the cellular level to the application of topical therapies—and the nurse's various roles along the way to support the best outcomes possible for each patient.

28.1 Cellular Response and Adaptation in Wound Healing

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Describe the anatomy and function of the skin
- Define the four phases of the wound-healing process
- Identify the major physiological aspects of wound healing

Let us understand the skin we are in. Aside from being the largest human organ, the skin is the first physical barrier a human body has against the external environment. In addition to protecting the underlying structures of the body, among other responsibilities, our skin must be able to protect itself and heal when an injury occurs. This module will explore the anatomy and physiology of our largest organ, review the phases of healing when a wound occurs, and discuss the physiological components that accompany the healing process.

Skin Anatomy and Physiology

The skin consists of three layers (see Figure 14.2). The outermost layer is the epidermis, the middle component is the dermis, and the deepest layer is subcutaneous tissue. Each layer plays an integral part in the external and internal roles of the skin. Therefore, in caring for different client populations, it is important to know and understand the skin's underlying structures.

Structure and Function

As previously mentioned, there are three major layers that compose the skin: the epidermis, the dermis, and subcutaneous tissue (see Figure 14.2). The epidermis is the waterproof outermost layer. It is **avascular**, or lacks blood vessels, and contributes to an individual's skin tone. Depending on its location in the body, the epidermis consists of four or five sublayers of cells. Moving from superficial presentation to deep, the typical four sublayers are the stratum corneum, stratum granulosum, stratum spinosum, and stratum basale. A fifth sublayer, typically found on thicker-skinned areas such as the palms of the hand or soles of the feet, is located between the stratum corneum and stratum granulosum and is called the stratum lucidum. This extra sublayer provides added strength and protection to the skin in regions where the skin is subject to constant pressure or rubbing. The melanocytes, which produce melanin, are located in the epidermis. It is the melanocytes that determine the pigment of skin, which can range from fair to dark with a variety of shades and hues.

The dermis contains hair follicles, blood vessels, lymphatic vessels, nerves, and sweat glands. This core layer is divided into two distinct sublayers, the papillary and reticular dermis. The subcutaneous layer, also known as the hypodermis, consists of fat and connective tissue. This layer links the skin to the underlying structures, which include fascia, muscles, and bones.

The functions of the skin include regulation of temperature, protection, mobility, sensation, endocrine activity, and exocrine activity (Table 28.1).

Function	Description
Protection	The layers of the skin work together to protect the body against microorganisms, dehydration, and mechanical damage. Skin pigmentation is a defense mechanism against UV radiation.
Temperature regulation	The skin regulates body temperature and homeostasis by conserving or releasing heat.
Mobility	The skin allows for smooth body movement. Damage to the skin (e.g., burns and scarring) and the healing process can cause restrictive movements.
Sensation	Sensation begins with the skin. Pain, temperature, and pressure are all felt due to receptors within the skin.

TABLE 28.1 General Functions of the Skin

Function	Description
Endocrine activity	The skin is involved with biochemical processes such as production of Vitamin D and prevention of excessive water loss.
Exocrine activity	The skin participates in exocrine activity by releasing water, urea, and ammonia. In addition, the skin secretes products including cytokines, pheromones, sweat, and sebum.

TABLE 28.1 General Functions of the Skin

Age Considerations

Skin development begins during the first trimester of gestation. The various structural features are formed by thirty-four weeks gestation, and maturation continues until full term. The **dermal-epidermal junction** acts as the barrier between the epidermis and the dermis. In preterm newborns, the dermal-epidermal junction is weaker, containing less collagen, water, and melanin than in older counterparts. As a result, newborn skin has a greater risk of heat loss and is more fragile, susceptible to infections, and vulnerable to toxicity from topical agents. The skin continues to mature through the first year of life and closely resembles adult skin by the time a person is two years old. Table 28.2 details how quickly a person's epidermal cells are renewed throughout the life span.

Age	Rate of Turnover in Days
Newborn to 3 months	Approximately every 2 days, depending on site
Infant	14 days
Teens to 20s	14–30 days
Adults 30s–40s	28–42 days
Adults 50+	45–85 days

TABLE 28.2 Epidermal Turnover Rates by Age (Rahma & Lane, 2022; Maeda, 2017)

LINK TO LEARNING

Watch this video for a visual and auditory review of the layers of skin (https://openstax.org/r/77skinlayersrev) including their various functions throughout the life span.

At the opposite end of the care spectrum, aging results in the thinning of the epidermis and dermis as well as a potential decrease of the hypodermis. The thinning of the hypodermis may result in reduced support, increasing the risk for pressure injury development, and impaired temperature regulation. As we age, the skin loses its elasticity due to impaired barrier function and a decrease in sebum production, which may result in dry skin and wrinkles. Melanocytes decrease with age as do the numbers of sweat glands, blood vessels, and nerves. These normal consequences of aging make the skin more susceptible to damage and cause wounds to heal up to four times more slowly.

LIFE-STAGE CONTEXT

Wound Healing in the Older Adult

Changes in the dermis in different age categories can affect how we approach treatment and support the patient in their wound-healing journey. Older adult patients generally heal more slowly than younger patients. Skin breakdown and delayed wound healing may result from comorbid conditions, inadequate nutrition intake, and dehydration. An

individual's body build can impair wound healing. For example, excessive adipose tissue impairs blood flow, while a lack of adipose tissue can delay healing due to lack of nutrition and oxygen transport.

Consider the following when caring for an older adult with a wound:

- Older patients may be at risk for chronic wounds due to comorbid conditions and impaired circulation.
- Nonsteroidal anti-inflammatory medications (NSAIDs), such as aspirin and ibuprofen, are often used to treat arthritis but may interfere with the inflammation stage of the healing process.
- Dry skin is more vulnerable to excoriation and infection.

Phases of Wound Healing

The physiological process of wound healing includes four phases (Figure 28.2). These phases occur in a predictable manner that resembles a cascade of events as opposed to a series of distinct steps. Regardless of wound etiology, the biological repair process is the same for all wounds. As soon as damage occurs, the healing process begins. Keratinocytes, fibroblasts, vascular endothelial cells, and immune cells all play essential roles in supporting inflammation, cell migration, and angiogenesis.

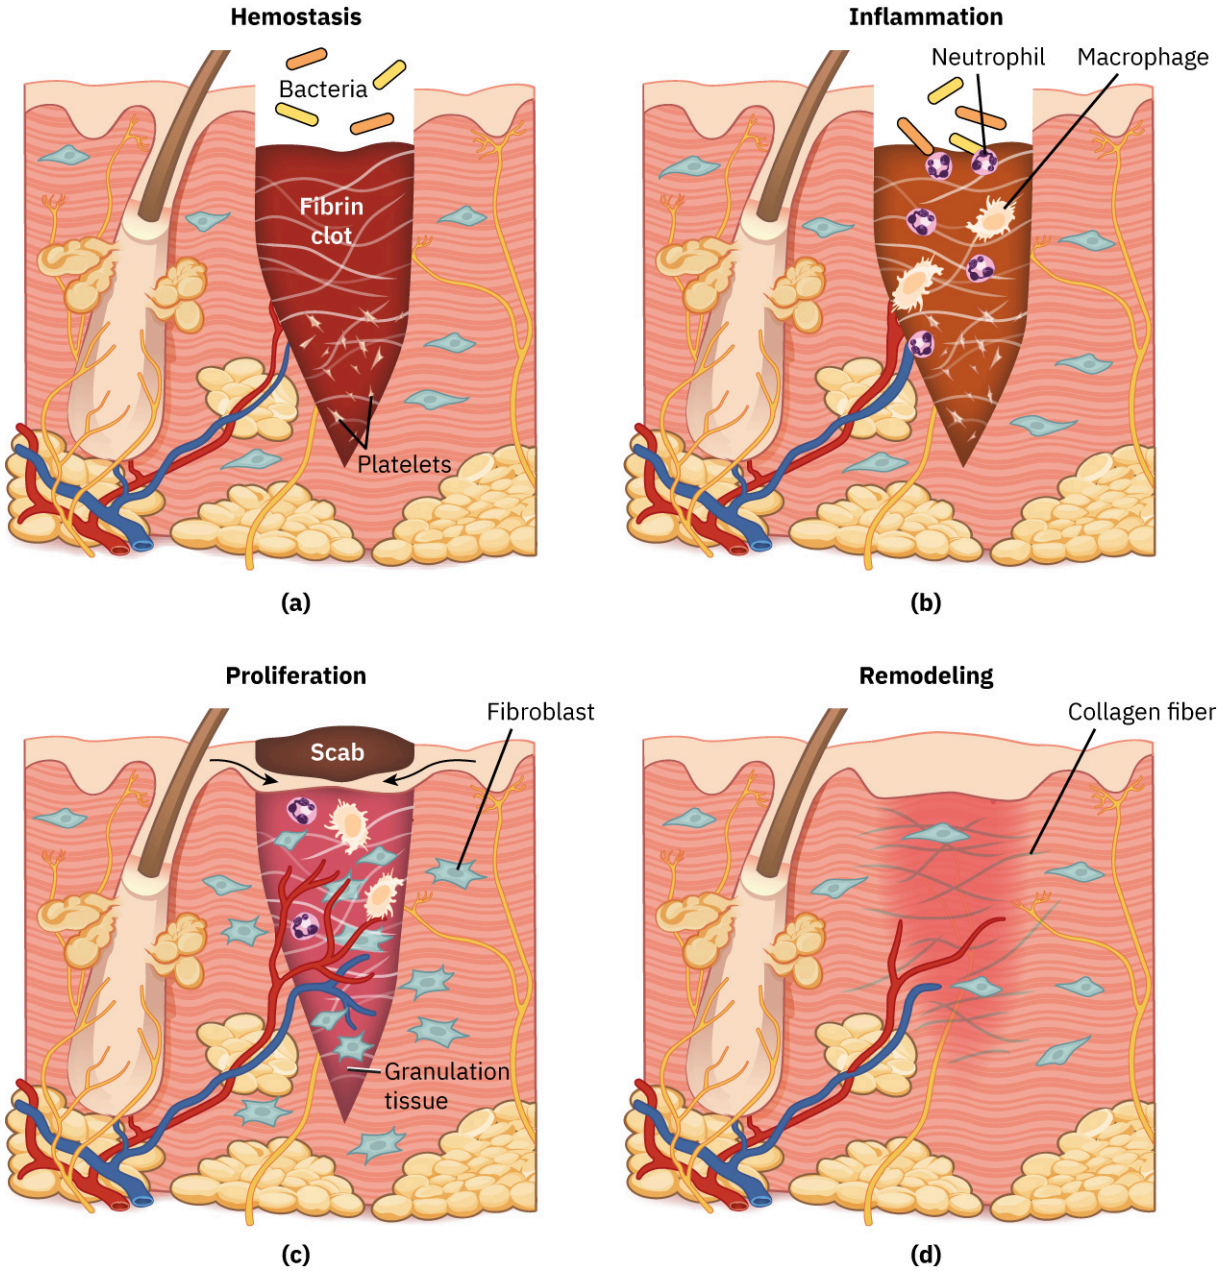

FIGURE 28.2 Wound healing is a physiological process that includes four phases: (a) hemostasis, (b) inflammation, (c) proliferation, and (d) remodeling. Each phase features cellular and molecular responses that resemble a cascade rather than a series of distinct steps. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Hemostasis

The first phase in the wound-healing cascade, called hemostasis, is marked by the cessation of bleeding (Wallace et al., 2023). When injury occurs, such as a break in the skin, blood vessels contract and clotting factors, such as fibrin, are released, which help stop the bleeding. In addition, platelets release growth factors that signal cells to start the repair process at the wound location. Depending on the severity of the injury, the hemostasis phase can last as much as sixty minutes.

Inflammation

The second phase of the wound-healing cascade is the **inflammation** phase. Acute inflammation begins immediately after injury and is essential for the orderly and timely healing of a wound. This phase is marked by vasodilation, facilitating the movement of white blood cells (neutrophils, macrophages, lymphocytes, mast cells) to the wound bed, where they start cleaning. Typically, the inflammation phase lasts three to seven days, depending on the injury. During the inflammatory process, the wound can present with redness, pain, swelling (edema), and

possibly exudate.

Proliferation

During the **proliferation** phase, the wound fills with new tissue, the wound margins contract, and the wound is covered. Proliferation does not have a specific starting point but can begin within a few days after the injury and last several weeks. This phase includes four distinct processes: epithelialization, angiogenesis, collagen formation, and contraction. The regeneration of the epidermis and the formation of granulation tissue is **epithelialization**. During epithelialization, various cell types actively proliferate to replace the damaged or loss tissue. For example, a **keratinocyte** is a cell that participates in the contraction and migration of cells across a wound bed to facilitate healing. They migrate from the wound edges, where they multiply until they meet in the middle of the wound bed. New connective tissue with fragile, thin-walled capillaries is called **granulation tissue**. In a healthy wound, granulation tissue can appear pink or red with an uneven texture. Healthy granulation does not bleed easily. If the granulation tissue appears dark and is friable (bleeds easily), it can be a sign of infection.

Proliferation also involves **angiogenesis**, the creation of new blood vessels. Additionally, cells called fibroblasts help to produce new collagen and repair the avascular epithelial tissue, causing the wound to contract.

Maturation and Remodeling

The maturation phase, also known as the **remodeling** phase, is the longest phase of wound healing, beginning around week three and lasting up to twelve months. Maturation involves the reorganization and transformation of collagen into scar tissue. Cellular activity slows, and the number of blood vessels in the wound is reduced. Collagen fibers continue to reorganize while the tissue remodels and matures. As a result, the tissue increases its tensile strength; however, the maximum strength is limited to 80 percent of the preinjured strength. During the maturation phase, any scarring may reduce in size, flatten, increase in strength, or change color.

28.2 Wound Healing Process

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Differentiate types of common wounds
- Distinguish between partial-thickness and full-thickness wounds
- Identify types of wound closure
- Describe barriers to wound healing

The wound-healing cascade, or process, is a complex overlapping system of biochemical and physiological pathways that secrete inflammatory cells and cytokines on the way to healing. Although the process contains the same four phases for all wounds, different types of wounds may require different approaches by the care team. This module will introduce the reader to the various types of wounds, as well as various methods for wound closure and barriers that wounds may encounter while healing.

Types of Wounds

Clinicians, including nurses, care for many types of wounds; it is important to understand the different types of wounds and their identifying characteristics, as each type has a specific treatment. Some therapies may be appropriate for one type of wound and detrimental to another. Understanding the wound's etiology helps foster treatment as well. For example, an acute wound progresses through the phases of healing without complication. In contrast, a chronic wound is a wound that fails to progress through the phases of wound healing in a timely fashion.

Open wounds are another important category in nursing practice. They involve an external or internal break in the tissue. Examples of open wounds include abrasions, lacerations, punctures, avulsions, skin tears, and incisions (Table 28.3).

Open Wound Type	Description
Abrasion	Removal of the skin from rubbing against a hard surface
Laceration	Torn or jagged wound caused by blunt force trauma
Puncture	Wound caused by a sharp, pointed object that penetrates the skin
Avulsion	Partial or complete tearing away of the skin and underlying tissue; also known as degloving
Skin tears	Wound caused by friction or shear, causing separation of skin layers
Incision	A surgical wound made to facilitate a procedure

TABLE 28.3 **Common Open Wound Types**

Other common wound types that a nurse may encounter include venous ulcers, arterial ulcers, diabetic foot ulcers, and pressure injuries.

Partial-Thickness vs. Full-Thickness Wounds

A **partial-thickness wound** is a superficial injury that involves the epidermis, dermis, or both. Partial-thickness wounds can present as a crater, abrasion, or blister. Although the topic of pressure injuries will be discussed in 28.3 Pressure Injury, it is important to understand that Stage 1 and 2 pressure injuries are considered partial-thickness wounds. In contrast, a **full-thickness wound** extends through all skin layers, potentially extending to the muscle fascia or bone. Stage 3, Stage 4, unstageable, and deep tissue injuries are examples of full-thickness injuries.

Types of Wound Closure

Wound closure from healing occurs through three methods: primary, secondary, or tertiary intention. Regardless of the closure method, a wound will progress and heal by moving through the four phases of wound healing.

Primary Intention

Primary wound closure, also referred to as healing by **primary intention**, is the fastest type of wound closure. Primary intention refers to the healing of a wound or injury with clean edges that can be **approximated**, or brought close together. The approximated edges allow wound contraction, proliferation, and epithelization to occur quickly, resulting in limited scarring. Surgical wounds closed by sutures, staples, or surgical glue typically heal by primary intention.

Secondary Intention

Healing by **secondary intention** occurs with wounds whose edges cannot be approximated or brought together, so the wound heals from the "bottom up" with granulation tissue. Secondary intention occurs when the wound cannot be surgically closed. This is often seen in wounds such as venous leg ulcers, pressure injuries, and skin tears. Wounds that heal by secondary intention are at a higher risk of infection and scar formation. Medical devices such as negative pressure wound therapy (NPWT) may assist with healing wounds from the bottom up. Therapies such as NPWT will be addressed later in the chapter.

Tertiary Intention

The term **tertiary intention**, also referred to as delayed primary intention, involves a plan to allow the wound to remain open. Reasons for the delayed closure could include waiting for the infection to resolve or preparing the wound for primary closure via a graft, flap, or skin substitute.

CULTURAL CONTEXT

Religious Considerations

Cultural competency is a cornerstone of patient-centered health care. Certain religious doctrines or cultures may define the appropriate consumption or use of certain animals and forbid the use of others. Some wound care products contain ingredients that are animal-derived. For example, certain skin substitutes are derived from pig placentas. However, religions such as Islam and Judaism, as well as some Christian denominations, forbid the use of pork products. If providing wound care to a Muslim or Jewish patient, the nurse would likely need to inform the patient about or use alternatives to pig-derived products. Furthermore, knowledge of animal-derived ingredients can help foster deeper conversations with patients about spiritual and cultural needs.

Barriers to Wound Healing

There are a variety of barriers to wound healing, such as those due to physical, physiological, local, and systemic origins. Several main risk factors that impede wound healing include age, immune status, perfusion, smoking, comorbidities, and immune and nutritional deficiencies. Comorbidities such as diabetes are directly linked to delayed wound healing. Extrinsic factors contributing to delayed wound healing include support surfaces, friction, and shearing forces.

Chronic wounds are wounds that fail to progress through the wound-healing cascade in a timely manner. According to the U.S. Centers for Medicare and Medicaid Services (CMS), if a wound has not closed or progressed within thirty days, it is considered chronic (Baranoski & Ayello, 2020). For a wound to heal or progress through the healing cascade, the wound bed must be prepared in a manner known as wound bed preparation (WBP). WBP begins with assessing the patient and their environment and determining their knowledge of their wound and health literacy. It is important for the nurse to assess the whole patient, not just the wound. Wound bed preparation is a nonsequential process of assessment, intervention, and evaluation that can be achieved through the acronym TIME, which stands for tissue, infection/inflammation, moisture, edges. The TIME principles of wound bed preparation guide the clinician in addressing the local barriers to healing and aligned interventions.

LINK TO LEARNING

The TIME principles focus on wound assessment and allow the clinician to assess the patient and wound in a systematic fashion. This article explains the evolution of TIME (https://openstax.org/r/77TIMEevolution) and its holistic nature, as well as how to implement TIME principles in practice.

Tissue Degradation

The presence of necrotic or devitalized tissue is a critical barrier to wound progression and healing; if the keratinocytes cannot migrate or granulation cannot fill a wound due to “roadblocks” of necrotic tissue, a wound will not heal. The **necrotic tissue**, or avascular debris, can appear as eschar, slough, or biofilm—a layer of microscopic bacteria or other microorganisms, usually combined with a polysaccharide matrix, which adheres to a wound surface. Necrotic or nonviable tissue requires debridement for removal. The purpose of wound bed debridement is to stimulate healing through the removal of necrotic tissue, elimination of dead space harboring bacteria, and drainage of pus; it also helps to reduce pressure, allowing for an inspection of underlying tissue, and optimize the site for topical preparations. The choice of the most appropriate debridement technique involves patient factors, wound appearance, environmental factors, and practitioner competence.

Infection and the Inflammatory Process

Many chronic wounds are identified as hosting bacteria or fungi. This is because the wound bed has typically been open for an extended period and becomes further exposed to environmental factors during each dressing change. Chronic wounds also often have poor perfusion to the wound bed, creating a favorable environment for organisms. Most chronic wounds are accompanied by biofilm development. A biofilm can perpetuate the inflammatory phase, inhibiting chronic wounds from healing (Ozgok & Regan, 2023). The best way to interrupt the biofilm is debridement.

If infection is evident, the provider may add antibiotics to the wound care orders.

Moisture Imbalance

Traditionally, people thought that drying out a wound sped healing. However, studies have shown, and best practices support, that a wound requires an amount of moisture to help facilitate the migration of keratinocytes to accelerate epithelialization (Nuutila & Eriksson, 2021). Achieving appropriate moisture balance involves the creation and maintenance of a warm, moist wound bed and the stimulation of components in the moisture that have a positive impact on wound healing, such as growth factors. An appropriate amount of moisture is needed for the optimal effects of growth factors and cytokines and for the growth of proliferating cells, such as keratinocytes, endothelial cells, and fibroblasts. Excessive moisture may lead to the maceration of wound edges, whereas inadequate moisture may inhibit cellular activities and promote eschar formation.

To address the excess or deficiency of moisture, depending on the institution's policy, the nurse or provider should select the appropriate wound care dressing or treatment. To add moisture, a hydrogel dressing or saline-moistened gauze is applied to the wound bed. Common dressings used to manage moisture include foam dressings, alginate dressings, gauze, or negative pressure wound therapy (NPWT).

Impact on the Edge of a Wound

One of the key indicators of a healing wound is progression of the edge of a wound in terms of epidermal cell and keratinocyte migration and wound contraction. Once tissue viability, infection, inflammation, and moisture have been addressed, wound edge advancement should indicate healing progression. Wound edge management is an important part of the healing process. Wound edges may become callused or rolled, or they may develop maceration, undermining, or tunneling. All these conditions require intervention so the wound may progress through closure.

The wound edge tells a story that the nurse must understand. If the wound edge has a callus, such as with a diabetic foot ulcer, the callus needs to be removed to allow the edge to epithelialize. Typically, this is achieved through sharp debridement. When wound edges become rolled instead of advancing across the wound surface, the condition is called **epibole**; it also requires debridement. The erosion of the tissue under edges of a wound is called **undermining**, whereas **tunneling** is the formation of a sinus tract, which can harbor bacteria. Undermining and tunneling require wound packing to advance toward healing.

Physiological Components of Wound Healing

The many processes involved with wound healing create a large metabolic demand that is met with oxygen and glucose transported to the wound site by newly formed endothelial vessels. Factors leading to vasoconstriction limit this blood supply and thus prevent proper wound healing. Causes of vasoconstriction include pain, cold, fear, nicotine, beta antagonists, and hypovolemia. Health-care providers attending to patients with healing wounds should be aware of these factors and control for them when possible. Patients should be screened for and counseled about the use of substances and medications that might impair or delay wound healing. Furthermore, comorbidities or underlying health or medical conditions can impact wound healing. Common conditions include diabetes, peripheral vascular disease (PVD), anemia, stress, peripheral neuropathy, and arterial disease. Patient education should include how comorbid conditions and lifestyle choices impact or influence the wound-healing process.

Nutritional Status

Nutritional status affects wound healing. The wound-healing process makes greater energy and nutrient demands on the body. Nutritional deficiencies, including low levels of vitamin C, zinc, iron, and vitamin A, have been linked to an increased risk of infection and decreased wound tensile strength (Ozgok & Regan, 2023).

Wound Complications

In addition to delayed wound healing, other complications can occur. Common wound complications include hematoma development, infection, and dehiscence.

A **hematoma** is an area of blood that collects outside of large blood vessels. A hematoma occurs when small veins and capillaries under the skin break. The development of a hematoma at a surgical site can lead to infection and incisional dehiscence. Upon inspection, hematomas related to wound care can appear as blood-filled blisters that are purple or deep red in color.

The separation of the edges of a surgical wound is called **dehiscence** (Figure 28.3). A dehisced wound can appear fully open, with visible tissue underneath, or with partial separation. The most common areas for dehiscence include abdominal surgeries and vascular surgical sites. Regardless of the incision site, patients with a history of stroke, chronic obstructive pulmonary disease (COPD), diabetes, or cancer have higher rates of dehiscence. Dehiscence is always a risk in a surgical wound, and the risk increases if the patient has obesity, is a smoker, or has other comorbidities, such as diabetes, that impact wound healing. Wound dehiscence can occur suddenly. Some signs of impending dehiscence include redness around wound margins and increasing drainage from the incision. The wound will also likely become increasingly painful.

FIGURE 28.3 Wound dehiscence can lead to further surgeries. (credit: modification of "Wound dehiscence following TKA in an obese patient" by *Journal of Orthopaedic Surgery and Research*, CC BY 2.0)

To prevent the dehiscence of a wound, surgical patients must carefully follow all postoperative instructions, including restricting activities, avoiding heavy lifting, and protecting the site from external damage.

28.3 Pressure Injury

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Define pressure injury
- Identify the causes of pressure injuries
- Identify the different stages of pressure injuries
- Discuss strategies for preventing and treating pressure injuries

Each year an estimated one to three million people in the United States are affected by skin and soft-tissue pressure injuries (Mondragon & Zito, 2024). According to the Agency for Healthcare Research and Quality, pressure injuries are considered "never events," meaning they are preventable and thus should never happen; nevertheless, they can result in devastating consequences, including death, to a patient (Smith et al., 2018). Pressure injuries have a long history of nomenclature, including terms such as *decubitus ulcer*, *pressure ulcer*, and *bed sore*. Preventing pressure injuries is an interdisciplinary team effort that requires diligence, creativity, and education. The cornerstone of pressure injury prevention is to reduce pressure, moisture, and friction to any at-risk sites. As the bedside providers, nurses are key to preventing injuries.

Pathophysiology

Per the National Pressure Injury advisory panel, a **pressure injury** is localized damage to the skin and underlying soft tissue, typically over a bony prominence (Figure 28.4). The injury can present as intact skin or an open ulcer and may be painful.

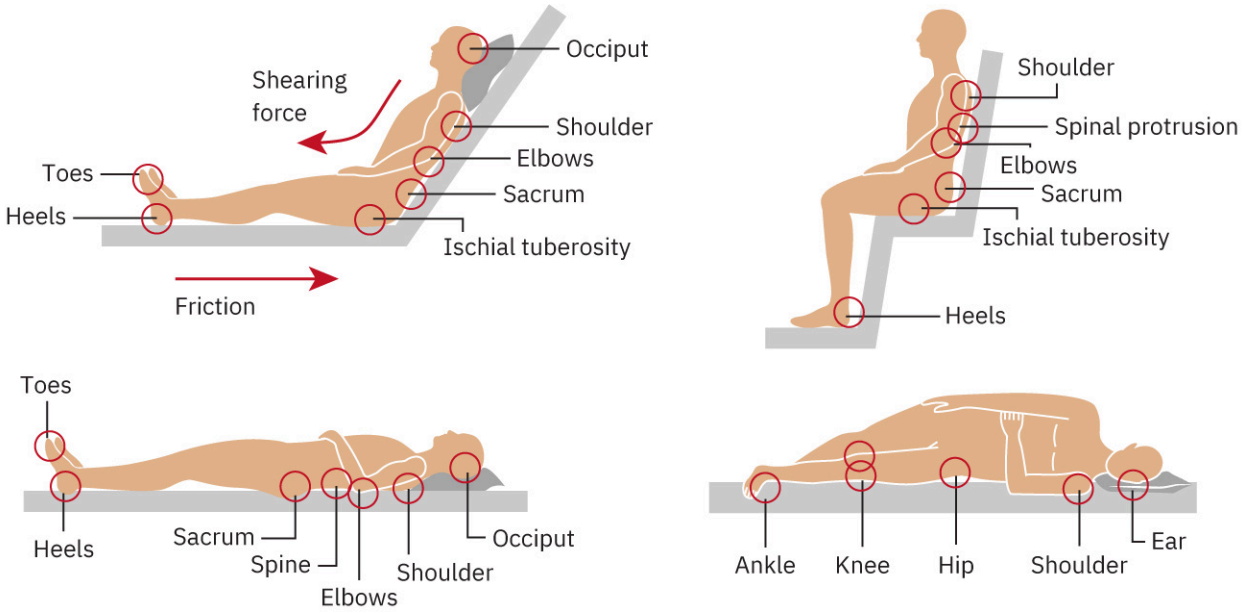

FIGURE 28.4 Pressure injuries commonly develop as people press bony prominences in their body against the surface upon which they are sitting or lying. As the patient changes positions, other areas become at risk. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Simplistically, a pressure injury occurs because of intense or prolonged pressure, or pressure in combination with shear, over a bony prominence. Thus, the causes may be multifactorial, involving both external and internal factors, but they all produce a common pathway that leads to ischemia and necrosis.

The tolerance of soft tissue for pressure and shear may also be affected by microclimate (e.g., skin temperature, moisture), nutrition, perfusion, comorbidities, and condition of the soft tissue. For example, moisture can cause ulcers and worsen existing ulcers via tissue breakdown and maceration.

LINK TO LEARNING

Visit the National Pressure Injury Advisory Panel site (https://openstax.org/r/77NPIAP) to access the most current and comprehensive guidelines for the prevention and treatment of pressure injuries.

Staging

The correct staging of a pressure injury has both clinical and legal implications. It is imperative to understand the pressure injury staging system when documenting the injury. Best practice tip: if the nurse is uncomfortable or unsure how to stage a pressure injury, it is best simply to describe the wound as it is assessed. Pressure injuries are the only wounds that are staged, and health-care workers must use the internationally accepted guidelines set forth by the National Pressure Injury Advisory Panel (NPIAP), the European Pressure Ulcer Advisory Panel (EPUAP), and the Pan Pacific Pressure Injury Alliance (PPPIA).

Stage 1

A Stage 1 pressure injury is considered intact skin with a localized area of nonblanchable erythema, or redness that does not fade when pressure is applied (Figure 28.5). In darkly pigmented skin, a Stage 1 pressure injury may appear as either a darker-pigmented or lighter-pigmented area over a bony prominence. Noticeable changes in sensation, temperature, or firmness may precede visual changes. Stage 1 changes do not include purple or maroon discoloration, as such findings may indicate deep tissue pressure injury.

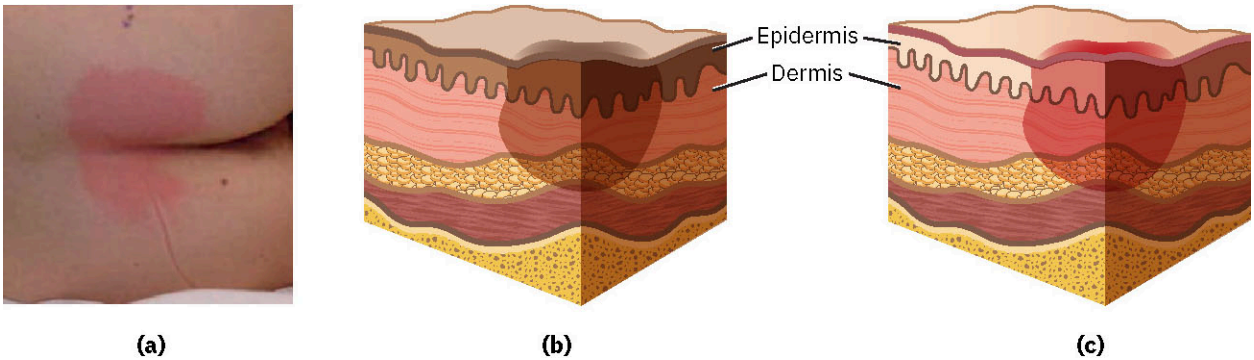

FIGURE 28.5 (a) A Stage 1 pressure injury appears as localized erythema. (b) In darkly pigmented skin, the area of concern is a different shade than the surrounding tissue on a bony prominence. (c) In a light-skinned individual, an area of pink and red erythema may be seen over a bony prominence. (credit a: Dweekat et al./*International Journal of Environmental Research and Public Health*, CC BY 4.0; credit b and c: attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Stage 2

A Stage 2 pressure injury is a partial-thickness loss of skin with exposed dermis (Figure 28.6). The wound bed is viable, moist, and pink or red; it may also present as an intact or ruptured, serum-filled blister. Adipose and deeper tissues are not visible. Granulation tissue, slough, and eschar (hard black dead tissue) are not present. This stage should not be used to describe moisture-associated skin damage (MASD), including incontinence-associated dermatitis (IAD), intertriginous dermatitis (ITD), medical adhesive-related skin injury (MARSI), or traumatic wounds (skin tears, burns, abrasions).

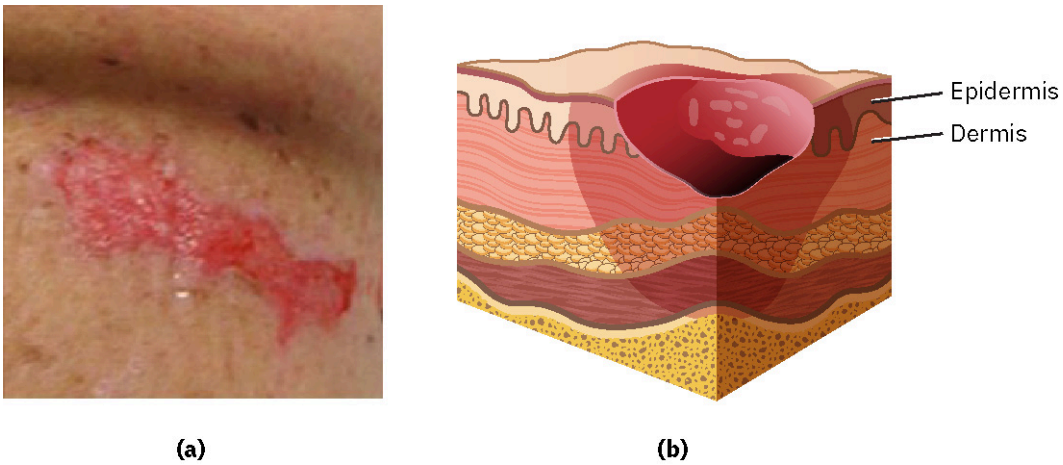

FIGURE 28.6 (a) A Stage 2 pressure injury is a partial-thickness loss of skin with exposed dermis but without visible underlying structures. (b) The diagram depicts a Stage 2 pressure injury. (credit a: Dweekat et al./*International Journal of Environmental Research and Public Health*, CC BY 4.0; credit b: attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Stage 3

A Stage 3 pressure injury is a full-thickness loss of skin; adipose tissue is visible in the ulcer, and granulation tissue and epibole are often present (Figure 28.7). Slough or eschar may also be visible. The depth of tissue damage varies by anatomical location; areas of significant adiposity can develop deep wounds. Undermining and tunneling may occur. Fascia, muscle, tendon, ligament, cartilage, and bone are not exposed. If slough or eschar obscures the extent of tissue loss, then such an injury is considered an unstageable pressure injury.

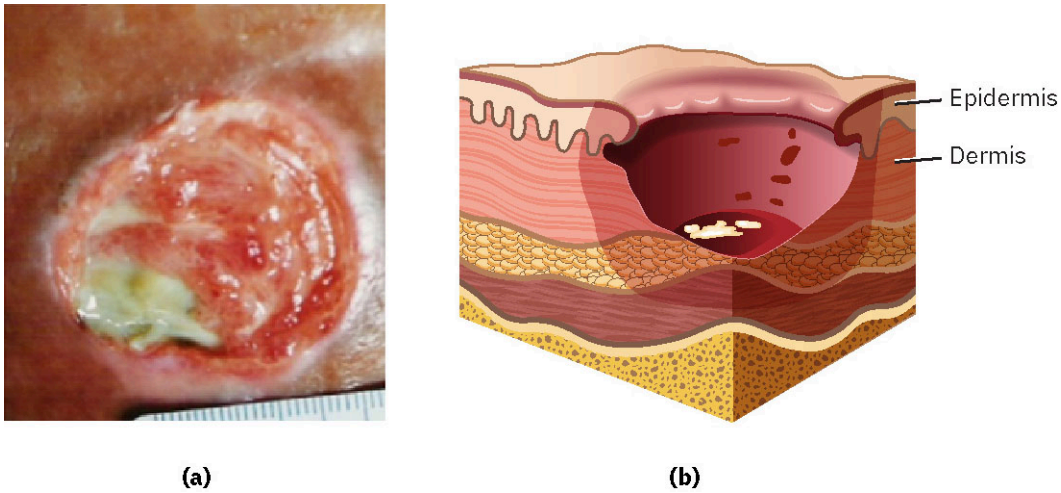

FIGURE 28.7 (a) This Stage 3 pressure injury has visible necrotic tissue and epibole. (b) The diagram shows a side view of the impact of underlying structures. (credit a: Dweekat et al./*International Journal of Environmental Research and Public Health*, CC BY 4.0; credit b: attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Stage 4

A Stage 4 pressure injury involves full-thickness skin and tissue loss with exposed or directly palpable fascia, muscle, tendon, ligament, cartilage, or bone in the ulcer (Figure 28.8). Slough or eschar may be visible. Epibole, undermining, or tunneling commonly occur. Depth varies by anatomical location.

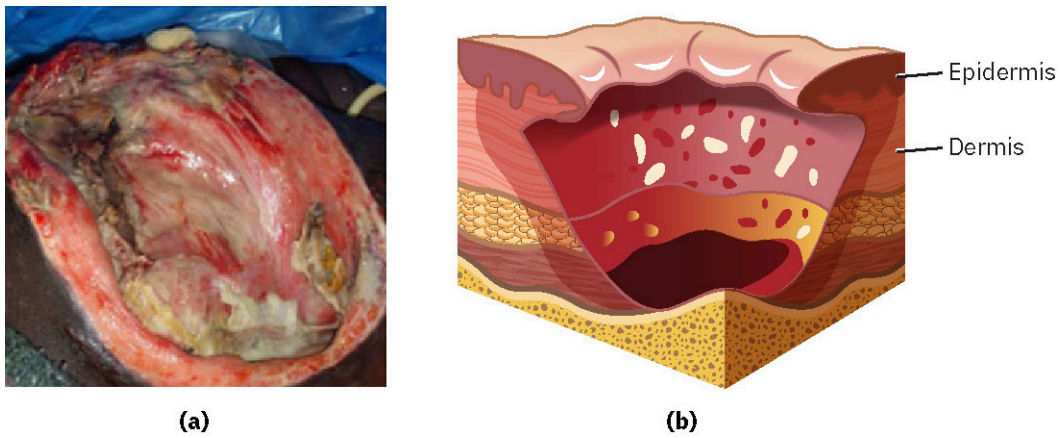

FIGURE 28.8 (a) This Stage 4 pressure injury extends to the bone, with necrotic tissue and epibole. (b) This side view shows the impact of a pressure injury on underlying structures. (credit a: Dweekat et al./*International Journal of Environmental Research and Public Health*, CC BY 4.0; credit b: attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Unstageable

An unstageable pressure injury is understood to have full-thickness skin and tissue loss, but the extent of tissue damage within the ulcer cannot be determined because it is obscured by necrotic tissue (Figure 28.9). If slough or eschar is removed, a Stage 3 or Stage 4 pressure injury will be revealed. Stable eschar on the heel or ischemic limb should not be softened or removed.

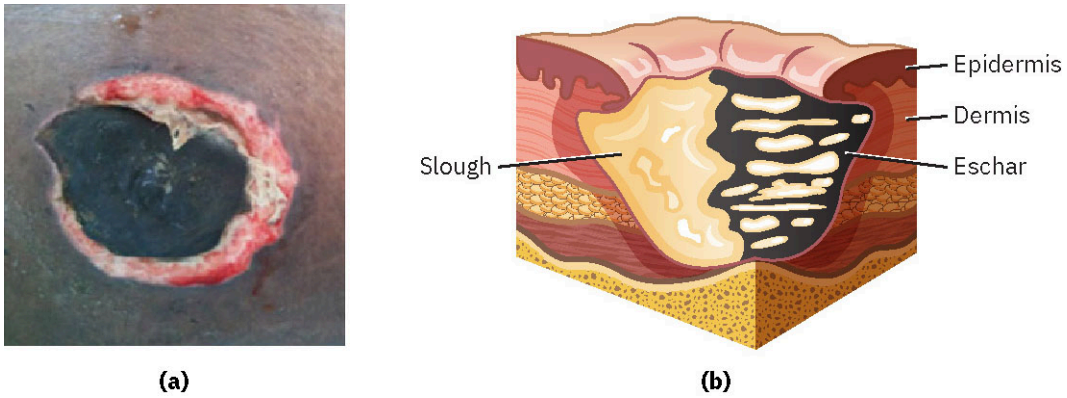

FIGURE 28.9 (a) The presence of both eschar and slough occludes the true depth of this pressure injury, making it unstageable. (b) This diagram shows the depth of damage that cannot be seen from the surface level. (credit a: modification of "Stages of pressure injuries (adapted from [1])" by ResearchGate, CC BY 4.0; credit b: attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Deep Tissue Injury

A deep tissue pressure injury (DTPI) is characterized by persistent, nonblanchable discoloration that is deep red, maroon, or purple (Figure 28.10). It may involve intact or nonintact skin with possible epidermal separation that reveals a dark wound bed or blood-filled blister. Discoloration may appear differently in darkly pigmented skin. This injury results from intense or prolonged pressure and shear forces at the bone-muscle interface. The wound may evolve to reveal the actual extent of tissue injury or resolve without tissue loss. If necrotic tissue, subcutaneous tissue, granulation tissue, fascia, muscle, or other underlying structures are visible, this indicates a full-thickness pressure injury that should be staged as Stage 3, Stage 4, or unstageable. Do not use DTPI to describe vascular, traumatic, neuropathic, or dermatologic conditions.

FIGURE 28.10 A deep tissue injury is seen on a patient's heel. Notice the deep-purple, blood-filled appearance. (credit: Dweekat et al./*International Journal of Environmental Research and Public Health*, CC BY 4.0)

Mucosal Membrane Pressure Injury

A mucosal membrane pressure injury occurs on mucous membranes with a history of a medical device used at the location of the injury. Due to the anatomy of the tissue, these ulcers cannot be staged. Examples of medical devices posing risk to mucosal membrane pressure injury development include nasogastric (NG) or orogastric (OG) tubes, oxygen cannulas or masks, endotracheal tubes, and urinary and fecal containment devices.

Medical Device-Related Pressure Injury

Medical device-related pressure injuries result from prolonged use of any device designed and applied for diagnostic or therapeutic purposes. The resultant pressure injury generally conforms to the pattern or shape of the device. The injury should be staged using the staging system. Examples of equipment and devices that may cause pressure injuries include but are not limited to:

- intravenous (IV) catheters, including hubs
- orthopedic devices
- SPO_2 probes
- wires or lines, such as from ECG, blood pressure cuff, or IV lines
- bed pans
- feeding tubes
- restraints
- ID bands
- braces and casts

Prevention

The best way to prevent pressure injuries is to alleviate pressure; it is also important to decrease the incidence of contributing factors such as friction, shear, and moisture. Often, this can be easier said than done. Typically, the unofficial rule of turning and repositioning every two hours is implemented for all patients at risk for skin breakdown; although this is a general rule, some patients require more frequent turns (or fewer manual turns if they are able to reposition themselves). Specialty beds, pillow usage, and foam dressing applications can help reduce pressure load on bony prominences, which in turn reduces the risk of pressure injuries. Protocols and interdisciplinary teamwork can help reduce and prevent pressure injuries from forming.

Some institutions have implemented a turn team to help implement a "quality turn"; this procedure ensures that the patient is off-loaded from at-risk bony prominences and not propped sideways.

REAL RN STORIES

Nurse: BC, RN
Years in Practice: Fifteen
Clinical Setting: Inpatient rehab
Geographic Location: Midwest

Pressure injury prevention is pretty straightforward: off-load the pressure areas to avoid breakdown, for example, by elevating heels off the bed with a pillow. But straightforward does not always mean easy. There are so many factors at play that can interfere with a plan for prevention such as medications, patient clinical status, pain, etc. One way to help with preventive measures is to engage the patient, which allows you to get a little creative.

Once I was caring for a sixty-seven-year-old female named Joyce. Joyce was in the unit for rehab after a heart attack. She was shaken up and very nervous about moving, which is a red flag for many things, including the risk of skin breakdown. I explained to her the importance of repositioning and movement for not only her skincare, but also for her overall health and recovery. She asked if she could have a "donut pillow," and I explained how they are actually one of the worst devices we could use, as they increase the pressure on the sacral area. We discussed why she was so anxious and devised a plan we called "move and groove." Every time she is in the chair, she would reposition every fifteen minutes by leaning to a side and singing a song chorus, and every hour or so she would stand with assistance and "wiggle it out." This empowered Joyce to take control, start to move more to prevent skin breakdown, and slowly gain confidence for the larger-scale rehab required.

Screening Tools

Common screening tools to help identify patients at risk for pressure injury development are the Braden Scale and the Norton scale.

- The **Braden Scale** assesses six risk factors—sensory perception, moisture, activity, mobility, nutrition, and friction and shear—on a scale from 1 (poor) to 4 (excellent). A total score of 12 or less represents high risk.
- The **Norton Scale** assesses five risk factors—physical condition, mental condition, activity, mobility, and incontinence—on a scale from 1 (poor) to 4 (excellent). A total score of 14 or less represents high risk, with a score of 10 or less indicating very high risk.

Although these tools are helpful, recent studies have demonstrated that a nurse's clinical judgment is just as, if not

more, effective at identifying individuals at risk for pressure injury development.

Risk Factors

Common risk factors for development of a pressure injury include advanced age, immobility, friction, shear, poor nutrition, excessive moisture and incontinence, altered level of consciousness, poor perfusion, certain skin infections, and comorbid conditions.

Patients at the highest risk are patients in an operating room and those in critical care settings due to hemodynamic instability and the increased use of medical and life-sustaining devices and vasoactive drugs. Other at-risk populations include older adults and immunocompromised individuals.

LINK TO LEARNING

Several tools are available to help prevent pressure ulcers in hospitals and assess risk (https://openstax.org/r/77pressureulcer) for skin breakdown and pressure injury development.

Treatment

Treatment of pressure injuries is similar to measures used for prevention. Keeping the patient off the wound is important to facilitate healing and remove the trigger. Treatment selection follows the same methodology described in the earlier discussion of prevention techniques: follow the principles of wound bed preparation and select the appropriate topical treatment. Nurses should conduct daily inspections of the wound for any signs of infection or decreased healing, collect data such as wound measurements (e.g., length, width, and depth), and administer any specialized wound treatment. When measuring length, use the patient's head as top and feet as bottom for a directional pathway. Measure width from the patient's right arm to left arm, and measure depth from the deepest part of the wound bed.

28.4 Debridement

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Define debridement
- Distinguish the various types of debridement
- Identify clinical implications and contraindications for debridement therapy

A wound cannot heal in the presence of necrotic or nonviable tissue. The first documented reference to the debridement of a wound for treatment dates to 25 CE, when a Roman author described the surgical removal of burned tissue to treat a wound (Heitzmann, Fuchs, & Schiefer, 2020). Debridement has become the cornerstone of the comprehensive management of patients with nonhealing wounds.

Necrotic tissue creates a physical barrier that prevents the cell migration that facilitates wound healing and acts as a medium for bacterial growth and infection. As tissue dies, it changes color, consistency, and adherence to the wound bed. It is critical for the nurse to both recognize and differentiate necrotic tissues from healing tissue. This module will focus on the importance of debridement in treating wounds by breaking down the various debridement methods and identifying the clinically appropriate debridement method for the wound.

Types of Debridement

Debridement is essential in treating acute and chronic wounds. Although nonviable tissue is devitalized, it may be burdened with senescent cells. A **senescent cell** is a nonfunctioning cell that has stopped dividing but has not died. The debridement process removes foreign debris, necrotic tissue, and bacteria from the wound's surface. Debridement stimulates a chronic wound's healing response by creating an acute wound and restarting the healing cascade.

Slough and eschar are two terms used to describe necrotic tissue in full-thickness wounds. The two are differentiated by appearance. The yellow or tan fibrin that typically lies on top of the wound bed is called **slough**. The texture of slough can be stringy, loose, or adherent. Slough should not be used interchangeably with purulence,

which is a sign of infection.

Necrotic tissue that is brown, black, or tan in appearance is known as eschar. Its texture can be soft or hard, depending on the location of the wound. It is essential to note stable intact eschar, like that found on the heels, should not be removed. Intact eschar is dry and adherent, with no signs of cracking or redness. In this instance, the eschar is a natural barrier to infection. If the eschar texture or appearance becomes unstable, then it should be debrided. Unstable eschar appears wet, boggy, loose, or draining, and it can be erythematous. Eschar is not the same as the word *scab*, and the two should not be used interchangeably. A scab is the formation of a crust by exudate or blood coagulation; in contrast, eschar is nonviable tissue.

Selecting a debridement method is based on the appearance of the wound bed, wound type, amount of necrotic tissue, patient condition, and care setting.

Autolytic Debridement

The most conservative type of debridement, called **autolytic debridement**, is the process of using the body's intrinsic debriding mechanism to remove nonviable tissue. This type of debridement involves a highly selective process that affects only necrotic tissue.

Autolytic debridement requires a moist environment, as this technique induces the softening—and, eventually, separation—of the necrotic tissues. Selecting the correct dressing will facilitate autolytic debridement. For example, if the necrotic tissue is dry, the clinician must "donate" moisture to facilitate debridement. Hydrogels or medicinal honey are common moisture-donating agents. If the tissue is already moist, hydrocolloid or foam dressings will work best. Dressing and product selection is discussed later in the section.

Autolytic debridement relies on a functioning immune system and is indicated for noninfected wounds through a process called autolysis: the destruction of cells by one's own enzymes. Compared with other forms of debridement, autolysis is a slow process and should be evaluated on a case-by-case basis (Heitzmann, Fuchs, & Schiefer, 2020). It is an adjunctive therapy for treatment of infected wounds in that it can be used with other debridement techniques. The overall effectiveness of autolytic debridement relies on the amount of devitalized tissue needed to be removed and the size of the wound. For example, if a wound measures 3 by 3 cm with thick, black eschar, autolytic debridement would take longer than taking a scalpel and removing the necrosis. In contrast, a 3 by 3 cm wound with yellow slough in the wound bed would likely benefit from autolytic debridement to further degrade and soften the necrotic tissue for removal.

Biological Debridement

The process of **biological debridement**, also known as maggot larval therapy (MT), uses sterile larvae of the *Lucilia sericata* species of the green bottle fly. The maggots are sterilely prepared and applied to the wound bed, either in a bio bag or free range, for one to four days. The success of maggot therapy is due to the secretion by the maggots of proteolytic enzymes, which break down the necrotic tissue. The maggots then ingest the liquified tissue. It is an effective mode of debridement, particularly appropriate in large, chronic wounds for which a painless method for removal of necrotic tissue is needed.

Enzymatic Debridement

The process of **enzymatic debridement**, also known as chemical debridement, is a selective method that uses an exogenous enzyme known as collagenase. Collagenase ointment, commercially known as SANTYL (from Smith+Nephew), actively debrides the necrotic tissue along the denatured collagen strand of the enzyme. Currently in the United States, SANTYL ointment is the only FDA-approved enzymatic debriding agent; it requires a prescription for use. Clinicians who are applying the ointment must follow the manufacturer's guidelines to ensure optimal therapeutic outcomes.

LINK TO LEARNING

Visit this site to learn more about the application of SANTYL Ointment (https://openstax.org/r/77SANTYLapp) to help with wound healing.

The application of SANTYL is critical to achieving therapeutic success for those cases in which it is used. Although

the application process itself is simple, if the wound is not prepared to receive the medication, the debridement will not be optimally efficacious, thus prolonging the wound-healing process.

Surgical Debridement

The process of **surgical debridement**, also known as sharp debridement, involves the use of a scalpel, forceps, curette, scissors, or other instruments to remove necrotic tissue from the wound base. The terms are used interchangeably and often reflect the site of care in which the therapy is used: the process can be done at the bedside, in an office setting or wound care center, or within an operating room. The location of service depends on the severity of the wound and the ability to control potential perioperative complications such as bleeding or pain. Surgical debridement should be performed by a skilled, trained, qualified provider who is licensed to provide surgical treatments. The main advantage of this type of debridement is the speed of wound cleaning and visualization. Disadvantages of this technique include adverse events from the procedure itself, such as blood loss or infection.

Surgical debridement is indicated for removing thick, adherent, or large amounts of nonviable tissue. This method can be used as a form of adjunctive therapy, in conjunction with other debridement modalities. Often the provider will add an antibiotic solution to be used as irrigation to avoid infection during wound care.

Mechanical Debridement

The process of **mechanical debridement** is a nonselective type of debridement in which physical force is applied to remove necrotic tissue. The procedure is nonselective in that it removes both devitalized tissue debris and viable tissue. Examples of mechanical debridement include wet-to-dry gauze dressings and wound irrigation. Mechanical debridement is indicated for acute and chronic wounds with moderate to large amounts of necrotic tissue, regardless of the presence of an active infection.

Wet-to-dry gauze dressings are well known. However, in recent years they have fallen out of favor as a clinical practice due to the frequency of dressing changes, associated pain, and nonselectivity. Wet-to-dry gauze dressings can be challenging and costly to apply and may cause maceration to the surrounding tissues. Moreover, wet-to-dry gauze dressings may release airborne organisms and cause cross-contamination.

Wound irrigation removes necrotic debris using pressurized fluids. Hydrotherapy is a form of wound irrigation, using specialized tubs with jets. Another example includes pulse lavage or high-pressure irrigation, which involves delivering between 8 to 12 pounds per square inch (psi) of fluid to the wound bed. The process may involve using a 35-ml syringe with 19-gauge angiocatheter to deliver fluid, such as saline, to the wound. The allotted pressure permits enough force to separate the necrotic tissue from the wound bed but not so much as to push bacteria into the wound bed. Clinicians performing this bedside procedure should wear personal protective equipment (PPE) to protect against potential bacterial contamination and the potential aerosolization of bacteria.

Clinical Implications

The debridement method selected for a wound is based on the wound's presentation, the provider's evaluation of the current treatment plan, and the patient's comprehensive history and physical. It is critical to remember the whole patient, not just "the hole in the patient."

For a bedside nurse, the most important role will be to support the patient by explaining the procedure, and anticipated outcomes. Understanding how to apply the prescribed therapy—whether collagenase ointment, hydrogel, or biobag—is critical for the nurse. Always refer to the institution's guidelines as well as policy and procedure for debridement therapy. The nurse's role can also include monitoring and evaluating the wound post-treatment, assessing and treating pain, providing emotional support, and facilitating dressing changes. For surgical debridement, the bedside nurse will support the provider performing the debridement by dressing the wound, assessing and evaluating the patient's tolerance for the therapy, and providing education to the patient.

Contraindications

Therapy contraindications must be considered, even in wound care and in the debridement processes. As a critical rule, it cannot be overstated that debridement is inappropriate if there is dry, stable eschar present, such as in unstageable pressure injuries with no overt signs of infection. In these instances, the dry eschar acts as a natural covering. Precautions should be taken for patients with poor perfusions, such as patients with arterial disease.

Beyond ensuring blood flow and stable eschar presentation, contraindications are specific to the specific debridement technique.

Contraindications for surgical debridement include accounting for the patient's overall condition and risk stratification. Examples of contraindications for surgical debridement include patients who are hemodynamically unstable, those with bleeding disorders, and those currently undergoing anticoagulation therapy. Surgical debridement is also contraindicated in patients with an intact eschar and no clinical evidence of an underlying infection. Depending on choice of modality of the mechanical debridement, contraindications include analyzing the presence of granulation tissue and the ratio of granulation tissue to devitalized tissue; providers must also consider the patient's level of perfusion and their own ability to control the patient's pain.

When using autolytic debridement, the clinician must consider the overall goal and presentation of the patient. Autolytic debridement takes several days to work. If the wound requires an immediate and significant decrease in necrotic tissue, a different modality should be considered. If autolytic debridement is selected and improvement is not observed within one or two days, a different debridement method should be considered for the patient. Contraindications to using biological debridement include pyoderma gangrenosum wounds in patients with immunosuppression therapy and abdominal wounds adjacent to the intraperitoneal cavity. Enzymatic debridement contraindications include use on wounds with a known infection and concurrent use with silver products. The therapy is also contraindicated if a patient is allergic to any of the ingredients within the enzymatic debriding agent.

28.5 Wound Care and Dressing

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Differentiate the etiologies for common lower leg ulcers
- Identify topical steps for wound bed preparation
- Compare the different types of topical dressing
- Select the appropriate dressings for the different wound etiologies

This module will introduce the reader to common lower leg ulcers and explain how the treatment of each differs. Then, we will explore the numerous treatment modalities for addressing and treating wounds of varying presentations.

Types of Wounds and Treatment Selection

Recall that wounds can be differentiated by time duration and tissue involvement. Chronic wounds are wounds that have failed to heal or progress toward healing within thirty days. Partial-thickness wounds involve the first two layers of skin and may require minimal intervention and topical therapy, whereas a full-thickness wound may require several topical wound care tools. Whether acute or chronic, partial-thickness or full-thickness, managing a wound with the appropriate dressing selection is key. When determining what is best for the wound and the patient, examine the wound etiology, current presentation, and goal for treatment.

Common Lower Leg Ulcer

Common chronic ulcers of the lower extremities may appear similar but require vastly different treatment approaches, as demonstrated in Table 28.4. To determine the appropriate treatment, it is important to understand the origin and pathophysiology of the wound. For example, venous leg ulcers (VLU) most often occur on the medial lower leg, are irregularly shaped, and present with extensive drainage (Figure 12.34). Skin can appear scaly, brown, red, or edematous. Treatment focuses on compression and wound management. VLUs involve changes to tissue as a complication of chronic venous insufficiency. A VLU can develop after a minor injury if the patient's lower extremity circulation is compromised.

Arterial ulcers, although also caused by impaired perfusion, commonly occur on the ankle or toes of the patient (see Figure 12.35). These ulcers can be very painful, and the pain can increase at night. Wounds appear punched out or circular and are typically dry. Arterial wound treatment focuses on moist wound healing. Due to the compromised circulation, compression is contraindicated unless the appropriate studies, such as an ankle-brachial index (ABI), have been performed.

LINK TO LEARNING

This video shows how to perform the ABI (https://openstax.org/r/77ABIhowto) typically conducted by a wound specialist or health-care provider. It is important to understand if the study has been performed and if perfusion is adequate before compressing any wound for a patient with a history of compromised circulation.

Diabetic foot ulcers (DFUs) are often located on the plantar, or bottom portion, of the foot and are caused by angiopathy and neuropathy (Figure 28.11). DFUs typically have a round, punched-out appearance with a callus surrounding the wound. DFUs are managed with off-loading devices and debridement of the devitalized tissue.

FIGURE 28.11 Diabetic foot ulcers have a punched-out appearance and have a thick callous surrounding the wound. (credit: modification of "Diabetic Foot Ulcer" by StatPearls/National Center for Biotechnology Information, CC BY 4.0)

Type of Wound	Cause	Location	Wound and Periwound Appearance	Common Treatment
Arterial wound	Compromised perfusion	Ankle, toes	Punched-out Dry Eschar	Moist wound healing
Venous leg ulcer (VLU)	Venous insufficiency	From knee to ankle; medial calf area "Gator area"	Irregularly shaped Moderate to heavy exudate Maceration Edema Red or brown staining	Exudate management Compression
Diabetic Foot Ulcer (DFU)	Neuropathy Angiopathy Glycemic control	Typically, plantar aspect of foot	Punched out/circular Calloused edges	Off-loading Glycemic control Debridement

TABLE 28.4 Common Lower Leg Ulcers

Wound Bed Preparation

Wound healing requires comprehensive and holistic management. The goal of wound bed preparation is to create a

local environment that supports healing. As discussed, wound bed preparation begins with assessing the wound bed and aligning with the TIME principles:

- T = Tissue (devitalized or necrotic)
- I = Infection/Inflammation
- M = Moisture balance
- E = Edges of wound/Epithelialization

Prepping the wound bed begins with cleansing and selection of topical therapies to facilitate a healing environment.

Cleansing Agents

Wound bed preparation begins with cleansing the wound. The goal in cleaning the wound is to remove as much devitalized tissue, bacterial burden, and exudate as possible without damaging proliferative cells. Appropriate noncytotoxic solutions include saline, commercial wound cleansers, and potable tap water. Cleansing of a dirty or infected wound requires 4 to 15 psi irrigating force and may involve antiseptics. Antiseptic solutions are generally preferred if the goal is to kill bacteria in an infected wound or one with abundant necrosis. Common examples of cytotoxic antiseptic solutions include Dakin's solution (sodium hypochlorite) and acetic acid, both of which provide temporary cleansing until the wound bed is clean.

Topical Dressing Materials

Dozens of wound dressings are commercially available. It is important to select the right dressing for a given wound type at a given time in the treatment process. Understanding the clinical implications and limitations of a primary or secondary dressing will allow the nurse to make the appropriate selection or offer an alternative if the wound changes and requires additional topical support. For example, primary dressings, such as gauze pads and nonadherent dressings, are like the first layer of protection directly on a wound, while secondary dressings, like adhesive bandages and foam dressings, provide extra cushioning or support over the primary dressing to aid in healing. Table 28.5 summarizes the common topical dressings used.

Type of Dressing	Use	Image
Foam (adhesive)	Exudate management	 (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)
Foam (nonadhesive)	Exudate management	 (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

TABLE 28.5 Common Topical Dressings

Foam Dressings

Foam dressings are very versatile dressings that can be used for almost any wound with exudate. Foam dressings are available in a variety of shapes and sizes, with or without borders; they may be adhesive or nonadhesive and may or may not have antimicrobial agents. Foam dressings can be used as either primary or secondary dressings. They are appropriate for low- to moderate-exudating wounds, as well as heavily draining wounds. Foam dressings help maintain a moist wound environment through absorption capacity while allowing enough moisture to remain in the wound bed to facilitate healing. The frequency of dressing change is dependent on the amount of exudate and the absorptive capacity of the dressing. Manufacturer guidelines commonly indicate the absorptive capacity of the dressing and the recommended timetable for changing the dressing.

Hydrocolloid

Hydrocolloid dressings are occlusive, wafer-like dressings made of gelatin materials. They are self-adhesive. Some hydrocolloids have a thin border around the dressing. Because the dressing is occlusive, water vapor cannot escape, and the dressing must absorb the moisture secreted by the skin together with the wound exudate. The dressing interacts with wound exudate, which allows for atraumatic removal. Hydrocolloids are appropriate for low-exudating, shallow wounds; because they are occlusive dressings, they are contraindicated in infected wounds. Wear time varies from three to seven days depending on the volume of exudate.

Alginates and Hydrofibers

Alginate dressings are often referred to as calcium alginate or seaweed dressings. These dressings are nonwoven and composed of polysaccharide fibers derived from seaweed. The dressings are available in ropes or sheets. Some alginates are impregnated with antimicrobial agents, such as silver. Alginate dressings absorb a moderate amount of exudate; some form a gel as they absorb the exudate, which allows for atraumatic removal. The frequency of dressing changes depends on the exudate amount but on average ranges from daily to every three days. Typically, alginates are reserved for moderately to highly draining wounds; they are not appropriate as the primary dressing choice for wounds with exposed tendons or bone.

Hydrofiber dressings are similar to alginates; however, hydrofibers are composed of sodium carboxymethylcellulose, making them highly absorptive. Similar to alginates, when the hydrofiber absorbs exudate, it forms a gel. Hydrofibers are available in ribbon or sheet form and can be plain or antimicrobial in design. Hydrofibers are also nonadherent, which means that a secondary dressing or cover dressing is always required. The frequency of dressing changes depends on the exudate amount but on average ranges from daily to every three days. Hydrofibers are indicated for moderately to heavily draining wounds and contraindicated in dry wounds, wounds with eschar, and third-degree burns.

Hydrogels

Hydrogels are designed to hydrate wounds through donation of water. There are two types of hydrogels: amorphous and solid gel dressings. Amorphous hydrogels are a combination of water and polymers, which can be applied

directly to the wound bed or to another dressing such as gauze. Amorphous hydrogels are available as viscous liquids and impregnated dressings, such as gauze, ropes, and strips. This type of hydrogel is typically used in wounds with depth or tunnels and for wounds with minimal exudate. Solid gel sheets are available with and without borders. They can absorb varying amounts of exudate and offer a cooling effect. Hydrogel dressings are ideal for any wound with minimal to no exudate. The frequency of dressing changes depends on the wound and dressing selected but on average changes occur about every three days.

Contact Layers

Contact layers are dressings placed in direct contact with the wound bed to help maintain a moist and protective environment. Contact layers are porous, allowing exudate to pass through for absorption by a secondary dressing while protecting the wound base from trauma. Typically, a contact layer is a single layer of nonadherent dressing material impregnated with petroleum derivatives; it may also be silicone-based. Contact layers are most appropriate for surface wounds, particularly extremity wounds. If utilized in a wound with depth, contact layers are appropriate for clean wounds (that is, wounds free of necrotic tissue). Contact layers are inappropriate for wounds with viscous exudate, wounds with undermining or tunneling, or third-degree burns. These dressings can remain in the wound for as long as one week, depending on the wound and manufacturer guidelines.

Transparent Film

Transparent film dressings are thin sheets of plastic or acrylic with a layer of adhesive on one side. Transparent films are widely used as primary and secondary dressings and most commonly to protect IV sites. A common brand name of transparent film is Tegaderm by 3M. The technology involved with transparent film allows for water vapor to transpire and evaporate out of the dressing, which in terms of wound care promotes autolytic debridement—a process known as moisture vapor transmission. Despite moisture vapor transmission, transparent films have no absorptive capacity. They are used for shallow, dry, or minimal exudate wounds or as cover dressings. Wear time varies and is dependent on wound depth, exudate level, location, and indication. When used as a primary dressing, the typical wear time is three to seven days.

Gauze

Gauze is a commonly used dressing that can be used for wound cleansing and as a wick, wound filler, or cover dressing. Gauze is available in a variety of forms, including rolls, sheets, or strips; it is also available in antimicrobial forms. Nonwoven gauze is usually preferred as a dressing, as woven gauze contains loose strands. All gauze can be cut to fit the wound bed and “fluffed” to help fill the wound depth. Overpacking a wound with gauze may interfere with perfusion and compromise granulation tissue development, so it is important to abide by the adage “fluff not stuff” when using gauze to pack a wound. Gauze is more appropriate as a secondary dressing; as it dries fairly quickly, it should be moistened prior to placement in contact with the wound bed.

Antimicrobial Wound Dressings

Management and treatment of infected and critically colonized wounds is a common issue facing clinicians. Ideal antimicrobial dressings provide sustained antimicrobial activity and a moist healing environment; they absorb and retain bacteria and are comfortable, conformable, and atraumatic upon removal. We will discuss some of the more commonly seen antimicrobial dressings. Each provides a unique but familiar mechanism of action to address wound care needs.

Cadexomer Iodine

Iodine has a broad spectrum of activity and works in various ways; however, not all preparations are suitable for wound care due to the cytotoxicity relative to overall concentration. Cadexomer iodine describes the mechanism of delivery rather than the iodine itself. Cadexomer iodine provides a sustained, steady release of iodine that is toxic to the bacteria but not the healthy cells. The dressing progresses from brown to cream colored as the iodine is released and should be changed every seventy-two hours depending on the amount of drainage. Contraindications for cadexomer iodine include known allergies to iodine, dyes, or shellfish. The cadexomer iodine also requires moisture to release the iodine; dry wounds may not activate the dressing.

Honey

Honey has been used on open wounds for centuries. Medical grade honey has unique properties that provide antimicrobial effects, including a highly acidic environment that is toxic to bacteria. Medical honey is also hygroscopic, meaning it draws moisture out of the environment, thus dehydrating the bacteria. Honey dressings are

available in alginate, hydrocolloid, and paste form. The dressing can be left in place for as long as seven days. Contraindications include an allergy to honey.

Silver

Silver has proven antimicrobial activity and has been used for centuries to treat wounds. Silver dressings work either by directly donating silver to the wound surface or destroying bacteria within the carrier or dressing. Silver is available in amorphous hydrogels, alginates, foams, silicones, ointments, irrigation solutions, negative pressure foams, and contact layers. Another modality, silver nitrate, is a chemical cauterization agent that can help achieve hemostasis on a variety of wounds, including epibole and hypergranulation tissue. Nurses can apply silver nitrate after the health-care provider has assessed the wound and placed an order.

CLINICAL SAFETY AND PROCEDURES (QSEN)

Patient-Centered Care: Dressing Changes

Always review and follow your institution's policy and procedure regarding dressing changes.

Procedure for changing a basic wound dressing without a drain:

1. Gather supplies: Supplies may include nonsterile or sterile gloves per policy, wound cleansing solution or sterile saline, sterile 2″ × 2″ gauze for wound cleansing, and advanced wound dressing as ordered.
    - Use the smallest size of dressing for the wound.
    - Take only the dressing supplies needed for the dressing change to the bedside to minimize waste.
2. Perform safety steps:
    - Perform hand hygiene.
    - Check the room for transmission-based precautions.
    - Confirm patient ID using two patient identifiers (e.g., name and date of birth).
    - Explain the process to the patient and ask if they have any questions.
    - Be organized and systematic.
    - Use appropriate listening and questioning skills.
    - Listen and attend to patient cues.
    - Ensure the patient's privacy and dignity.
    - Assess ABCs.
3. Prepare the environment.
    - Ensure proper body mechanics and create a comfortable position for the patient.
    - Adjust the height of the bed and turn on the lights for good visibility to assess the wound.
    - Premedicate, if indicated, to ensure the patient's comfort before and during the procedure.
4. Perform hand hygiene.
5. Arrange supplies at bedside.
    - Place a clean, dry barrier on the bedside table.
    - Create a sterile field if indicated by agency policy.
6. Pour sterile normal saline into opened sterile gauze packaging to moisten the gauze.
    - A normal saline container must be used for only one patient and dated and discarded within at least twenty-four hours of being opened.
    - Commercial wound cleanser may also be used, if indicated or ordered.
7. Expose the dressing.
8. Perform hand hygiene and apply nonsterile gloves.
9. Remove the outer dressing.
10. Remove the inner dressing if necessary.
11. Remove gloves, perform hand hygiene, and put on new gloves.
12. Assess the wound.
13. Drape the patient with a water-resistant underpad, if indicated, to protect the patient's clothing and linen.
14. Apply gloves and other PPE as indicated, such as goggles, face shield, or mask.
15. Cleanse the wound based on agency policy, using moistened gauze, commercial cleanser, or sterile irrigant.

- When using moistened gauze, use one moistened 2″ × 2″ sterile gauze per stroke. Strokes should move from a clean area to a dirty area and from top to bottom.
- Note: A suture line is considered the "least contaminated" area and should be cleansed first.

16. Apply new dressing, using nontouch technique so that the dressing touching the wound remains sterile/clean.
17. Apply outer dressing if required. Secure the dressing with tape or transparent film as needed.
18. Remove gloves and perform hand hygiene.
19. Assist the patient to a comfortable position; ask if they have any questions.
20. Ensure safety measures when leaving the room:
    - Bed is at the lowest position and locked.
    - Call light is within reach.
    - Side rails are up and secured.
    - Side table is within reach.
21. Perform hand hygiene.
22. Document the procedure and assessment findings.
23. Compare the wound assessment to previous documentation and analyze healing progress. Report any concerns according to institution's policy.

28.6 Medical Management

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Explain the clinical implications of hyperbaric oxygen therapy
- Describe other common treatment modalities for wound care
- Examine the interdisciplinary team members and their roles in the treatment of the wound care patient

Sometimes wounds require specialized therapy or medical interventions. This module explores several treatment options used to manage and treat complex wounds. For example, **hyperbaric oxygen therapy (HBOT)** is known for treating deep sea divers affected by rapid changes in pressure around them. HBOT is also used to treat a variety of health problems, including wounds. As with all aspects of health and patient care, teamwork is essential for specialized interventions. From the bedside nurse to the occupational therapist, every team member plays a role in helping the patient achieve their wound care goal.

Hyperbaric Oxygen Therapy

HBOT involves breathing pure oxygen in a pressurized environment, known as a chamber. This type of therapy helps to heal wounds. There are two types of hyperbaric chambers: monoplace and multiplace. A monoplace chamber accommodates one person. It is a long plastic tube that resembles an MRI machine. The patient lies on a table within the chamber and breathes oxygen while the pressure slowly increases. A multiplace chamber (or room) can accommodate two or more people. Patients breathe oxygen through a mask or hood. HBOT prevents reperfusion injury and encourages formation of new collagen. Therapy typically lasts two hours. Examples of wound types treated by HBOT include radiation injuries, infections, burns, crush injuries, necrotizing fasciitis, decompression sickness, and gas gangrene. The most significant contraindication to HBOT is untreated pneumothorax. Other contraindications for HBOT include patient claustrophobia, COPD, history of seizures, febrile patients, or the presence of a pacemaker or implantable device.

Nursing Considerations

Hyperbaric oxygen therapy nurses are specially trained to assist with HBOT and supervise patients undergoing this type of therapy. The most common complication after HBOT is trauma to the middle ear; therefore, HBOT should not be used by those with recent ear injury or ear surgery (Sibbald et al., 2021). The primary safety concern during the administration of HBOT is that the use of concentrated oxygen is a fire hazard. Thus, fire prevention is critical. Use of scented perfumes, creams, or lotions is not advised while in the chamber. Examples of other prohibited items include all flammable materials, oils, silk, wool, synthetic textiles, matches, lighters, battery operated materials, electronic hearing aids, metal framed eyeglasses, contact lenses, jewelry, watches, dentures, and other devices. Patients are provided with 100 percent cotton gowns to wear rather than street clothes.

Other Common Wound Treatment Options

Some wounds require additional support to foster healing and or closure. Here we will discuss some of the common treatment options beyond topical.

Negative Pressure Wound Therapy

Vacuum assisted wound closure, or **negative pressure wound therapy (NPWT)**, is a therapeutic technique that applies negative pressure to the wound bed to manage exudate and facilitate healing. The negative pressure applied to the wound bed allows for cells to quickly stretch to the point of replication, facilitating a healing environment for the stalled or difficult-to-heal wound. There are two types of NPWT: traditional therapy and single-use therapy (or portable therapy). Traditional NPWT includes open cell foam filler, cover dressing, fluid collection system, tubing, and a suction pump. Single-use therapy is typically used for incision management or shallow, difficult-to-heal wounds and may include a dressing attached to a pump that can be disposed of when therapy is complete. NPWT pressure ranges from 75 mmHg to 145 mmHg, depending on the type of wound, exudate level, and goal of therapy. Dressing changes occur every forty-eight to seventy-two hours, depending on the exudate level and dressing stability. Single-use devices may be worn as long as seven days. Contraindications to NPWT include untreated osteomyelitis, active sepsis, coagulopathies, allergies to NPWT components, and unexplored fistulas.

LINK TO LEARNING

This video describes how to use negative pressure wound therapy (https://openstax.org/r/77negpressthera) by applying a wound vac to a wound bed.

Drains

Surgical drains are tubes placed near surgical incisions in the postoperative patient to remove exudate, blood, or other fluid to prevent fluid accumulation in the body. The type of drain used is based on patient need, type of surgery, and amount of drainage. Common drains include the Jackson-Pratt, a soft, pliable tube and compressible bulb that creates negative pressure, and the Penrose, a flat, ribbonlike drain with gauze applied at the end to absorb drainage. The nurse's role in managing drains includes assessing the insertion site, securement, drainage amount, and patency.

Interdisciplinary Collaboration

Wound care is a common concern across multiple disciplines, which is why interdisciplinary collaboration is critical to patient care. The team approach incorporates all facets of wound management into a cohesive treatment plan. Some of the team members are surgeons, nurses, podiatrists, physical therapists, dietitians, and accompanying specialists.

Wound Care Nurses Certifications

Wound care nurses assess, treat, and create care plans for patients with complex wounds. They also provide wound prevention recommendations, strategies, and interventions for at-risk patients. There are several avenues to obtaining a wound care certification, and not all programs are created equal. Table 28.6 explains the various certifications a nurse can pursue.

Nursing Credentials	Certification Board	Description
Certified Wound Ostomy Continence Nurse (CWOCN) Certified Wound Ostomy Nurse (CWON) Certified Wound Care Nurse (CWCN) Certified Continence Care Nurse (CCCN) Certified Ostomy Care Nurse (COCN) Certified Foot Care Nurse (CFCN)	Wound Ostomy Continence Nursing Certification Board (WOCNCB)	Only accredited certification by the Accreditation Board of Specialty Nursing Includes Advanced Practice designations RN and BSN minimum requirements Only designated for RNs
Certified Wound Specialist (CWS)	American Board of Wound Management (ABWM)	Requires BSN or higher Any licensed health-care, sales, or marketing professional can obtain
Wound Care Certified (WCC)	National Alliance of Wound Care and Ostomy (NAWCO)	Any licensed professional can obtain

TABLE 28.6 Wound Care Certifications

Physical Therapists and Occupational Therapists

Patients who are weak or struggling to ambulate may require the assistance of a physical therapist (PT). Physical therapists can create an exercise plan that strengthens the patient to help facilitate healing. Some physical therapists focus on wound care and are often the providers performing and making recommendations for care.

Occupational therapists (OT) also have a role within the interdisciplinary team. Prevention of wounds is critical, as discussed, and OTs are experts in the repositioning, placement, and use of equipment while analyzing patient activity. OTs can teach patients how to manage wounds while safely engaging in daily tasks. OTs also have special training to incorporate techniques to assist with the management of lymphedema.

Dieticians

Nutrition, though sometimes overlooked, is critical to successful wound management. For example, macronutrient and micronutrients are essential for proliferation. A dietician can create appropriate meal plans according to a patient's dietary and nutritional needs for healing.

Pain Assessment and Management in Wound Care

A complete pain assessment enables the patient and care team to develop an effective pain regimen. Pain is commonly overlooked when assessing a wound. Dressing changes, debridement, infection, turning, and repositioning are some of the factors that can cause wound-related pain. Pain treatment varies according to the specific wound etiology and associated factors. For example, if pain results from dressing changes, it may be necessary to administer pain medication prior to changing the dressing or dressing type.

28.7 Nursing Management and Care Plan

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Identify components of a comprehensive wound assessment
- Examine best practices with wound documentation
- Discuss legal implications of wound care documentation

Comprehensive and concise wound care documentation is as critical as the assessment and care provided to the

patient. Wound care documentation fosters interdisciplinary communication and protects the nurse and patient from legal consequences. This module will explore the components of the comprehensive wound assessment and examines best practices and legal implications for ensuring wound care documentation is complete.

Wound Assessment

A **comprehensive wound assessment** is the written record and picture of the wound's current status and progress. The wound assessment is the culmination of observation, data collection, and evaluation at each encounter. The initial assessment serves as the baseline for future comparisons; because a wound can change rapidly, it is important to assess for changes in the wound and surrounding skin to signify a need for treatment modifications. Tenderness to touch and the amount of pain the patient reports are essential assessment components. Wound pain is one of the secondary signs of infection, and it is important to differentiate between constant pain and episodic pain, such as that felt only during a dressing change.

CULTURAL CONTEXT

Importance of Skin Color

When caring for a patient, the nurse must be "color aware." Being color aware acknowledges the relevance of skin color to health. Most skin care guides are based off light skin tones and do not reflect the skins tones of all patients. For example, when assessing an at-risk bony prominence of a darker-skinned individual for a Stage 1 pressure injury, the increased amount of melanin in the skin may mask the blanch response. Instead, after applying light pressure, look for an area that is darker than the surrounding skin or skin that is taut, shiny, or indurated (hardened).

Exudate description and language is important to understand and incorporate. Nurses should use multiple senses when assessing a wound. Visual inspection, palpation, and odor are components of the assessment to guide documentation and intervention. Table 28.7 and Table 28.8 list types of wound exudate and the language to describe the amount of exudate, respectively.

Exudate Type	Appearance
Serous	Clear, amber, thin, watery
Serosanguineous	Clear, pink, "blood tinged," watery
Sanguineous	Bloody, reddish, thin, watery
Purulent	Opaque, thick, yellow, green
Seropurulent	Yellow, tan, cloudy, thick; not to be confused with slough
Fibrinous	Cloudy, thin with strands of fibrin
Hemorrhagic	Red, thick

TABLE 28.7 Wound Exudate Types and Their Appearances

Term	Quantity
None	Wound is dry.
Scant	Tissue is moist.

TABLE 28.8 Terms Used to Describe Exudate Quantity for Wound Documentation

Term	Quantity
Small	Wound bed is wet, with moisture evenly distributed. Drainage encompasses up to 25% of dressing
Moderate	Wound bed is saturated. Drainage encompasses 25–75% of dressing
Large	Wound bed is bathed in fluid. Drainage is freely expressed and involves more than 75% of dressing

TABLE 28.8 Terms Used to Describe Exudate Quantity for Wound Documentation

When assessing the odor of a wound, it is important to wait until after the dressing is discarded and the wound is cleaned. Due to microbes and the wound's environment under a dressing, odor there is not uncommon; however, the persistence of foul odor after the cleansing of a wound can indicate infection. Descriptors of wound odor may include terms like strong, foul, pungent, fecal, and musty.

Patient History

A comprehensive patient assessment includes both visually inspecting the wound and the whole patient. A wound assessment encompasses not only the wound but the entire patient profile. When assessing wound components, interviewing the patient, and reviewing the patient's chart, the nurse should assess for wound location, etiology, length of duration, treatments completed or previously attempted, and patient compliance. An assessment includes reviewing accompanying laboratory data. Typical laboratory data to consider and assess for wound care patients include complete blood count (CBC), serum albumin, prealbumin, and blood glucose. A CBC is important to monitor for anemia and infections. Serum albumin and prealbumin are plasma proteins produced by the liver. Low serum albumin counts correlate with increased risk for pressure injury. However, prealbumin is more reliable than albumin in determining the effect of nutritional interventions. Blood glucose is monitored to indicate healing capability. Increased glucose levels are associated with an increased risk of impaired wound healing.

Wound Measurement

Measurement is a critical part of wound care assessment, providing valuable information on the progression or nonprogression of wounds. Consistency and accuracy when measuring a wound are important for meaningful evaluation that can determine the need for treatment modification. All medical institutions should develop and disseminate a protocol for wound measurement, including frequency of assessment, to ensure accuracy. A decrease in wound size is usually an indication of healing.

Wounds should not be compared to objects such as a coin. Rather, wound size should be measured and recorded in centimeters with a measuring device such as a paper or plastic ruler. The most used measurements are length, width, and depth of a wound, as determined and recorded using the linear method, also referred to as the clock method (Figure 28.12). The linear method, with a ruler, is inexpensive, readily available, and causes little to no patient discomfort. Note that this assessment technique does not include the periwound, only the wound base. Imagine the body as the face of an imaginary clock: the head is 12:00 and the feet are 6:00. Length is measured by placing the ruler at the point of maximum length, or from 12:00 to 6:00. Width is measured by placing the ruler at the point of maximum width, or from 3:00 to 9:00. Depth can be assessed by placing a clean cotton tipped applicator into the deepest part of the wound, marking it at the level of the wound edge, and measuring upon removal—similar to the process of assessing a tunnel. Although many wounds are irregularly shaped, the clock method allows for clear communication among assessing clinicians (Figure 28.13).

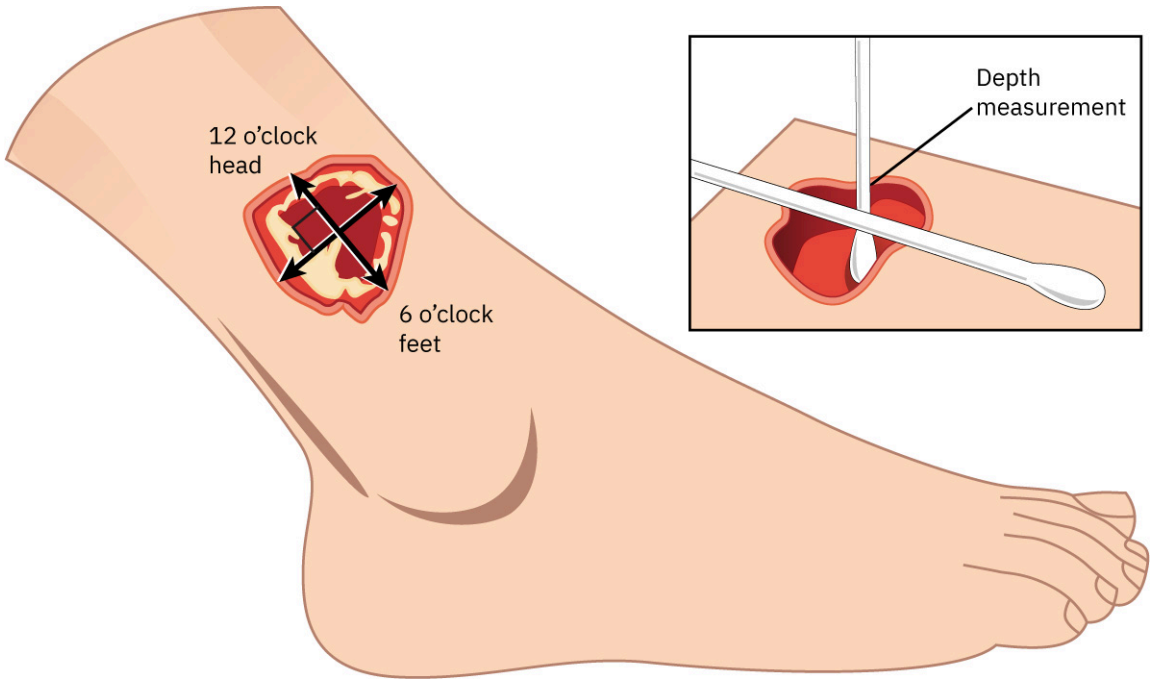

FIGURE 28.12 Determining wound measurements, a clinician measures the maximum length and width of the wound bed. The length is measured from the client's head to toe. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

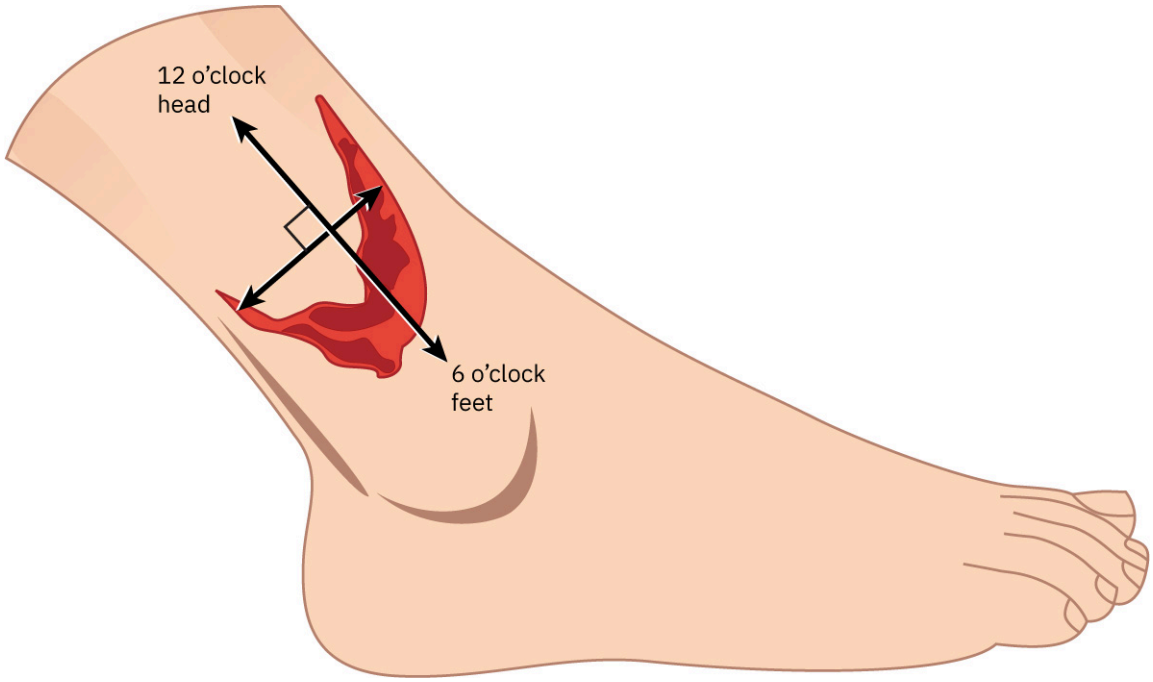

FIGURE 28.13 The same principles apply for irregularly shaped wounds: follow the head-to-toe method and measure the maximum length and width in cm. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

This method can also be applied to foot wounds. When assessing the plantar surface, the toes would be 12 o'clock and the heel 6 o'clock. The "clock" is also a helpful tool for identifying and recording landmarks or other wound assessment components, such as sinus tracts or undermining. For example, a wound might have undermining at 2 cm from 11 o'clock to 2 o'clock, with one 3 cm tunnel at 12 o'clock. This creates a visual image for all clinicians assessing the wound and can prevent unwarranted trauma to the otherwise friable tissue.

Wound Base

The wound base tissue reveals the phase and progress of wound healing through observation of color, degree of moisture, and amount of epithelialization. As previously discussed, a moist wound bed moves fibroblasts,

macrophages, collagenase, and other chemical components across the wound bed, progressing to healing. When assessing the wound base, we refer to the wound bed preparation to guide our visual assessment. Begin by assessing the wound bed, which may appear red, pink, yellow, or black. Clean, granular wounds are typically described as red or pink. If devitalized tissue is present, yellow or black necrotic tissue may also be present. Determine whether the bed is moist or dry and whether granulation is present.

Sometimes a wound can have **hypergranulation**: excess granulation tissue filling the wound bed beyond the height of the surface of the wound. Hypergranulation must be removed. If more than one tissue component is present, such as both granulation and necrotic burden, document the amount as a percentage. For example, the wound may have 75 percent granulation tissue and 25 percent yellow, adherent fibrin. Assessing the amount of each tissue type at each encounter allows the nurse to more easily track progress or regression of wound healing and determine whether wound treatment needs to be modified.

Periwound Assessment

The **periwound** is the skin surrounding a wound. It provides valuable information to the assessing clinician. Erythema and warmth at the periwound may indicate inflammation or infection. Interruptions in the periwound skin integrity may indicate reactions to adhesives. The presence of desiccation or maceration may indicate the dressing is ineffective in managing the wound. The presence of excessive dryness in the periwound is known as **desiccation**. On the other hand, **maceration** is the presence of excessive moisture.

When assessing and documenting the periwound, it is imperative to note the condition of the skin, hydration, skin abnormalities, color, hair and nail growth if appropriate, temperature, and presence of edema. Table 28.9 provides the detailed rationale of selected periwound assessment components.

Assessment Finding	Indication
Condition and quality of skin	• Is the skin thin, fragile, or transparent? Is it prone to tearing or further injury? • Note whether the periwound tissue is dry or cracked, which indicates too little moisture. Conversely, note if maceration is present. • Note any scars, rashes, or abnormalities that indicate other underlying health conditions.
Color	• The color of the periwound and surrounding skin can indicate potential problems. A certain amount of erythema is expected; however, excessive redness should spark concern for infection. • Is the tissue blanchable? Is the skin lighter in color than the surrounding tissue? If so, this may indicate ischemia. • A dusky color of the skin may represent severe ischemia

TABLE 28.9 Periwound Assessment Components

Wound Documentation

Wound documentation is an essential component of wound assessment and should be undertaken thoroughly, accurately, and consistently. Typically, wounds should be documented upon patient admission and transfer or discharge; between these milestones, documentation should happen weekly, with each dressing change, and with any significant changes to the wound or periwound.

Evidence-Based Practice for Wound Care

Documenting a wound care assessment should include all pieces discussed during the evaluation of a wound: type of wound, measurements, description of the wound base and periwound, drainage, odor, pain, and patient response to treatment. Agencies may have their own charting system or sheet to help with the wound assessment and documentation process, but it is imperative that the bedside provider includes all necessary components in the documentation. Documentation should be thorough, objective, and use simple language. There are many terms involved with wound and skin care, and sometimes it can be difficult to remember them all. The most important component of documenting a wound care assessment is describing precisely what is seen—using the correct terms

is helpful but not as important as a precise description. When documenting a wound, you are painting a picture to enable the next clinician or chart reader to visualize what you observed as you assessed and cared for the patient. Using simple terms is acceptable. There are legal implications for incorrectly documenting a term: for example, if a partial-thickness wound on the forearm is documented as a Stage 2 wound, this legally indicates that the wound is a pressure injury. Only pressure injuries should be staged. Timely recording is also a best practice for wound care documentation. If a record is documented after an extended period, note the reason for the delay in the record.

Photography

Wound photography provides a visual record of the wound; when done correctly, it can assist in care decisions and provide litigation support. However, photography should not replace bedside assessments. It is necessary to permanently mark on each photograph the time, date, and patient identification information while maintaining privacy: for example, by using a patient's initials rather than full name. Each photograph should include a sample measure, such as a 5-cm strip of tape for reference. Clinicians need appropriate training and must consistently follow their institution's wound photography protocol and policies. Angle of the camera, lighting, and distance can alter the perception of the wound assessment.

Legal Implications

Medico-legal issues in wound management can arise from low quality documentation. To review, the main purpose of wound care documentation is to communicate a wound's condition and progress to all future providers of the patient. Accurate and clear documentation enables the health-care team to collaborate and share pertinent information about the treatment and care plan. Consistency in documentation is important and prevents gaps in charting. If a patient's chart is presented during a legal proceeding, gaps in documented care or other omitted information make it more difficult for providers to exonerate themselves; they may even be interpreted as evidence of negligence.

The Centers for Medicare and Medicaid Services (CMS) sets reimbursement rates for medical services rendered and equipment used for the care of patients receiving Medicare. Fees and reimbursement rates vary, including for wound care. In terms of wound care reimbursement, CMS's documentation standards reflect the previously discussed best practices. Documentation for a wound should include:

- wound dimensions and depth
- presence and extent or absence of necrotic tissue and devitalized or nonviable tissue
- correct description and location of undermining or tunneling
- report of infection by describing wound exudate

It is important to describe the wound in simple, objective terms, without assigning blame or opinionating. When in doubt, describe what you see in clear, concise language as if you are painting a picture for the next clinician to care for the patient.

Another important nursing role with respect to wound care is educating patients on how to care for their wound; nurses should document all education provided. Lawsuits rarely involve wound care itself; rather, they revolve around not following standards of care, improper documentation, or lack of education around the patient's wound and care.

Summary

28.1 Cellular Response and Adaptation in Wound Healing

- The skin consists of three main layers: epidermis, dermis, and subcutaneous tissue. Each layer and its sublayers play an integral part in the external and internal roles of the skin.
- Regardless of wound etiology, all wounds undergo the same biological repair process, which consists of four phases.
- Understanding the four phases—hemostasis, inflammation, maturation, and remodeling—is important to understanding how to approach the wound and develop a comprehensive care plan.

28.2 Wound Healing Process

- The wound-healing cascade involves complex biochemical and physiological pathways. It includes the secretion of inflammatory cells and cytokines to facilitate healing.
- Various types of wounds require specific treatments based on their characteristics and etiology. Open wounds, such as abrasions, lacerations, punctures, avulsions, and incisions, involve breaks in tissue integrity. Chronic wounds fail to progress through healing phases in a timely manner.
- Wounds can heal through primary, secondary, or tertiary intention. Primary intention involves rapid closure with closely approximated edges, while secondary intention occurs when edges cannot be closed. Tertiary intention involves delayed closure, often to resolve infection or prepare for further intervention like grafting.
- Barriers to wound healing include physical, physiological, local, and systemic factors. Factors like age, immune status, perfusion, smoking, and comorbidities impede healing. The wound bed must be prepared using the TIME principles: tissue, infection/inflammation, moisture, and edges.

28.3 Pressure Injury

- Pressure injuries are preventable occurrences. It is the responsibility of every clinician and health-care provider to prevent them.
- Understanding the risk factors and pathophysiology of pressure injury development is critical for prevention.
- Pressure injuries should be staged.
- Pressure injury treatment follows the same method as other wounds and is accomplished through assessment and maximizing the principles of wound bed preparation.

28.4 Debridement

- Debridement, a cornerstone therapy in wound progression, has five current modalities: autolytic, biological (MT), enzymatic, mechanical, and surgical/sharp.
- Choosing the mode of debridement requires considering the presentation of the wound and the whole patient.
- Contraindications to debridement therapy rely on the specific modality. Regardless of the technique used, the removal of devitalized tissue is critical to facilitating wound progression.

28.5 Wound Care and Dressing

- There are more than a dozen topical therapy options and hundreds of wound care products on the market today. As a nurse, it is important to have a basic working knowledge of the categories of topical therapy and of the basic principles that govern patient care.
- Common lower leg ulcers encountered in wound care practice include venous leg ulcers, arterial ulcers, and diabetic foot ulcers.
- Any patient with a history of compromised circulation must have an ABI performed. If compression occurs and perfusion is compromised, the patient may risk losing or severely damaging the limb.

28.6 Medical Management

- Wound care is a collaborative effort among the interdisciplinary team. Often wounds are complex and require extensive or innovative measures to help heal.
- Specialized therapies include HOBT, NPWT, and drain management.
- As a nurse, it is important to understand what different treatment modalities are available to a patient and how to monitor the therapy.

- If a nurse is interested in specializing in wound care, there are options to continue education and obtain a board certification.
- Wound care is constantly evolving and needs specialists to help educate other clinicians, patients, and caregivers on wound care best practices.

28.7 Nursing Management and Care Plan

- A comprehensive wound assessment documents the status and progress of a wound. It includes a record of the observation, data collection, and evaluation and serves as the baseline for future comparisons.
- The comprehensive wound assessment includes patient history, wound measurement, observation of the wound base, and periwound assessment.
- Wound documentation should occur upon patient admission and transfer or discharge. Additional documentation should occur weekly, with each dressing change, and with any changes in the wound or periwound.
- Documentation should include type of wound, measurements, description of the wound base and periwound, drainage, odor, pain, and patient response to treatment in simple, objective terms.
- Documentation that is not thorough can be considered low quality and can lead to medico-legal issues. Consistency is important and prevents gaps in charting.
- Incomplete documentation can be interpreted as evidence of negligence and may also lead to issues with reimbursements for medical services rendered.

Key Terms

angiogenesis creation of new blood vessels
approximated brought close together, as in the case of wounds with sealed, clean edges
autolytic debridement process of using the body's intrinsic debriding mechanism to remove nonviable tissue
avascular lacking blood vessels
biological debridement use of sterile bottle fly larvae to remove nonviable tissue; also known as maggot larval therapy (MT)
Braden Scale risk assessment tool with six criteria for determining the risk of skin breakdown
comprehensive wound assessment complete, holistic, written, and visual record of the wound's current status and progress
dehiscence separation of the edges of a surgical wound
dermal-epidermal junction barrier between the epidermis and the dermis, which ensures strong resistance to physical stress
desiccation excessive dryness in the periwound
enzymatic debridement selective method of debridement that uses an exogenous enzyme known as collagenase; also known as chemical debridement
epibole severely rolled wound edges
epithelialization regeneration of the epidermis and the formation of granulation tissue
full-thickness wound injury extending through all skin layers, potentially involving muscle, fascia, or bone
granulation tissue new connective tissue with fragile, thin-walled capillaries
hematoma area of blood that collects outside large blood vessels
hyperbaric oxygen therapy (HBOT) therapy in which patients breathe pure oxygen in a pressurized environment to help wound progression and healing
hypergranulation excess granulation tissue filling the wound bed beyond the height of the surface of the wound
hypodermis layer of fat and connective tissue that links skin to the underlying structures
inflammation second phase of wound healing, characterized by the movement of white blood cells to the wound bed
keratinocyte cell that participates in the contraction and migration of cells across a wound bed to facilitate healing
maceration excessive presence of moisture in the periwound, which affects the integrity of the surrounding skin
mechanical debridement nonselective type of debridement that applies physical force to remove necrotic tissue
necrotic tissue avascular debris that can appear as eschar, slough, or biofilm
negative pressure wound therapy (NPWT) therapeutic technique that applies negative pressure to the wound bed to manage exudate and facilitate healing

Norton Scale risk assessment tool with five criteria for determining the risk of skin breakdown
partial-thickness wound superficial injury that involves the epidermis, dermis, or both
periwound skin surrounding a wound
pressure injury localized damage to the skin and underlying soft tissue, typically over a bony prominence or the site upon which a medical device was placed
primary intention healing of a wound with clean, approximated edges
proliferation third phase of wound healing, characterized by epithelialization, angiogenesis, collagen formation, and contraction
remodeling final phase of wound healing, characterized by regrowth and reorganization of collagen
secondary intention healing of a wound from the "bottom up," due to edges that cannot be approximated
senescent cell nonfunctioning cell that has stopped dividing but has not died
slough fibrinous necrotic tissue located on top of the wound bed; characterized as loose or stringy and yellow or tan
surgical debridement use of a scalpel, forceps, curette, scissors, or other instruments to remove necrotic tissue from the wound base; also known as sharp debridement
tertiary intention plan to delay healing while the wound remains open
tunneling formation of a sinus tract under any part of a wound's edge
undermining erosion of tissue under the edges of a wound

Assessments

Review Questions

1. What phase of wound healing is characterized by the migration of keratinocytes across the wound's surface?
   a. hemostasis
   b. inflammation
   c. proliferation
   d. maturation

2. What process involves the regeneration of the epidermis and the formation of granulation tissue?
   a. epithelialization
   b. maturation
   c. angiogenesis
   d. remodeling

3. The maturation phase of wound healing begins around week three. How long can it last?
   a. twelve months
   b. six months
   c. sixty days
   d. thirty days

4. What is the first phase of the wound-healing process?
   a. maturation
   b. proliferation
   c. hemostasis
   d. inflammation

5. What type of wound closure would most likely occur with a dehisced surgical wound?
   a. primary intention
   b. secondary intention
   c. tertiary intention
   d. delayed primary intention

6. What are the most common types of wounds? Select all that apply.

a. incision
b. puncture
c. abrasion
d. avulsion

7. What is the likeliest barrier to wound healing?
a. exercising three times a week
b. nutritional deficiencies
c. borderline hypertension
d. previous surgeries

8. A patient presents with a pressure injury to their right ischial tuberosity. The wound is 3×5 cm wide and 4 cm depth with exposed muscle. What stage would the nurse document for this pressure injury?
a. full-thickness
b. Stage 3
c. Stage 4
d. unstageable

9. What does the intense or prolonged pressure of a pressure injury lead to?
a. ischemia and necrosis
b. immobility and paralysis
c. infection and death
d. aphasia and apraxia

10. What is the most likely cause of pressure injury development?
a. compromised immunity
b. respiratory conditions
c. immobility
d. obesity

11. What are some pressure injury prevention strategies? Select all that apply.
a. use of specialty beds or pillows
b. early assessment screening
c. off-loading bony prominences
d. frequent repositioning

12. A nurse asks a nursing student what the purpose of collagenase therapy is. Which explanation best reflects the student's understanding?
a. "This medication is a debriding agent you apply to a necrotic wound to help prevent infection or biofilm from forming."
b. "Debriding the wound with this medication allows for the removal of nonviable tissue to facilitate wound progression."
c. "By applying this topical therapy, you are slowing the healing process of the wound and cleaning the wound at the same time."
d. "Collagenase is the only therapy available to debride or remove necrotic tissue from a wound."

13. What situation is a clinical implication for debridement therapy?
a. chronic nonhealing wound
b. dry, stable eschar present
c. hemodynamically unstable
d. recent anticoagulant therapy

14. What are the types of debridement? Select all that apply.

a. enzymatic
b. mechanical
c. chemical
d. autolytic

15. A nurse is assessing a patient's venous leg ulcer. The wound measures 3 cm × 5 cm and is extremely weepy. What dressing should the nurse select to manage the exudate volume?
a. foam dressing
b. alginate rope
c. transparent film
d. hydrocolloid

16. What wound presentation best describes a diabetic foot ulcer?
a. a dry, oval wound on the medial ankle
b. an oval wound with a callus on the plantar foot
c. a weepy, irregularly shaped wound on the calf
d. a punched-out, dry wound on the great toe

17. What clinical presentation is contraindicated for hyperbaric oxygen therapy? Select all that apply.
a. a patient arriving at therapy in street clothes
b. a critically ill patient
c. a patient with untreated pneumothorax
d. a claustrophobic patient

18. What is an example of data entry that exemplifies a best practice in wound care documentation?
a. "Wound WNL. Dressing changes without complications."
b. "Stage 2 arterial wound on arm. 4×4 cm. No drainage noted. Dressing changed per order without complications."
c. "Wound to left calf measures 3×5 cm. Minimal serious drainage noted. Redness to periwound, from 12 to 3 o'clock. Dressing applied per order, no complications."
d. "Pressure injury to left elbow. Provider notified. Foam dressing applied for prevention. Educated patient to keep arm elevated as much as possible. Will continue to monitor."

19. What characteristics of a wound should be included in the documentation of a wound assessment? Select all that apply.
a. exudate
b. measurements
c. any undermining
d. any noted odor

Check Your Understanding Questions

1. What are the three main layers of the skin?

2. Describe cues that would indicate a patient is at risk for developing a pressure wound.

3. A patient with necrotic tissue in their lower leg wound visits the health-care facility for debridement therapy. The patient asks the nurse which debridement method would be best for their wound. Describe the five types of debridement techniques and contraindications for each modality.

4. Describe the difference between arterial leg ulcers and venous leg ulcers. Include clinical presentation and common treatment options.

5. Explain the legal importance of an accurate and comprehensive wound care assessment. Provide examples.

Reflection Questions

1. Describe five of the main functions of the skin. Include examples of each.
2. A patient arrives at the unit postoperatively on oxygen via nasal canula, a foley catheter, and a chest tube. They are recovering from a six-hour procedure under general anesthesia. What factors place this patient at risk for pressure injury development? What pressure injury prevention measures should the nurse anticipate and implement?
3. What is the role of the wound care nurse in providing patient care? How does the role of the wound care nurse differ from that of the bedside nurse?
4. Imagine you are assessing a patient with a wound. What signs and symptoms would you recognize as potential infection?

What Should the Nurse Do?

Mrs. Ramos, a sixty-five-year-old female, visits her primary care physician with a nonhealing wound on her lower leg. She reports experiencing persistent pain, swelling, and foul-smelling discharge from the wound for the past three weeks. Mrs. Ramos has a medical history of type 2 diabetes and hypertension. On examination, her vital signs are within normal limits, but her lower leg wound reveals signs of infection and delayed healing.

1. Consider Mrs. Ramos's medical history of diabetes. How does this information contribute to the analysis of the wound's healing challenges, and what potential complications should be considered in the context of diabetes?
2. As the nurse, what immediate actions would you initiate to manage the infection and promote wound healing, and how would you collaborate with the health-care team to address Mrs. Ramos's overall health and comorbidities?

A new patient is admitted to the nurse's unit from a long-term care facility with a urinary tract infection. The nurse is performing a head-to-toe skin assessment on admission. The only injuries to note are intact "caps" of dry eschar on both heels.

3. What information relating to the wounds should the nurse include in their skin documentation, and how should the nurse stage them?
4. Which treatment modality should the nurse anticipate for the bilateral pressure injuries?
5. What preventive measures should the nurse implement?

Mr. Dickinson, a seventy-year-old male, checks into the emergency room with a chronic leg ulcer on his right lower extremity. He reports persistent pain, foul-smelling discharge, and difficulty in ambulation. Mr. Dickinson has a medical history of peripheral vascular disease and type 2 diabetes, both of which contribute to compromised blood circulation and delayed wound healing. On examination, his vital signs are stable, with a blood pressure of 130/80 mmHg, heart rate of 78 bpm, respiratory rate of 18 breaths per minute, and a body temperature of 98.6°F (37°C). The leg ulcer exhibits signs of infection, including redness, warmth, and purulent discharge. Necrotic tissue is present, indicating impaired tissue viability.

6. Considering the signs of infection and necrotic tissue in the leg ulcer, how do these cues inform the nurse's analysis of the clinical implications for debridement therapy? What potential complications should be considered during the analysis?
7. What debridement methods and wound care interventions would you recommend for Mr. Dickinson, considering the presence of infection and necrotic tissue? How would you tailor these solutions to meet his individual needs and promote effective wound healing?

Ms. Lankford, a fifty-five-year-old female, arrives at the emergency room with a nonhealing diabetic foot ulcer on her right foot. She reports persistent pain, foul-smelling discharge, and difficulty in bearing weight on the affected limb. Ms. Lankford has a medical history of type 2 diabetes and peripheral vascular disease. On examination, her vital signs reveal a blood pressure of 130/80 mmHg, heart rate of 88 bpm, respiratory rate of 20 breaths per minute, and body temperature of 98.7°F (37.1°C). The diabetic foot ulcer exhibits signs of infection and delayed healing.

8. What specific cues in Ms. Lankford's medical history and the presentation of the diabetic foot ulcer indicate the potential need for hyperbaric oxygen therapy, and how would you communicate these cues to the wound care team?

9. What other common treatment modalities, aside from hyperbaric oxygen therapy, would you recommend for Ms. Lankford's diabetic foot ulcer, and how would you tailor these solutions to meet her specific needs and promote effective wound healing?
10. The provider has ordered for a postoperative patient to have his wound photographed. What would the nurse verify before photographing the wound?

Competency-Based Assessments

1. Suppose that you work for an assisted living facility. The demographics of the patients you serve are mainly over the age of seventy. Develop a five-minute presentation for your monthly quality improvement meeting. Your presentation should include discussion regarding wound healing in older adults.
2. The nurse is caring for a patient who has a postoperative knee incision. The wound is slightly edematous and not approximated, with some yellow exudate present. What next steps will the nurse take?
3. Develop a pamphlet to present to your peers comparing and contrasting partial-thickness and full-thickness wounds.
4. Identify the cause of pressure injury development and discuss the roles of sustained pressure, shear, and friction in the pathophysiology of pressure injuries. How does this knowledge influence the nurse's approach to prevention and care for patients at risk?
5. Discuss pressure injury prevention strategies, considering both primary and secondary prevention measures. How can nurses collaboratively work with patients, families, and interdisciplinary teams to implement and maintain effective prevention strategies?
6. As a nursing student, how would you outline the essential steps for wound bed preparation, emphasizing the importance of each step in promoting optimal wound healing?
7. Given a scenario involving a venous leg ulcer, describe the rationale for selecting a compression bandage as part of the wound care plan.
8. Develop a sample wound care documentation entry for a pressure ulcer on the lower right leg of a patient.

CHAPTER 29

Immunological Function

FIGURE 29.1 In June 1987, a small group of strangers gathered in a San Francisco storefront to document the lives they feared history would neglect. Their goal was to create a memorial for those who had died of AIDS, and to thereby help people understand the devastation. The quilt grew over time and is shown on the National Mall in Washington, DC. (credit: Carol M. Highsmith Archive, Library of Congress, Prints and Photographs Division, Public Domain)

CHAPTER OUTLINE

INTRODUCTION The immune system plays a vital role in preventing or limiting infection. When a body comes in contact with harmful bacteria, viruses, or other substances that can cause illness, its immune system kicks into action. Fundamentally, the immune system is designed to recognize "self" from "nonself." That is, it should be able to distinguish between cells that are part of the body's own tissues (self) and substances that come from substances outside it (nonself), which can include bacteria and other pathogens, as well as toxins. These nonself substances are "invaders," and the immune system must differentiate them from cells and tissues of the body so that it can mount an appropriate response. Immunocompromise impedes the body from mounting such a response.

29.1 Immune Response

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the normal anatomical and physiological findings of an immune response
- Identify key components to incorporate into an immune system–focused assessment
- Discuss the effects and role of immunosuppressive medication in patient care
- Discuss recent advances in immunology

The body's specific, protective response to a foreign agent or organism is known as **immunity**. Through a variety of responses, both antibody mediated and cell mediated, the healthy immune system eliminates foreign substances or invaders it deems to be "nonself." Patients who are **immunocompetent** have an efficient immune system that is able to carry out functions properly. Patients who are **immunocompromised** do not have a properly working immune system; as a result, they are at risk for hypersensitivities, autoimmune disorders, infections, and immunodeficiencies.

Anatomy and Physiology Overview

The immune system is an intricate and complex system of specialized physiological structures that work in tandem to protect the body. The immune system's main tasks include the following (Institute for Quality and Efficiency in Health Care, 2020a):

- recognizing and neutralizing harmful substances from the environment
- recognizing and destroying malignant cells
- fighting and removing from the body disease-causing pathogens, such as bacteria, fungi, viruses, and parasites
- removing and destroying dead or damaged cells

Although it is always at work, a properly functioning immune system carries out its tasks automatically and without a person's conscious awareness. As long as they feel well, a person likely will not think about how hard their immune system is working. A weakened immune system is noticeable, however; a person will become ill after being exposed to an agent that the body cannot adequately defend against and develop symptoms that draw their attention to their state of ill health.

To effectively care for patients with a weakened or improperly functioning immune system, the nurse must understand the system's anatomy and physiology. The nurse also needs a solid educational foundation in these topics to educate patients and their families, thereby promoting optimal health and preventing disease.

Anatomy of the Immune System

The immune system is made up of many cells, tissues, and organs (Figure 29.2). White blood cells, or leukocytes, are the primary cells involved in an immune response. These cells are produced in the bone marrow and move through the body in a colorless fluid called lymph, which also contains water, fats, proteins, electrolytes, and antibodies.

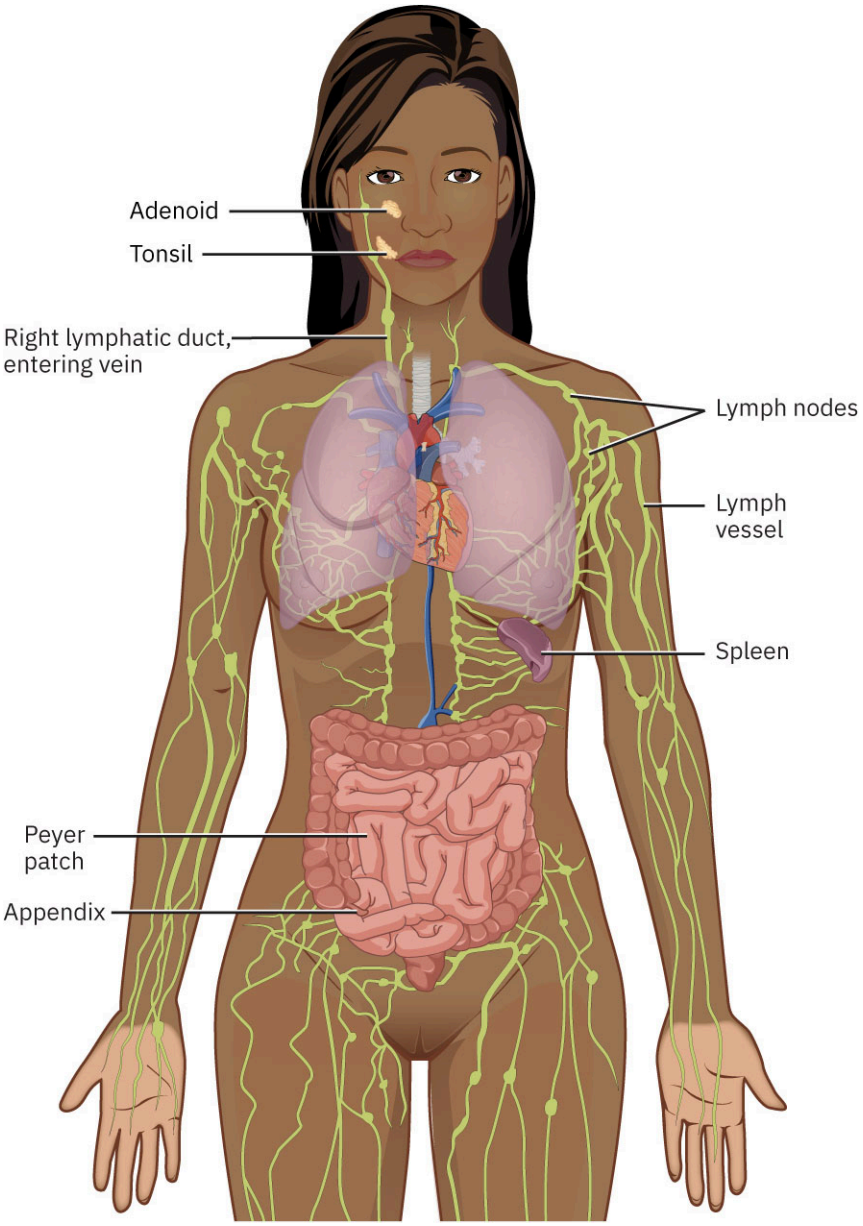

FIGURE 29.2 Various organs, cells, and tissues make up the immune system. Each plays a vital role in how the immune system functions. (credit: modification of work from *Anatomy and Physiology 2e*. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Leukocytes can be divided into different types (Figure 29.3), including granulocytes (neutrophils, eosinophils, and basophils), monocytes, and lymphocytes (T cells, B cells, and natural killer cells). Granulocytes are white blood cells that are involved in defending against infections (Tigner 2022). The different types of granulocytes are the following:

- Neutrophils are the most common type. They quickly respond to infections and destroy bacteria and fungi.
- Eosinophils help fight off parasites and are involved in allergic reactions.
- Basophils are the least common type. They release chemicals like histamine during allergic reactions to help the immune response.

Monocytes are cells that become macrophages when they move into tissues. They eat and digest bacteria, dead cells, and other debris. Lymphocytes are crucial for the body's immune response. The three types of lymphocytes are the following:

- T cells help other immune cells and kill infected or cancerous cells.
- B cells make antibodies that target and neutralize invaders like bacteria and viruses.
- Natural killer (NK) cells destroy infected or cancerous cells without needing to recognize a specific antigen.

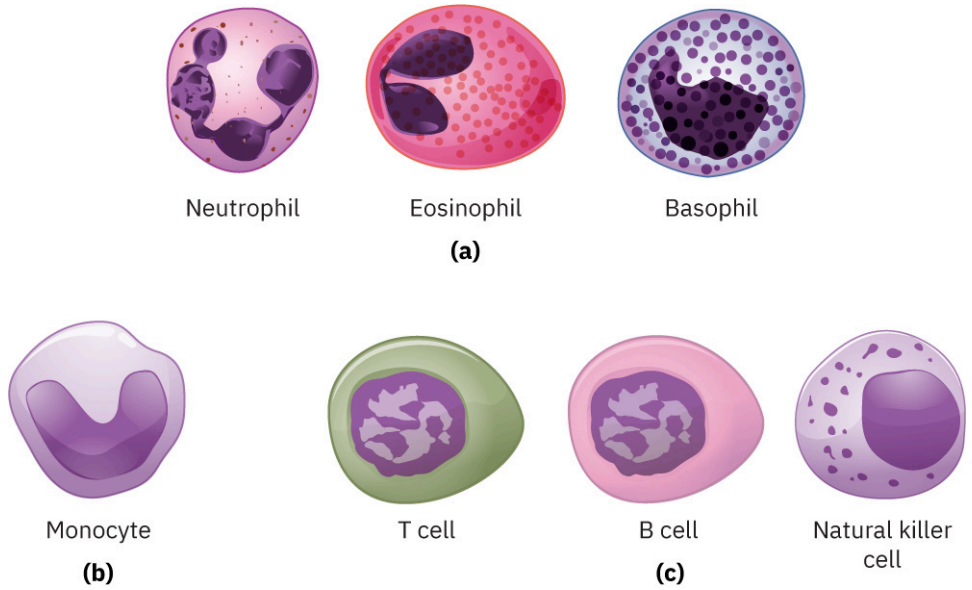

FIGURE 29.3 (a) Granulocytes are derived from myeloblasts and include basophils, neutrophils, and eosinophils. (b) Monocytes are derived from monoblasts. (c) Lymphocytes are derived from lymphoblasts and include T cells, B cells, and natural killer cells. (credit: modification of work from *Anatomy and Physiology 2e*. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Lymphoid tissues include the spleen and lymph nodes (Figure 29.4). The red pulp of the spleen is where injured and old red blood cells are destroyed and the iron recycled back into the body. The white pulp of the spleen houses a concentration of lymphocytes. The lymph nodes keep foreign material from entering the bloodstream by removing it from the lymph system via channels and capillaries. The lymph nodes also serve as a center for proliferation of immune cells.

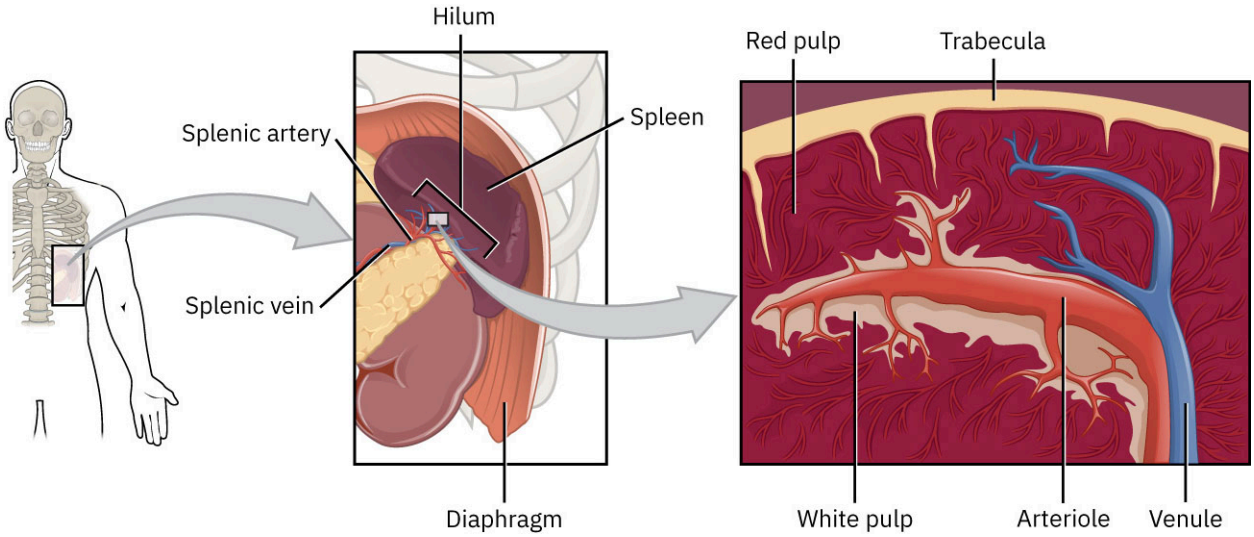

FIGURE 29.4 The spleen, located in the upper left abdomen, is an oval-shaped organ. It consists of a fibrous outer capsule, red pulp for filtering blood, and white pulp for immune functions. The red pulp of the spleen filters and breaks down old or damaged red blood cells, while the white pulp is involved in immune responses, producing and monitoring white blood cells. (credit: modification of work from *Anatomy and Physiology 2e*. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Other lymphoid tissues and organs include the appendix, thymus, intestines (specifically the Peyer patches), tonsils, adenoids, and bronchus-associated lymph tissues. These organs house immune cells that defend the body's mucosal surfaces against pathogens and microorganisms (Rawer, 2021).

Function of the Immune System

The overall function of the immune system is to recognize and destroy foreign antigens. The body's **natural immunity** (also called innate or nonspecific) is present at birth, and its **acquired immunity** (also called adaptive or specific) develops after birth (Table 29.1). Each type plays a distinct role in defending the body, but the respective components are co-dependent.

Characteristic	Natural (Innate) Immunity	Acquired (Adaptive) Immunity
Type	Inherited	Acquired during life (exposure, vaccination)
Duration	Life	Varies
Specific	No (broad)	Yes
Mechanisms	Innate immune cells, barriers/defenses (physical, chemical)	Antibodies (T, B cells)
Vaccination	No	Yes
Timing	Immediate response	Gradual response
Memory	No	Yes

TABLE 29.1 **Innate versus Acquired Immunity Comparison** (Institute for Quality and Efficiency in Health Care, 2020b)

Natural Immunity

Natural immunity is the first line of a host's defense. The innate immune system reacts quickly when contact is made with pathogens. White blood cells are key to an effective response. The macrophages work to digest and dissolve pathogens. Monocytes play a role in **phagocytosis**, engulfing and destroying foreign bodies. Eosinophils protect against parasites; they also increase in number in response to allergic reactions and stress. Basophils release chemotactic substances, such as serotonin, histamine, and heparin, in allergic reactions. Where inflammation occurs, the neutrophils are the first cells to arrive. The **natural killer cells** destroy tumor, fungi, and viral-infected cells as well as foreign tissues.

Other substances also play roles in the innate immune response, including several proteins: **interferons** signal the substances involved in defense against viruses, and **interleukins** are sent messages to direct the actions of the immune system cells, including modulating inflammation. Mucous membranes throughout the body produce secretions that bind invaders until they can be destroyed or removed. Hairlike structures called **cilia** (singular: cilium) remove invaders found in the respiratory tract. The cough reflex is also part of the natural immune response, as the body attempts to remove antigens from the respiratory or digestive system and inhibit them from invading the body further.

The stomach and intestines also play roles in the innate immune response. The stomach produces hydrochloric acid and enzymes that break down proteins and decompose foreign pathogens. The intestinal flora also fend off infections as antibody-producing cells live in the intestinal mucosa (Rawer, 2021).

Acquired Immunity

Acquired immunity is adaptive and complex. It responds to a specific threat, or antigen, by producing antibodies that are designed to target that antigen. It must be able to remember all the various antigens that it encounters to efficiently respond when particular antigens make recurrent attacks.

Lymphocytes play key roles in the adaptive immune system. This is how they break down. B cells, which mature in the bone marrow, form antibodies (also called immunoglobulins) that target specific antigens. T cells, also known as T lymphocytes, mature in the thymus, function to control viral infections, destroy cancer cells, and are also involved in hypersensitivity reactions. T lymphocytes also migrate through the host to monitor body cell surfaces for changes. When T cells make contact with a recognition mark or antigen, they activate to stimulate B-lymphocyte division. T killer cells then terminate infected or degenerated cells. T-helper cells support the immune response. The T-suppressor cells dismiss the immune response and also reduce the risk of autoimmune diseases or allergic reactions by suppressing the immune response in certain interactions (Rawer, 2021).

CLINICAL SAFETY AND PROCEDURES (QSEN)

QSEN Competency: Safety. Infection Prevention

Disclaimer: Always follow the agency's policy for infection prevention.

Definition: Minimizes risk of harm to patients and providers through both system effectiveness and individual performance.

Knowledge: The nurse will analyze basic safety principles, understand evidence-based practice infection prevention standards, and reflect on unsafe nursing practices.

Skills: Demonstrate effective infection prevention strategies to reduce the risk of harm when providing care to patients. This may include but is not limited to practicing frequent, proper handwashing, using personal protective equipment (PPE), using aseptic technique, following disinfection procedures, practicing safe injection, providing patient education, participating in surveillance, and staying current on evolving standards and practices that help prevent infection in the health-care and community settings.

Attitudes: The nurse will respect their individual role in preventing infection by adhering to safe, evidence-based practice standards.

(QSEN Institute, n.d.)

Assessment of the Immune System

Assessment of the immune system starts with obtaining the health history of the patient and performing a physical examination. The nurse should determine the patient's nutritional status and history of immunizations, infections, allergies, surgeries, medications, blood transfusions, and disease and disorder states, such as cancer, chronic illnesses, or autoimmune conditions. The nurse should also palpate the lymph nodes to assess for signs of inflammation or illness, including tenderness, enlargement, and movability. For example, firm, painless lymph nodes can be a sign of cancer, while inflamed lymph nodes from an infection can be tender and movable.

Additionally, the nurse will assess the skin and mucous membranes as well as the neurosensory, cardiovascular, genitourinary, musculoskeletal, gastrointestinal, and respiratory systems, for specific and nonspecific signs of illness, injury, and inflammation, such as redness, fever, and swelling.

Health History

The health history of a patient is an important indicator of how well the immune system functions. Older adults are at a greater risk for **immunosenescence**, the gradual deterioration of the immune system due to natural aging processes (Borgoni et al., 2021). Changes due to aging contribute to a variety of problems and put older adults at an increased risk for infections, metabolic diseases, autoimmune diseases, neurological disorders, and osteoporosis. The aging immune system's inability to recognize malignant cells may also be a contributing factor of cancer in older people (Borgoni et al., 2021).

Gender is another important component. There are differences in immune system functions between males and females. Sex hormones contribute to the development and activity of the immune system. Both innate and adaptive immune systems have receptors for sex hormones and respond to hormonal cues (Moulton, 2018). Consequently, differences in sex hormones help to explain the greater prevalence of autoimmune diseases in females than in males (Pennell et al., 2012)

A person's nutritional status likewise is vital to the efficiency of their immune status. Nutritional deficiencies in micronutrients have been linked to a decline in immune function. Specifically, deficiencies in zinc are associated with several diseases, because zinc plays an important role in immune function, homeostasis, and apoptosis, which is the normal and controlled death of cells. An inadequate intake of protein can result in the atrophy of lymphoid tissue, decreased production of T cells, impaired phagocytic function, and a reduced antibody response—all factors that can make a person more susceptible to infection (Venter et al., 2020).

The nurse should also ask the patient about their immunization history throughout their lifespan. This includes

vaccinations, such as influenza, COVID-19, pertussis, herpes simplex, and pneumococcal disease, as well as childhood and adolescent immunizations, such as measles, mumps, rubella, hepatitis A and B, DTaP, human papillomavirus (HPV), polio, rotavirus, and meningococcal. This history allows the nurse both to assess the patient's immunity against diseases and to determine if a patient needs an immunization. It also provides the nurse with an opportunity to educate the patient about the need for vaccines.

LINK TO LEARNING

The Centers for Disease Control and Prevention (CDC) provides free resources outlining vaccine schedules for children and adolescents (https://openstax.org/r/77vaccine) from birth to 18 years old as well as adults 19 years of age and older.

Another important component of the patient's health history is the patient's known past or present exposure to various infections that can contribute to immunodeficiency, including lifestyle risk factors. The nurse will want to assess the patient's exposure to tuberculosis; blood-borne pathogens, such as hepatitis B, C, D, or HIV; and sexually transmitted infections, such as gonorrhea, syphilis, HPV, and chlamydia. Assess lifestyle risk factors as well, including sexual partner history and drug use. Finally, the nurse should assess for recurrent infections, fevers of unknown origins, lesions, and any type of drainage from a lesion or wound, noting known or suspected dates of exposure, test results, and types of and responses to treatment.

The nurse should ask the patient about allergies. Allergies may include dust, pet dander, cosmetics, pollens, plants, medications, latex, vaccines, or food. The nurse should assess the symptoms experienced, their severity, and the presence or absence of any seasonal variation. The history includes asking about allergy testing, treatments, and effectiveness of treatments. It is crucial that the nurse document all patient allergies and, for those reporting food or medication allergies, create identification bands and alerts to notify other members of the health care team.

History: Disorders and Diseases

Autoimmune disorders result when the immune system malfunctions and attacks the body's own healthy cells, tissues, or organs. Instead of attacking a nonself tissue or invader, the body attacks itself (Figure 29.5). Autoimmune disorders can affect any part of the body and weaken bodily function. Examples include diabetes, lupus, rheumatoid arthritis, and multiple sclerosis (U.S. Department of Health and Human Services, 2022). It is important that the nurse assess for autoimmune conditions to determine how well the patient's immune system functions and if the patient is at risk for infections. The nurse should obtain information about the onset, severity, remissions, and exacerbations of each documented disorder, along with any functional limitations and the types and effectiveness of current or past treatments. The nurse should also obtain information about any family history of autoimmune conditions, because there can be a genetic predisposition.

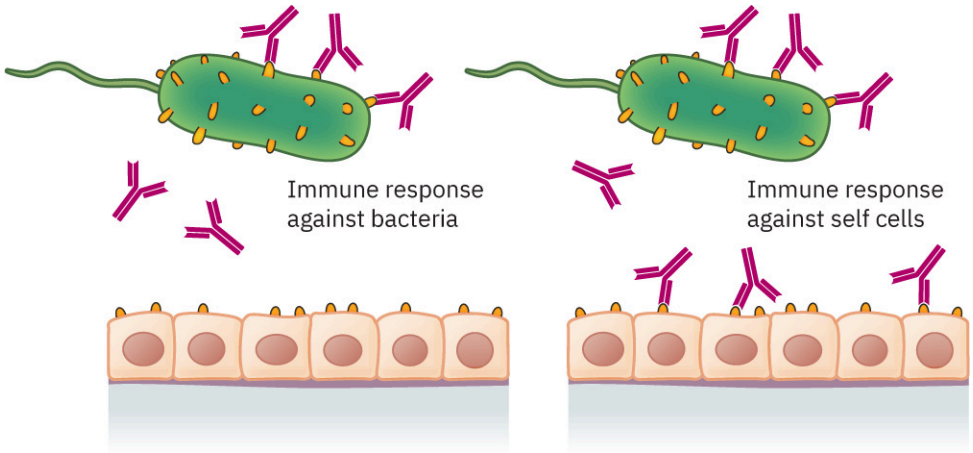

FIGURE 29.5 In an autoimmune disorder, the immune system attacks the body's healthy cells. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Neoplastic diseases are conditions that cause a **neoplasm**, or tumor—an abnormal growth of cells in a confined

area, which may be benign or malignant. A benign tumor is noncancerous and unable to spread to other tissues or organs. A malignant tumor is cancerous and can spread to other tissues or organs in the body, a process known as metastasis. The nurse should obtain the patient and family history of cancer, including type, onset, test results, past and current treatments received, alternative therapies used, and response to treatments; family histories should also include the maternal or paternal relationship of the affected family member to the patient. Immunosuppression can contribute to the development of cancer, and cancer treatment can further contribute to immunosuppression. For example, chemotherapy can diminish bone marrow function and destroy the important lymphocytes needed for adequate immune responses (Cancer Research UK, 2021).

History: Psychoneuroimmunology Factors

The study of how the immune system and central nervous system interact is called **psychoneuroimmunology**. Neurotransmitters, hormones, and neuropeptides have been found to regulate immune cells; in turn, immune cells are capable of communicating with nervous tissue through the secretion of a wide variety of cytokines. The hypothalamus can communicate a warning to the body when it recognizes a potential predator. The hypothalamus can also recognize the release of prostaglandins, interleukins, interferons, histamine, and serotonin during the inflammatory response.

Determining the psychological status of the patient is an important component of the health history. Stress can negatively affect the effectiveness of the immune system and contribute to illness or infection. This is due to the elevated levels of cortisol-releasing hormone, adrenocorticotropic hormone, and cortisol, which can affect the immune system cells in both the short and long term by suppressing the immune response and, over time, reducing its effectiveness (Tausk et al., 2008). Behavioral strategies, including meditation, relaxation, biofeedback, imagery techniques, and hypnosis, can improve a patient's immune response; the nurse should assess the patient's response to and use of these strategies, as applicable.

REAL RN STORIES

Nurse: Casey, RN
Years in Practice: Ten
Clinical Setting: Community health clinic
Geographic Location: Chicago

When I think about the effect that stress can have on the body, I think about a patient I saw quite a bit over the last year after her messy divorce. Alicia was a 35-year-old teacher who had been married for nine years when she discovered her husband had been cheating on her. They had a young son together, and the divorce and custody battle that ensued took a lot out of her. She explained this to me over the course of several appointments that year when she came to the clinic with respiratory infections. She laughed it off and said it was just that her son was "bringing home first-grade yuck" and giving it to her, but I had a feeling the chronic stress and trauma she was experiencing were affecting her immune system. In better times, her body probably would have been much better able to fend off those kiddo germs, but in her completely stressed-out state, she was much more at risk for infection. I explained this to her and asked if she had anyone to talk to, like a counselor. She seemed to have an "ah-ha" moment and said that before the divorce she hardly ever got colds and couldn't even remember the last time she'd had the flu. But over the last few months, it just seemed like she was constantly sick and picking up every bug that went around. She admitted that she hadn't found a therapist to talk to but knew that she probably needed to "work through it all" with a professional. I made sure to connect her with one of our mental health team members before she left her appointment. It has been a few months since she came in with respiratory symptoms, so reducing her stress may have helped bolster her immune system.

History: Medications and Blood Transfusion History

Part of obtaining a health history includes asking the patient for a list of current and past medications. Medications, such as antibiotics, nonsteroidal anti-inflammatory drugs, corticosteroids, cytotoxic agents, and anesthetic agents can suppress the immune system. The nurse should also ask about the use of over-the-counter medications and herbal supplements. While there has not been rigorous testing of all herbal supplements and over-the-counter medications, some are known to cause immunosuppression. It is best practice to obtain information about the

patient's usage and educate them about problematic effects that may alter their immune response. For example, red yeast rice may be used to lower high-density lipoprotein and low-density lipoprotein. This herb has been found to work as an immunosuppressant, however.

The patient's blood transfusion history is also important, because previous exposure to foreign antigens through a transfusion can be linked to an improperly functioning immune system. Although blood to be transfused is tested for HIV prior to being administered and the risk of HIV from a blood transfusion is extremely low, a small risk is still possible.

History: Lifestyle Considerations

A person's lifestyle can greatly affect how well their immune system functions. Factors, such as smoking, poor nutritional status, alcohol consumption, sexually transmitted infections, illicit drug use, stress, lack of sleep, and environmental exposure to radiation and pollutants have been linked to an impaired immune system. Conversely, someone who overexercises is also at risk for a poor functioning immune system due to the physiological stress on their body. The nurse must ask questions to determine any lifestyle factors that may affect the patient's immune system.

Following are examples of questions the nurse may ask to elicit this key information from a patient:

- Do you smoke? How much and for how long?
- What do you normally eat and drink?
- Do you drink alcohol? How much and for how long?
- Do you use any substances? Which ones and for how long?
- Are you feeling stressed out? How would you rate your stress from low to high? What do you to do manage your stress?
- How do you sleep? What time do you go to bed and wake up? Do you feel rested?
- Do you get physical activity during the day? Do you have a workout routine? Are you sitting for most of the day without a break to stand up and move around?
- Are you sexually active? What steps do you take to protect yourself from sexually transmitted infections? Have you ever been diagnosed with a sexually transmitted infection, had symptoms of one, or had a partner who had one?
- Are you concerned about exposure to chemicals at your job or at home? Have you had tests like medical scans that used radiation? Are you concerned about the air quality or levels of pollution in your community?
- Have you been sick recently? Has anyone in your home had a contagious illness recently?
- Do you take any medications or use supplements, including over-the-counter vitamins, medicines, or alternative medicine therapies?

The nurse should also educate the patient and family on the importance of modifying lifestyle factors to promote optimal health (Harvard Health Publishing, 2021).

CLINICAL JUDGMENT MEASUREMENT MODEL

Analyze Cues: Asking Subjective Questions

Before analyzing cues, the nurse must make sure they have enough data to interpret the information. For example, if a patient reports a sore throat, the nurse must recognize the sore throat as a cue to ask follow-up questions such as these: "When did it start?" "How severe is the pain?" "Is there anything that makes it worse or better?" "What other symptoms are you having?" "Have you been exposed to anyone with an illness that you are aware of?" The patient's response will allow the nurse to begin critically thinking about the information in order to hypothesize the likely cause and appropriate treatment. By asking subjective questions, the nurse is able to determine what actions to take next.

Physical Assessment

A physical examination to assess a patient's immune system includes palpation of the lymph nodes found in the anterior and posterior cervical areas, as well as the supraclavicular, axillary, and inguinal lymph nodes. The nurse will determine whether any nodes are swollen or tender. The nurse will also check the skin and mucous membranes

for any lesions, purpura, urticaria, dermatitis, inflammation, or discharge. Take the patient's temperature and assess their joints for tenderness, edema, warmth, or limited range of motion. The nurse should also assess the patient's neurosensory, cardiovascular, genitourinary, musculoskeletal, gastrointestinal, and respiratory systems for signs of possible immune dysfunction, including fever, weakness, fatigue, weight loss, and pain. The nurse must document all findings.

Diagnostic Evaluation

Diagnostic evaluation of the immune system includes various blood and skin tests (Table 29.2). These tests may include humoral, or antibody-mediated, immunity tests, or cellular, or cell-mediated, immunity tests.

Category	Test	What It Checks For
Humoral immunity (antibody mediated)	B-cell quantification with monoclonal antibodies	Number of B cells, overall immune system functioning, and signs of deficiency
	Specific antibody response	Antibodies for specific antigens, signs of specific infections, assess response to vaccines
	Total serum globulins	Number of globulins, health of immune system, signs of deficiency
	Individual immunoglobulins (IgG, IgA, IgM)	Levels of specific antibodies, health of immune system, response to vaccines
Cellular immunity (cell mediated)	Total lymphocyte count	Number of immune cells, health of immune system, signs of deficiencies
	Cytokine production	Number of cytokines being produced, signs of inflammation, infection, autoimmune disease
	Helper and suppressor T-cell functions	T cells' ability to control immune response, health of immune system, and signs of deficiency
	T-cell quantification with monoclonal antibody	Number of specific T cells
	Delayed hypersensitivity skin test	T-cell function by reaction to a harmless substance, assess vaccine response or look for immunodeficiencies
	Lymphocyte response to antigens, mitogens, and allogenic cells	Immune cell reaction to different triggers, assess immune system health, signs of deficiencies
Other tests	Bone marrow biopsy	Immune cells in bone marrow, diagnose diseases of bone marrow or causes of poor immune response

TABLE 29.2 Immune Tests

Collaborative Management with Immunosuppressive Therapy

Collaborative management of a patient with immunodeficiency will vary depending on the diagnosis and severity. The interdisciplinary team may include nurses, psychologists, primary care physicians, infectious disease doctors, rheumatologists, oncologists, endocrinologists, social work, physical therapists, dietitians, or occupational therapists. Treatments may vary to include medications, infusions, surgery, chemotherapy, radiation, lifestyle

modifications, counseling, or rehabilitation.

The interdisciplinary team is involved in the diagnosis and management of immune function disorders, and all members must be aware of the physical discomfort and psychological reactions that may be associated with testing and treatments. Patients may experience grief or anxiety associated with test results or possible implications of a diagnosis that may affect their personal relationships, employment, and future health. The nurse should counsel, educate, and be supportive throughout the process as well as provide resources on counseling and education when needed.

Medical management may include immunosuppressive therapy. This therapy may be prescribed for autoimmune diseases or for those undergoing organ or stem cell transplantation. Immunosuppressive therapy is designed to stop the immune system from mistakenly attacking healthy cells and tissues. Prior to organ or stem cell transplants, immunosuppressive agents are prescribed to prevent the body from rejecting or attacking the transplanted material. Potential side effects of these agents may include hyperglycemia, fatigue, hair loss, headaches, high blood pressure, osteoporosis, tremors, weight gain, nausea, and/or vomiting. The nurse or prescriber must educate the patient to take their medications as prescribed, despite any side effects, as skipping a dose can result in a flare-up or worsening of the condition the drug is intended to treat. It could even cause the patient's body to reject the transplanted organ or cells.

Taking immunosuppressants can have more serious, even life-threatening, consequences, as suppressing the immune system puts the patient at increased risk of infection from any number of pathogens. The patient should be educated on signs and symptoms of infection and the need to immediately report symptoms, such as a fever of 100.5°F (38°C) or greater, decreased urine output, bloody urine, flu-like symptoms, tenderness around the transplanted organ, and skin changes such as rashes or lesions with drainage or redness (Cleveland Clinic, 2023).

Advances in Immunology

Chapter 31 Cancer explores in detail advances in immunology such as stem cells and immunotherapy for cancer, but it is worth briefly discussing each topic in the context of immunological function.

The **stem cells** are cells in the earliest stage of development, before they have become specialized—that is, before they have become blood cells, liver cells, muscle cells, and so on. Stem cells can be **multipotent** (can become the cell type they came from) or **pluripotent** (can become any other kind of cell). Consequently, they can develop into many different cell types in the body during early life and growth. They also continually replenish the body's supply of red and white blood cells. When a stem cell divides, the resulting two daughter cells may both be stem cells; they may also both be differentiated, or specialized. Alternatively, the division may result in one stem cell and one differentiated cell (U.S. Department of Health and Human Services, 2021). Table 29.3 lists the main categories of stem cells (U.S. Department of Health and Human Services, 2021).

Embryonic Stem Cells	Nonembryonic ("Adult") Stem Cells	
	Multipotent	Induced Pluripotent
They are found in embryos.	They are found in fully developed tissues and organs.	They are adult stem cells that have been transformed in a laboratory to become pluripotent (or nearly so).
They are pluripotent, which means they can become any of the cell types in the adult human body.	They can become only the type of cell that makes up the tissue or organ where they came from.	They appear to be identical to embryonic cells and can turn into multiple cell types, but so far scientists have not been able to make them fully pluripotent.

TABLE 29.3 Stem Cell Categories (Stanford Medicine Children's Health, 2024)

Studies have shown stem cell transplantation to have therapeutic effects. In some cases, it has even restored destroyed immune systems (Ebrahimi et al., 2021). Research is ongoing, however, and concerns remain regarding the efficacy and safety of the therapy.

The emerging field of **genetic engineering** is designed to enable the replacement of defective or missing genes using recombinant deoxyribonucleic acid (DNA) technology. There are two facets of this technology relevant to immunotherapy. In one, scientists combine genes from two different types of organisms to produce proteins, lymphokines, and monokines, which have the ability to improve the functioning of the immune system. In the other, scientists attempt to restore normal gene function when a particular gene is missing or defective. This generally involves inserting a recombinant gene into a harmless virus; when the virus joins with a cell in the immune system, it inserts the missing gene into the cell's DNA, fixing the anomaly (Lanigan et al., 2020).

Remember that one function of the immune system is to find and attack malignant cells. Some cancer cells may go undetected by the body due to genetic changes that make them less noticeable, proteins on the cell surface that turn off immune cells, or changes to the normal cells around the cancer that alter how the immune system responds. Immunotherapy treatments are designed to boost a person's own immune system to better recognize and destroy cancer cells. This knowledge has led to more and better treatment options, such as vaccines, monoclonal antibodies, immune checkpoint inhibitors, and cytokines (National Cancer Institute, 2019).

29.2 Autoimmunity

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Define autoimmune disease and identify common pathophysiology of autoimmune disease
- Recognize common autoimmune disorders

The immune system is a network of cells, tissues, and organs that function to protect its host from viruses, bacteria, and other malignancies. To do this work, the immune system must be able to distinguish between "self" and "nonself"—that is, between the body's own, healthy components and threats to its health. With **autoimmunity**, the immune system fails at this fundamental task; it mistakenly targets and attacks the body's own healthy tissues, organs, and cells. The exact cause of this immune malfunction is unknown. It is likely to have a genetic predisposition. Autoimmunity can affect any part of the body and weaken its ability to function; it can even be life-threatening (U.S. Department of Health and Human Services, 2022).

Pathophysiology of Autoimmune Disease

There are several types of autoimmune disorders. While the exact cause of any type is unknown, all such disorders stem from the same fundamental error: the immune system misidentifies the body's own tissues as "foreign" rather than as its "self." Scientists have learned that many autoimmune disorders are characterized by irregular B- and T-cell reactivity to the normal components of the host. Recall that T-helper cells stimulate B cells to produce autoantibodies, and cytotoxic T cells kill or damage potential threats. Mutations of B and T cells may interrupt their normal abilities to recognize foreign antigens and lead to autoimmune disorders.

The autoantibodies, a critical diagnostic finding for autoimmune disease, form immune complexes that deposit within tissues and activate the complement system, which produces inflammation. When there is a pathogen to fight, this response is helpful. But when it is turned on the body, it damages healthy tissue. In some autoimmune conditions, the complexes start in a particular organ because the response has been triggered by a mix-up involving damaged or compromised pieces of genetic material (the acids that make up DNA and RNA). Autoantibodies may also bind to molecules in the blood, which can trigger an immune response via the complement system (Pisetsky, 2023).

According to the American Autoimmune Related Diseases Association, 50 million Americans have one or more autoimmune diseases (2019). This translates to one in five Americans being diagnosed with an autoimmune disorder. Of those affected, 75 percent are women.

LINK TO LEARNING

The American Autoimmune Related Diseases Association has a flier that provides facts about autoimmune disorders (https://openstax.org/r/77autoimmune), including statistics, types, and potential causes and treatments.

Common Autoimmune Disorders

There are more than 100 autoimmune disorders, affecting a wide variety of body parts and systems. While there are important distinctions to be made among them, the nurse will find that they share some commonalities in presentation, diagnosis, and treatment. The signs and symptoms of autoimmune disease can be widespread as well as specific to the organ system(s) being targeted. Nonetheless, nurses will often note general signs and symptoms of inflammation, and assessments for these manifestations, including a physical exam, blood tests, and imaging, are common elements of the diagnostic process. Nursing interventions that are intended to help manage inflammation and its consequences, which may include counseling patients about taking preventive steps to avoid flare-ups as well as providing patient education and ongoing support, will be common.

Many autoimmune diseases have complex disease processes that are discussed in greater detail in other chapters. Table 29.4 describes the pathogenesis of common autoimmune disorders of the endocrine, hematologic, cardiac, gastrointestinal, integumentary, and musculoskeletal systems.

Disorder	Pathogenesis
Endocrine System	
Type 1 diabetes mellitus	In patients with this disorder, the body's immune system destroys the insulin-producing islet cells in the pancreas. Because the body depends on insulin to move sugar from the bloodstream into cells, patients can develop life-threatening hyperglycemia (Shimura & Kobayashi, 2004).
Graves disease	Thyroid-stimulating hormone signals the thyroid to make thyroid hormone as the body needs it. With Graves disease, autoantibodies are activated that stimulate thyroid hormone synthesis and secretion as well as thyroid growth, resulting in a goiter (Shimura & Kobayashi, 2004).
Hashimoto disease	This disorder causes antithyroid antibodies to form and attack thyroid tissue, causing fibrosis. This is thought to be due to the infiltration of lymphocytes and cytokines (Mincer & Jialal, 2022).
Hematologic and Cardiac System	
Idiopathic thrombocytopenic purpura	With this disorder, the macrophages of the immune system attack and destroy platelets, which the body needs to control clotting. The resulting deficiency can lead to easy bruising and internal bleeding (Olsson et al., 2013).
Autoimmune hemolytic anemia	This disorder causes anti-erythrocyte autoantibodies to destroy erythrocytes at a rate faster than the bone marrow can produce new red blood cells (Barcellini, 2015).
Rheumatic heart disease	Streptococci bacteria can cause rheumatic fever. Rheumatic heart disease results from valvular damage caused by an abnormal immune response to *Streptococcus pyogenes* infection (Dass & Kanmanthareddy, 2023).
Gastrointestinal System	
Inflammatory bowel disease (Crohn disease and ulcerative colitis)	Inflammatory bowel disease is driven by the T-cell response. The dysfunctions of the immune pathways leading to Crohn disease are considered to be driven by T-helper-1 cells (cell-mediated immune cells) (Zhang & Li, 2014).

TABLE 29.4 The Pathogenesis of Common Autoimmune Disorders

Disorder	Pathogenesis
Celiac disease	Gluten is a protein found mainly in wheat flour. With this disorder, gluten-derived peptides initiate an altered immune response. The CD4 T lymphocytes trigger a chain of altered immune reactions that lead to chronic inflammation of the small intestine (Parzanese et al., 2017).
Irritable bowel syndrome	Changes in mucosal immunocytes, mast cells, and microbiota are thought to be due to infections such as gastritis or to psychological stress. These changes can lead to inflammation characterized by increased production of cytokines, altered population of circulating cells, and mucosal infiltration of immune cells (Saha, 2014).
Integumentary System	
Psoriasis	The inflammation characteristic of this skin disorder is due to disturbances in the immune response that lead to uncontrolled keratinocyte proliferation and dysfunctional differentiation. Psoriatic plaque is composed of macrophages, T cells, neutrophils, and dermal dendritic cells (Rendon & Schäkel, 2019).
Scleroderma	With this disorder, the immune system triggers cells to produce too much collagen, which is deposited into organs and skin, causing hardening and thickening of the affected areas. This is thought to be due to an altered balance of the innate and acquired immune systems that leads to an overabundance of cytokines, chemokines, and autoantibodies that stimulate the activation of fibroblasts (Rosendahl et al., 2022).
Musculoskeletal System	
Rheumatoid arthritis	The pathogenesis of this disorder involves many types of cells, including macrophages, T and B cells, fibroblasts, chondrocytes, and dendritic cells. It is likely caused by environmental triggers at the mucosal surfaces that induce peptidyl arginine deiminases, which modify arginine to citrulline. These modified proteins are then presented to T cells after being processed by dendritic cells. Vascular permeability is increased in the synovium that triggers synovial cells, leading to inflammation in the joints (Firestein & Guma, 2023).
Multiple sclerosis	The cause of this disorder is multifactorial, so the exact pathogenesis is unclear. Genetic predisposition and environmental factors trigger an immune response that leads to neuronal cell death, nerve demyelination, and neuronal dysfunction. The inflammation of the central nervous system tissues is due to immune cell and cytokine infiltration. T-helper cells initiate interactions between antigen-presenting cells and T lymphocytes that can affect the initiation and progression of this disease (Ghasemi et al., 2017).
Multiple Systems	
Lupus	With this disorder, the immune system attacks its own tissues, causing widespread inflammation and tissue damage affecting the joints, skin, kidneys, brain, lungs, and blood vessels. The main culprits that contribute to the altered immune response are dendritic cells, neutrophils, T cells, B cells, complements, cytokines, immune complexes, and kinases of the intracellular matrix (Pan et al., 2020).

TABLE 29.4 The Pathogenesis of Common Autoimmune Disorders

29.3 Immunodeficiency

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Define primary immunodeficiencies
- Differentiate between HIV and AIDS

The result of the malfunctioning of an underactive or weakened immune system is termed **immunodeficiency**. This is different from an autoimmune disease, in which the body's immune system overreacts and mistakenly attacks the body. While autoimmune disease may attack normal, healthy tissue, immunodeficiency may lead to an inadequate response to pathogens. As such, immunodeficiency disorders impair the immune system's ability to defend the body against foreign invaders. They may lead to infections that develop and recur often and that are typically more severe and longer lasting than usual. They may also result in the development of lymphomas or other types of cancers. There are two types of immunodeficiency disorders: primary and secondary.

Primary Immunodeficiencies

The **primary immunodeficiencies** generally are present at birth; they are genetic and usually hereditary. These disorders typically become evident during infancy or childhood, but some may not be recognized until adulthood. There are more than 100 primary immunodeficiency disorders, and all are quite rare.

CULTURAL CONTEXT

Race and Ethnicity in Primary Immunodeficiency

Because primary immunodeficiencies are linked to genes, the nurse should be aware of the cultural considerations when providing assessment and care. A patient's racial/ethnic background may predispose them to certain primary immunodeficiencies. For example, while it is known that sickle cell disease is more prevalent in Black individuals, systemic racism and bias can often be barriers to diagnosis and treatment (Pokhrel et al., 2023). Navajo Nation and Apache populations have a higher incidence of Athabaskan severe combined immunodeficiency, a secondary combined immunodeficiency linked to the *DCLRE1C* gene (Kniffen, 2023).

Pathophysiology

Primary immunodeficiencies may be caused by mutations to a specific gene. For example, most immunodeficiencies are congenital and have an X-linked (autosomal recessive) inheritance pattern. Mutated genes on the X sex chromosome occur most often in males. Immune cells involved in immunodeficiencies include B and T lymphocytes. B cells transform into plasma cells that produce many antibodies (immunoglobulins) to fight off extracellular microorganisms. If there is a problem with B cells, a person has a high susceptibility to pneumonia, otitis, and other infections caused by extracellular bacteria.

T cells differentiate into helper, cytotoxic, or suppressor T cells. Helper T cells stimulate antibody production. In T-cell deficiencies, antibody production may be compromised to some degree. T cells also fight intracellular microorganisms, such as fungi and viruses, as well as tumors. Microorganisms can infect and tumors may flourish in individuals with HIV, severe combined immunodeficiency, hyper-immunoglobulin M syndrome, and other T-cell deficiencies (Valliant & Qurie, 2022).

Clinical Manifestations

Clinical manifestations of primary immunodeficiencies include infections with opportunistic or unusual organisms, persistent infections despite aggressive treatment, failure to thrive, and a positive family history. Signs of infection will vary depending on the disorder but may include fever, thrush, gingivitis, warts, pus-filled sores, loss of appetite, abdominal pain, liver or spleen enlargement, ear infections, and/or skin infections.

Assessment and Diagnostics

To diagnose an immunodeficiency, nurses should complete a full-body assessment to identify signs and symptoms that could be associated with a disorder. For example, the spleen may be enlarged. In addition, nurses must obtain a family history. The patient should be asked questions about recent infections and their signs, severity, and duration.

A true diagnosis may require genetic testing or blood tests. A complete blood cell count with manual differential can reveal abnormal levels of serum IgG, IgM, and IgA. Antibody responses to vaccines should also be evaluated to detect a humoral immunodeficiency. Genetic testing can assess for gene mutations and whether or not a genetic predisposition exists. Biopsies of samples of the bone marrow or lymph nodes can assess whether immune cells are present.

Prevention

Prevention of primary immunodeficiencies may include family planning to address future pregnancies. Genetic testing can be done in utero to determine the likelihood that the fetus will acquire the disorder. Live vaccines are contraindicated in patients with antibody deficiencies because their bodies may not be able to defend against the weakened form of the virus in the vaccine. Patients should always consult with their provider for the best course of action on an individual basis regarding vaccines. Furthermore, all patients with immunodeficiency should be educated on the measures that can be taken to reduce their risk of infection and illness, such as safe sex practices, antiretroviral drugs, cancer treatment when needed, and blood sugar control (Fernandez, 2023). Infection prevention measures like avoiding public places and masking when in public; frequent, proper hand hygiene; and social distancing are also important for immunocompromised patients.

Collaborative Management

Immunodeficiencies require an interdisciplinary approach. A primary care physician may begin initial testing but generally refers the patient to an immunologist, because affected individuals are at risk for developing severe infections and warrant early detection and medical management. Some individuals are psychologically affected by an immunodeficiency and may need group therapy or individual counseling with a licensed professional. Social work may be needed as well to help affected individuals find resources; treatment and care can become extensive and expensive. Depending on the course of treatment, the patient may need a stem cell transplant, typically performed by a hematologist or oncologist.

To prevent infections in those with immunodeficiencies, the nurse should educate the patient to perform good oral hygiene, avoid eating undercooked food or drinking contaminated water, receive immune globulin treatments if ordered by the physician, and avoid individuals with infections (Fernandez, 2023). Nurses should also educate the patient and family member how to administer therapy at home, if prescribed.

INTERDISCIPLINARY PLAN OF CARE

Plan of Care for Patient with HIV

For a patient with HIV, a comprehensive interdisciplinary plan of care would be crucial to address both medical management and holistic support needs. Infectious disease specialists would lead the medical management, focusing on antiretroviral therapy (ART) initiation or adjustment based on viral load and CD4 count monitoring. They would collaborate with the patient's primary care physician to coordinate overall health maintenance and manage potential drug interactions with other medications.

Other team members may include psychiatrists or psychologists, social workers, nutritionists, pharmacists, and infectious disease nurses. Psychiatrists or psychologists would provide crucial support in addressing mental health aspects, such as depression, anxiety, or adjustment issues related to the HIV diagnosis. They would conduct regular assessments, offer counseling, and monitor the patient's emotional well-being throughout treatment.

Social workers would assess the patient's social support network, financial resources, and housing stability. They would assist in navigating insurance coverage for medications, accessing community resources for HIV support groups, and addressing any legal or employment concerns.

Nutritionists would assess the patient's dietary intake and nutritional status, providing tailored dietary recommendations to support immune function and overall health. They would monitor weight changes and collaborate with the health care team to manage any nutritional deficiencies or gastrointestinal symptoms related to HIV or its treatment.

Pharmacists specializing in HIV care would ensure proper medication adherence, educate the patient on potential

side effects, and monitor for drug interactions. They would also assist in managing medication schedules and addressing any concerns the patient may have about their treatment regimen.

Infectious disease nurses provide ongoing education on HIV transmission prevention, medication adherence strategies, and symptom management. They monitor the patient for any signs of opportunistic infections and collaborate closely with the infectious disease specialist to optimize treatment outcomes.

This interdisciplinary approach ensures that the patient with HIV receives comprehensive care addressing medical, psychological, social, nutritional, and pharmaceutical aspects of their health. It emphasizes the collaborative effort needed to manage HIV effectively and improve the patient's quality of life.

Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

More common than a primary immunodeficiency is a secondary immunodeficiency. Secondary immunodeficiencies generally develop later in life and are caused by another disorder or the use of certain medications, such as chemotherapy or corticosteroids. A well-known example is acquired immunodeficiency syndrome (AIDS), which is caused by the human immunodeficiency virus (HIV) (see 22.2 Viral and Fungal Infections). This section briefly describes HIV to provide insight into how it relates to immunity. Human immunodeficiency virus is a blood-borne virus that may be spread by sexual contact, sharing needles, or accidentally sticking oneself with a needle previously used by an infected individual. Although the risk is low, blood transfusions are also associated with the spread of HIV, though most blood products today are screened for the virus. Maternal-child transmissions may occur through the placenta, during childbirth, or through breast milk.

Pathophysiology

Human immunodeficiency virus binds to and enters host T cells via $CD4^+$ molecules and chemokine receptors. Then, RNA and several HIV-encoded enzymes are released into the host cell. Viral replication requires reverse transcriptase copy HIV RNA to produce viral DNA. This mechanism is altered with this infection and results in frequent mutations and new HIV genotypes. These mutations enable the generation of HIV that refuses control by the immune system. This causes progressive destruction of the cell-mediated immune system and eliminates $CD4^+$ T-helper lymphocytes. Eventually, HIV progresses into AIDS, especially if untreated. Characterized by extremely low levels of helper T cells, AIDS leaves the affected individual at risk for a range of life-threatening infections. The time of progression varies depending on when treatment is started and how aggressive treatment is.

Prevention

Prevention includes safe sex practices, such as using condoms and limiting the number of sexual partners, as well as abstinence from sex or exchange of sexual fluids. The use of pre-exposure prophylaxis, such as tenofovir disoproxil fumarate and emtricitabine, may be necessary for high-risk patients, for example, to reduce their chances of acquiring HIV if they are exposed.

The drug treatment regimen of choice will differ depending on a person's risk factors. For example, if they are at risk from sexual exposure or needles used to inject drugs, the treatment differs. The person-at-risk should undergo frequent testing every three months to ensure they have not become infected. Other preventive measures include avoiding sharing razors, toothbrushes, needles, sex toys, or any article that may be contaminated with blood. Affected individuals should be educated to ask if they will accept blood, plasma, sperm, or organ donation. In addition, they should be encouraged to inform any past, present, or future sexual partners of their diagnosis and to adhere to any treatment regimen that is prescribed.

LINK TO LEARNING

Visit this website from the U.S. Department of Health and Human Services for information about HIV prevention (https://openstax.org/r/77hivprevention) that includes where to get tested, what to expect when starting and continuing treatment, and how to live well with HIV. The initial diagnosis can be overwhelming, so the nurse should consider giving patients time to review the information at home.

Risk Reduction of Transmission to Health-Care Providers

To reduce the risk of transmission of blood-borne infection, take standard precautions with any patient, regardless of their HIV status. This includes hand hygiene, use of personal protective equipment, proper handling of soiled equipment and patient laundry, environmental control, respiratory hygiene, use of resuscitation equipment to avoid contact with oral secretions, and sharps safety. In the event of a needlestick injury, the provider should first wash their hands, then immediately report the incident to their infectious disease representative at their facility or per their policy. When possible, blood samples should be taken from the patient to confirm whether they have a blood-borne infection. Postexposure prophylaxis should also be taken as soon as possible, as long as it is with seventy-two hours of possible HIV exposure (CDC, 2024). This includes taking an antiretroviral medication.

Stages of HIV Infection

There are three stages of HIV infection. These stages vary and are dependent on history, physical examination, laboratory testing, signs and symptoms, and other infections or malignancies. Stage one is an acute HIV infection, stage two is a chronic HIV infection, and stage three is AIDS. A person's CD4 count is a tool used to determine their stage of infection (Cachay, 2023), as shown in Table 29.5. If an affected person's CD4 count increases with therapy, however, the patient does not return to a previous stage.

Stage	Name	CD4 Count
1	Acute HIV	≥500 cells/μL
2	Chronic HIV	200 to 499 cells/μL
3	AIDS	<200 cells/μL

TABLE 29.5 Stages of HIV Infection by CD4 Count

Assessment, Diagnostics, and Clinical Manifestations

In the initial stages of HIV infection, a patient may be asymptomatic or have nonspecific flu-like symptoms, such as fatigue, headache, or rash. In the later stages of HIV, a patient may have more immune system–specific symptoms and sequelae, including the following:

- fever
- fatigue
- malaise
- dermatitis
- sore throat
- lymphadenopathy
- herpes
- vaginal candidiasis
- pneumococcal infections
- decreased appetite
- weight loss
- wasting syndrome
- cancer
- skin changes, such as crusted scabies, disseminated bartonellosis, anal carcinoma, and/or Kaposi sarcomas (Figure 29.6)

FIGURE 29.6 Kaposi sarcoma is often seen in patients with AIDS. Diagnostics include CD4 count, plasma HIV RNA levels, and antibody tests (Cachay, 2023). (credit: "Kaposi's Sarcoma," National Cancer Institute, public domain)

LIFE-STAGE CONTEXT

Life Span Considerations and HIV

The number of adults 50 years of age and older who have HIV or AIDS is rising (HIVinfo, 2024). While some were diagnosed in younger years and are benefiting from treatment, there are others who are undiagnosed. Older adults are less likely to get tested, as the signs and symptoms of HIV can be mistaken for age-related changes, such as pain. Older adults with HIV are more at risk for other comorbidities, including heart disease and diabetes (Roomaney et al., 2022). It is therefore essential to assess patients and obtain a history to determine whether they may need to be tested.

Treatment of HIV Infections

Members of an interdisciplinary team for treating HIV infections may vary but could include primary care providers, pharmacists, psychiatrists or other licensed mental health professionals, social workers, and nurses. Antiretroviral therapy (ART) is a treatment designed to suppress HIV replication to reduce HIV-associated morbidity, restore and preserve immunological function, suppress plasma HIV viral load, and prevent HIV transmission. The nurse should encourage the patient to adhere to treatment regimens as well as educate the patient on their disease status, treatment, and prevention. Social workers may be needed to help patients locate resources, such as finances, housing, or food.

Complementary and alternative medicine (CAM) therapies may include mind-body practices, such as massage or yoga, which may be helpful at lowering blood pressure, pain, and anxiety. Other CAM therapies include exercise and adequate nutrition. Patients may be advised to eliminate food allergens, coffee, trans-fatty foods, and refined foods; eat quality protein sources and foods high in vitamins, antioxidants, and minerals; and drink at least 64 oz of filtered water each day (St. Luke's Hospital, 2016).

Emotional and Ethical Concerns

A diagnosis of HIV or AIDS can be devastating to an individual. They may be unsure of when or how they contracted the disease or from whom. While it is important to contact previous sexual partners so they can be tested and treated, patients may find this task prohibitively embarrassing or even frightening. All health care providers on the team must remember to be sensitive to the patient's feelings, preserve their dignity, and encourage therapeutic communication.

While the emphasis is on the patient, providers may also be confronted with complex emotions and reactions to treating patients with HIV. Nurses may fear exposure or infection and have concerns about the patient's

confidentiality. To assuage these fears, precautions should be meticulously followed to avoid the risk of contracting the infection. The nurse has a duty to inform other members of the interdisciplinary team to ensure they are able to continue providing quality care safely. The nurse should also safeguard and protect the patient's privacy from others.

Despite the stigma that may still surround HIV and AIDS, there are legitimate reasons for infected patients to remain optimistic about their prognosis. The mortality rate of those infected was much higher in the 1980s, during the early years of AIDS. In recent decades, researchers have made significant progress, and patients are living longer today because more treatments are available to control the disease's progression. Some people with HIV can go into remission, meaning that they have such low levels of the virus in their body, they no longer need to take ART to prevent progression (Deeks et al., 2021).

Summary

29.1 Immune Response

- The immune system is an intricate and complex system of specialized cells, organs, and tissues.
- The main functions of the immune system are to recognize and destroy harmful substances or malignant cells, fight and remove disease-causing pathogens, and remove and destroy dead or damaged cells.
- Natural (innate) immunity is nonspecific and present at birth. Acquired (adaptive) immunity develops after birth in response to specific pathogens.
- Assessment of the immune system starts with obtaining the health history of the patient and performing a physical examination.
- Assessment should include the patient's nutritional status and history of immunizations, infections, allergies, surgeries, medications, blood transfusions, and disease and disorder states (such as cancer, chronic illnesses, or autoimmune conditions).
- Lifestyle considerations should be taken into account when assessing the patient's immune system.
- Physical examination should include palpation of the lymph nodes and assessment of the skin and mucous membranes, as well as the neurosensory, cardiovascular, genitourinary, musculoskeletal, gastrointestinal, and respiratory systems.
- Immunosuppressive therapy is designed to stop the immune system from mistakenly attacking healthy cells and may be prescribed for autoimmune diseases or for those undergoing organ or stem cell transplantation.
- There have been several advances in immunology, such as stem cells, genetic engineering, and immunotherapy.

29.2 Autoimmunity

- With autoimmunity, the immune system mistakenly targets the body's own healthy tissues, organs, and cells and attacks itself.
- The exact cause of autoimmunity is unknown, but it is thought to have a genetic predisposition.
- There are over 100 autoimmune conditions, and one in five Americans has been diagnosed with at least one autoimmune disorder.
- Common autoimmune disorders include lupus, type 1 diabetes mellitus, Graves disease, Hashimoto thyroiditis, idiopathic thrombocytopenic purpura, autoimmune hemolytic anemia, rheumatic heart disease, inflammatory bowel disease, celiac disease, irritable bowel syndrome, psoriasis, scleroderma, rheumatoid arthritis, and multiple sclerosis.
- Many autoimmune disorders have a complex disease process and their own unique pathogenesis.

29.3 Immunodeficiency

- Immunodeficiency is the result of malfunctioning of the immune system. This may lead to infections that develop and recur often and are typically more severe and last longer than usual.
- Primary immunodeficiencies generally are present at birth, genetic, and hereditary.
- Primary immunodeficiencies may be caused by mutations in a specific gene. Immune cells involved in primary immunodeficiencies include B and T lymphocytes.
- Clinical manifestations vary and may include fever, thrush, gingivitis, warts, pus-filled sores, loss of appetite, abdominal pain, liver or spleen enlargement, ear infections, or skin infections.
- Secondary immunodeficiencies generally develop later in life and are caused by another disorder or the use of various medications. An example is HIV, which progresses into AIDS.
- HIV destroys the body's cell-mediated immunity, leaving affected individuals at risk for life-threatening infections from other pathogens.
- Symptoms of HIV may include fever, fatigue, malaise, dermatitis, sore throat, lymphadenopathy, herpes, vaginal candidiasis, pneumococcal infections, decreased appetite, various cancers, wasting syndrome, and skin changes such as crusted scabies, disseminated bartonellosis, anal carcinoma, and Kaposi sarcomas. There are three stages of HIV infection: acute, chronic, and AIDS.
- Prevention is key for secondary immunodeficiencies. Standard precautions should be used for all patients. Prevention measures should include safe sex practices, avoiding individuals with illness or infection, and avoiding sharing needles or anything that could be contaminated with blood. Pre- and postexposure

prophylactic measures can be taken. Those with HIV or AIDS are not to donate blood, organs, or plasma.

Key Terms

acquired immunity (also: *adaptive or specific immunity*) immunity that develops after birth
apoptosis normal, controlled process of cell death
autoimmunity disordered state in which the immune system mistakenly targets and attacks the body's own healthy tissues, organs, and cells
cilium (plural: *cilia*) hairlike structure that removes invaders from the respiratory tract
genetic engineering emerging field that uses recombinant deoxyribonucleic acid (DNA) technology to enable the replacement of defective or missing genes
immunity body's specific, protective response to a foreign agent or organism
immunocompetent state of having an efficient immune system that is able to carry out functions properly
immunocompromised state of not having a properly working immune system
immunodeficiency result of the malfunctioning of an underactive or weakened immune system
immunosenescence gradual deterioration of the immune system due to natural aging processes
interferon protein that signals the substances involved in defense against viruses
interleukin protein that serves as the messenger substance of the immune system
multipotent stem cells that can become the cell type they came from
natural immunity (also: *innate* or *nonspecific immunity*) immunity that is present at birth
natural killer cell white blood cell in the innate immune system
neoplasm tumor that may be benign or malignant
phagocytosis engulfing and destroying of foreign bodies by monocytes
pluripotent description of stem cells that can become any other kind of cell
primary immunodeficiency immunodeficiency that is genetic and typically hereditary and present at birth
psychoneuroimmunology study of how the immune system and central nervous system interact
secondary immunodeficiency immunodeficiency that generally develops later in life, caused by another disorder or the use of various medications
stem cell cell in the earliest stage of development, before it has become specialized

Assessments

Review Questions

1. What is a component of the immune system? Select all that apply.
   a. cells
   b. blood vessels
   c. tissues
   d. organs

2. The nurse is educating a new mom on natural versus acquired immunity. What is an example of a statement by the mother that shows the nurse that she understood the teaching?
   a. "Natural immunity develops when my baby receives immunizations."
   b. "Natural immunity is only present before the baby is born."
   c. "Acquired immunity develops after birth."
   d. "Acquired immunity develops only after exposure to an illness."

3. What is a rationale that reflects the importance of the nurse asking a patient about their immunization history?
   a. to assess the patient's immunity against diseases and determine the need for further immunizations
   b. to evaluate the patient's dietary habits and potential nutrient deficiencies
   c. to identify any genetic predispositions to autoimmune diseases
   d. to determine the patient's level of compliance for preventive care

4. What is a statement that correctly contrasts benign tumors and malignant tumors?

a. Benign tumors are noncancerous and can spread to other cells; malignant tumors are cancerous and do not spread to other cells.
b. Benign tumors are cancerous and can spread to other cells; malignant tumors are noncancerous and do not spread to other cells.
c. Benign tumors are cancerous and do not spread to other cells; malignant tumors are noncancerous and can spread to other cells.
d. Benign tumors are noncancerous and do not spread to other cells; malignant tumors are cancerous and can spread to other cells.

5. The nurse is reviewing the chart of a patient who has been prescribed tacrolimus to prevent organ rejection after a transplant. What category of immunosuppressant does this drug fall into?
a. corticosteroid
b. antimetabolite
c. calcineurin inhibitor
d. monoclonal antibody

6. What is the primary characteristic of an autoimmune disease?
a. The immune system fails to recognize foreign pathogens.
b. The immune system attacks the body's own healthy tissues.
c. The immune system is overactive and produces excessive antibodies.
d. The immune system is suppressed and cannot fight infections effectively.

7. What disease is a common autoimmune disorder of the gastrointestinal system?
a. Crohn disease
b. Guillain-Barré syndrome
c. Addison disease
d. Sjögren syndrome

8. A patient has recently been diagnosed with psoriasis, and a nurse is educating them about the disorder. What is an example of a statement by the mother that shows the nurse that she understood the teaching?
a. "Too much collagen is produced and deposited into the skin, leading to buildup."
b. "Uncontrolled keratinocyte proliferation causes plaque buildup."
c. "Inflammation from the joints spreads to the skin."
d. "Contact with allergens leads to inflammation of the skin."

9. Primary immunodeficiencies are passed through what mechanism?
a. IgM
b. B cells
c. antibodies
d. autoantibodies

10. What disease is an example of secondary immunodeficiency?
a. X-linked agammaglobulinemia
b. severe combined immunodeficiency
c. Addison disease
d. AIDS

11. The nurse is reviewing blood results for an HIV patient. The nurse knows that the patient is at stage 2 when the CD4 count is at what level?
a. 534 cells/μL
b. 601 cells/μL
c. 100 cells/μL
d. 250 cells/μL

Check Your Understanding Questions

1. Describe the components of the nursing assessment of the immune system.
2. Describe the pathophysiology of autoimmune disorders.
3. Describe primary immunodeficiencies.

Reflection Questions

1. What information might you need to include when educating a patient on signs and symptoms that might indicate a compromised immune system and thus should be reported?
2. Your patient was just diagnosed with an autoimmune disease. What specific educational points should the nurse prioritize to ensure the patient understands their condition and treatment plan?
3. What information might you need to include when educating a newly diagnosed HIV patient on prevention measures?
4. What information might you include when educating a newly diagnosed HIV patient on the stages of the disease?

What Should the Nurse Do?

Mary, a 45-year-old female, presents to the outpatient clinic with complaints of persistent fatigue, recurrent infections, and unexplained weight loss over the past few months. She reports a medical history significant for rheumatoid arthritis, for which she has been taking immunosuppressive medications for the past two years. On assessment, her vital signs are within normal limits, but she appears fatigued and has a low-grade fever of 99.5°F (37.5°C). Physical examination reveals generalized lymphadenopathy and mild hepatomegaly. Mary expresses concern about her recent health decline and seeks guidance on managing her symptoms.

1. What signs and symptoms in Mary's case might indicate a compromised immune response? How do these cues align with the normal and abnormal physiological findings discussed in the module?
2. What interventions can the nurse implement to address Mary's symptoms and optimize her immune response? How can the nurse support Mary in managing her condition effectively?

Maria, a 35-year-old female, presents to the clinic complaining of fatigue, joint pain, and recurring fevers over the past few months. She reports a medical history of type 1 diabetes diagnosed during childhood. Vital signs reveal a slightly elevated temperature of 100°F (37.8°C), blood pressure within normal limits, and a heart rate of 80 beats per minute. Upon further examination, Maria also mentions experiencing dry eyes and mouth recently. Given her symptoms and medical history, autoimmune disease is suspected.

3. Based on the initial assessment findings and suspected autoimmune etiology, what immediate interventions would you implement to address Maria's symptoms and prevent complications?
4. After initiating treatment for Maria's suspected autoimmune disease, how would you monitor her progress and evaluate the effectiveness of interventions? What indicators would suggest a positive response to treatment?

Lee, a 32-year-old, has been living with HIV for the past five years. They present to the clinic with complaints of chronic fatigue, recurrent respiratory infections, and unexplained weight loss over the past few months. They have been inconsistent with their antiretroviral therapy due to side effects and difficulties maintaining the medication schedule. On assessment, their vital signs are within normal limits, but they appear fatigued and have a low-grade fever of 99.3°F (37.4°C). Physical examination reveals oral thrush and swollen lymph nodes. Lee expresses concerns about their declining health and seeks guidance on managing their condition effectively.

5. What should the nurse do first to address Lee's symptoms and concerns?
6. How should the nurse educate Lee about the differences between HIV and AIDS to enhance their understanding of their condition?

Competency-Based Assessments

1. Prepare a fifteen-minute teaching plan covering the anatomy and physiology of the immune system.

2. Compare and contrast the effects of immunosuppressive medications on the immune system with the physiological findings of a normal immune response. How might an understanding of these concepts influence your patient care decisions?
3. Discuss how recent advances in immunology, such as targeted biologic therapies and the study of the microbiome's role in immune function, can contribute to the understanding and management of a patient's condition.
4. Prepare a graphic organizer that compares and contrasts common autoimmune disorders of the endocrine system.
5. Describe two examples of primary immune deficiency diseases and briefly explain how they affect the immune system.
6. Prepare a bullet point list of risk reduction strategies of HIV transmission for health care workers.
7. Create a pamphlet that the nurse educating a newly diagnosed patient with HIV could use to provide teaching on the need to notify past, present, and future sexual partners of their diagnosis.

CHAPTER 30
Genetics

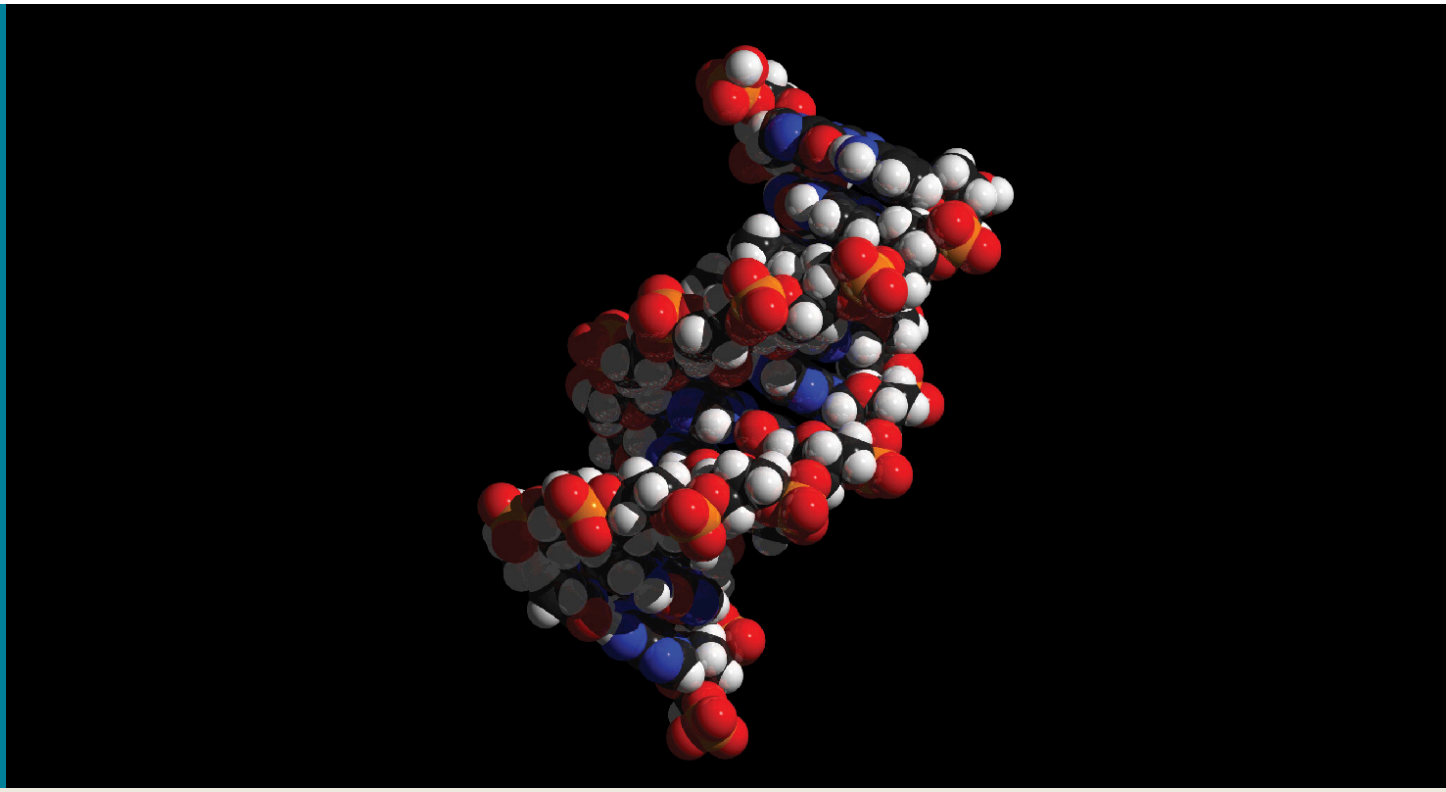

FIGURE 30.1 The deoxyribonucleic acid (DNA) molecule contains the codes for the building blocks of life. (modification of work from *Anatomy and Physiology* 2e. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

CHAPTER OUTLINE

INTRODUCTION Genetics involves the study of how characteristics and traits are passed on from parent to offspring through the transmission of genes. It encompasses the understanding of the structure, function, and behavior of genes, as well as how they interact with each other and the environment to influence organisms' physical and biological traits. These traits include everything from eye color and height to susceptibility to certain diseases and conditions.

In nursing practice, a comprehensive understanding of genetics and genomics is crucial. Genetics focuses on the role of individual genes and their impact on health and disease, whereas genomics involves the study of all of a person's genes, including interactions among genes and between genes and the environment. These fields are integral to comprehending how genetic variations affect patient care, influence disease risk, and determine responses to treatment. This knowledge is essential for nurses to provide personalized care, to educate patients about their genetic risks, and to guide patients in making informed decisions about genetic testing and interventions.

This chapter will provide an in-depth overview of genetics and genomics, including fundamental concepts and the latest advancements in the field. It will explore how genetic and genomic information is used in clinical practice, including risk assessment, diagnostic testing, and the development of individualized care plans. The module will also cover genetic and genomic information's ethical, legal, and social implications, preparing nurses to address

these complex issues with sensitivity and professionalism. By understanding the principles of genetics and genomics, nurses will be better equipped to improve patient outcomes and contribute to the advancement of health care.

30.1 Genetic Disorders

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Differentiate between genetics and genomics
- Identify common chromosomal and genetic conditions
- Consider the nurse's role in the field of genetics
- Discuss the genomic framework's impact on patient care

Many of the leading causes of death in the United States, such as cardiac diseases, cancers, and cerebrovascular disease, include genetic or genomic factors (Khoury, 2024). In fact, nearly all health conditions have some genetic or genomic factors that will affect health throughout the life span.

Increasing recognition of the significance of such factors has implications for health care professionals (HCPs) at all levels. Nurses, who compose the largest group among health care HCPs and who interact with patients at multiple levels, are in a unique position to integrate genetic and genomic concepts into clinical practice areas, including screening and prevention, diagnostics, therapeutic interventions, and evaluation of outcomes. The clinical application of genetic and genomic knowledge has major implications for the entire nursing profession regardless of academic preparation, role, or practice setting.

What Is Genetics?

The field of **genetics** refers to the study of heredity, focused on patterns of inheritance of specific characteristics or traits, including variations of a trait within a population. Composed of deoxyribonucleic acid (DNA) sequences located in an individual's chromosomes, a **gene** is the basic functional unit of heredity found in the nucleus of every cell (Figure 30.2). DNA carries the genetic instructions that determine the development of physical and biologic characteristics. Ribonucleic acid (RNA), a nucleic acid present in all living cells, acts as a messenger carrying instructions from the DNA for controlling the synthesis of proteins. These instructions are coded in four amino acid chemical bases; adenine (A), guanine (G), cytosine (C), and thymine (T), which form a double-stranded helix held together by the hydrogen bonds of the base pairs of A paired with T, and C paired with G (Montgomery, 2021).

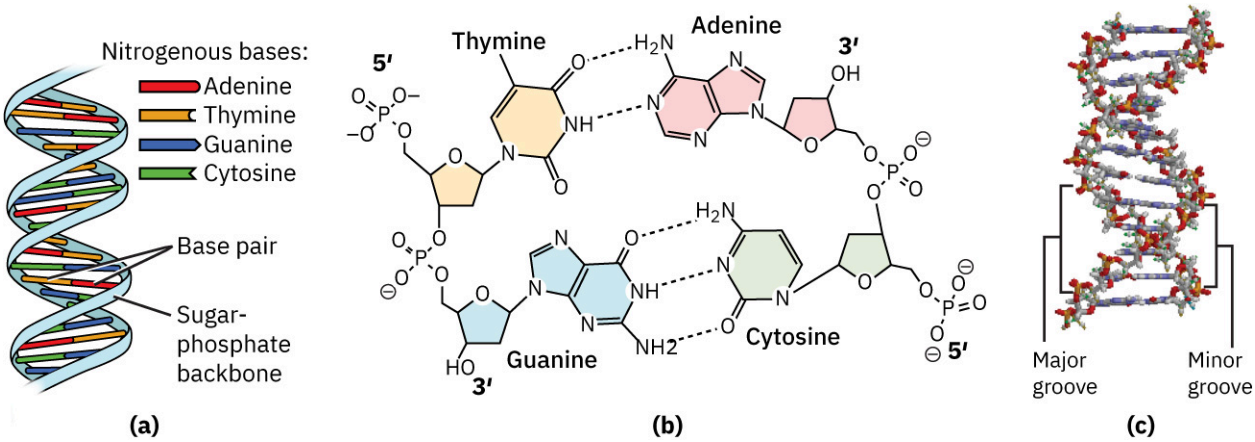

FIGURE 30.2 DNA has (a) a double helix structure and (b) phosphodiester bonds; the dotted lines between thymine and adenine, and between guanine and cytosine, represent hydrogen bonds. (c) The major and minor grooves are binding sites for DNA-binding proteins during processes such as transcription (the copying of ribonucleic acid [RNA] from DNA) and replication. (modification of work from *Biology* 2e. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

The primary focus of genetics DNA research involves the structure and function of single genes as well as possible variations of a gene and its distribution among a population.

Genomics

The study of genes and how they interact with each other and the environment is called **genomics** (National Human Genome Research Institute [NHGRI], 2018). It includes the study of complex diseases such as heart disease, chronic obstructive pulmonary disease (COPD), diabetes, and cancer, disorders typically related more to a combination of environmental and genetic factors than to individual genes. A genomic approach to health care uses knowledge about genetic variation and environmental effects to augment the planning and provision of health care to individuals, families, and the community. This approach reveals opportunities for new diagnostic methods as well as new possible treatment modalities. Let's look at an example of how planning is augmented in a case of familial hypercholesterolemia (FH).

- Background: Familial hypercholesterolemia (FH) is a genetic condition characterized by high cholesterol levels, specifically low-density lipoprotein (LDL) cholesterol, which increases the risk of cardiovascular disease. Early detection and management are crucial to prevent severe health outcomes.
- Genomic approach in planning and provision of care:
  Risk assessment:
  - Genetic testing: Genetic testing can identify mutations in genes such as low-density lipoprotein receptor (LDLR), apolipoprotein B (APOB), and proprotein convertase subtilisin/kexin type 9 (PCSK9), which are known to cause FH. This testing allows for early identification of individuals who are at high risk, even before symptoms appear.
  - Family history: Collecting a detailed family history helps to identify other family members who might be at risk. This information is crucial for planning screening and preventive measures for relatives.

  Personalized care plan:
  - Tailored treatment: Based on genetic test results, a personalized treatment plan can be developed. For instance, individuals with certain genetic mutations may respond better to specific medications such as statins, PCSK9 inhibitors, or other lipid-lowering therapies.
  - Lifestyle modifications: Understanding how genetic variations interact with lifestyle factors allows nurses to provide personalized advice on diet, exercise, and other lifestyle changes to manage cholesterol levels effectively.

  Community and family interventions:
  - Family screening programs: Implementing family-based screening programs ensures that relatives of the affected individual are also tested and monitored. This proactive approach helps in early diagnosis and intervention, potentially reducing the overall burden of cardiovascular disease in the community.
  - Educational initiatives: Nurses can lead educational sessions for families and communities to raise awareness about FH, its genetic basis, and the importance of early detection and management.

  Ongoing monitoring and support:
  - Regular follow-ups: Establishing a schedule for regular follow-ups allows for continuous monitoring of cholesterol levels and adjustment of treatment plans as necessary. This ongoing care is tailored to the individual's genetic profile and response to treatment.

Human Genomic Variation

Although there is a considerable amount of genetic variation among humans, any two people's genomes are about 99.6 percent identical and about 0.4 percent different (NHGRI, 2023). These differences, or genomic variants, are what make individuals unique. External factors such as environment, diet, and lifestyle also contribute to uniqueness. Some genomic variations do not affect genome function, such as eye color, skin color, and height, whereas other variations can influence how a person responds to medications or influence development of certain conditions (NHGRI, 2023).

Genetic Conditions and Chromosomal Differences

A **genetic condition** is any condition caused by a single gene mutation. To take a quick step back, a **mutation** refers to a change in the DNA sequence of an organism's genetic material and can occur spontaneously during DNA replication or as a result of exposure to environmental factors such as radiation, chemicals, or viruses. Mutations can affect a single nucleotide (point mutation), a small segment of DNA, or large sections of chromosomes. Mutations can have various effects on an organism, depending on where they occur in the genome and the specific nature of the mutation. Some mutations may be harmless or have no noticeable effect, whereas others can lead to alterations in protein structure or function, potentially causing genetic disorders, diseases, or changes in an organism's traits.

Sickle cell disease is a genetic condition caused by production of an abnormal type of hemoglobin, called hemoglobin S, which delivers less oxygen to tissues and causes erythrocytes to assume a sickle (or crescent) shape, especially at low oxygen concentrations. These abnormally shaped cells can then become lodged in narrow capillaries because they are unable to fold in on themselves to squeeze through, blocking blood flow to tissues and causing a variety of serious problems including painful joints, delayed growth, and even blindness and cerebrovascular accidents (strokes).

A **chromosome** is a structure made of protein and a single molecule of DNA that carries genetic information in the form of genes. Sometimes a genetic disease is not caused by a mutation in a gene but by the presence of an incorrect structure or number of chromosomes. This is known as a **chromosomal condition**. For example, Down syndrome is caused by the presence of an extra copy of chromosome 21, a condition known as trisomy 21. The most common cause of trisomy 21 is chromosomal nondisjunction during meiosis, or simply an error in the distribution of chromosomes during meiosis. The frequency of nondisjunction events appears to increase with age, so the frequency of bearing a child with Down syndrome increases in females over the age of 36. The age of the male parent matters less because nondisjunction is much less likely to occur in a sperm than in an egg.

Whereas Down syndrome is caused by having three copies of a chromosome, Turner syndrome is caused by women having just one copy of the X chromosome. Women with Turner syndrome are sterile because their sexual organs do not mature.

Genomic Conditions

A disorder that is caused by the loss or gain of DNA material is called a **genomic condition**. Recall that genomics is the study of genes and how they react with each other and the environment. Complex diseases, such as asthma, diabetes mellitus, and heart disease, are characterized by a multifactorial etiology. This means that multiple genes, each with a small effect, interact with environmental and lifestyle factors to influence disease risk (NHGRI, 2018). In contrast, Mendelian diseases are typically caused by mutations in a single gene with a clear pattern of inheritance (dominant, recessive, etc.). For instance:

1. Asthma involves genetic predispositions (e.g., variations in genes related to immune system function) interacting with environmental triggers such as allergens, pollution, and respiratory infections.
2. Diabetes, particularly type 2, is influenced by genetic variants affecting insulin production and glucose metabolism, combined with factors such as diet, physical activity, and higher weight.
3. Heart disease encompasses various genetic components related to cholesterol metabolism, blood pressure regulation, and inflammatory responses, alongside lifestyle factors such as diet, smoking, and exercise.

Nursing Practice and the Genomic Framework

With greater understanding of genetics and genomic science has come a revolutionary reframing of our understanding of human health and disease, recognizing genomics as a central component of health, illness, risk for disease, and response to treatment. As a result, all health care disciplines, including nursing, have developed initiatives to promote the application of genomic knowledge into clinical practice. Nurses are uniquely positioned to incorporate genomic knowledge across all aspects of the health care system, enhancing the provision of health care across the life span, addressing the needs of the individual patient, the family, and the community.

Essential competencies for nursing practice, regardless of role or level of preparation include

- integrating and applying genetic/genomic knowledge;

- demonstrating an understanding of genetics as related to screening, health promotion, and illness prevention;
- obtaining a comprehensive family history and developing a three-generation pedigree (visual representation of a family's health history);
- analyzing findings to identify risk factors;
- identifying those who may benefit from genetic counseling services;
- making appropriate referrals for specialty care; and
- providing patient/family education and support.

Precision Health and Care

Precision health refers to the provision of personalized treatment based on individual needs. There can be a great deal of variability in the way different individuals respond to the same medication. Therapeutic response depends on a complex series of physiologic reactions; the medication is initially absorbed and distributed to the target tissue, where it is further metabolized, then finally excreted. Genetic variables have been found to account for 15 to 30 percent of the variability in drug response among different individuals. This percentage means that genetics explains a substantial portion of why people respond differently to the same drug. Luckily, genetic variables are not the sole factor (Anunobi, 2024).

Pharmacogenetics and Pharmacogenomics

Pharmacogenetics and *pharmacogenomics* are two very new terms in the realm of health care, which overall refer to an area of research examining how genes affect the response to medications. Although with similar meanings they may be seen used interchangeably, each has a specific distinguishing factor. The study of the variability of therapeutic responses to medications, as influenced by variations in single genes, is called **pharmacogenetics**. It examines factors such as specific drug receptors, and how drugs are metabolized and transported in the body, with the goal of developing individualized treatment based on the optimal choice of drug at the most effective dose.

The study of variations in multiple genes as associated with variable drug responses, rather than in single genes, is called **pharmacogenomics**. Pharmacogenomic studies investigate genetic variation among large population groups to ascertain differences in therapeutic responses for differing ethnic groups (NHGRI, 2018).

30.2 Patterns of Inheritance and Mutations

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Explain the pattern of inheritance
- Differentiate between autosomal and recessive patterns of inheritance
- Discuss the pathophysiology of genetic mutations
- Explain the varying types of genetic mutations
- Discuss the nurse's role in providing patient support through genetic diagnoses and care

Our contemporary understanding of genetics rests on the work of a nineteenth-century monk. Working in the mid-1800s, long before anyone knew about genes or chromosomes, Gregor Mendel discovered that garden peas transmit their physical characteristics to subsequent generations in a discrete and predictable fashion. When he mated, or crossed, two pure-breeding pea plants that differed by a certain characteristic, the first-generation offspring all looked like one of the parents. For instance, when he crossed tall and dwarf pure-breeding pea plants, all of the offspring were tall. Mendel called tallness dominant because it was expressed in offspring when it was present in a purebred parent. He called dwarfism recessive because it was masked in the offspring if one of the purebred parents possessed the dominant characteristic.

This section will explore the pattern of inheritance, as well as the different types and pathophysiology of genetic mutations, and how that translates into providing nursing care.

From Genotype to Phenotype

Each human body cell has a full complement of DNA stored in twenty-three pairs of chromosomes. Figure 30.3 shows the pairs in a systematic arrangement called a **karyotype**. Among these is one pair of chromosomes, called the **sex chromosomes**, that determines the sex of the individual (XX in females, XY in males). The remaining twenty-two chromosome pairs are called **autosomal chromosomes**. Each of these chromosomes carries hundreds or even

thousands of genes, each of which codes for the assembly of a particular protein—that is, genes are "expressed" as proteins. An individual's complete genetic makeup is referred to as their **genotype**. The characteristics that the genes express, whether they are physical, behavioral, or biochemical, are a person's **phenotype**.

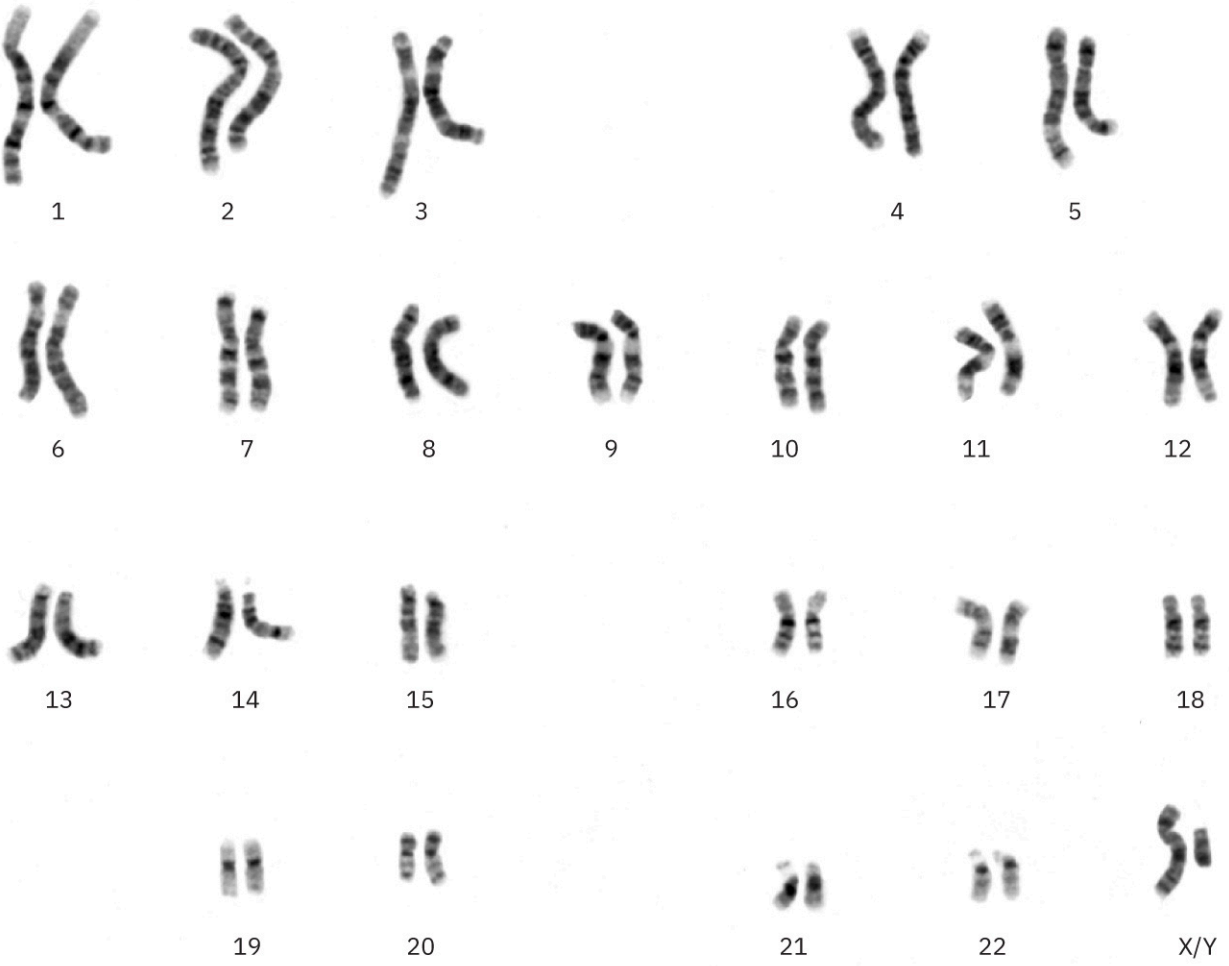

FIGURE 30.3 Each pair of chromosomes contains hundreds to thousands of genes. The banding patterns are nearly identical for the two chromosomes within each pair, indicating the same organization of genes. As is visible in this karyotype, the only exception to this is the XY sex chromosome pair in males. (credit: National Human Genome Research Institute, Public Domain)

In genetics and reproduction, *parent* is often used to describe the individual organisms that contribute genetic material to offspring, usually in the form of gamete, or sex, cells and their chromosomes. The concept of a genetic parent is distinct from social and legal concepts of parenthood, and may differ from those whom people consider their parents.

Individuals inherit one chromosome in each pair—a full complement of twenty-three—from each parent. This occurs when the sperm and oocyte combine at the moment of conception. Homologous chromosomes—those that make up a complementary pair—have genes for the same characteristics in the same location on the chromosome. Because one copy of a gene, an **allele**, is inherited from each parent, the alleles in these complementary pairs may vary. Take for example an allele that encodes for dimples. A child may inherit the allele encoding for dimples on the chromosome from the one parent and the allele that encodes for smooth skin (no dimples) on the chromosome from the other parent.

Although a person can have two identical alleles for a single gene (a **homozygous** state), it is also possible for a person to have two different alleles (a **heterozygous** state). The two alleles can interact in several different ways. The expression of an allele can be dominant, for which the activity of this gene will mask the expression of a nondominant, or recessive, allele. Sometimes dominance is complete; at other times, it is incomplete. In some

cases, both alleles are expressed at the same time in a form of expression known as codominance.

In the simplest scenario, a single pair of genes will determine a single heritable characteristic. However, it is quite common for multiple genes to interact to confer a feature. For instance, eight or more genes—each with their own alleles—determine eye color in humans. Moreover, although any one person can only have two alleles corresponding to a given gene, more than two alleles commonly exist in a population. This phenomenon is called multiple alleles. For example, there are three different alleles that encode ABO blood type; these are designated I^A, I^B, and i.

More than 100 years of theoretical and experimental genetics studies, and the more recent sequencing and annotation of the human genome, have helped scientists to develop a better understanding of how an individual's genotype is expressed as their phenotype. This body of knowledge can help scientists and medical professionals to predict, or at least estimate, some of the features that an offspring will inherit by examining the genotypes or phenotypes of the parents. One important application of this knowledge is to identify an individual's risk for certain heritable genetic disorders. However, most diseases have a multigenic pattern of inheritance and can also be affected by the environment, so examining the genotypes or phenotypes of a person's parents will provide only limited information about the risk of inheriting a disease. Only for a handful of single-gene disorders can genetic testing allow clinicians to calculate the probability with which a child born to the two parents tested may inherit a specific disease.

Pattern of Inheritance

As a result of a series of studies of the heredity of traits among pea plants, Gregor Mendel observed "units of inheritance," now referred to as genes. Mendel's research resulted in the development of the principles of inheritance, the "laws" defining how genetic traits are inherited and expressed (Table 30.1).

Law of Inheritance	Description
Law of segregation	Each inherited trait is defined by a gene pair. Offspring inherit one gene from each parent.
Law of independent assortment	Genes for different traits are sorted separately from one another. Inheritance of any specific trait is not dependent on the presence of any other.
Law of dominance	When there are alternate forms of a gene in a pair, offspring will express the dominant trait.

TABLE 30.1 Mendel's Principles of Inheritance

The pattern of inheritance describes the way certain conditions are passed from parent to offspring through a single gene. These include autosomal, X-linked, mitochondrial, Y-linked, and codominant patterns.

Autosomal Dominant

When the dominant allele is located on one of the twenty-two pairs of autosomes (non-sex chromosomes), we refer to its inheritance pattern as **autosomal dominant**. An example of an autosomal dominant disorder is neurofibromatosis type I, a disease that induces tumor formation within the nervous system that leads to skin and skeletal deformities. Consider a two individuals in a relationship in which one parent is heterozygous for this disorder (and who therefore has neurofibromatosis), *Nn*, and one parent is homozygous for the normal gene, *nn*. The heterozygous parent would have a 50 percent chance of passing the dominant allele for this disorder to their offspring, and the homozygous parent would always pass the normal allele. Therefore, four possible offspring genotypes are equally likely to occur: *Nn, Nn, nn*, and *nn*. That is, every child of this couple would have a 50 percent chance of inheriting neurofibromatosis.

Autosomal Recessive

When a genetic disorder is inherited in an **autosomal recessive** pattern, the disorder corresponds to the recessive phenotype. Heterozygous individuals will not display symptoms of this disorder, because their unaffected gene will

compensate. Such an individual is called a **carrier**. Carriers for an autosomal recessive disorder may never know their genotype unless they have a child with the disorder.

An example of an autosomal recessive disorder is cystic fibrosis (CF). CF is characterized by the chronic accumulation of a thick, tenacious mucus in the lungs and digestive tract. Decades ago, children with CF rarely lived to adulthood. With advances in medical technology, the average life span in developed countries has increased into middle adulthood. CF is a relatively common disorder that occurs in approximately 30,000 people in the United States. A child born to two CF carriers would have a 25 percent chance of inheriting the disease. This is the same 3:1 dominant: recessive ratio that Mendel observed in his pea plants, which applies here.

On the other hand, a child born to a CF carrier and someone with two unaffected alleles would have a 0 percent probability of inheriting CF but would have a 50 percent chance of being a carrier. Other examples of autosome recessive genetic illnesses include the blood disorder sickle cell disease, the fatal neurological disorder Tay-Sachs disease, and the metabolic disorder phenylketonuria.

X-linked Dominant or Recessive Inheritance

An **X-linked transmission** pattern of inheritance involves genes located on the X chromosome of the twenty-third pair. Recall that a male has one X and one Y chromosome. When a male parent transmits a Y chromosome, the child is male, and when a male parent transmits an X chromosome, the child is female. A female can transmit only an X chromosome, as both her sex chromosomes are X chromosomes.

X-linked Dominant

When an abnormal allele for a gene that occurs on the X chromosome is dominant over the normal allele, the pattern is described as **X-linked dominant**. This is the case with vitamin D–resistant rickets: an affected male would pass the disease gene to all of the female offspring, but none of the male offspring, because the male transmits only the Y chromosome to male offspring. If it is the female parent who is affected, all of the offspring—male or female—would have a 50 percent chance of inheriting the disorder because the female parent can only pass an X chromosome on to children. For an affected female, the inheritance pattern would be identical to that of an autosomal dominant inheritance pattern in which one parent is heterozygous and the other is homozygous for the normal gene (Figure 30.4).

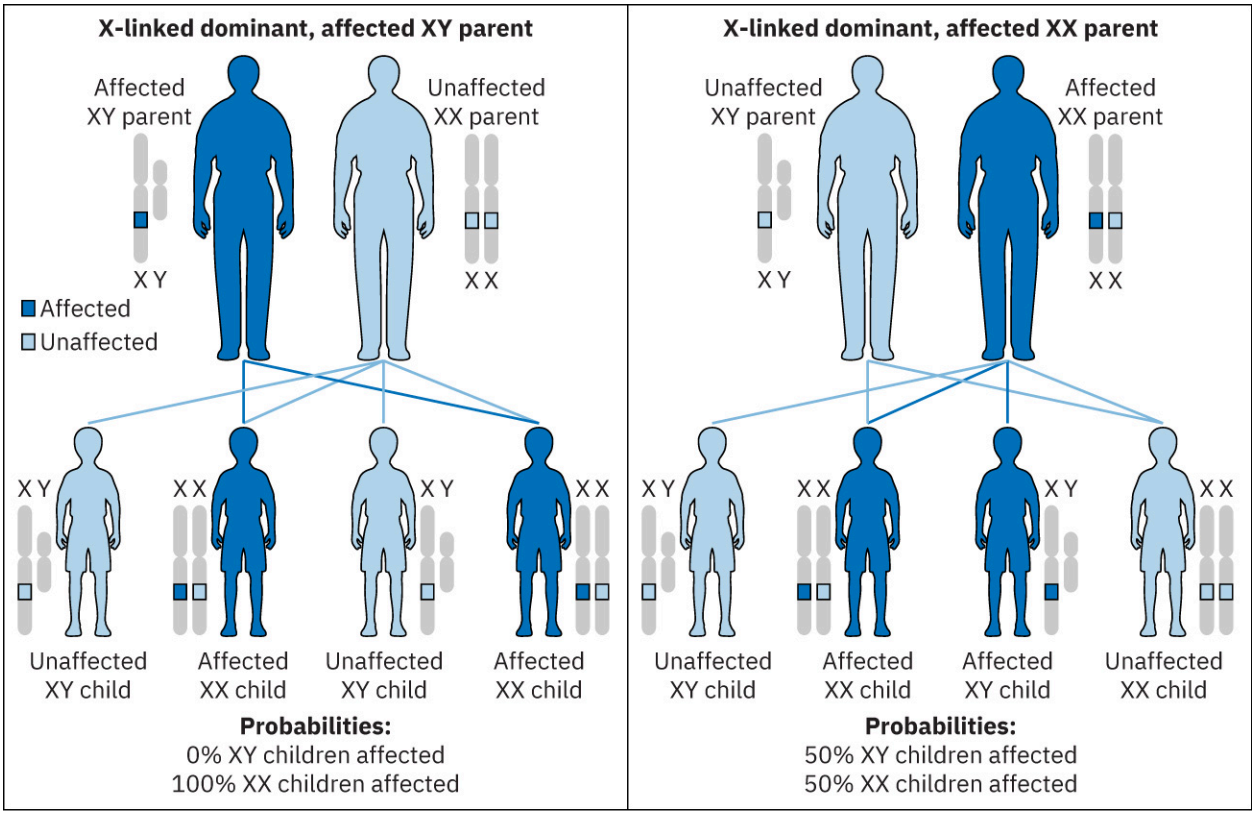

FIGURE 30.4 X-linked dominant inheritance patterns differ depending on which parent is affected with the disease. (a) When the XY parent is affected, 100% of XX children are also affected. (b) When the XX parent is affected, all children have a 50% chance of being affected. (credit: modification of work from U.S. National Library of Medicine, Public Domain)

X-Linked Recessive

X-linked recessive inheritance is much more common because females can be carriers of the disease yet still have a normal phenotype. Diseases transmitted by X-linked recessive inheritance include color blindness, the blood-clotting disorder hemophilia, and some forms of muscular dystrophy. For an example of X-linked recessive inheritance, consider parents in which the female is an unaffected carrier and the male is normal. None of the female offspring would have the disease because they receive a normal gene from their male parent. However, they have a 50 percent chance of receiving the disease gene from their female parent and becoming a carrier. In contrast, 50 percent of the male offspring would be affected (Figure 30.5).

With X-linked recessive diseases, males either have the disease or are genotypically normal—they cannot be carriers. Females, however, can be genotypically normal, a carrier who is phenotypically normal, or affected with the disease. A female can inherit the gene for an X-linked recessive illness when the female parent is a carrier or affected, or the male parent is affected. Female offspring will be affected by the disease only if they inherit an X-linked recessive gene from both parents. As you can imagine, X-linked recessive disorders affect many more males than females. For example, color blindness affects at least one in twenty males, but only about one in 400 females.

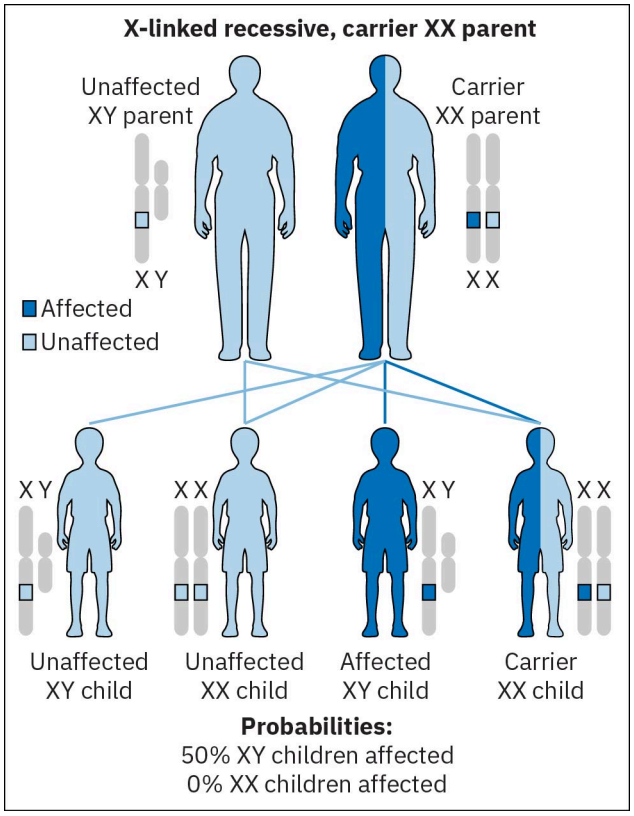

FIGURE 30.5 Given two parents in which the male is normal and the female is a carrier of an X-linked recessive disorder, a male offspring would have a 50 percent probability of being affected with the disorder, whereas female offspring would either be carriers or entirely unaffected. (credit: modification of work from U.S. National Library of Medicine, Public Domain)

Mitochondrial

A mitochondrion (plural = mitochondria) is a membranous, bean-shaped organelle that is the energy-conversion factory of the cell. The pattern of **mitochondrial inheritance** is transmitted only by mothers because mitochondrial genes are only inherited from the mother. Both male and female offspring can be affected, but only mothers can pass the pattern on to their children, whether or not they have any signs or symptoms. An example of mitochondrial inheritance is Leber hereditary optic neuropathy (LHON). LHON an inherited form of central vision loss that usually begins during the teens or twenties.

Y-linked Inheritance

A pattern of inheritance that comes from one of the Y chromosomes of the father is called **Y-linked inheritance**. Because Y chromosomes are only present in males, expression and transmission is exclusively from father to son (MedlinePlus, 2021). Examples include Y chromosome infertility, hypertrichosis of the ears (hairy ears), and retinitis pigmentosa.

Incomplete Dominance

Not all genetic disorders are inherited in a dominant–recessive pattern. In incomplete dominance, the offspring express a heterozygous phenotype that is intermediate between one parent's homozygous dominant trait and the other parent's homozygous recessive trait. An example of this can be seen in snapdragons when red-flowered plants and white-flowered plants are crossed to produce pink-flowered plants. In humans, incomplete dominance occurs with one of the genes for hair texture. When one parent passes a curly hair allele (the incompletely dominant allele) and the other parent passes a straight-hair allele, the effect on the offspring will be intermediate, resulting in hair that is wavy.

Codominant Inheritance

The equal, distinct, and simultaneous expression of both parents' different alleles is called **codominance**. A classic example of codominance in humans is ABO blood type. People are blood type A if they have an allele for an enzyme that facilitates the production of surface antigen A on their erythrocytes. This allele is designated I^A. In the same manner, people are blood type B if they express an enzyme for the production of surface antigen B. People who have

alleles for both enzymes (I^A and I^B) produce both surface antigens A and B. As a result, they are blood type AB. Because the effect of both alleles (or enzymes) is observed, we say that the I^A and I^B alleles are codominant. There is also a third allele that determines blood type. This allele (*i*) produces a nonfunctional enzyme. People who have two *i* alleles do not produce either A or B surface antigens: they have type O blood. If a person has I^A and *i* alleles, the person will have blood type A. Notice that it does not make any difference whether a person has two I^A alleles or one I^A and one *i* allele. In both cases, the person is blood type A. Because I^A masks *i*, we say that I^A is dominant to *i*. See Table 30.2 for a summary of the expression of blood type.

Blood Type	Genotype	Pattern of Inheritance
A	I^AI^A or I^Ai	I^A is dominant to *i*
B	I^BI^B or I^Bi	I^B is dominant to *i*
AB	I^AI^B	I^A is codominant to I^B
O	*ii*	Two recessive alleles

TABLE 30.2 Expression of Blood Types

Lethal Alleles

Certain combinations of alleles can be lethal, meaning they prevent the individual from developing in utero, or cause a shortened life span. In **recessive lethal inheritance** patterns, a child who is born to two heterozygous (carrier) parents and who inherited the faulty allele from both would not survive. An example of this is Tay-Sachs, a fatal disorder of the nervous system. In this disorder, parents with one copy of the allele for the disorder are carriers. If they both transmit their abnormal allele, their offspring will develop the disease and will die in childhood, usually before age 5.

In **dominant lethal inheritance** patterns, neither heterozygotes nor homozygotes survive; therefore, they are much rarer. Of course, dominant lethal alleles that arise naturally through mutation and cause miscarriages or stillbirths are never transmitted to subsequent generations. However, some dominant lethal alleles, such as the allele for Huntington disease, cause a shortened life span but may not be identified until after the person reaches reproductive age and has children. Huntington disease causes irreversible nerve cell degeneration and death in 100 percent of affected individuals, but it may not be expressed until the individual reaches middle age. In this way, dominant lethal alleles can be maintained in the human population. Individuals with a family history of Huntington disease are typically offered genetic counseling, which can help them decide whether or not they wish to be tested for the faulty gene.

Genetic Mutations

Mutations can arise spontaneously from errors during DNA replication, or they can result from environmental insults such as radiation, certain viruses, or exposure to tobacco smoke or other toxic chemicals. Because genes encode for the assembly of proteins, a mutation in the nucleotide sequence of a gene can change the amino acid sequence and, consequently, a protein's structure and function. Spontaneous mutations occurring during meiosis (creation of sperm and egg cells) are thought to account for many spontaneous abortions (miscarriages).

Beneficial and Harmful Mutations

Beneficial mutations help an organism to adapt to changes in the environment. As beneficial mutations increase an organism's chances of survival and thus increase the chance to reproduce, they are likely to become more prevalent over time. In recent years, scientific interest has been piqued by the discovery of a few individuals from northern Europe who are resistant to HIV infection. In 1998, American geneticist Stephen J. O'Brien at the National Institutes of Health (NIH) and colleagues published the results of their genetic analysis of more than four thousand individuals. These results indicated that many individuals of Eurasian descent (up to 14 percent in some ethnic groups) have a deletion mutation, called CCR5-delta 32, in the gene encoding CCR5 (O'Brien & Nelson, 2004). CCR5 is a coreceptor found on the surface of T cells that is necessary for many strains of the virus to enter the host cell. The mutation leads to the production of a receptor to which HIV cannot effectively bind and thus blocks viral entry.

People homozygous for this mutation have greatly reduced susceptibility to HIV infection, and those who are heterozygous have some protection from infection as well. Other examples include mutations that serve as protection against developing heart disease or diabetes, regardless of factors such as tobacco use or obesity.

In contrast, harmful mutations may result in harmful genetic disorders, such as cystic fibrosis, or a predisposition to develop cancer. Cancer is associated with mutations affecting genes that regulate the cell cycle during two main phases of this cycle, interphase and mitosis, allowing abnormal cells to proliferate into masses of cells. It is thought that a random change in DNA is more likely to result in a protein that does not function normally, or may not function at all, leading to a harmful effect (Mercadante & Kasi, 2023).

Types of Genetic Mutations

In genetic mutations, a change in the DNA sequence is conferred to mRNA through transcription, and may lead to an altered amino acid sequence in a protein on translation. Because proteins carry out the vast majority of cellular functions, a change in amino acid sequence in a protein may lead to an altered phenotype for the cell and organism. Mutations can be categorized in several ways. One that results from extraneous exposure is an **induced mutation**, and one that occurs due to processes within the body is a **spontaneous mutation**. Three major types of mutation are base substitutions, deletions, and insertions.

A base substitution, or **point mutation**, is when a single nucleotide in a DNA sequence is substituted by another nucleotide. Different types of point mutations include silent mutation, missense mutations, and nonsense mutations (Table 30.3).

Type of Mutation	Definition	Example
Silent mutation	One single nucleotide in a DNA sequence is substituted by another, but has *no effect* on the codon, amino acid sequence, or protein produced.	A DNA sequence is mutated from AGC to AGA, changing corresponding RNA from UCG to UCU. Because both codons translate to the same amino acid, the protein created remains the same.
Missense mutation	One single nucleotide in a DNA sequence is substituted by another. This changes the codon to encode for a different amino acid sequence that *may or may not* alter the protein produced.	In sickle cell disease, a single substitution in the beta-hemoglobin gene causes an alteration in the amino acid sequence and the protein produced, affecting the shape of red blood cells.
Nonsense mutation	One single nucleotide in a DNA sequence is substituted by another. This converts a codon encoding an amino acid into a stop codon (a nonsense codon), resulting in the synthesis of a protein that is typically not functional.	A nonsense mutation occurring in the gene that encodes the CFCR protein can lead to cystic fibrosis.

TABLE 30.3 Types of Point Mutations

Because codons are triplets of nucleotides, insertions or deletions in groups of three nucleotides may lead to the insertion or deletion of one or more amino acids and may not cause significant effects on the resulting protein's functionality. However, a **frameshift mutation**, caused by insertions or deletions of a number of nucleotides that are not a multiple of three are extremely problematic because they cause a shift in the reading frame. Because ribosomes read the mRNA in triplet codons, frameshift mutations can change every amino acid after the point of the mutation. The new reading frame may also include a stop codon before the end of the coding sequence. Consequently, proteins made from genes containing frameshift mutations are nearly always nonfunctional.

An example of a frameshift mutation is fragile X syndrome, where about two hundred CGC nucleotide repeats are inserted to the *FMR1* gene, making it nonfunctional. Another example is Prader-Willi syndrome, which is caused by the deletion of a portion of chromosome 15.

Germline Mutation

A **germline mutation** originates in the parent's reproductive cells (eggs or sperm) and is generally passed into every cell of the offspring's body. Germline mutation is implicated in the occurrence of genetically inherited predispositions for cancer. An example is Lynch syndrome, which is an inherited syndrome caused my germline mutations of the *MLH1* and *MSH2* genes; it is associated with colorectal cancer (Momma et al., 2019).

Somatic Mutation

A **somatic mutation** is any mutation that arises in cells at some point after fertilization and does not involve the germline. Somatic mutations are a normal part of the aging process, occurring throughout the life cycle. They may occur as spontaneous mutations or may be induced by environmental exposures, such as to ultraviolet radiation or toxic chemicals. Somatic mutations are associated with triggering the formation of cancer by affecting genes that have the potential to cause cancer, tumor-suppressor genes, and DNA repair mechanisms, therefore allowing tumor growth and survival (Miles & Tadi, 2023).

Nursing Practice Considerations

Competencies for nursing practice include nursing assessment and analysis of findings to identify risk factors. Steps in risk assessment can be summarized using the acronym RISK, beginning with the primary care nurse, as follows:

- Thoroughly assess collected data related to personal and three-generation family histories, including any related ancillary or laboratory information along with findings of the physical exam.
- Identify data to determine elements of risk.
  - Known genetic disorder in family
    - two affected immediate relatives (mother, father, siblings)
    - three or more affected parental relatives (grandparents, parents' siblings)
    - risk factors on both sides of the pedigree
  - Early onset of disease (< 50–60 years old)
    - breast, ovarian, endometrial cancers
    - colon cancer
    - prostate cancer
    - coronary artery disease
    - type 2 diabetes
    - dementia
  - Sudden unexpected cardiac death
  - Ethnic predisposition
    - Black and African American—sickle cell disease
    - Ashkenazi Jewish—Tay-Sachs disease
    - Southeast Asian—alpha thalassemia
- Select the level of probable risk of occurrence.
  - Average population risk
  - Moderate risk
  - High risk
- Keep the patient informed.
  - Risk communication; likelihood of disease occurrence
  - Management strategies
    - improve health
    - reduce risk
  - Referrals
    - genetic specialist

(Montgomery, 2021)

Patient Resources and Education

On completion and review of the assessment, results should be shared and appropriate referrals provided. If a risk for an inherited disorder is identified, referrals may include genetic counseling and/or genetic testing. A genetic counselor will provide information about the genetic disorder of concern and discuss genetic testing and

implications of positive results. Genetic testing may be used to determine whether there is a mutation present that may not occur until later in life, such as those related to *MLH1* mutation. It can assist in identifying measures that may reduce the risk of disorder occurrence, strategies for management of care, and appropriate therapeutic interventions (Montgomery, 2021).

30.3 Testing and Detection

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Identify parameters for genetic screening and testing
- Discuss legal implications for genetic screening and testing
- Review ethical and social concerns for genetic screening and testing

Genetic testing began in the 1950s when scientists discovered that the cause of Down syndrome was an additional copy of chromosome 21 (Snedden, 1999). In the 1960s, newborn screening for phenylketonuria was developed (National Association for Rare Disorders, 2021). Since then, genetic testing has evolved to be routine in identifying and treating diseases, and in preventative medicine. Nurses today encounter genetic testing in the inpatient, outpatient, and community settings. This section will describe parameters used for genetic testing and screening, as well as legal, ethical, and social considerations the nurse may encounter.

Genetic Testing

The process of **genetic testing** identifies mutations in a person's DNA, and it can provide guidance in the type of medical care a person receives. Reasons a person may have genetic testing include

- learning if a person has a genetic condition inherited by their parents;
- diagnosing a genetic condition based on signs and symptoms;
- discovering if a person has a genetic condition they may pass on to their children; and
- informing cancer screening or treatment.

Types of genetic testing include single-gene testing, panel testing, and large-scale genetic testing. Single-gene testing looks for variation in a specific gene and is often done when looking for a specific syndrome or condition based on symptoms, such as sickle cell disease. Panel testing evaluates a group of genes for variation, when the provider is evaluating nonspecific signs or symptoms, such as poor muscle tone. Large-scale genetic testing can be done to look at the entire DNA, all genes in the DNA, or genes related to medical conditions. This is done in people with complicated medical histories or for research purposes (Centers for Disease Control and Prevention, 2022).

Population Screening Tests

The process of **genetic screening** evaluates a person's risk of developing a genetic condition. The process of **population screening** refers to large-scale screening programs offering the general population testing for genomic disorders, such as hereditary breast and ovarian syndrome, Lynch syndrome, and familial hypercholesterolemia, that may be prevented or effectively mitigated with early detection.

Screening may be focused on identifying the presence of genetic mutations that may cause disease in the individual or that may be transferred to offspring. An example of the first type of screening is seen in the United States with newborn screenings for genetic disorders within forty-eight hours of birth. Genetic carrier screening identifies the risk for having a child with inherited disorders, such as cystic fibrosis or Tay-Sachs disease, and promotes informed decision-making regarding reproductive options (Montgomery, 2021).

Principles guiding genetic screening programs include characteristics of the disease, the test, and the health care system resources. The condition should be relatively common and considered a serious disorder to ensure that benefits warrant the costs. There should be an acceptable readily available treatment. The test should be valid and reliable, easy to perform, inexpensive, and acceptable to the population. The health care system must have the resources needed to offer further diagnosis and subsequent treatment of the disorder. A means for effective and efficient communication of results is a necessary component as well (Montgomery, 2021).

Diagnostic Genetic Testing

The purpose of **diagnostic genetic testing** is to confirm or rule out a specific genetic disorder using a DNA-based

test. Linkage analysis determines the presence of a chromosome associated with a specific disease gene, considered an indirect genetic diagnosis. The test requires typing of numerous family members, and the possibility of recombination is a source of diagnostic errors. Direct diagnosis, where the specific mutation causing the disease is detected, is the most commonly used approach for diagnosis. This test uses a sample of the individual's DNA and does not require additional family information. Although testing identifies the presence of a specific causative gene, it often does not determine disease severity or predict the age of onset. Examples include testing for cystic fibrosis and Huntington disease.

Nurse's Role in Testing and Screening for Adult-Onset Conditions

Nurses serve as educators, providing patients with comprehensive information about genetic testing, including its purpose, potential benefits, limitations, and implications for health management, as well as preparing and assisting patients during the testing process. They ensure that patients clearly understand the testing process, its potential outcomes, and any associated risks or ethical considerations. After testing, nurses are responsible for following up with patients to communicate test results. This may involve interpreting the results in collaboration with the health-care team, explaining the implications for the patient's health, and addressing any questions or concerns that arise. (Montgomery, 2021).

Health Assessment

The first step for assessing genetic/genomic risk involves collection of data through the personal and family health history, physical examination, and review of additional information, such as laboratory or radiology reports. Critical personal information includes race/ethnicity, age, significant therapies, present and past medications, medical and surgical history, history of any genetic testing, and reproductive history. If the personal history involves a cancer diagnosis, information to be obtained includes the type of cancer, age of onset, pathology reports, exposure to carcinogens, and medical or surgical treatment regimes. In the presence of high risk for cancer, information about any chemoprevention therapy or risk-reducing surgery should be included. Information about behavioral factors such as tobacco use, drug or alcohol use, and sexual history, and environmental factors such as radiation or toxin exposure, should also be addressed. The physical exam should include observations regarding anomalies or dysmorphic characteristics that may be associated with a genetic disorder (Montgomery, 2021).

The family history records the health and disease concerns experienced within the family over three generations. In conjunction with the personal history, the family history further enhances risk assessment, augments diagnosis, helps establish rapport to promote prevention and disease management, and facilitates effective decision-making. A three-generation pedigree can serve as a visual representation, revealing relationships and patterns that may indicate inherited disorders (Montgomery, 2021).

Upon completion of collection, the data should be reviewed to identify "red flags," factors that may be associated with risk for an inherited disease or a familial predisposition. This step facilitates identification of at-risk individuals, so that interventions to reduce risk can be implemented, as well as establishing the need for genetic testing or for preventative treatment regimes. Genetic red flags include known genetic disorders, sudden unexpected cardiac death, early onset of disease (under age 50), and ethnic predisposition for a genetic disorder (Montgomery, 2021).

Based on the red flags, the level of risk probability and empiric risk can be determined. The likelihood that an individual carries a genetic mutation predisposing the person for developing disease is their **risk probability**. The chance for the occurrence of a disease based on personal and family history and other data is the **empiric risk**. Thorough review of the data is important for determining whether the patient is at population, moderate, or high risk.

If the history reveals red flags related to risk for inherited disorders, a referral for genetic counseling is indicated. Provide the patient and family with information about testing, the types of tests, benefits or risks, and the reasons testing is needed. Many people may have a level of risk for noninherited disorders based on behavioral factors or environmental exposures. Such concerns warrant discussion of risk-reduction interventions such as preventative strategies, lifestyle modifications, and measures for early detection. As there is an element of risk for any individual regardless of history or physical exam findings, measure to reduce risks should be a routine component of practice, addressing topics such as healthy lifestyle behaviors, age-appropriate immunizations, smoking cessation or avoidance, and seat belt use, as well as promoting screening for early detection (e.g., colonoscopy, mammography) (Montgomery, 2021).

Ethical, Legal, and Social Concerns

The **ethical, legal, and social implications (ELSI)** associated with advances in genetic and genomic knowledge include informed decision-making, informed consent for genetic testing, consent related to genetic/genomic research, privacy and confidentiality, and discrimination prevention (Soleymani-Lehmann et al., 2022). The term ELSI has its origins in the Human Genome Project, and it has generated complex ethical and legal issues related to health care. Nurses are called upon to integrate genetic and genomic knowledge and principles into the scope of practice, including an understanding of ELSI concerns (Soleymani-Lehmann et al., 2022).

LINK TO LEARNING

The Human Genome Project (https://openstax.org/r/77GenomeProj) was a monumental international scientific research endeavor that aimed to unravel the mysteries of human DNA. It sought to identify, map, and sequence all the genes of the human genome, providing a comprehensive understanding of our genetic makeup from both a physical and functional perspective.

Ethical and Legal Considerations

Informed decision-making centers on assuring that individuals clearly understand the nature, risks, and benefits of any procedure and have given consent freely without any coercion. Nurses will be increasingly involved in discussing genetics-related issues involving informed decision-making, especially in the areas of gathering family history and obtaining medical information from patients and their family members. The nurse discusses the need for gathering family history data to obtain the patient's verbal consent for the process. Similarly, it may be necessary to obtain information directly from other family members, or from medical records, necessitating discussion with the family members and obtaining written consent.

Genetic testing procedures also require assuring that the patient clearly understands the purposes, benefits, and risks involved with testing, facilitating informed decision-making and consent (Soleymani-Lehmann et al., 2022). Genetic testing from preconception and throughout the life span presents unique issues related to informed consent. For example, an issue associated with newborn screening is that results also reveal information about family members. A newborn with a diagnosis of phenylketonuria (PKU) reveals that both parents are carriers. In turn, then, there is the risk for parents' siblings being carriers as well. A psychological/emotional effect may be in the form of parental guilt. A known diagnosis may affect the ability to obtain health insurance, and it may lead to future employment discrimination. It is essential that in-depth counseling assuring informed consent is a central aspect of genetic testing.

Genome-Wide Association Studies

An expanded area of research, referred to as **genome-wide association studies (GWAS)**, aims to identify common genetic factors that influence health and disease. To facilitate GWAS research, the NIH has developed policies regarding the sharing of GWAS-related data, including a central repository for such data. Informed consent, again, is a critical issue, ensuring that research participants have a full understanding regarding data sharing and its implications. Three levels of consent are under consideration. Traditional consent involves participants' consent to participate in the research study and for public release of their data. Binary consent allows participants to agree to participate in the study but choose not to allow release of their data. Tiered consent allows participants to be in the study and offers several options related to data sharing, giving them control over whether or not data are shared, how that is done, and with whom it is shared. Nurses must be aware of any changes in processes related to informed consent to be able to provide information for those considering participating in GWAS research (Uffelmann et al., 2022).

Privacy and Confidentiality

Maintaining privacy and confidentiality regarding genetic health information has the potential for presenting complex concerns for nursing practice. For example, the American Nurses Association (ANA) Code of Ethics defines *privacy* in terms of the individual's right to control their own personal information. It defines *confidentiality* as the nurse's obligation to protect that right and prohibits disclosure of information provided in confidence to another person. The potential for a dilemma arises in that genetic information for one person may also imply risks for others.

On one side, the nurse is obligated to protect the patient's rights. On the other, the nurse may feel the duty to warn others of their potential health risks. The nurse must be aware that there is no legal authority allowing the breach of confidentiality with disclosure of genetic information about one person with another.

Discrimination

Discrimination based on genetic information, primarily involving insurance and employment practices, was recognized early in the Human Genome Project. The concerns centered on the potential that insurance providers would limit or deny coverage based on genetic information, or that employers might use the information as a basis for hiring and firing. The **Genetic Information Nondiscrimination Act (GINA)** prohibits discrimination based on genetic information in both areas. Title I addresses health insurance, specifying that health insurers may not use genetic information to determine eligibility for coverage and may not request that individuals undergo genetic testing or provide genetic information. Title II addresses employment practices, prohibiting the use of genetic information in making employment decisions, and it restricts employers from requesting genetic testing and the disclosure of any genetic information (National Human Genome Research Institute, 2020).

LINK TO LEARNING

Learn more about how you can prevent genetic discrimination (https://openstax.org/r/77GenticNonDisc) through the Genetic Information Nondiscrimination Act of 2008.

Social and Spiritual Considerations

People of some religions are hesitant to receive genetic testing, especially during pregnancy. For example, some Christians, particularly those with conservative or traditionalist views, may hold beliefs that life begins at conception and, therefore, view selective abortion based on genetic abnormalities as morally unacceptable. Hesitancy around genetic testing in some cultures stems from a lack of understanding or education about the purpose and importance of genetic testing in certain situations.

CULTURAL CONTEXT

Availability of Genetic Services

A took aim at the ethical, social, and cultural issues associated with delivery of genetic services in low- and middle-income countries (LMICs) (Zhong et al., 2021). Nine themes emerged:

1. Genetic counseling has a tendency of being directive.
2. Genetic services have psychosocial consequences that require improved support.
3. Medical genetics training is inadequate.
4. Genetic services are difficult to access.
5. Social determinants affect uptake and understanding of genetic services.
6. Social stigma is often associated with genetic disease.
7. Family values are at risk of disruption by genetic services.
8. Religious principles pose barriers to acceptability and utilization of genetic services.
9. Cultural beliefs and practices influence uptake of information and understanding of genetic disease.

The World Health Organization (WHO) provides some guidance on the implementation of community genetic services in LMICs to prevent congenital disorders and genetic diseases. This review is an important step toward informing the development of evidence-based, ethical, and culturally appropriate genetic services in LMICs (Zhong et al., 2021).

Nursing Responsibilities

The ANA identified nursing competencies guiding professional practice in the realm of ethical issues related to genetics and genomic health care. Professional responsibilities include the following:

- recognizing when one's own attitudes and values may affect provision of care

- advocating for the rights of all patients to autonomous, informed decision-making and voluntary action
- identifying ethical issues, (ethnic, cultural, religious, legal, fiscal, and social) related to genomic information and technologies
- defining issues that compromise patients' rights for autonomous, informed decision-making and voluntary action
- providing accurate, relevant, and the most current information, resources, services, and technologies that promote informed decision-making

Summary

30.1 Genetic Disorders

- Genetics refers to the study of heredity, focused on patterns of inheritance of specific characteristics or traits, including variations of a trait within a population.
- Although there is a considerable amount of genetic variation among humans, any two people's genomes are about 0.4 percent different, and these genomic variants are what make individuals unique.
- Genetic conditions are conditions caused by a single gene mutation, such as sickle cell disease, whereas chromosomal conditions are caused by an incorrect number or structure of chromosomes, such as Down syndrome.
- Genomics is the study of genes and how they interact with each other and the environment.
- A genomic approach to health care uses knowledge about genetic variation and environmental effects to augment the planning and provision of health care to individuals, families, and the community.
- Essential nursing practice concepts in genomics include integrating knowledge, demonstrating understanding, obtaining a comprehensive patient and family history, making appropriate referrals, and providing patient education and support.
- *Pharmacogenetics* and *pharmacogenomics* are two very new terms in the realm of health care, which overall refer to an area of research examining how genes affect the response to medications.

30.2 Patterns of Inheritance and Mutations

- Each human body cell has a full complement of DNA stored in twenty-three pairs of chromosomes; each of these chromosomes carries up to thousands of genes, each of which codes for the assembly of a particular protein.
- An individual's complete genetic makeup is referred to as their genotype; the characteristics that the genes express, whether they are physical, behavioral, or biochemical, are a person's phenotype.
- The pattern of inheritance describes the way certain conditions are passed from parent to offspring through a single gene. These include autosomal, dominant, x-linked, mitochondrial, Y-linked, and codominant patterns.
- Certain combinations of alleles can be lethal, meaning they prevent the individual from developing in utero, or cause a shortened life span.
- Mutations can arise spontaneously from errors during DNA replication, or they can result from environmental insults such as radiation, certain viruses, or exposure to tobacco smoke or other toxic chemicals; mutations can also be beneficial and aid in survival in a changing environment.
- A point mutation is when a single nucleotide in a DNA sequence is substituted by another nucleotide; it may or may not have an effect on the expressed protein.
- Frameshift mutations, caused by insertions or deletions of a number of nucleotides that are not a multiple of three, are extremely problematic because they cause a shift in the reading frame.
- Nursing practice considerations include nursing assessment and analysis of findings to identify risk factors; on completion and review of the assessment, results should be shared, and appropriate referrals provided. If a risk for an inherited disorder is identified, referrals may include genetic counseling and/or genetic testing.

30.3 Testing and Detection

- Genetic testing identifies mutations in a person's DNA and can provide guidance in the type of medical care a person receives.
- The first step for assessing genetic/genomic risk involves collection of data through taking a thorough personal and family health history, physical examination, and review of additional information, such as laboratory or radiology reports.
- If the history reveals red flags related to risk for inherited disorders, a referral for genetic counseling is indicated.
- Advances in genetic and genomic knowledge have generated complex ethical and legal issues related to health care.
- An expanded area of research, referred to as genome-wide association studies (GWAS), aims to identify common genetic factors that influence health and disease.
- Nurses are called upon to integrate genetic and genomic knowledge and principles into the scope of practice,

including understanding of ELSI concerns: informed decision-making, informed consent for genetic testing, consent related to genetic/genomic research, privacy and confidentiality, discrimination prevention, and the addressing of cultural or religious considerations.

Key Terms

allele alternative form of a gene that occupies a specific locus on a specific gene
autosomal chromosome in humans, the twenty-two pairs of chromosomes that are not the sex chromosomes (XX or XY)
autosomal dominant pattern of dominant inheritance that corresponds to a gene on one of the twenty-two autosomal chromosomes
autosomal recessive pattern of recessive inheritance that corresponds to a gene on one of the twenty-two autosomal chromosomes
carrier heterozygous individual who does not display symptoms of a recessive genetic disorder but can transmit the disorder to their offspring
chromosomal condition condition related to changes in chromosome structure or number
chromosome structure made of protein and a single molecule of DNA that carries genetic information in the form of genes
codominance equal, distinct, and simultaneous expression of both parents' different alleles
diagnostic genetic testing testing performed to confirm or rule out a specific genetic disorder using a DNA-based test
dominant lethal inheritance inheritance pattern in which individuals with one or two copies of a lethal allele do not survive in utero or have a shortened life span
empiric risk chance for the occurrence of a disease based on personal and family history and other data
ethical, legal, and social implications (ELSI) concerns related to advances in genetic and genomic knowledge that include informed decision-making, informed consent for genetic testing, consent related to genetic/genomic research, privacy and confidentiality, and discrimination prevention
frameshift mutation mutation caused by insertions or deletions of a number of nucleotides that are not a multiple of three
gene basic functional unit of heredity found in the nucleus of every cell; composed of deoxyribonucleic acid (DNA) sequences located in an individual's chromosomes
genetic condition condition caused by a single gene mutation
Genetic Information Nondiscrimination Act (GINA) U.S. law that prohibits discrimination based on genetic information
genetic screening process that evaluates a person's risk of developing a genetic condition
genetic testing testing that identifies mutations in a person's DNA
genetics study of heredity focused on patterns of inheritance of specific characteristics or traits, including variations of a trait within a population
genome-wide association studies (GWAS) expanded area of research to identify common genetic factors that influence health and disease
genomic condition disorder caused by the loss or gain of DNA material
genomics study of genes and how they interact with each other and the environment
genotype complete genetic makeup of an individual
germline mutation mutation that originates in the parent's reproductive cells (eggs or sperm) and is generally passed into every cell of the offspring's body
heterozygous having two different alleles for a given gene
homozygous having two identical alleles for a given gene
induced mutation genetic mutation from an extraneous exposure
karyotype systematic arrangement of chromosome pairs
mitochondrial inheritance pattern of inheritance transmitted only by mothers
mutation change in the DNA sequence of an organism's genetic material
pharmacogenetics study of the variability of therapeutic responses to medications, as influenced by variations in single genes
pharmacogenomics study of variations in multiple genes as associated with variable drug responses

phenotype physical or biochemical manifestation of the genotype; expression of the alleles
point mutation mutation in which a single nucleotide in a DNA sequence is substituted by another nucleotide
population screening large-scale screening programs offering the general population testing for genomic disorders that may be prevented or effectively mitigated with early detection
recessive lethal inheritance pattern of inheritance in which individuals with two copies of a lethal allele do not survive in utero or have a shortened life span
risk probability likelihood that an individual carries a genetic mutation, predisposing the person for developing disease
sex chromosomes pair of chromosomes involved in sex determination; in males, the XY chromosomes, and in females, the XX chromosomes
somatic mutation mutation that arises in cells at some point after fertilization and does not involve the germline
spontaneous mutation genetic mutation that occurs due to processes within the body
X-linked dominant pattern of dominant inheritance that corresponds to a gene on the X chromosome of the twenty-third pair
X-linked recessive pattern of recessive inheritance that corresponds to a gene on the X chromosome of the twenty-third pair
X-linked transmission pattern of inheritance that involves genes located on the X chromosome of the twenty-third pair
Y-linked inheritance pattern of inheritance that comes from one of the Y chromosomes of the father

Assessments

Review Questions

1. What distinguishes the study of genomics from the study of genetics?
   a. Genomics considers the effects of environmental factors.
   b. Genomics examines variations in trait expression.
   c. Genomics involves the study of single genes.
   d. Genomics research concerns DNA.

2. Sickle cell disease is considered what kind of condition?
   a. chromosomal condition
   b. genetic condition
   c. condition of translocation
   d. condition of deletion

3. What characteristic differentiates pharmacogenetics and pharmacogenomics in the study of therapeutic drug response?
   a. Pharmacogenetics is the study of single gene variations; pharmacogenomics is the study of multiple genes.
   b. Pharmacogenetics is the study of multiple genes; pharmacogenomics is the study of a single gene.
   c. Pharmacogenetics is the study of a single chromosome; pharmacogenomics is the study of multiple chromosomes.
   d. Pharmacogenetics is the study of multiple chromosomes; pharmacogenomics is the study of a single chromosome.

4. What is a description of the affect of the genomics framework on patient care?
   a. It focuses solely on the treatment of rare genetic disorders.
   b. It primarily emphasizes the development of new medications.
   c. It incorporates genetic and genomic knowledge to enhance health care across all aspects of the system.
   d. It limits health care initiatives to research and development.

5. What is one of the essential competencies for nursing practice in the context of genomics?

a. prescribing genetic medications
b. integrating and applying genetic/genomic knowledge
c. conducting laboratory genetic tests
d. developing health care policies

6. Genetic testing reveals the presence of an X-linked recessive trait. With an affected male, what is the risk of transmission to offspring?
a. All female offspring will be affected.
b. All female offspring will be carriers.
c. All male offspring will be affected.
d. All male offspring will be carriers.

7. What is a defining characteristic of mitochondrial inheritance?
a. It affects only male offspring.
b. It is transmitted only by females.
c. Its expression follows a dominant pattern of inheritance.
d. Males can pass the trait to male offspring.

8. If a person inherits I^A and I^B alleles, what blood type will they have?
a. AB
b. O
c. B
d. A

9. In a point mutation, what happens to a single nucleotide in a DNA sequence?
a. It is deleted.
b. It is incomplete.
c. It is multiplied.
d. It is substituted.

10. What is an example of population screening?
a. newborn metabolic screen
b. Papanicolaou (Pap) tests
c. screening mammogram
d. screening colonoscopy

11. What is a characteristic of single-gene testing?
a. It determines disease severity.
b. It identifies a specific gene.
c. It predicts age of onset.
d. It requires testing of family members.

12. What is a description of tiered informed consent?
a. It allows public release of data.
b. It gives several options for data sharing.
c. It involves consent to participate in the study.
d. It restricts all release of data.

13. Which is a specific component of Title I of the Genetic Information Nondiscrimination Act (GINA)?
a. It allows for genetic testing to be requested.
b. It permits using genetic information for hiring.
c. It restricts using genetic testing for coverage eligibility.
d. It prevents disclosure of genetic information.

Check Your Understanding Questions

1. Explain ways that nurses can incorporate genomic knowledge into clinical practice.
2. Your 23-year-old patient just learned that they have Lynch syndrome. What are some things that you, as the nurse, would encourage the patient to do?

Reflection Questions

1. Based on your understanding of genomics, what types of factors do you think would be investigated in the study of COPD?
2. Describe the difference between germline and somatic mutations, and provide an example of each.
3. How would you describe the concept of inheritance to a patient, incorporating examples related to colon cancer and considering its effects on the patient's family?
4. What are the professional responsibilities of nurses regarding genetic testing?

What Should the Nurse Do?

Ms. Lewis, a 28-year-old female, visits the genetic counseling clinic for guidance regarding her family history of genetic conditions. She expresses concerns about the potential risk of passing on certain conditions to her future children. Ms. Lewis's medical history is unremarkable, but her family has a history of neurogenetic disorders, specifically Huntington disease. She reports experiencing anxiety about her reproductive decisions and is seeking information on genetic testing options. Ms. Lewis's maternal grandmother was diagnosed with Huntington disease, and her mother is currently undergoing genetic testing to determine if she carries the gene mutation. This family history has prompted Ms. Lewis to seek advice on family planning. Vital signs are within normal limits, with a blood pressure of 120/80 mm Hg, a heart rate of 76 bpm, a respiratory rate of 18 breaths per minute, and a body temperature of 98.6°F (37°C).

1. How does the family history of Huntington disease affect the analysis of potential genetic risks for Ms. Lewis, and what additional information or assessments might be helpful to further understand the implications for her reproductive decisions?
2. What interventions and strategies would you propose to support Ms. Lewis in her decision-making process regarding family planning, and how would you tailor these solutions to address her unique emotional and informational needs?

Mr. Dias, a 45-year-old male, presents at the genetics clinic concerned about his family's history of colon cancer. He reports that his father passed away from colon cancer, and his paternal grandmother also had a history of the disease. Mr. Dias has been experiencing occasional abdominal pain, changes in bowel habits, and noticeable weight loss. Given his family history, Mr. Dias is worried about his own risk and expresses interest in genetic testing for colon cancer susceptibility. Vital signs are stable, with a blood pressure of 120/80 mm Hg, a heart rate of 78 bpm, a respiratory rate of 18 breaths per minute, and a body temperature of 98.6°F (37°C).

3. How might Mr. Dias's family history and symptoms influence the analysis of potential genetic risks for colon cancer, and what additional information or assessments might be needed for a comprehensive understanding of his situation?
4. As the nurse, what immediate actions would you initiate to address Mr. Dias's current concerns and informational needs, and how would you collaborate with the genetic counseling team to ensure comprehensive support?

Mrs. Hernandez, a 28-year-old female, arrives at the genetics clinic seeking guidance on genetic screening and testing due to a family history of breast cancer. Her mother was diagnosed with breast cancer at the age of 40, prompting Mrs. Hernandez to proactively explore her own risk. She reports occasional breast tenderness and is concerned about the potential implications for her health. Mrs. Hernandez has no prior history of cancer. Vital signs are within normal ranges, with a blood pressure of 118/76 mm Hg, a heart rate of 82 bpm, a respiratory rate of 16 breaths per minute, and a body temperature of 98.7°F (37.1°C).

5. As the nurse, what immediate actions would you initiate to address Mrs. Hernandez's current concerns and informational needs, and how would you collaborate with the genetic counseling team to ensure comprehensive support?

6. After implementing interventions and providing support, how would you monitor and assess Mrs. Hernandez's progress in addressing her concerns about genetic screening, and what specific outcomes would indicate successful support and understanding?
7. Describe how you will engage Mrs. Hernandez in a discussion about the ethical and social concerns related to genetic screening. What strategies would you employ to ensure her values and beliefs are respected throughout the decision-making process?

Competency-Based Assessments

1. Given a family medical history, how would you identify potential genetic risks and recommend appropriate genetic testing or counseling for common conditions such as Down syndrome or cystic fibrosis?
2. Create a chart showing ways that genomics can be integrated into patient care. How does it affect treatment decisions and outcomes? How would you communicate this information to a patient?
3. Complete your own three-generation comprehensive family history. What are your findings? Did you identify any risk for inherited conditions?

CHAPTER 31
Cancer

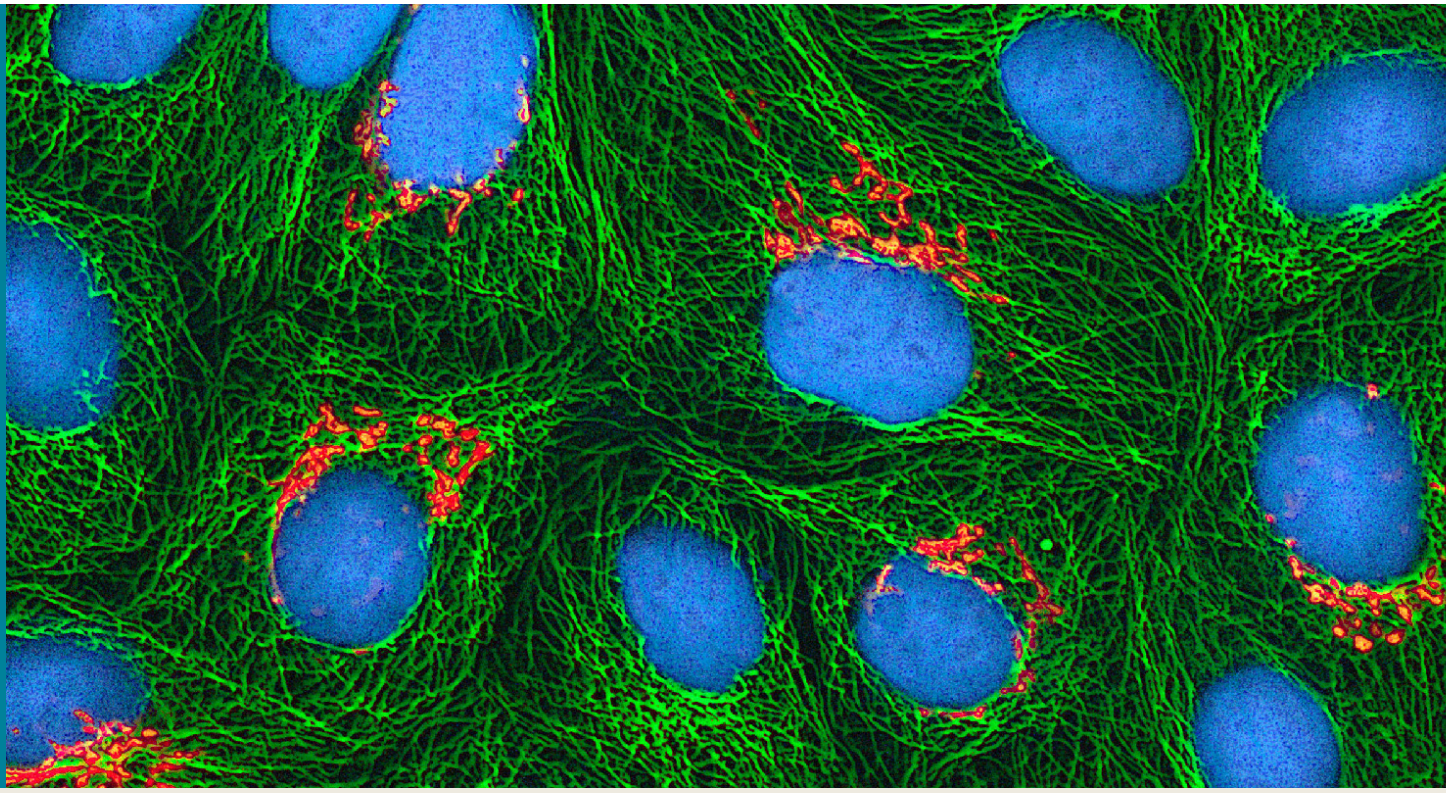

FIGURE 31.1 HeLa cells are a cell type in an immortal cell line used in scientific research. It is the oldest and most used human cell line. The line was derived from cervical cancer cells taken in 1951 from Henrietta Lacks, who eventually died of her cancer. (credit: "HeLa Cells" by NIH/National Cancer Institute, Public Domain)

CHAPTER OUTLINE

INTRODUCTION Nurses caring for individuals with cancer may work in hospital settings, clinics, research organizations, or in the home. Care often includes teaching about the diagnostic and disease process, supporting the individual through side effects of both cancer and treatment, and assisting with the delivery of chemotherapy or radiation therapy. The nurse empowers the individual to express their emotions and needs, guiding the decision-making process throughout the journey. Regardless of care setting, the nurse provides a caring and comforting presence while assisting with the navigation from diagnosis through survivorship or death.

31.1 Oncological Disorders

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiology, risk factors, and clinical manifestations of cancer
- Differentiate the major types of cancer

There are more than 200 types of **cancer**, all characterized by uncontrolled and abnormal cell growth (Cancer Research UK, 2023). This results in cells that are poorly differentiated and unable to perform their function within

the body. The primary effect of cancer is the disruption of typical body functions. The goal of treatment is to interrupt the uncontrolled growth of abnormal cells to manage the disease and restore normal function.

Cancer is thought to be caused by three main factors (National Cancer Institute [NCI], n.d.; Nationwide Children's, 2023; Stanford Medicine, n.d.):

1. Systemic issues—often due to immune dysfunction or chronic inflammation
2. Environmental exposures—chronically poor diet, pollution, certain viruses
3. Genetic determinants—inherited or acquired

These factors may intersect to increase the risk of cancer development.

Pathophysiology

A normal cell has deoxyribonucleic acid (DNA), which gives the cell correct instructions about its work in the body and when the cell should die. The process of normal cell death as part of a controlled and normal process is called apoptosis. To allow cancer to develop, a mutation must be initiated. Often, the initiation of a mutation is caused by repeated or prolonged insults to the cell's DNA, such as consistent skin tanning or repeated chemical exposure at work. In medical terms, an insult is the cause of some kind of physical injury. The DNA insult initiates a mutation and apoptosis is avoided. This is the beginning of most cancer types.

Smoking is a classic example of an insult as cigarettes contain many known carcinogens. **carcinogen** is a cancer-causing substance. The cell easily repairs damage from early exposure, but errors in the DNA and cell instructions become increasingly likely to occur. Recall that DNA contains the instructions needed for development, survival, and reproduction (National Human Genome Research Institute, 2020). If the DNA and its instructions are altered, the cells produced are not fully functional. Lung cells are damaged from inhaled carcinogens and the DNA instructions for the new lung cells are also damaged. This cycle continues, with each replication of lung cells exhibiting more damage and less expected functionality as part of the lung tissue. Eventually, this process creates cancerous cells. Then lung cells cannot serve the purpose of exchanging gases. Early symptoms of the cellular and tissue changes in lung cells include coughing or a change in breathing. The symptoms associated with disrupted function are usually what causes an individual to seek care.

The process the body uses to search for, identify, and destroy foreign pathogens and cancerous cells using cytotoxic T lymphocytes (or T cells), activated macrophages, and natural killer cells is called **immunosurveillance** (Figure 31.2). When enough cancerous cells have evaded immunosurveillance, a malignant, or cancerous, growth begins.

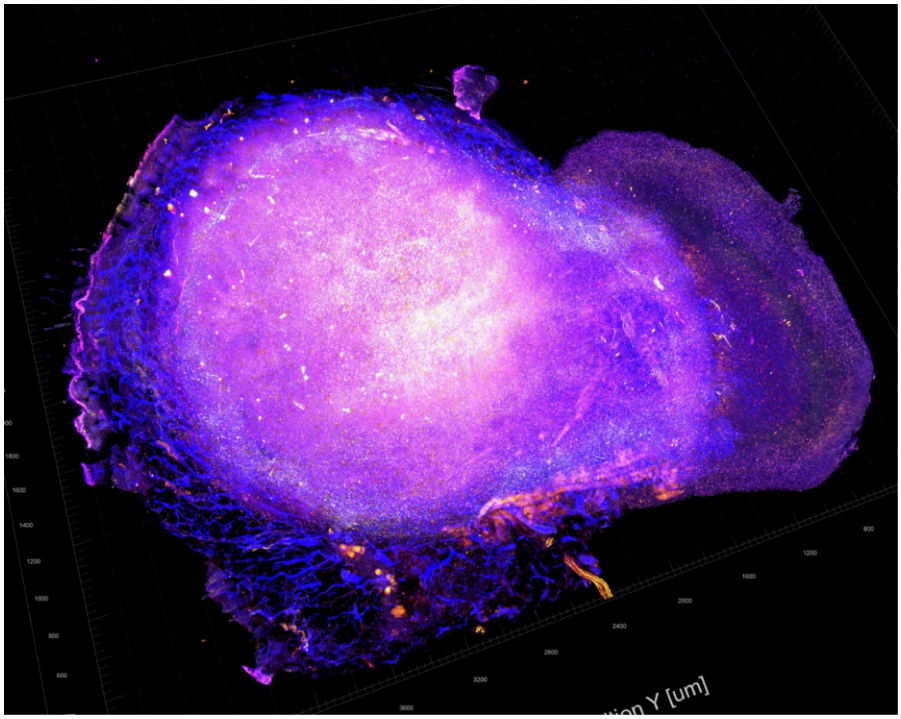

FIGURE 31.2 Transparent tumor tomography visualizes cytotoxic T cells (yellow, red, and blue) attacking the tumor after an antitumor immune response was initiated by a novel therapy. (credit: "Anti-Tumor Immune Response" by NIH/National Cancer Institute, Public Domain)

Tumors are malignant or benign. A malignant growth is cancerous, grows uncontrollably, and invades other areas of the body. They represent a threat to life, regardless of which part of the body is affected. A **benign** tumor grows slowly and does not spread. Whether they are a threat to life depends on their location and size. A benign tumor can grow and cause dysfunction by

- displacing tissues,
- pressing on nerves or vessels, or
- causing organ damage.

The hallmarks of a malignant growth are as follows:

- metastasis: cancerous cells can spread, usually via the bloodstream or lymphatic system (Figure 31.3)
- angiogenesis: cancerous cells can form their own network of blood vessels to obtain needed nutrients and oxygen and to allow tumor cells to leave the primary tumor site and metastasize to other parts of the body
- proliferation: cancerous cells have the ability to sustain their own growth without external stimuli
- evasion: cancerous cells can avoid growth suppression and apoptosis, or cell death
- immortality: cancerous cells have unlimited replication potential

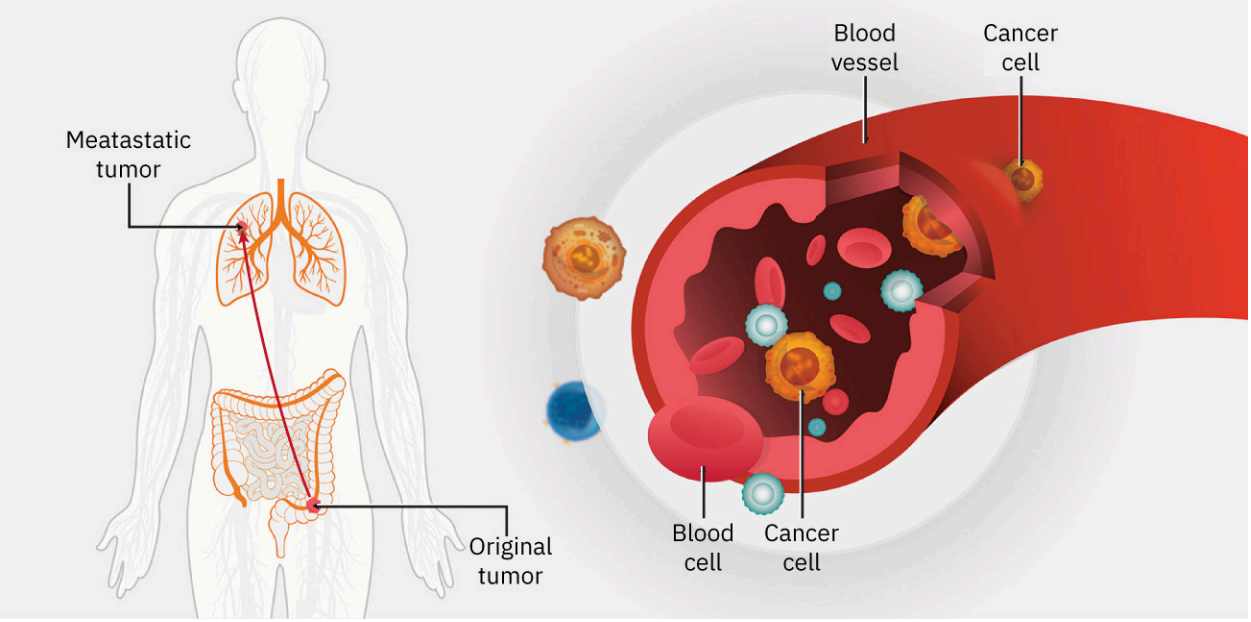

FIGURE 31.3 Cancer cells break away from the tumor of origin and travel in the body through blood vessels or the lymphatic system, creating additional tumor sites. (credit: "What is Metastasis?" by NIH/National Cancer Institute, Public Domain)

LINK TO LEARNING

Read about Henrietta Lacks and her immortal cells (https://openstax.org/r/77helacells) to see uncontrolled cell growth at work in medical research. Consider reading more about Henrietta Lacks and unethical research practices in *The Immortal Life of Henrietta Lacks* by Rebecca Skloot.

Risk Factors

Not all cancers can be attributed to known risk factors, and scientific researchers and clinicians may not be able to determine their origin. However, this does not mean there are not any risks that might be controlled or modified. Many cancers do have risk factors that can be managed.

Preventable causes of mutations that may lead to cancer include the following:

- smoking
- dietary fat intake
- alcohol consumption
- low fiber intake
- low intake of micronutrients (beta-carotene, vitamin A, vitamin C, vitamin E)
- passive smoking (second-hand exposure)
- prolonged exposure to sex hormones (early menarche, exogenous hormones)
- occupational exposures (asbestos, benzene, ionizing radiation, lead, sun exposure)
- viruses (hepatitis B, human papillomavirus [HPV], Epstein-Barr virus, human immunodeficiency virus [HIV])

An imbalanced diet is linked to cancer development (NCI, 2023a). Often, imbalanced diets contain too little anti-inflammatory food and too much pro-inflammatory food. Naturally protective, anti-inflammatory compounds are found in foods such as blueberries, apples, olive oil, kale, almonds, and salmon. Conversely, chronic inflammation is triggered by red meat (due to its chemical digestive by-products) and processed foods, which contain preservatives, dyes, and other substances that are not natural to the human body.

The use of tobacco, in any form, and alcohol are linked to multiple types of cancer (Figure 31.4). Inactivity for long periods of time and obesity are also attributable to multiple types of cancer. Many of these risks will coexist for an individual, compounding the risk of cancer development.

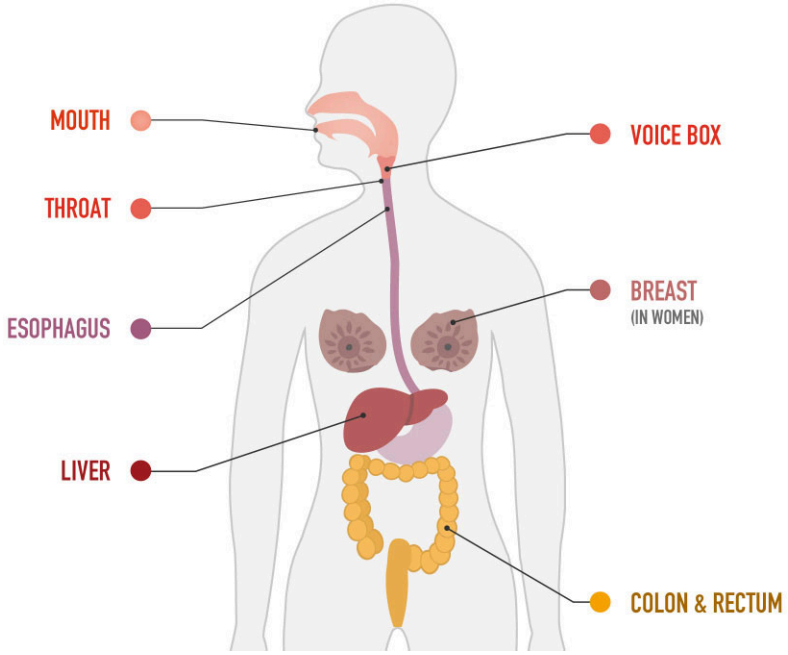

FIGURE 31.4 Alcohol use has a strong connection to multiple cancer types. The risk increases with higher volumes and consistency of use. (credit: "Cancers Associated with Drinking Alcohol" by NIH/National Cancer Institute, Public Domain)

Other factors that may initiate cell dysregulation include exposure to industrial chemicals or environmental pollution, prolonged time in the sun, infections such as hepatitis B and C or HPV, and hormone replacement or dysfunction.

Nonmodifiable causes of mutations that may lead to cancer include the following:

- age
- biological sex
- ethnicity
- genetic predisposition

Age is a risk factor that cannot be modified, but screenings for cancer are adjusted according to age and the established risk. With each year of age, mutations accumulate in DNA of cells. As they accumulate, it is more likely that a DNA change will occur that the body cannot control.

Genetics plays a significant role in cancer development. Genetic factors can be considered innate (being present during fetal development) or acquired (developed over time).

Innate Genetic Factors

Mutations that are inherited involve an **innate genetic factor**. This should be suspected if an individual has, or had, a close relative who developed cancer at a young age. For example, a patient may indicate that they have a first-degree relative who was diagnosed with breast cancer or colon cancer when the relative was in their 30s or 40s. The nurse recognizes the familial disposition of these specific cancer types and makes recommendations based on the appropriate high-risk guidelines.

A **tumor suppressor gene** normally regulates cell replication (Figure 31.5). Normally, these tumor suppressor genes produce tumor suppressor proteins that prevent cancer development by stabilizing the cell's genetic material. During the cell repair process, these genes provide instructions to prevent the replication of insulted or damaged cells, leading to the death of the damaged cell. When these genes are inactivated (or turned off), they cannot suppress cell proliferation or tumor growth. This loss of function allows cancer cells to grow even though their DNA is damaged and should trigger apoptosis in the cell cycle.

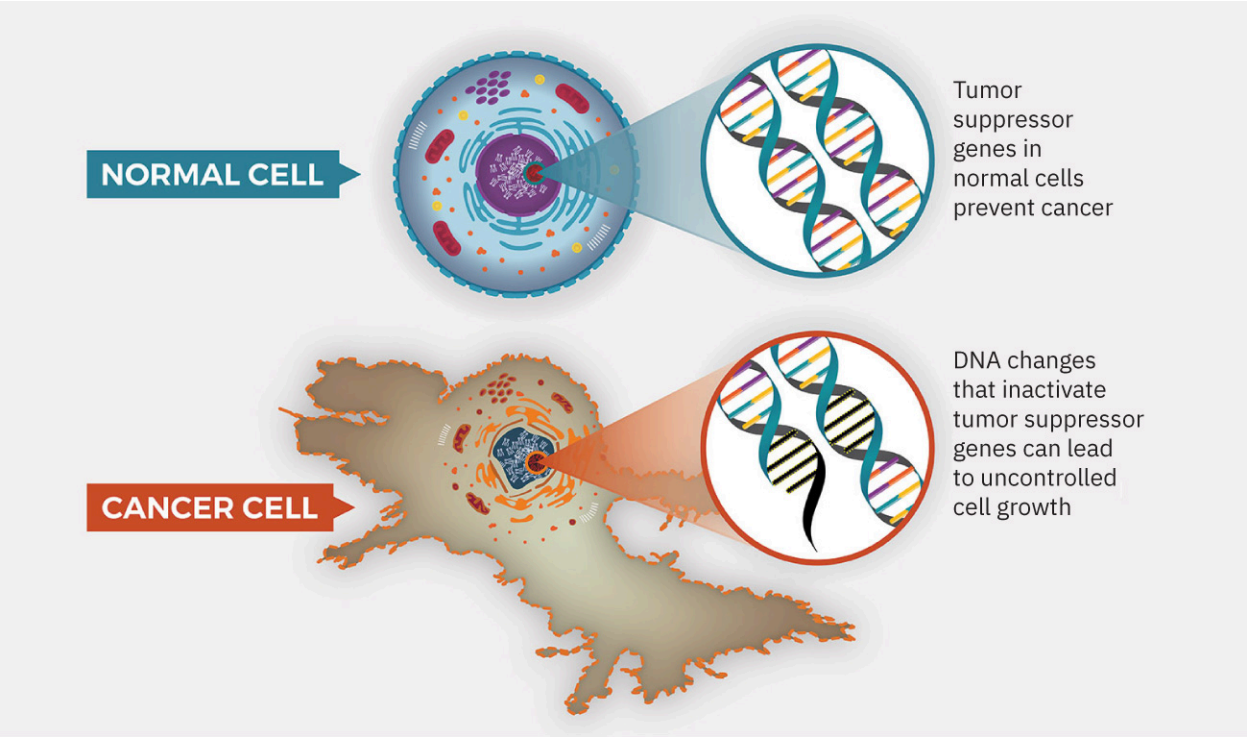

FIGURE 31.5 Functional tumor suppressor genes prevent or slow cancer growth. DNA changes inactivate these genes and the function to suppress cancer cell growth. (credit: "What Are Tumor Suppressor Genes?" by NIH/National Cancer Institute, Public Domain)

Well-known examples of innate genetic factors are the *BRCA1* and *BRCA2* genes (Figure 31.6). When these genes are mutated or inactive, the risk for development of breast, ovarian, prostate, and pancreatic cancer increases. Mutations in the *BRCA1* and *BRCA2* genes are inherited. If an individual knows the mutation is in their family or has been personally tested for its presence, they can control risk factors, increase screening vigilance, or request preventive treatment, such as surgical removal of the organ or tissue.

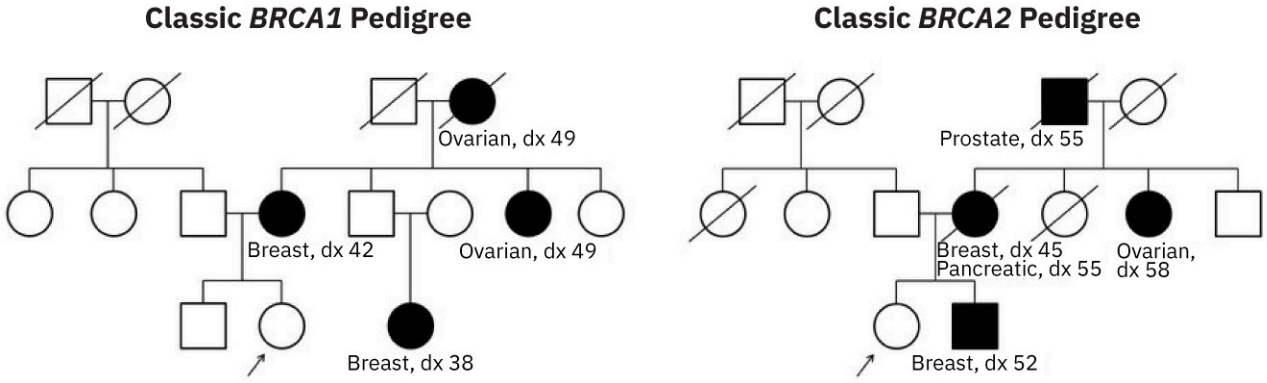

FIGURE 31.6 The *BRCA1* pedigree shows some classic familial features across three generations. The *BRCA2* pedigree shows classic features affecting family members with breast (including male), ovarian, pancreatic, and prostate cancers with young age of cancer onset. (credit a: "Classic BRCA1 Pedigree" by NIH/National Cancer Institute, Public Domain; credit b: "Classic BRCA2 Pedigree" by NIH/National Cancer Institute, Public Domain)

Lynch syndrome, also known as hereditary nonpolyposis colorectal cancer, is an inherited condition characterized by mutations in genes responsible for repairing DNA replication errors. This syndrome significantly increases the risk of developing colorectal and endometrial cancers. In individuals with Down syndrome, the presence of an extra chromosome 21 elevates the risk of leukemia, testicular cancer, and solid tumors. This increased risk is thought to be related to genetic factors that affect cell growth and division.

Acquired Genetic Factors

Changes that often develop from exposure to risk factors, such as unhealthy daily habits, exposure to toxins, or hormone disruptions, are an **acquired genetic factor**. A somatic mutation is one that occurs over an individual's

lifetime—insults accumulated from actions such as smoking or random failure of the DNA to replicate correctly while reproducing cells. Whenever cells are damaged, they move through the cell cycle faster than usual to try to repair the damage. This faster pace increases the chance of random replication errors. Genomic instability refers to the mutations that occur in the cell's DNA repair and replication systems. This instability leads to more changes in the genetic material and increases the likelihood of replication errors. A gene that becomes cancerous when activated or turned on is called an oncogene. Acquired mutations trigger oncogenes to be active and promote cell growth and division. Overactive cell replication mechanism signaling produces a pro-cancer effect, encouraging cancer cells to grow. Examples of oncogenes include the following:

- *HER2* (certain breast cancers)
- *KRAS* (colorectal or pancreatic cancer)
- *ABL1* (chronic myeloid leukemia)
- *EGFR* (lung cancer and glioblastoma)

Each of these oncogenes has its own path for causing cancer: improperly promoting cell division, activating cell growth pathways continuously, increasing cell proliferation, inhibiting cell death, or producing substances that drive uncontrolled cell growth. Identifying oncogenes and tumor suppressor genes gives clinicians new ways to predict the likelihood of a cancer developing or being present.

Clinical Manifestations

Signs and symptoms are unique to each type of cancer. There are a few manifestations that are common to most cancers; however, they are nonspecific and often lead to delays in diagnosis. Fatigue is the most frequently reported manifestation, affecting as many as 91 percent of patients (NCI, 2024b). The fatigue is persistent, not relieved by rest, and not proportional to the energy that the patient expended. This can be attributed to the systemic response to the cancer, its impact on normal physiological functions, or other cancer-related physiological changes such as sleep disturbances, nausea, infection, anorexia, dyspnea, or anemia.

Weight loss is a common manifestation of cancer. Unexplained weight loss, a common question on hospital admission paperwork, is sudden and unintentional. An example would be a 5 percent weight loss over the past three months. The reasons for this weight loss often align with the type of cancer and not just the body’s work in fighting the cancer.

Changes that are unique to a given cancer type and require diagnostic investigation include the following:

- Solid and site-specific tumors, usually have symptoms of
  - pain,
  - lumps,
  - swelling,
  - skin changes,
  - difficulty breathing,
  - difficulty swallowing,
  - changes in bowel or bladder habits,
  - the appearance of blood in stool or urine, or
  - persistent cough or voice changes.
- Blood and lymphatic cancers usually have symptoms of
  - fever and
  - unusual bruising.

Major Types of Cancers

Cancers are named and classified based on where they start in the body.

- A **carcinoma** is a cancer that creates solid tumors in epithelial tissue.
- A **sarcoma** is rare and is often related to bone cancers.
- A **lymphoma** applies to any cancer that begins in the lymphatic system.
- A **leukemia** refers to cancers of the blood-forming tissues, such as bone marrow.

Globally, cancer is the leading cause of death (World Health Organization [WHO], 2022). The most common types of cancer for males are prostate, lung, colorectal, and urinary bladder. For females, breast, lung, colorectal, and uterine

cancers are the most commonly occurring. Cancer of the lung and bronchus results in the most deaths, followed by colorectal cancer (American Cancer Society [ACS], 2024a).

Brain Cancer

Brain tumors are dangerous whether they are benign or malignant due to the constricted amount of space in the skull. Benign tumors may grow and cause dysfunction and symptoms related to their position in the brain and tumor size. Symptoms are related to the space the tumor occupies and its effect on the brain. Common symptoms are headaches, nausea or vomiting, seizures, changes in vision, problems with speech or balance, and cognitive changes.

Types of brain tumors include gliomas, astrocytomas, oligodendrogliomas, meningiomas, and medulloblastomas. The names refer to the specific cell or neuron type in the brain from which they develop. Brain tumors can originate in the brain, although metastatic brain growths are also common. Treatment, especially surgery, depends on the location and type of brain tumor. Prognosis and outcomes also vary widely depending on the location and type of tumor.

Bone Cancer

Primary bone cancer originates in the bone. Types include osteosarcoma, chondrosarcoma, and Ewing sarcoma. Benign tumors result in the same symptoms as malignant tumors because bones are a finite space and cannot accommodate the additional space-occupying mass. Symptoms include localized bone pain, swelling, and possible fractures without traumatic injury. Radiation treatment for other cancers increases the risk of developing cancer of the bone.

Treatment of primary bone cancer varies according to the type and location of the tumor. Metastatic bone cancer occurs when other cancers, such as breast, lung, or prostate, spread to the bone. In the case of bone metastasis, the treatment is usually still determined by the primary tumor type, but this depends on a variety of factors. Bone metastasis is more common than primary bone cancer (ACS, 2024b).

Breast Cancer

Cancer of the breast tissue cells is the most common cancer in females across the world (WHO, 2024). Campaigns for screening and early diagnosis continue to improve survival rates (Todor et al., 2024). Risk of breast cancer occurrence can often be mitigated across lifestyle factors such as hormone use, diet, alcohol consumption, and physical activity.

Types of breast cancer are classified by their

- occurrence in the lining of the breast duct (ductal),
- presence in the milk glands (lobular), and
- relationship to hormone receptors or specific tumor markers (e.g., triple-negative breast cancer).

Symptoms vary by type of cancer but encompass changes in the appearance of breast tissue and breast function. Treatment options include solitary therapies and combinations of therapy types, such as surgery, radiation, chemotherapy medications, hormone therapy, or targeted therapy.

Colon and Rectal Cancer

Colon cancer and rectal cancer begin in the large intestine, often starting as a polyp in the inner lining, or epithelium. Colonoscopies are an effective screening tool, assisting in early detection. Nonhereditary occurrence of colon cancer, like breast cancer, can often be reduced by addressing lifestyle factors such as activity level, alcohol use, smoking, and intake of red meats and processed foods. Early symptoms are changes in bowel habits or stool appearance and microscopic blood loss. Later symptoms can include visible bleeding, fatigue, or weight loss.

Lung Cancer

Cancer of the lung is one of the leading cause of cancer deaths across the world. There are two main types: non-small cell and small-cell. There are many types of non-small cell lung cancer, each named for the types of cells and their appearance. One example is adenocarcinoma, which forms in the alveoli lining. Small-cell lung cancer is heavily linked to smoking and is very aggressive in how it grows and spreads, contributing to the lethality.

Symptoms of lung cancer include weight loss, a chronic cough, shortness of breath, hoarse voice, and recurrent

respiratory infections. These symptoms are typically associated with smoking or chronic chemical exposure, which can result in delayed medical care that is ineffective for advanced cancer. Low-dose computed tomography (CT) scans should be used for regular screening.

Skin Cancer

Skin cancer is very common; one in five individuals in the United States will develop skin cancer (American Academy of Dermatology, 2024). The primary risk factor for its development is ultraviolet radiation exposure from the sun or from artificial sources such as tanning beds. Basal cell and squamous cell carcinomas are common and considered less lethal than melanoma, which metastasizes readily if not detected early (Figure 31.7). Melanoma can develop on the body in areas not typically exposed to the sun, such as between the toes as well as on genitals. Everyone, but particularly fair-skinned people, should pay close attention to changes in moles, lesions, and sores.

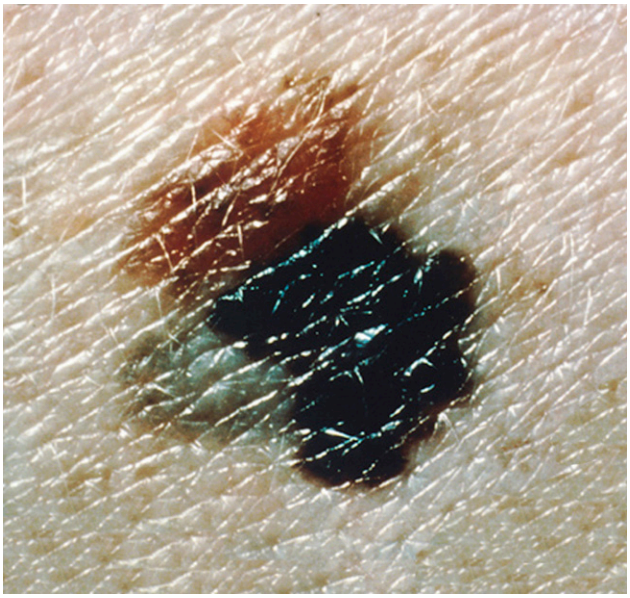

FIGURE 31.7 This invasive malignant melanoma shows a characteristic blue-black color and notched (irregular) border and surface. (credit: "Melanoma" by NIH/National Cancer Institute, Public Domain)

LINK TO LEARNING

The American Academy of Dermatology provides a body mole map (https://openstax.org/r/77bodymolemap) to educate people on the ABCDEs of detecting melanoma, how to perform a self-examination, and sun safety.

Blood Cancer

Stem cells differentiate into mature cells (Figure 31.8) as follows:

- Red blood cells—erythrocytes—transport oxygen to tissues.
- Platelets—thrombocytes—assist with coagulation to stop bleeding.
- White blood cells—lymphocytes—provide an immune response to infection and disease.

Hematologic cancers affect the bone marrow and can cause changes to how blood cells are produced and their ability to perform their necessary functions in the body.

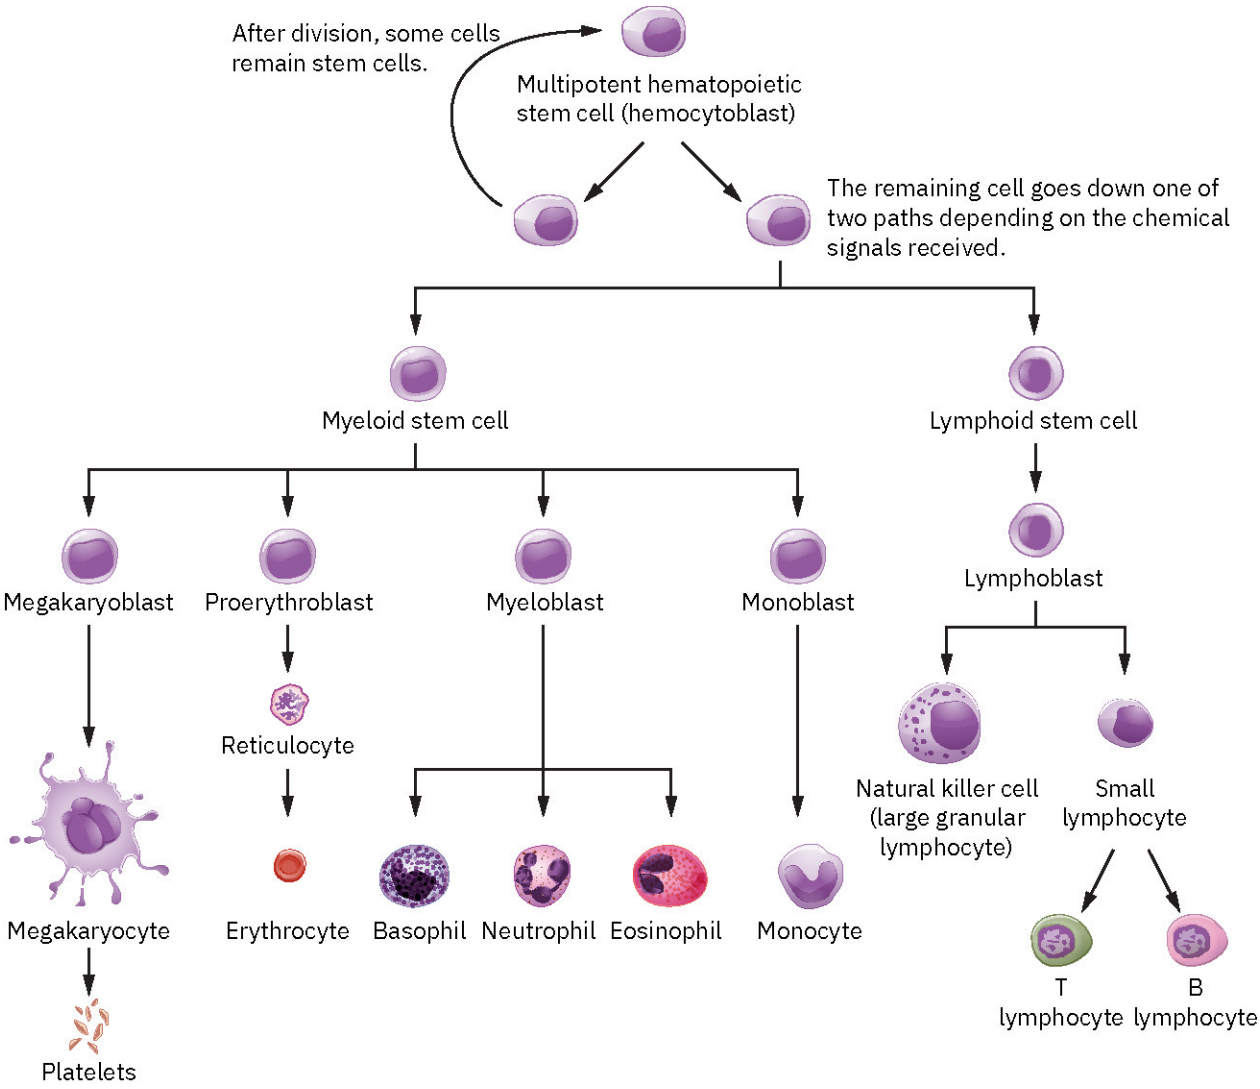

FIGURE 31.8 Stem cells differentiate to produce blood cells, such as erythrocytes, thrombocytes, and lymphocytes. (credit: modification of work from *Anatomy and Physiology*, 2e. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Initial symptoms of hematological cancers include fatigue and paleness due to reduced numbers of red blood cells (anemia), bruising or other abnormal bleeding due to low platelets (thrombocytopenia), and infections due to immature white blood cells (neutropenia). A reduced number of all blood cells (pancytopenia) is increasingly likely after treatment begins.

Blood cancers include leukemia, lymphoma, and myeloma. Leukemia is the profuse development of abnormal and immature white blood cells that are so numerous that they crowd out healthy cells. Lymphoma affects the lymphatic system, which changes how the lymph system functions as part of the immune system. Myeloma is a cancer that affects plasma cells, which are a type of white blood cell.

Therapies for hematological cancers include chemotherapy medications, targeted drug therapies, immunotherapy, radiation therapy to the bone marrow (often affecting the central nervous system), or a stem cell transplant to reestablish healthy bone marrow. Supportive therapies include transfusion of blood products and administration of colony-stimulating factors to induce the growth of white blood cells.

Leukemia

There are four main types of leukemia:

- acute lymphoblastic leukemia (ALL)
- acute myeloid leukemia (AML)
- chronic lymphocytic leukemia (CLL)

- chronic myeloid leukemia (CML)

Although leukemia is a disease of the white blood cells, pancytopenia is typical, sometimes at diagnosis and throughout treatment. Myeloblasts proliferate rapidly, crowding out the growth of healthy bone marrow components, affecting red blood cell count, platelet count, and the number of functioning white blood cells available.

REAL RN STORIES

Nurse: Katherine
Years in Practice: Five
Clinical Setting: Oncology
Geographic Location: Tennessee

A 23-year-old Hispanic patient was admitted with fatigue and laboratory tests indicating severe and untreated diabetes as well as acute myelogenous leukemia (AML). The levels of anemia and neutropenia were severe on admission. To add to this, the patient presented with a new and comorbid diagnosis of diabetes.

Once the patient's anemia and glucose levels were stable, the doctors began discussing treatment right away. Induction therapy for AML is aggressive and aimed at achieving remission. Induction therapy destroys most normal bone marrow cells as well as the leukemia cells. Chemotherapy commonly known as a 7 + 3 regimen, cytarabine is given continuously for seven days along with doses of anthracycline for the first three days. Close and continual monitoring is essential due to the many complications and side effects that are possible. Antibiotics, electrolyte replacements, and blood transfusions are common, and the required nursing care is intense.

After induction therapy was completed, the patient needed to undergo consolidation therapy called HiDAC. High-dose cytarabine is administered on a cycle over about one month. Inpatient hospitalization was an ongoing requirement while additional and more intensive therapies were administered to try to bring about a remission of the AML. During this time, the risk increases for side effects such as bleeding due to thrombocytopenia and infection related to neutropenia. Each shift is full of administering platelets, packed red blood cells, antibiotics, potassium, magnesium, and other supportive therapies. This continues until white blood cells, red blood cells, and platelets begin to recover in the postchemotherapy period and the effective protection is restored. Eventually the patient was safely discharged to continue any needed maintenance therapies on an outpatient basis.

Lymphoma

Lymphoma develops in the lymphatic system. Lymphomas are associated with certain infections, such as Epstein-Barr virus, HIV, certain strains of herpes virus, and hepatitis C seropositivity. There are two primary types of lymphoma: Hodgkin and non-Hodgkin. Both affect the lymphatic system and share similar risk factors, symptoms, diagnostics, and treatment options.

Reed-Sternberg cells are a defining feature of Hodgkin lymphoma (HL). HL tends to have a good prognosis. Non-Hodgkin lymphoma (NHL) is classified by subtypes of B-cell or T-cell, though there are more than forty major subtypes. It is the most common hematological malignancy worldwide, and is more common in males and those over the age of 65 years (Thandra et al., 2021).

In addition to typical hematologic cancer symptoms, patients may experience enlarged lymph nodes, night sweats, and fever. Treatment outcomes vary widely and depend on many factors, including how early treatment begins.

Myeloma

Multiple myeloma, also known simply as myeloma, is a type of blood cancer that affects plasma cells (Figure 31.9). A type of white blood cell, plasma cells produce antibodies; therefore, multiple myeloma—a condition in which abnormal plasma cells multiply uncontrollably within the bone marrow—leads to reduced immunity.

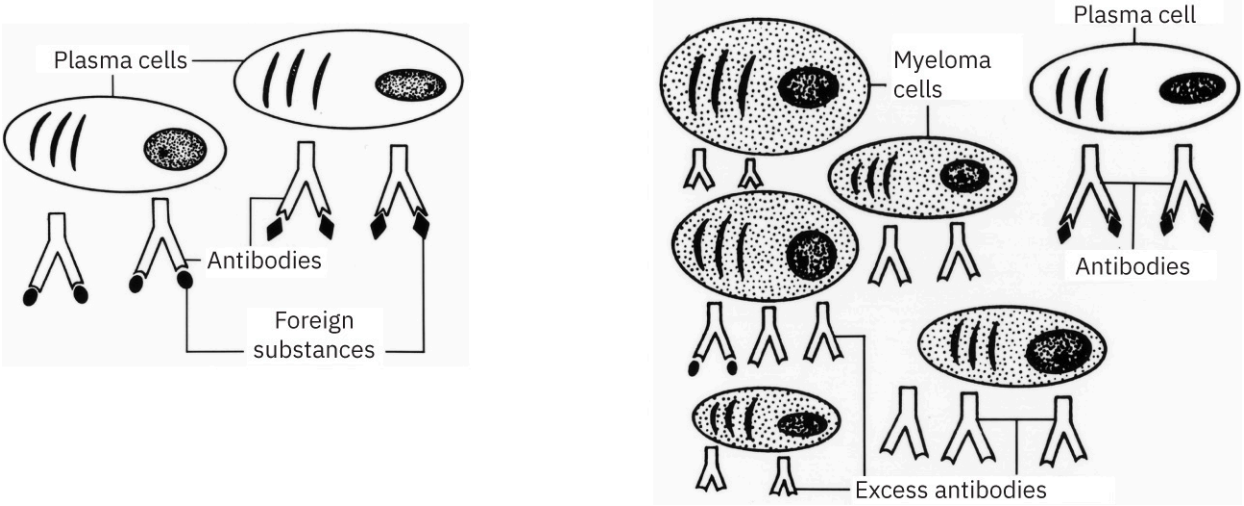

FIGURE 31.9 As the number of multiple myeloma cells increases, more antibodies are made. The result is thickened blood and a reduction in the ability of the bone marrow to make healthy cells. Multiple myeloma also weakens the bone. (credit: "Normal Plasma Cells and Myeloma Cells" by NIH/National Cancer Institute, Public Domain)

Bone pain and weight loss are common. Fatigue and increased infection risk also occur. Maintenance therapy and surveillance often continue for years after diagnosis with the goal of controlling the disease and relieving symptoms.

31.2 Detection and Prevention of Cancer

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Describe the diagnostics and laboratory values of select cancers
- Summarize systems of staging cancers and grading tumors
- Discuss strategies for cancer prevention

Diagnostics for cancer identification encompass imaging studies such as computed tomography (CT) scans and magnetic resonance imaging (MRI) that are classically used to detect alterations to organs and tissues along with identifying the presence of a malignant mass. Laboratory testing includes biomarkers specific to the presence of specific types of cancer. Biopsies are used to obtain a sample of suspected cancerous tissue and examine its properties under a microscope, evaluating cellular characteristics unique to cancerous change in cells.

Once detected and evaluated, a stage and grade are assigned to the cancerous cells. These assignments assist the provider in guiding treatment, predicting the outcome, understanding how quickly or aggressively the cancerous cells may grow and spread, and the likelihood of complications due to these factors.

Cancer prevention strategies center around risk reduction. A controllable and well-established primary prevention method for reducing risk is lifestyle modifications to include healthier diet options, routine physical activity, and avoiding carcinogens such as tobacco and alcohol. Vaccination against carcinogenic viruses, notably human papillomavirus (HPV) and hepatitis B (HBV), is another important primary prevention strategy. Secondary prevention, including early detection with screenings for cancers, is the next-best option to detect cancer early and limit its ability to grow and spread. Examples of secondary prevention include mammograms for breast cancer, colonoscopies for colorectal cancer, and the cotest for HPV and the Pap test for cervical cancer.

Detecting and Diagnosing Cancer

Detection and diagnosis involve a combination of screening tests at recommended intervals, imaging studies, and often a biopsy of the suspected malignancy. An example of this process is the use of mammography to detect breast cancer in females and males who are genetically at risk (Figure 31.10). Low-dose CT scanning helps detect lung cancer in individuals who are at greater risk due to long-term inhaled chemical exposure. Endoscopies, such as a colonoscopy for colorectal cancer, are performed to detect precancerous or cancerous polyps and lesions. Pathologists can examine biopsied cells for abnormalities, such as is done in a Pap test or Pap smear for cervical cancer. Physical assessment of the skin helps to detect skin cancer. Blood tests, such as the prostate-specific

antigen test for prostate cancer, help detect tumor markers. Genetic testing is used to screen for genetic mutations that affect development of certain cancer types, and when applicable, can also be used determine the best course of treatment.

FIGURE 31.10 An x-ray machine is used to take pictures of breast tissue as it is pressed between two plates. The technician will attempt to include any axillary breast tissue. (credit: "Mammogram" by NIH/National Cancer Institute, Public Domain)

Diagnostic Tests

X-rays are used to detect abnormalities that a tumor would create in soft tissues and bones. However, x-rays are not a recommended diagnostic tool for detection of other types of cancers, such as tumors of the lungs. For more detailed images of deeper structures and organs, CT scans can be performed. Even when they cannot precisely detect a tumor, a CT scan can often show abnormalities that lead to further testing or indicate the need for a biopsy. MRI also creates detailed images and is good for detecting abnormalities in soft tissues. Rather than being performed to initially detect cancer, MRI is a good diagnostic tool to gather additional imaging of suspected tumors. Ultrasound uses sound waves to create images from inside the body, making it useful for guiding biopsies by showing the tumor location and allowing precision when obtaining tissue samples.

Blood tests are useful to detect specific tumor markers, proteins, or substances that indicate the likely presence of cancer. Additionally, blood tests are often used to gauge the effectiveness of treatment or during periods of remission to determine recurrence.

A biopsy is the removal of a tissue or cell sample for the pathologist to examine for abnormal cells. The sample can be removed using a needle or during a surgical or endoscopic procedure. A biopsy is the most reliable method to confirm a cancer diagnosis.

Cancer Staging and Grading

Grading and staging systems standardize diagnosis, the likely prognosis, and the treatments to consider. The term

grading describes the cellular characteristics and aggressiveness of cancer cells and, by extension, how sensitive the cells will be to treatment. Tumor grading scales provide a grade from GX to G4, where GX denotes inability to assess the grade of the cells (Figure 31.11). Undifferentiated cells (G4), indicate that cells, when examined under a microscope, do not resemble the tissue cells from which they came.

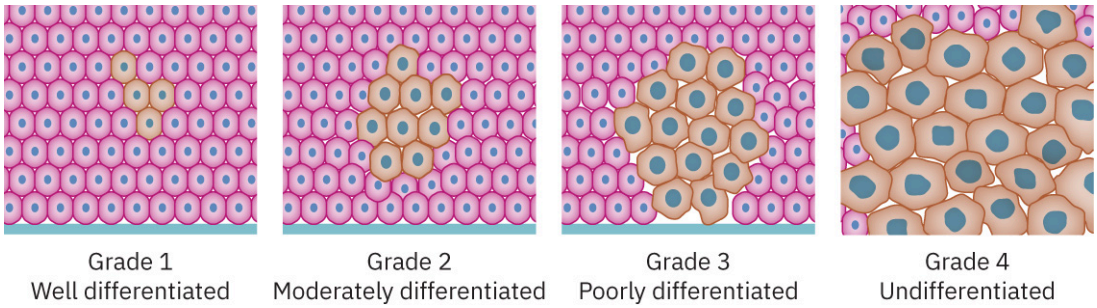

FIGURE 31.11 Cells are graded based on how abnormal they look under a microscope. This grading helps clinicians determine how quickly the cancer cells are likely to grow and spread. The higher the grade, the more abnormal the cells appear. The clinician expects poorly differentiated and undifferentiated cells to grow and spread rapidly. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Cell **differentiation** is the process cells undergo to become specialized in both structure and function. Specialized cell examples are muscle cells, nerve cells, and skin cells. This form and function allows the cells to form a group and perform as their designated tissue or organ should. If the pathologist examines a sample of healthy tissue that was biopsied from a lung, the tissue should be well differentiated. In this example, a well differentiated cell should look the same as any other sample of lung tissue. A healthy cell is matured. It is a specialized cell designed to function in the respiratory process. Even if the pathologist looked at biopsies obtained from many different lung sites, all lung cells should be very similar in appearance—e.g., uniform size, shape, and nucleus. Cancer cells, however, will have a different appearance than normal cells; pathologists use these differences to grade cancer in each patient.

The **staging** system is different for every type of cancer, but it generally refers to whether the tumor is confined to one space or has spread to other areas of the body. The basic **TNM system** (tumor, node, and metastasis) represents the anatomic extent of solid tumors, and it gauges the size and extent of tumor (T), lymph node involvement (N), and systemic involvement or metastasis (M) for prognostic implications. Tumor invasiveness is denoted with a number of 1 through 4 (T1, T2, T3, T4). The term **carcinoma in situ** indicates that abnormal cells have been found but have not spread (Figure 31.12).

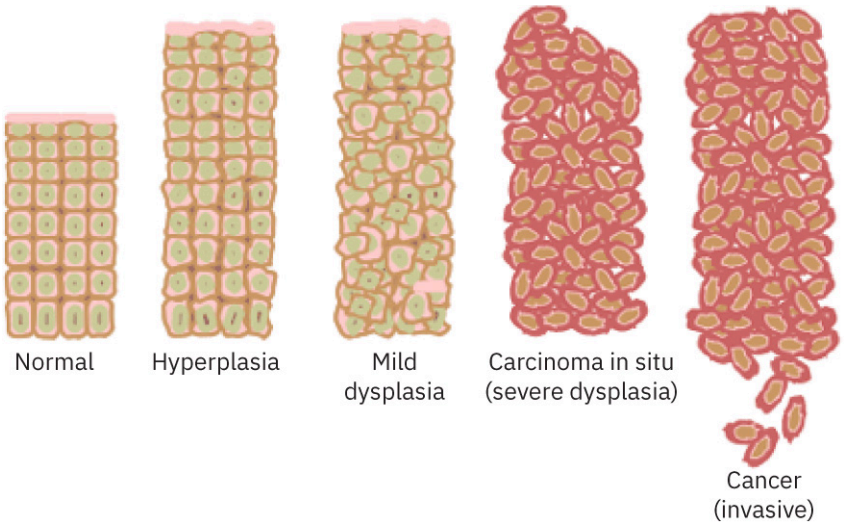

FIGURE 31.12 Carcinoma in situ are abnormal cells identified only in their place of origin. They can become cancerous. (credit: "Carcinoma in Situ" by NIH/National Cancer Institute, Public Domain)

The TMN system does not apply to leukemia because it is a blood cancer and not a cancer with a tumor. There are other staging systems that can also be applied to specific types of cancer, such as skin or colon cancer. When the tumor, lymph nodes, or metastasis cannot be assessed, this is denoted with an X (TX, NX, MX). An example of the

TMN system application is shown in Table 31.1. This system is then applied to determine the cancer stage.

Bladder Cancer (Transitional Cell Carcinoma)	Skin Cancer (Melanoma)
T1 N0 M0 Stage I	T2 N1 M0 Stage IIA
T1: the cancer has invaded the connective tissue of the bladder lining but has not reached the muscle layer N0: no regional lymph node involvement M0: no distant metastasis	T2: the melanoma is between 1.01 and 2.0 millimeters thick N1: cancer has spread to one nearby lymph node M0: no distant metastasis

TABLE 31.1 An Application of the TNM System

The TNM system is only one method for assessing cancer and is only a guideline for prognosis and treatment considerations. The application of the system varies according to each type of tumor, and the guidelines for staging are extensive.

LINK TO LEARNING

Nurses are responsible for understanding what the staging indicates but are not responsible for knowing the details for each type of cancer. Read more about cancer staging systems (https://openstax.org/r/77cancerstaging) developed by the American Joint Committee on Cancer (AJCC).

Cancer Prevention

Prevention focuses on reducing the risk of developing cancer. This involves lifestyle changes to reduce general cancer risk as well as specific interventions to reduce the risk of cancers known to affect certain populations. There are three levels of prevention: primary, secondary, and tertiary.

Primary Prevention

Avoiding known risk factors to prevent the development of disease is ideal. Primary prevention promotes healthy lifestyle choices. Moderate or eliminate tobacco exposure, alcohol intake, and the intake of fatty or processed foods (Figure 31.13). Engage in regular physical activity and attain or maintain an acceptable weight. Ensure all recommended vaccines are kept up to date. Consistently and frequently eat foods rich in antioxidants and fiber, including fruits and vegetables.

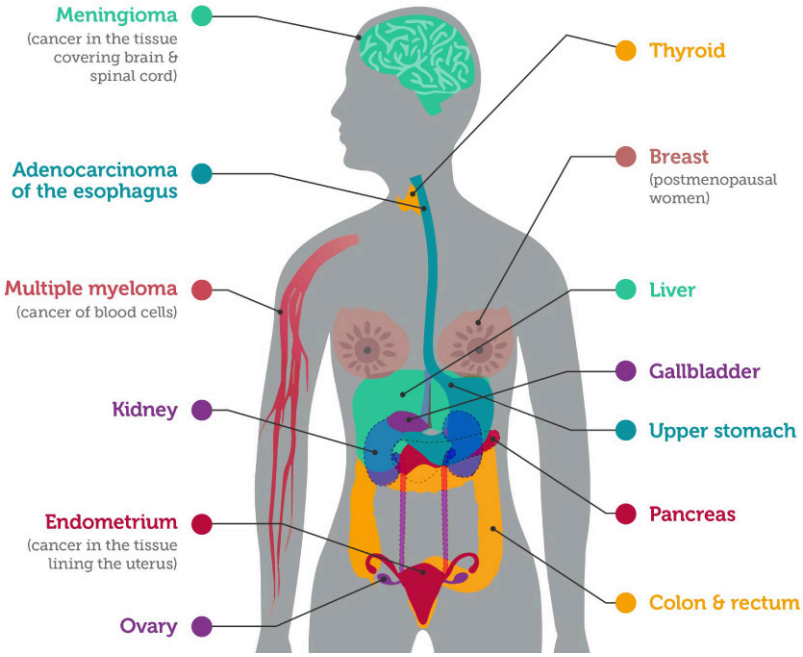

FIGURE 31.13 Obesity increases the risk of cancer by instigating hormonal and inflammatory changes in the body. (credit: "Obesity and Cancer" by NIH/National Cancer Institute, Public Domain)

Secondary Prevention

Secondary prevention involves detecting cancer when treatment has the best chance of a desired outcome. Awareness advertisements to bring attention to screening recommendations and annual consultation with a provider increase the likelihood of catching cancer early. Screening at suggested intervals and awareness of early cancer signs is the focus. These recommendations are reviewed frequently and new guidelines made available. Providers may choose which recommendations to follow when suggesting screening tests.

Some screenings are performed annually, such as mammograms and colonoscopies, even in those with no risk factors other than that of the corresponding population (biological sex, ethnicity, economic demographic, age). Testicular cancer screening is done by a provider at each annual screening, and individuals with testicles are advised to check monthly for lumps or changes. Skin cancer screening (in addition to self-surveillance) can also be done during the annual exam unless the patient has other risk factors.

REAL RN STORIES

Nurse: Jerry
Years in Practice: Twenty-three
Clinical Setting: Oncology infusion
Geographic Location: Urban hospital, southeastern United States

Joy was a boisterous, large, loud woman who was suddenly thrown into the world of acute myelogenous leukemia (AML) treatment. A new diagnosis of AML brings on a hard and fast slew of tests, specialists, intravenous lines, procedures, and an essentially foreign language of new medical terms.

The screening that brought her to us was her annual eye exam. During the eye exam, the optometrist noted petechiae in her eye. Neither she nor her husband would have noticed these tiny spots of bleeding inside her eyes. The fundoscopy procedure, looking at the back of the eye, examined the blood vessels of her eyes and discovered the issue. Her only reported symptom before that eye exam? A bit of fatigue. Participating in her regular annual exams was key to providing her treatment.

Screening is also based on individual needs such as family history, lifestyle risk factors, and relevant medical society guidelines. For example, liver cancer screening is possible, but would only be done in conjunction with risk factors

such as liver disease or hepatitis B or C infection. Lung cancer screening with low-dose CT scans is not routinely considered for individuals with no smoking or chemical exposure history. Colorectal cancer screening should be aggressive and early for individuals with a personal or familial history of Lynch syndrome.

Among medical society guidelines, there are different recommendations for cancer screenings. The organizations differ on the age to begin, age to cease screening, and length of intervals for screening; they conflict with each other in their published recommendations and supporting evidence. Organizations making recommendations vary by disease, but could include the American Cancer Society (ACS), World Health Organization (WHO), Centers for Disease Control and Prevention (CDC), United States Preventive Services Task Force (USPSTF), or the American College of Obstetricians and Gynecologists (ACOG).

Screening guidelines for common cancers are outlined in Table 31.2. It should be noted, however, that screening recommendations may differ by source and according to individual patient factors. Recommendations may be updated frequently. Ultimately, screenings to perform are chosen after a conversation between the clinician and the patient, accounting for variations between patients of average risk and those with individualized risk factors.

	Screening Test	Recommended Age/ Frequency	Notes
Breast cancer	Mammogram	Females ages 40–74: every two years (based on individual risk)	Females with high risk may require earlier or more frequent screenings.
	Clinical breast exam (CBE)	Not routinely recommended for females with average risk.	Not recommended as part of routine screening.
Cervical cancer	Pap smear (Pap test)	Females ages 21–29: every three years	Continue screening until age 65 with normal results.
	HPV test	Females ages 30–65: every five years (alone or in combination with Pap)	Pap plus HPV testing every five years; HPV testing alone every five years.
Colorectal cancer	Colonoscopy	Begin at age 45: every ten years	Alternatives include stool-based tests (e.g., FIT) or flexible sigmoidoscopy. Screening can be personalized based on patient risk factors.
	Fecal immunochemical test (FIT)	Annually for individuals with average risk	Alternative to colonoscopy for those who prefer or have contraindications.
Lung cancer	Low-dose CT scan	Adults ages 50–80 with a twenty pack-year smoking history: annually	Recommended for current or former smokers with a significant smoking history. Screening should be discontinued once a person has not smoked for fifteen years.

TABLE 31.2 Summary of U.S. Preventive Services Task Force Recommendations for Cancer Screenings

	Screening Test	Recommended Age/ Frequency	Notes
Prostate cancer	Prostate-specific antigen (PSA) test	Males ages 55–69: discuss with health-care provider	Screening decisions should be individualized, considering potential benefits and harms. Routine screening is not recommended for males under 55 or over 69.
Skin cancer	Visual skin examination	Regular self-exams and professional exams as needed	The USPSTF does not have a specific recommendation for routine skin exams; emphasis is on self-awareness and dermatologic evaluation if abnormalities are detected.

TABLE 31.2 Summary of U.S. Preventive Services Task Force Recommendations for Cancer Screenings

Tertiary Prevention

The focus of tertiary prevention is reduction of symptoms and complications related to the disease process. This includes accessing the correct treatments, symptom management, emotional and social supports, and maintaining or regaining physical and emotional health after treatment has ended. Nurses assist patients in making behavior changes to improve their condition, planning their care to support their desired quality of life, and reinforcing or elaborating on decisions surrounding their care.

31.3 Care of the Patient with Cancer

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss common complications faced by patients with cancer
- Apply nursing concepts and plan associated nursing care for the patient with cancer
- Evaluate the efficacy of nursing care of a patient with cancer
- Describe the medical therapies that apply to the care of the patient with cancer
- Explain the role of the health-care team as continued partners in coordinated health-care delivery

Cancer care requires a multifaceted approach to provide comprehensive care for patients. Nurses must apply tailored nursing care plans to address the complex needs of patients with cancer, ensuring evidence-based, patient-centered interventions. Evaluating the efficacy of nursing care is crucial for optimizing outcomes, as it involves continuous assessment and adjustment of care plans based on patient response and clinical indicators. Understanding and implementing appropriate medical therapies, including chemotherapy, radiation, and immunotherapy, is essential for effective cancer treatment. Central to this holistic approach is the role of the care team, which emphasizes the importance of collaboration, communication, and continuity of care to achieve coordinated health-care delivery. Together, these elements ensure that patients with cancer receive the highest quality of care throughout their treatment journey.

Common Complications of Cancer

Holistic assessment for a patient with cancer is the same as for any other patient; it includes the typical assessment activities of the physical examination, psychosocial assessment, and spiritual and cultural evaluation. Physical assessment includes evaluating the patient's overall appearance. Look for signs of cachexia and assess skin color to determine proper perfusion, good oxygenation, and any evidence of jaundice or bleeding. Additionally, be vigilant for other complications that may arise from cancer or its treatment.

Specific assessment will depend on the type of cancer and the patient's current treatment plan. For instance, multiple myeloma causes bone pain and can lead to fractured bones; the nurse assesses for these complications. Chemotherapeutic agents can also create complications for the patient. For example, the class of platins and taxanes can cause serious neurological toxicities and can affect a patient's ability to walk or function, reducing their quality of life.

Symptom Management and Palliation

To assist the patient in managing unpleasant symptoms, the nurse must evaluate physiological, psychological, and situational factors to determine what is worsening or alleviating the symptoms. Each symptom should also be assessed for the quality and intensity (e.g., acute, dull), duration (e.g., consistent with a certain event, intermittent, continuous), and degree of suffering it causes because people experience and tolerate unpleasant symptoms very differently.

Common side effects of cancer therapy include the following:

- Head and neck
  - memory and concentration problems
  - delirium
  - hair loss (alopecia)
  - mouth and throat issues (stomatitis, mucositis)
- Generalized
  - fatigue
  - flu-like symptoms
  - weight loss
- Hematologic
  - anemia
  - bleeding and bruising (thrombocytopenia)
  - infection (resulting from neutropenia)
- Gastrointestinal
  - appetite loss (anorexia)
  - nausea and vomiting
  - constipation or diarrhea
- Skin and nails
  - brittle nails
  - fragile skin
- Peripheral nervous system
  - peripheral neuropathy
- Lymphatic system
  - edema or lymphedema
- Genitourinary
  - urinary and bladder problems
- Reproductive system
  - sexual dysfunction
  - fertility issues

Fatigue and Pain

Fatigue is a nearly universal reported symptom among patients with cancer and patients undergoing treatment for cancer. Both the disease process and the therapies contribute to physical fatigue, and the fatigue is often profound and cumulative over the course of treatment. Reduced sleep in the hospital, anxiety over relationships and finances, along with physiological issues including pain, anemia, and inflammatory processes can significantly contribute to fatigue in patients. Regular physical activity is the only intervention with evidence to reduce fatigue, but safety should be a priority and activity must be balanced with rest periods.

Pain is a common issue and can come from a variety of sources. Medications can be one cause, including colony-stimulating factors that are administered to increase white blood cell growth but can also cause bone pain. Pain can also stem from the site of the tumor. Pain should be managed to the patient's desired comfort level, often necessitating multiple modalities and the off-label use of some medications to achieve relief. Medications such as narcotics require careful monitoring and management to minimize side effects. Ultimately, the goal of pain management is to enable the patient to participate in day-to-day activities and enjoy their desired quality of life.

Altered Gastrointestinal Function

The gastrointestinal tract is often affected by cancer treatments, from the oral cavity all the way through to the anus.

Cell death caused by chemotherapy can cause pain and alterations in the mucosal lining, called **mucositis**. Patients can often have **stomatitis**, which is mucositis specifically in the mouth. This condition results in pain with chewing; in the esophagus, there may be difficulty swallowing.

Ulcerations and infections occur more frequently as the mucosal surface is compromised. Having the patient gargle four times each day with a mixture of warm water, salt, and baking soda can help prevent these complications and can reduce the severity or aid in healing. The nurse can also offer a variety of soft food options that require little chewing, are easy to swallow, and are nutrient-rich. Yogurt, peanut butter milkshakes, and protein-rich supplements are useful. At the end of the gastrointestinal tract, rectal bleeding and infection risk are affected by factors such as mucosal alterations, constipation, thrombocytopenia, and neutropenia.

LINK TO LEARNING

Learn more about the interventions to treat oral mucositis (https://openstax.org/r/77oralmucositis) from the Oncology Nursing Society.

Nausea and vomiting are often caused by the action of chemotherapy in the **chemoreceptor trigger zone** of the brain but can also be caused by opiates, antibiotics, metabolic alterations, increased intracranial pressure, constipation, and anxiety about treatments (psychogenic response). To help limit patient nausea, remove the lids of food trays before entering the hospital room, as the steam from hot food can increase strong odors. Cold foods generally have milder smells than hot foods and are often a good choice for patients with stomatitis. Additionally, gastric ulcers can be prevented with the prophylactic use of a proton-pump inhibitor. Nausea and vomiting are treated aggressively, typically with multiple antiemetic medications (Table 31.3).

Medication Class	Medication Example
Prokinetic	Metoclopramide
Serotonin antagonists	Ondansetron
Neurokinin inhibitors	Aprepitant
Corticosteroids	Dexamethasone
Benzodiazepines	Lorazepam
Dopamine receptor antagonist	Haloperidol
Phenothiazines	Prochlorperazine
Cannabinoids	Dronabinol
Antihistamines	Diphenhydramine
Antimuscarinics	Scopolamine

TABLE 31.3 **Antinausea Medications for Patients with Cancer**

Altered Clotting and Immunity

Hematological complications can occur in patients with hematological cancer, but also in any patient receiving chemotherapy or radiation treatment. Anemia can be severe. The nurse will watch for changes in blood pressure but will also be alert for more subtle cues such as dizziness when changing positions. The goals of therapy should be lower-than-normal hematocrit and hemoglobin values with resolution of symptoms and prevention of complications.

There is a severe risk of bleeding if the platelet count drops below 50,000 platelets per microliter of blood (reference range: 150,000 to 450,000 platelets per microliter of blood). Below 10,000 platelets per microliter of blood, spontaneous bleeding is a serious concern. Monitor for petechiae, pinpoint spots of bleeding that look, at first glance, as a rash (Figure 31.14). Petechiae begin in areas with dependent fluid movement, such as the lower legs, but can occur anywhere. Petechiae are noted before frank bruising or bleeding. Platelet transfusions can be given, but the goal of this transfusion is only to prevent bleeding, not to achieve an acceptable reference range.

FIGURE 31.14 Petechiae are small and flat. They can be red, purple, or brown in appearance. They are nonblanching evidence of broken capillaries. The lower extremities are a common location for petechiae to first appear. (credit: Peter Rammstein/Wikipedia Commons, Public Domain)

Infection can be life-threatening for the patient with a decreased white blood cell and neutrophil count. Because the immune system is hampered, the nurse does not expect typical signs of infection or sepsis. Typical signs of infection require functional white blood cells and immune responses. A slight temperature elevation or a low temperature could be the only early alteration in vital signs. Cognitive changes are often noticed first, similar to the expected assessment results in the older adult patient.

Altered Nervous System Functions

Certain therapies can affect the brain and nerves, resulting in **neuropathy**. Nerve damage causes tingling, numbness, or pain in the hands or feet. This affects quality of life and can alter the ability to safely perform certain tasks. Balance and gait can be affected by certain other chemotherapeutic agents.

Cognitive changes, sometimes referred to as “chemo brain,” can result from any chemotherapy. These changes manifest as problems with memory and attention to tasks. Sometimes treatment-related cognitive changes are a safety issue, especially when driving or cooking, when attention to task is critical.

Social isolation can occur when an individual experiences difficulty recalling faces, events, and names. This impairment in memory can lead to a sense of disconnection and frustration, making social interactions challenging. As a result, the person may withdraw from social activities and relationships, further exacerbating feelings of loneliness and isolation. The inability to engage in meaningful conversations and maintain relationships can diminish a patient’s overall quality of life and contribute to emotional distress. Nurses help patients create a plan to address memory issues and provide support to help individuals stay connected with their social networks.

Skin Impairment

Skin and hair changes, such as alopecia, are typical. Nails can become brittle or discolored. Dry skin requires attention and care, because breaks in the skin barrier increase the risk of infection or bleeding. Patients often lose

body hair, eyebrows, and eyelashes as well as scalp hair. Losing hair is a distressing psychosocial event for many patients. Sometimes a cold cap is offered to reduce this occurrence. The cooling decreases the metabolic rate in the follicles and decreases medication uptake in the scalp. More long-term studies are needed to assess the risk of cutaneous scalp metastasis (Silva et al., 2020).

Oncological Emergencies

An **oncological emergency** is an acute issue that may cause mortality or morbidity. Early detection of an oncological emergency is critical. It is the result of either the cancer itself or the treatment regimen for the cancer. These conditions can develop over months or hours, but the results are devastating if they are not caught and treated emergently. These can be classified by how they occur.

Metabolic Emergencies

Metabolic emergencies include tumor lysis syndrome (TLS), hypercalcemia, and syndrome of inappropriate antidiuretic hormone (SIADH). TLS is more common in hematological malignancies such as acute leukemia and non-Hodgkin lymphoma. TLS is a dangerous complication of cancer treatment, characterized by the rapid breakdown of cancer cells leading to metabolic disturbances. It can result in electrolyte imbalances such as hyperkalemia, hyperphosphatemia, hypocalcemia, and hyperuricemia, which can lead to serious complications. The nurse monitors labs every four hours during therapy when this complication is likely. Intravenous hydration is very aggressive and urine output is strictly monitored.

Hypercalcemia is often associated with multiple myeloma due to bone destruction and an overproduction of a hormone that mimics the action of parathyroid hormone. Aside from calcium levels, the nurse assesses for manifestations of hypercalcemia, including mental functioning and muscle weakness. SIADH is usually associated with small-cell lung cancer and ectopic production of antidiuretic hormones by the tumor cells. The nurse assesses sodium levels and may note nausea, constipation, and muscle weakness. Sodium levels are corrected slowly and carefully with ongoing assessment.

Hematologic Emergencies

Hematologic emergencies encompass conditions such as febrile neutropenia (neutropenic fever) and **hyperviscosity syndrome**. Neutropenic fever, commonly seen in patients who have leukemia or are undergoing chemotherapy who have an absolute neutrophil count below 500 cells/ per mm^3 and a slightly elevated temperature (100.4°F, or 38°C), requires prompt management, including consultation with the infectious disease department. Failure to recognize and treat neutropenic fever can result in septic shock. Disseminated intravascular coagulation (DIC) can occur, especially in cases of sepsis or other cancer-related complications, leading to a dangerous cycle of simultaneous clotting and bleeding, often with lethal consequences.

Hyperviscosity syndrome is associated with conditions that overproduce proteins, such as multiple myeloma and certain types of leukemia. With multiple myeloma, abnormal plasma cells produce excessive amounts of a specific immunoglobulin, making the blood thicker and more prone to clotting. In certain types of leukemia, particularly chronic lymphocytic leukemia, the increased production of lymphocytes can also contribute to hyperviscosity. Symptoms include headache or dizziness, and the condition can lead to serious complications such as a cerebrovascular accident, myocardial infarction, or organ damage. Using plasmapheresis to filter out the excess proteins reduces symptoms.

Structural Emergencies

Structural emergencies are due to a tumor's encroachment on an organ or tissue. Examples include superior vena cava syndrome, spinal cord compression, and malignant pericardial or pleural effusion. Lung cancer is a common cause of structural emergencies, although many other types of cancer can impinge on structures and cause emergent issues. Superior vena cava syndrome results from obstruction of blood flow through the superior vena cava. Manifestations of this issue are a direct result of impaired blood flow: facial and neck edema, cough, and shortness of breath at rest. Spinal cord compression can cause back pain early in its course and can progress to disrupted functions related to compression on spinal nerves: difficulty urinating, constipation, and alterations in lower extremity sensation. If not treated, spinal cord compression results in paralysis. Pericardial and pleural effusions represent the accumulation of malignant fluid. Heart sounds or lung sounds may be muffled or absent. Systemic issues follow and are typical of what the nurse expects from decreased perfusion or decreased oxygenation findings.

Nursing Care of the Patient with Cancer

Nursing care for individuals with cancer addresses physical, psychosocial, cultural, and spiritual needs. Though the focus of much of this chapter is about managing physiologically based risks and complications, cancer care typically continues for weeks, months, and years. A holistic approach that keeps the patient's dignity at the forefront is essential. The nurse is frequently able to facilitate communication between the patient and loved ones and to advocate for the patient's needs with the providers and interdisciplinary team. Physical care involves symptom management, medication administration, and monitoring for side effects, complications, and therapeutic outcomes.

Recognizing Cues and Analyzing Cues

Nurses look for cues in abnormal test results, new symptoms, and changes in the patient's condition that indicate additional testing or intervention is needed. Nurses actively monitor abnormal test results, new symptoms, and changes in a patient's condition that may signal the need for further testing or intervention. They also assess and manage side effects of treatments such as radiation, chemotherapy, and immunotherapy, which can have diverse and potentially serious complications that require prompt recognition and intervention to ensure patient safety.

Planning care for patients with cancer necessitates ongoing clinical judgment to interpret cues effectively. The care plan addresses common issues in cancer treatment, such as electrolyte and fluid imbalances, as well as comfort-related concerns such as nausea, pain, and fatigue. Additionally, it considers alterations in the patient's overall quality of life, encompassing both psychosocial and physiological aspects. The nurse's care plan also anticipates potential oncological emergencies based on the patient's unique pathophysiology, type of cancer, treatment regimen, and individual responses.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

When the nurse knows how to interpret common clinical cues, it becomes quick work to determine which issue the patient may be experiencing, from common side effects to life-threatening complications.

For example, if a patient undergoing chemotherapy treatment has a low white blood cell count and a temperature that is trending upward, the nurse prioritizes the hypothesis that the patient likely has an infection. Initial solutions are aimed at controlling the immediate physiological risks and include monitoring pulse, blood pressure, and respirations to determine if additional interventions (e.g., administering fluids, oxygen therapy) are needed to maintain hemodynamic stability. Next, the nurse obtains cultures, such as blood and urine, followed by obtaining orders for antibiotics and other supportive therapies, such as antipyretics. This sequence of actions effectively and efficiently addresses the patient's needs and works to achieve the best possible outcomes (Table 31.4).

Clinical Cue/ Problem	Hypothesis	Solutions	Actions/Interventions
Fatigue	• Chemotherapy or radiation therapy side effect • Anemia	• Encourage rest balanced with activity.	• Monitor energy. • Adjust activity for level of intolerance. • Assess complete blood cell count.
Nausea or vomiting	• Chemotherapy side effect • Ileus or obstruction	• Antiemetic medication • Evaluate meals.	• Administer antiemetics. • Prevent dehydration. • Offer foods without strong odor.

TABLE 31.4 Managing Side Effects and Complications

Clinical Cue/ Problem	Hypothesis	Solutions	Actions/Interventions
Alopecia	• Chemotherapy side effect	• Provide support.	• Assist with scalp and hair care. • Offer support. • Provide information on wig services.
Constipation	• Side effect of opioids or chemotherapy • Ileus or obstruction	• Increase bowel motility. • Increase patient mobility.	• Assist with ambulation. • Provide frequent fluids. • Administer stool softeners or laxatives.
Confusion	• Infection • Brain metastasis • Medication side effects	• Ensure safety. • Look for data to support or refute each hypothesis.	• Put on bed alarm. • Discuss with bedside visitors. • Consult with other nursing staff. • Evaluate temperature and common infection sources. • Consult with provider about potential metastasis. • Examine medications for interactions or dose changes.
Petechiae	• Thrombocytopenia • Sepsis • Drug reaction • Disseminated intravascular coagulation (DIC)	• Ensure safety. • Look for evidence to support or refute each hypothesis.	• Discuss with the patient other sources of potential bleeding. • Instruct patient to avoid injury. • Assess lab values. • Evaluate medications for side effects. • Monitor vital signs.

TABLE 31.4 Managing Side Effects and Complications

Evaluating Outcomes

The nurse assesses often for the patient's understanding of their condition, treatment plan, and self-care instructions, adjusting whenever the patient's outcomes are not being met or when there are changes to the plan of care (Table 31.5). Evaluation of outcomes is ongoing because interventions that were effective before may not work in the future for the individual. Cancer care spans weeks, months, and years throughout diagnosis, treatment, remission, maintenance, and potential recurrence. Pain tolerance changes, food preferences change, and ongoing disability may change the individual's ability to cope.

Complication	Explanation	Intervention	Cue for Revision	Intervention
Infection	Patient is immunocompromised due to chemotherapy.	• Administer appropriate antibiotics. • Maintain infection control measures.	New pathogen	• Obtain new blood and urine cultures for recurrence of fever. • Alter therapy based on culture results and clinical response. • Consider cessation of cancer treatment until white blood cells recover.
Bleeding	Thrombocytopenia due to chemotherapy	Administer random donor platelets.	• Post-transfusion platelet count does not change. • Bleeding or petechiae continue.	Administer single donor platelets (HLA-matched platelets are difficult to obtain, but are an option).
Anemia	Patient is anemic due to chemotherapy's effect on the bone marrow.	• Iron supplements • Administer erythropoiesis-stimulating medications. • Blood transfusion	Hematocrit and hemoglobin do not resolve to necessary levels to maintain perfusion.	Look for sources of bleeding.

TABLE 31.5 Evaluating Outcomes and Revising Interventions

Encouraging nutritional intake can be a daily challenge for the patient. A favorite food may taste great on one day, only to be revolting to the patient on the next day. This can often develop into a frustrating and confusing experience. Protein-rich foods are needed, but patients are often too fatigued to chew their food, requiring the nurse to become creative with meeting revolving nutritional needs. Typical protein sources such as nuts or meat may not be good choices, depending on the patient's condition. If strong smells are offensive and result in nausea, the patient may not tolerate peanut butter. If the patient is experiencing a great deal of fatigue, they may not be able to eat steak or grilled chicken. When the patient has severe mucositis, foods that are coarse, salty, or sharp cause intense pain. The nurse determines the patient's comfort after interventions for pain and nausea, obtaining and administering additional doses or different medication as needed to meet the desired comfort level. Ideally, a dietitian is involved in the patient's care. A nutritional supplement is typically offered with each meal. Often, the

nurse assists the patient to determine what they can or cannot tolerate throughout each day. One modification to the nutritional supplement, such as the nurse adding ice cream to create a milkshake, can make the difference for the patient's caloric and nutrient intake.

CLINICAL JUDGMENT MEASUREMENT MODEL

Evaluate Outcomes: Did It Help?

The patient was admitted late Friday afternoon, just around the time of the scheduled shift change. The patient presented with difficulty voiding, constipation, and bilateral changes to sensation in her lower extremities. A new diagnosis of cancer with a spinal cord compression was diagnosed, and treatment was begun. Oncological emergencies must be treated quickly. The evening nurse reported on Saturday morning that the patient had not shown improvement in the roughly sixteen hours since she had been admitted, and high-dose radiation was being arranged to begin over the weekend. In comparing this situation to others, the oncoming nurse recognized that this is not the expected outcome or therapy and could represent a problem. Recognizing these cues, the nurse reenters the clinical judgment cycle.

During shift report, the nurses were required to review orders and chart information from the previous shift. The oncoming nurse asked about steroid doses because it was not evident in the chart, and this is a standard treatment for spinal cord compression. The off-going nurse stated that there were no steroid orders. Together, they examined the previous day's orders. It was a very long list and squeezed in with small handwriting at the bottom of the order sheet was the order for high-dose steroids to be administered every six hours. The error was caught because the nurse knew the way the patient should respond to standard therapy for the presenting condition. The error was corrected because the nurse evaluated the patient's outcomes, realized that they were not adequate or expected, and began to evaluate why and what else might need to occur.

Medical Therapies and Related Care

Treatment options vary widely based on individual patient factors, including age, overall health, type of cancer, and stage of progression. Medical therapies may include surgery to remove tumors or affected tissues, targeted therapies that attack specific molecules, hormone therapy for hormone-driven cancers, stem cell transplants to replace diseased bone marrow, and genetic profile-specific medicine. The most commonly used therapies are external or internal radiation, chemotherapy, and immunotherapy drugs.

Therapy-Specific Nursing Care

Each type of therapy requires specific nursing care. Nursing care for patients with cancer involves a comprehensive approach tailored to individual factors such as age, overall health, cancer type, and stage of progression. Nurses play a crucial role in preparing patients for surgery, providing preoperative and postoperative care, and monitoring for complications. For patients receiving targeted therapies, nurses monitor for side effects and educate patients on their specific treatment plan. Hormone therapy requires close monitoring for hormonal changes and potential side effects, with nurses providing education and support. Stem cell transplant patients require meticulous monitoring for signs of infection or graft-versus-host disease, with nurses providing supportive care. Additionally, nurses play a key role in administering radiation, chemotherapy, and immunotherapy drugs, monitoring for side effects, and managing symptoms to improve quality of life.

REAL RN STORIES

Nurse: Catherine, BSN
Years in Practice: One

Clinical Setting: Medical-oncology unit
Geographic Location: Metropolitan Nashville area

I was still a new nurse and was excited to finally be allowed to solely care for a patient with AML (acute myelogenous leukemia). Renette had been through a whirlwind for two days. Just like any patient with this diagnosis, her life had almost instantly gone from normal to having an acute illness and a required hospitalization marked by a blur of testing, medical professionals, and the business of learning new medical terminology. The bone marrow biopsy had been done, chemotherapy had started, and the requisite labs were being drawn every few hours. Every hour or two, something was being done for her. It was a storm of overwhelming new information and sensations.

Although she looked well, her labs certainly indicated that she was clearly critically ill. At about 5 p.m., one of her providers came by to order additional labs. He entered the room to explain the new addition to her treatment plan. I gathered supplies and entered the room to gather the urgent lab samples. Renette shoved her food tray at both of us and yelled, "Can you not leave me alone long enough to eat one meal!?" The doctor and I both stood back in shock.

That's when I realized that she didn't feel cared for. She felt these things were being done to her. I had failed to truly include her. We had failed to help her determine her boundaries. The only space she had where she might create some normalcy was that patient room that we were barging in and out of all day. I had allowed myself to get so caught up in her physiological needs, which were serious and many, that I had not addressed her very real need to be treated with respect, dignity, and compassion. The doctor finished what needed to be said, and I informed her I would have to be back within thirty minutes to complete the tasks.

This was Renette's remission induction phase of AML treatment. I remained her primary nurse for the many months that she needed leukemia treatment. We developed a terrific relationship, and more than twenty years later, I have a gift on my nightstand from her, a token to promote sleep. She still reminds me to take care of myself and to advocate for patients during their storms.

Radiation Therapy

There are many types of **radiation therapy** available, and their use depends on individualized factors. Radiation therapy is a cancer treatment that uses radiation to kill cancer cells or shrink tumors. Every effort is made to reduce the effects of radiation on healthy tissue. Radiation oncologists work closely with the patient to ensure the best outcome based on the treatment goals.

The most common is **external beam radiation**. This treatment uses a machine outside the body to deliver a radiation dose to the cancer site (Figure 31.15). External beam radiation therapy typically occurs on most days of the week for a set number of days. Initially, the patient needs teaching about the treatment, side effects, and issues to report to the provider. Fatigue is also a common side effect of radiation therapy.

FIGURE 31.15 Radiation therapy is delivered via a machine and doses are targeted to the cancer site. (credit: "Woman Prepared for Radiation Therapy" by NIH/National Cancer Institute, Public Domain)

As treatment days accrue, side effects accumulate and increase in severity. For example, the patient's skin may develop a reddened area at the irradiated site that worsens with each treatment. Radiation dermatitis requires special care, and the patient should

- avoid constricting garments,
- limit the use of lotions or creams to those approved by the radiation oncologist, and
- employ pain management for comfort.

Internal radiation therapy, or **brachytherapy**, is a type of radiation treatment in which a radioactive source is placed inside the body near the tumor (Figure 31.16). There are special precautions for nurses and visitors, depending on the type of brachytherapy in use (e.g., sealed, unsealed). The nurse will consider the principles of time, distance, and shielding. Care is grouped to reduce exposure time, and the nurse will work behind a lead shield while keeping as much distance as is reasonable for the required task.

FIGURE 31.16 Radioactive seeds are one type of internal radiation. They are placed in or near the tumor, minimizing damage to healthy cells. (credit: "Breast Cancer Treatment Using Iridium Seeds" by NIH/National Cancer Institute, Public Domain)

Other types of radiation are more specialized. Stereotactic radiosurgery delivers high radiation doses with a great degree of precision. Proton therapy uses protons to deliver radiation doses to the tumor (Figure 31.17). Intensity-modulated radiation therapy uses computer-controlled beams of radiation from multiple angles.

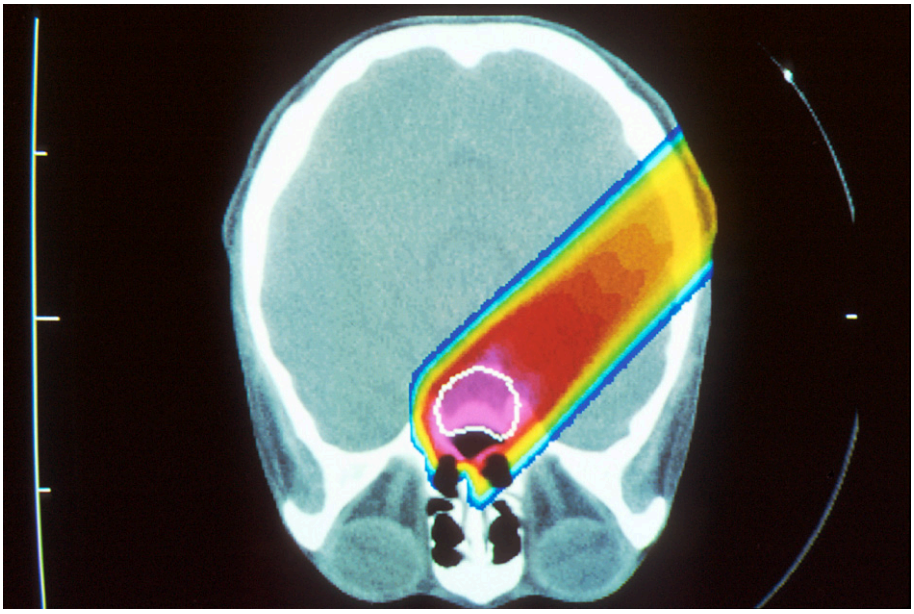

FIGURE 31.17 The tumor is noted in red with a proton beam noted by the yellow line. (credit: "Proton Beam Therapy" by NIH/National Cancer Institute, Public Domain)

CLINICAL SAFETY AND PROCEDURES (QSEN)

Safety: Radiation Therapy

Radiation enters body fluids and is eliminated in feces and urine, meaning that waste products are radioactive and should not be directly touched. Safety of the patient, visitors, and staff are always at the forefront of radiation care. The following precautions are taken with patients who have sealed radioactive implants:

- A sign is placed on the door to indicate radiation is present and that staff and visitors should not enter without

speaking to the nurse.
- Portable lead shields and/or lead-lined rooms are required.
- The door to the room should remain closed.
- Hospital policies to monitor and reduce exposure should be followed.
- Pregnant staff and those who are trying to become pregnant should not care for the patient.
- Visitation time should be limited. Other restrictions are usually related to age and pregnancy status.
- Radioactive source should never be touched with your hands. If it becomes dislodged, tongs are used to move it to a lead container in the room.
- Bed linens are saved in the room; meal trays are disposed. All trash and linen remains in the room until the radioactivity level is cleared by the radiation department.
- Equipment can either be dedicated to the room or it can be safely used between patients.
- Look for orders to include an indwelling urinary catheter and medications to cause constipation in some instances. This is an effort to contain waste materials and prevent dislodgment of the radiation source.

Chemotherapy

A class of drugs used to destroy cancer cells known as **chemotherapy** targets cells that are rapidly dividing, a hallmark of cancer cells. Chemotherapy can be used to induce remission of cancer, control its growth, or relieve complications such as a tissue or organ obstruction.

Nurses must be certified to deliver chemotherapy doses to a patient. Chemotherapeutic agents are also known as antineoplastic medications and require special handling when being prepared, administered, and discontinued. Institution protocols dictate requirements for personal protective equipment (PPE) that must be worn and certain cleanup techniques for spills, for example. These medications are marked with a bright yellow sticker to alert the nurse about the hazardous nature of the drug.

Teaching is unique to the drug regimen used in the patient's therapy. In general, chemotherapy destroys any rapidly dividing cells in the body, including blood cells and cells that make up the mucosal lining of the mouth and entire gastrointestinal tract. However, each class of chemotherapeutic medication has its own adverse effect profile. The unwanted effects of therapy are often severe, and the nurse is often responsible for interdisciplinary coordination to aggressively manage the unwanted effects.

Many therapy regimens begin with a course of pre-administration medications to prevent or reduce common side effects. To prevent or reduce nausea, medications such as lorazepam (a benzodiazepine) and ondansetron (a serotonin receptor antagonist) may be given. Chemotherapy is known for causing chills or fever, so one or more antihistamines may be used prior to each dose of the medication. The nurse also monitors the patient during intravenous chemotherapy infusions for any reactions.

LINK TO LEARNING

Cancer therapies have the potential for causing infusion reactions. Even though infusion reactions (https://openstax.org/r/77infusionreact) all involve the immune system, they are not all true allergic reactions.

Immunotherapy

A type of treatment that helps the immune system fight cancer is called **immunotherapy**. Immunotherapy enhances the ability of the immune system to recognize and destroy cancer cells. Common antitumor agents are listed in Table 31.6. The most essential nursing care for the patient receiving immunotherapy is often observing for flu-like reactions during intravenous infusions. Immune-mediated therapy induces the body's immune system to destroy cancer cells, leading to a high risk of a hypersensitivity reaction. Typical reactions can include urticaria, hypotension, angioedema, bronchospasm, rigors (sudden feeling of cold with severe shivering, and a sharp rise in body temperature), and body aches. Reactions can occur regardless of how often the patient has received this drug in the past. The protocol for administration of immunotherapy should include pre-administration medications, beginning infusion rates to test the patient's tolerance, and administration of medications such as intravenous steroids if certain reaction parameters are met.

Medication Class or Therapy	Mechanism of Action
Antimetabolites	• Interfere with DNA and RNA synthesis • Lead to cell death during S phase of cell cycle
Antitumor antibiotics	• Bind directly to DNA, disrupting function • Inhibit RNA synthesis; prevent cell replication
Antimitotics	• Interfere with microtubule function during cell division • Prevent mitosis; cause arrest of cell cycle
Alkylating agents	• Cause DNA cross-linking and strand breaks • Prevent DNA replication
Topoisomerase inhibitors	• Inhibit enzymes necessary for DNA replication
Targeted agents (not an all-inclusive list)	• Target specific molecules that cancer cells need
- Tyrosine kinase inhibitors	• Block tyrosine kinase enzyme • Inhibits cell proliferation
- Epidermal growth factors	• Block epidermal growth factor receptor • Prevent activation of signaling pathways
- Angiogenesis inhibitors	• Inhibit formation of new blood vessels (angiogenesis) • Starve tumor of nutrients and oxygen
- Vascular endothelial inhibitors	• Block vascular endothelial growth factor (VEGF) • Prevent formation of new blood vessels to supply the tumor
- Monoclonal antibodies	• Bind to specific antigens on cancer cell surface • Mark cancer cells for destruction by the immune system or block growth signals
Cancer vaccines	• Prevent cancer from developing • Treat cancer by strengthening natural immunity
CAR T-Cell therapy	• T cells are removed from patient and modified to produce chimeric antigen receptors. • After reinfusion into the patient, the immune system can better recognize cancer cells.

TABLE 31.6 Antitumor Agents

Coordination of Care

Cancer care requires a truly comprehensive coordination of care among interdisciplinary team members. The

complex and ongoing nature of cancer care often requires specialized providers that are unique to patients with cancer.

INTERDISCIPLINARY PLAN OF CARE

Care Providers Met throughout Cancer Treatment

1. Medical oncologists
    - Role: Determine overall treatment plan, prescribe chemotherapy, immunotherapy, or other systemic treatments.
    - Intervention: Request consults with other specialists as needed and adjust treatment plans based on patient response.
    - Coordination: Regularly communicate with the care team to ensure cohesive treatment and monitor progress.
2. Radiation oncologists
    - Role: Determine the type, dose, and schedule of radiation therapy.
    - Intervention: Administer radiation treatments, monitor for side effects, and adjust treatment as necessary.
    - Coordination: Work with the medical oncologist and other team members to integrate radiation therapy into the overall treatment plan.
3. Surgical oncologists
    - Role: Perform biopsies, stage cancer, and conduct supportive surgeries (e.g., placing ports).
    - Intervention: Reduce tumor burden, relieve obstructions, and improve quality of life through surgical interventions.
    - Coordination: Collaborate with oncologists and other specialists to plan surgical procedures and postoperative care.
4. Nurses
    - Role: Provide direct patient care, manage side effects, and offer education and support.
    - Intervention: Administer therapies, monitor for complications, teach patients about their condition and treatment, and provide emotional support.
    - Coordination: Communicate with other team members to ensure comprehensive care and early identification of emergencies.
5. Clinic nurses
    - Role: Manage outpatient care for patients not requiring twenty-four-hour support.
    - Intervention: Administer treatments, monitor for side effects, and provide patient education and support.
    - Coordination: Work with home health nurses and other team members to ensure continuity of care.
6. Home health and hospice nurses
    - Role: Provide in-home care and support, particularly for patients transitioning from hospital to home or those in hospice care.
    - Intervention: Monitor patient health, manage symptoms, and ensure adequate in-home support.
    - Coordination: Work with the health-care team to address urgent needs and provide comfort care.
7. Palliative care nurses
    - Role: Manage symptoms and provide supportive care for serious illnesses.
    - Intervention: Offer interventions to relieve symptoms, improve quality of life, and support both curative and noncurative treatment goals.
    - Coordination: Collaborate with other team members to integrate palliative care into the overall treatment plan.
8. Research nurses
    - Role: Manage patients participating in clinical trials.
    - Intervention: Document care, assess patient trends, and ensure adherence to research protocols.
    - Coordination: Work closely with the research team and other health-care providers to support trial requirements.
9. Patient navigators

- Role: Assist patients and families in navigating the health-care system.
- Intervention: Coordinate care, access resources, and address service gaps.
- Coordination: Communicate with all team members to ensure the patient receives comprehensive support.

10. Social workers/case managers
    - Role: Support patients with logistical, financial, and emotional needs.
    - Intervention: Provide counseling, financial assistance, and referrals to outside support services.
    - Coordination: Collaborate with the health-care team to address holistic patient needs.
11. Pharmacists
    - Role: Manage medication regimens and monitor for interactions and side effects.
    - Intervention: Provide medication counseling, manage prescriptions, and assist with obtaining financial assistance for medications.
    - Coordination: Work with oncologists and nurses to ensure safe and effective medication use.
12. Dietitians
    - Role: Provide dietary guidance and manage nutritional needs.
    - Intervention: Develop nutrition plans, address limitations to chewing or swallowing, and offer creative dietary solutions.
    - Coordination: Collaborate with the health-care team to ensure nutritional needs are met in both hospital and home settings.
13. Physical and occupational therapists
    - Role: Support physical functioning and activities of daily living (ADLs).
    - Intervention: Develop exercise programs, provide adaptive techniques, and address in-home obstacles.
    - Coordination: Work with the health-care team to support patient mobility and independence.
14. Mental health providers
    - Role: Provide emotional and psychological support.
    - Intervention: Offer counseling, support groups, and psychiatric care.
    - Coordination: Collaborate with the health-care team to address the psychosocial aspects of cancer care.
15. Plan implementation
    - Initial meeting: All disciplines meet to discuss the patient's case and create an initial care plan.
    - Regular updates: Weekly or biweekly interdisciplinary meetings to update the plan based on patient progress and new assessments.
    - Communication: Utilize a shared electronic health record (EHR) system for real-time updates and communication among team members.
    - Patient and family involvement: Include the patient and family in care planning meetings to ensure their preferences and concerns are addressed.
    - Education: Provide ongoing education to the patient and family about the disease process, treatment options, and available support services.

Many of the roles on the care team can be filled by nurses, including case managers, patient navigators, infusion nurses, and oncology nurse specialists. The Oncology Nursing Society (ONS) is a professional organization dedicated to advancing the field of oncology nursing. The ONS provides educational resources, certification programs, and practice guidelines to support oncology nurses in delivering high-quality care. The organization also advocates for policies that benefit patients with cancer and the nursing profession.

In each of these roles, nurses are integral to delivering holistic, patient-centered care. Their diverse expertise and dedication ensure that patients with cancer receive the support they need throughout their treatment journey, from diagnosis to survivorship or end-of-life care.

31.4 Survivorship

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Define *cancer survivor* and discuss components of survivorship care
- Describe the physical and emotional impact of cancer recurrence and secondary cancers
- Discuss the role of the health-care team for patients who have experienced cancer in improving their quality of life
- Identify strategies to improve coordination of survivorship care

Survivorship

Cancer treatments, as with all medicine, have changed greatly over the past 300 years. In the 1700s and 1800s, scientists discovered connections between environmental factors, such as chimney soot, and the occurrence of certain cancers, such as squamous cell carcinoma. In the 1800s and 1900s, the use of radiation, tissue-sparing surgical techniques, genetic differences, bone marrow and stem cell transplantation, and medications such as combination chemotherapy, monoclonal antibodies, and hormone therapy expanded cancer treatment options. In the 2000s, the creation of vaccines against known cancer-causing viruses and the introduction of immunotherapy in cancer treatment have improved patient outcomes (McAleer, 2022).

LINK TO LEARNING

Read a more detailed timeline of the history (https://openstax.org/r/77cancerhistory) of cancer treatments.

Cancer, in general, is now largely considered a chronic condition to be managed, according to the ACS (2024). Disease can be controlled or described as stable. About 18.1 million people in the United States are cancer survivors, and that number is expected to climb to 26 million by 2040 (Tonorezos et al., 2024). Consider, also, that 67 percent of individuals are age 65 or older at the time of diagnosis. The term **survivorship** embraces the reality of individuals living beyond the cancer diagnosis. Some survivors are completely cancer-free whereas others are living with cancer. Anyone with a history of cancer is considered to be in survivorship (NCI, 2024a).

LINK TO LEARNING

This article outlines developing a national standard of care for cancer survivorship (https://openstax.org/r/77cancersurvcare) with a goal to enhance delivery of survivorship care across the nation.

Challenges for health-care providers include understanding the complexity of chronic management, implementing ongoing surveillance and follow-up care, providing support, ensuring care access, and maintaining good communication with the individual and the care team. To help providers and their patients, there are still many opportunities to enhance availability and quality of health-related services for survivors and to empower individuals to advocate for themselves and use community support services.

Challenges faced by cancer survivors may be psychological, social, emotional, spiritual, or physical. Psychosocial needs include issues with insurance and financial assistance, memory loss, parenting and work guidance, and emotional health. Physical concerns include fatigue, physical functioning, weight changes, chemotherapy-induced peripheral neuropathy, cardiomyopathy, and fertility and sexuality concerns.

Physiological Effects

A delayed effect, or **late effect,** of cancer treatment is one that arises months or years after diagnosis and treatment. The American Society of Clinical Oncology and the Oncology Nursing Society are among the organizations guiding physicians and nurses in how best to navigate these challenges with patients. These late effects vary somewhat according to the type of cancer, its stage, surgical procedures performed, the chemotherapy medications used, radiation therapy and site, use of hormonal or other systemic therapies, and genetic components.

Psychosocial Effects

The emotional burden of a cancer diagnosis is significant, often accompanied by a pervasive fear of recurrence. The uncertainty and waiting associated with regular diagnostics can exacerbate this fear, leading to heightened levels of anxiety, depression, and trauma-related stress. Patients may experience a sense of helplessness, especially during watchful waiting periods, where they are tasked with monitoring symptoms and alerting their health-care team to any changes. This constant vigilance can be mentally exhausting, adding to the overall psychological strain of the diagnosis.

Cancer diagnosis and treatment can also have profound effects on personal relationships. Familial dynamics may shift as roles and responsibilities within the family unit are redefined. Partners, spouses, and significant others often face unique challenges as they navigate providing support while dealing with their own fears and emotions. Intimate relationships may undergo strain as the focus shifts to managing the physical and emotional demands of the illness, potentially altering the dynamics of the relationship.

Parent-child interactions can be deeply affected by a cancer diagnosis, with parents grappling with feelings of guilt or worrying about the impact of their illness on their children. Children, in turn, may experience fear, confusion, and anxiety about their parent's health and the changes occurring within the family dynamic. Siblings, too, may experience a range of emotions as they navigate their own responses to the family's new reality, from fear and sadness to resentment or guilt.

Maintaining social connections outside of the immediate family can be challenging for individuals with cancer. Friends and acquaintances may struggle to offer support, and unintentionally hurtful comments or actions can lead to feelings of isolation and loneliness. Despite these challenges, many individuals find that their relationships become more meaningful and resilient in the face of adversity. Shared experiences of facing cancer can create bonds of empathy and understanding that strengthen personal relationships and provide much-needed support during a difficult time.

A cancer diagnosis not only affects the individual's physical health but also has far-reaching effects on their emotional well-being and personal relationships. It is essential for health-care providers to address these emotional and relational aspects of cancer care, providing support and resources to help patients and their loved ones cope with the challenges they face.

Sexual Health and Fertility Effects

Fatigue is a significant obstacle to maintaining healthy sexual intimacy. Teaching for the patient and the partner is crucial; this includes setting expectations around thoughts of returning to prediagnosis libido. Shortness of breath may result from physical changes or surgeries, scarring from radiation, or prolonged inactivity during treatment. Other physical changes might include hormonal changes. In women, this can lead to vaginal dryness and discomfort. If radiation or surgery was performed in the pelvic or genital areas, sexual tissues and organs may not respond effectively to arousal. Changes in body image can have a significant mental impact and create possible embarrassment. Depending on the diagnosis, physical changes could include loss of a breast, reconstruction of the labia, or partial removal of the penis, all of which could affect sexual performance and satisfaction. Alternative sexual positions or acts may be a viable solution for the individual or couple involved.

Effective communication is vital for survivors of cervical cancer and their partners as they navigate the impact of the disease and its treatment on their sexual health and intimacy. Survivors should be empowered with language and information to express their feelings and concerns openly. Nurses can facilitate this by providing education on the physical and emotional effects of cervical cancer and its treatment, as well as strategies for communicating about these issues. For example, a nurse may encourage a survivor to use “I” statements to express their feelings and needs, such as saying, “I feel anxious about intimacy” or “I need reassurance and understanding.” This approach can help the survivor communicate their emotions without placing blame on their partner, fostering a supportive and empathetic dialogue.

Additionally, partners of survivors may struggle to express their desires or concerns about sexual intimacy. Nurses can offer guidance on how partners can support their loved ones while also expressing their own needs and feelings. This may include encouraging partners to listen actively, validate their partner’s feelings, and openly share their own emotions and concerns.

Nurses can also emphasize the importance of emotional connection and intimacy in maintaining a healthy sexual relationship. By reinforcing that sexual intimacy is based on more than just physical attraction, nurses can help survivors and their partners prioritize emotional connection and communication in their relationship.

Overall, effective communication can help survivors of cervical cancer and their partners navigate the challenges of sexual intimacy after treatment. Nurses play a crucial role in empowering survivors to communicate their needs and feelings and supporting partners in understanding and responding to these needs.

LIFE-STAGE CONTEXT

Effect of Cancer on Females of Childbearing Age

Cervical cancer can significantly affect family planning decisions for women of reproductive age, often requiring an interdisciplinary approach involving nurses. The diagnosis may lead to concerns about fertility preservation and the ability to have children in the future, prompting women to seek guidance from health-care providers, including nurses.

For females yet to complete their family planning, the diagnosis can be distressing. Treatments such as radical hysterectomy, radiation therapy, and chemotherapy can affect fertility, necessitating discussions about fertility preservation options. Nurses play a crucial role in educating patients about these options, coordinating care, and providing emotional support throughout the decision-making process.

The emotional and psychological toll of cervical cancer and its treatment can also strain relationships and affect decision-making about family planning. Nurses, through their ongoing care and support, help patients and their partners navigate these challenges, offering counseling and resources to address the emotional aspects of the diagnosis and treatment.

In some cases, women may choose to delay cancer treatment to pursue fertility preservation options, highlighting the need for a coordinated approach involving nurses, oncologists, and fertility specialists. Nurses help patients weigh the risks and benefits of such decisions, ensuring they receive comprehensive care that considers their fertility goals alongside their cancer treatment needs.

Cancer Recurrence and Secondary Cancers

Cancer is a complex disease that often defies a definitive cure. Instead, treatments aim to achieve **remission** or control over the disease. Remission signifies a period when cancer is not detectable or actively growing, whereas control involves managing the disease to prevent its progression or symptoms. However, cancer can return after a period of remission, which is known as **recurrence**. Recurrence indicates that the cancer has resurfaced and is no longer under control or stable.

Secondary cancer can arise in two primary ways. First, factors that contributed to the initial cancer, such as tobacco use, alcohol consumption, or an unhealthy diet and environment, can increase the risk of developing a different type of cancer. Second, cancer survivors may develop a new cancer because of previous cancer treatments. For example, childhood cancer survivors treated with radiation may develop thyroid cancer years later due to radiation-induced cellular damage.

It is important to note that cancer is always named based on its original site of origin. For instance, if small-cell lung cancer spreads to the bone, the malignant bone lesions are still classified as small-cell lung cancer. Despite successful treatment for one type of cancer, individuals can develop a completely different type of cancer. This phenomenon is exemplified by sports analyst Dick Vitale, who faced separate battles with melanoma, lymphoma, and vocal cord cancer, each requiring its own treatment and management (ESPN, 2023).

Additionally, the risk of cancer tends to increase with age, irrespective of an individual's cancer history. This means that even without a prior cancer diagnosis, the likelihood of developing cancer later in life is higher. Therefore, promoting overall health and well-being remains crucial throughout survivorship to mitigate the risk of developing new cancers or other health complications. The risk of cancer increases as a person ages, regardless of their history, and an unrelated cancer can develop and appear later in life. This is one reason why health promotion continues to

be a high priority throughout survivorship.

The Nurse's Role in Survivorship Care

The primary responsibilities of the nurse in survivorship care are health promotion and symptom management. Ways to improve sleep, nutrition, and activity levels are important to discuss. Cessation of tobacco or alcohol use reduces inflammation and reduces the risk of cancer recurrence. Complementary therapies such as acupuncture, physical therapy, and massage are used by many patients to address symptoms, such as ongoing pain or nausea. In multiple studies, exercise has been demonstrated to be the only intervention that consistently and effectively reduces fatigue and improves overall energy (Campbell et al., 2019; Fabi et al., 2020).

LINK TO LEARNING

The National Comprehensive Cancer Network (NCCN) has published the NCCN Guidelines for Patients (https://openstax.org/r/77nccnguidelines) to provide information that can be shared as part of patient teaching about fatigue management.

It is essential that the nurse reinforces teaching about follow-up appointments, diagnostic testing for surveillance of ongoing remission or recurrence, medication adherence, side effect management, and when to seek medical attention. Additional teaching is often needed regarding manifestations that indicate cancer has recurred or progressed. These teaching points are determined by the type of cancer and subsequent treatments.

Coordination of Survivorship Care

As with active cancer management, survivorship care requires coordination between oncologists, physical therapists, psychologists, or other specialties and services that are involved in a patient's ongoing care. This can include consultations with dietitians who can assist with appetite loss or protein calorie malnutrition; counseling services to assist with any needs that arise from navigating relationship changes or from psychiatric medication management; and financial assistance programs for people struggling with hospital bills, paying for prescriptions, or returning to work. The nurse may need to refer the patient to support groups or other programs that allow survivors the opportunity to share personal experiences, seek additional information, make connections with others, and develop coping strategies.

INTERDISCIPLINARY PLAN OF CARE

Working Together for Cancer Survivors

In the heart of a southern state, a camp designed exclusively for cancer survivors is a beacon of hope and healing. Twice a year, nurses, social workers, and oncology educators unite to create a nurturing environment for adult cancer survivors, including those during treatment. There, participants can openly share their journeys, finding solace in the understanding of others who have walked a similar path.

A nurse's role extends beyond giving medical assistance to providing emotional support and facilitating therapeutic activities. Survivors discuss the impact of their surgeries on their intimate relationships, sharing vulnerabilities and coping strategies. These interactions are invaluable, offering a safe space for emotional release and healing. Hearing these stories and the advice that helps patients assists the care team members in learning how to better help other patients in the future.

The impact of this camp is not one-sided. Although the focus is on supporting survivors, the camp health-care staff—nurses, social workers, and oncology educators—benefit greatly from this experience. Working in the often-intense environment of inpatient settings, they witness immense suffering and loss. The camp allows them to rejuvenate and to celebrate life with individuals who embody resilience and gratitude. It serves as a reminder of why they chose their professions and a source of inspiration to continue providing compassionate care to those in need.

Summary

31.1 Oncological Disorders

- Cancer is thought to be caused by systemic issues, environmental exposures, and genetic determinants.
- Cancer is characterized by uncontrolled and abnormal cell growth, which typically develops over years due to repeated insults to the cell's genetic material.
- Tumors are malignant or benign. Malignant growths are cancerous, grow uncontrollably, and invade other areas of the body. Benign tumors grow slowly and do not spread.
- Preventable causes of mutations that may lead to cancer include smoking, alcohol consumption, poor nutrition, and viruses. Nonmodifiable causes of mutations that may lead to cancer include age, biological sex, ethnicity, and genetics.
- Signs and symptoms are unique to each type of cancer, but fatigue and unexplained weight loss are the most commonly reported clinical manifestations.
- Cancers are named and classified based on where they start in the body. A carcinoma is a cancer that creates solid tumors in epithelial tissue. A sarcoma is rare and is often related to bone cancers. A lymphoma applies to any cancer that begins in the lymphatic system. A leukemia refers to cancers of the blood-forming tissues, such as bone marrow.
- The major types of cancers are brain cancer, bone cancer, breast cancer, colon and rectal cancer, lung cancer, skin cancer, and blood cancer.

31.2 Detection and Prevention of Cancer

- Detection and diagnosis involve a combination of screening tests at recommended intervals; imaging studies, such as x-ray, MRI, or CT scans; and biopsies. Blood tests are useful to detect specific tumor markers, proteins, or substances that indicate the likely presence of cancer. They also help gauge the effectiveness of treatment or check for recurrence during periods of remission.
- Grading and staging systems standardize diagnosis, the likely prognosis, and the treatments to consider. Grading describes the cellular characteristics and aggressiveness of cancer cells and, by extension, how sensitive the cells will be to treatment. The higher the grade, the more abnormal the cells appear.
- The staging system is different for every type of cancer, but it generally refers to whether the tumor is confined to one space or has spread to other areas of the body. The basic TNM system represents the anatomic extent of solid tumors and gauges the size and extent of tumor (T), lymph node involvement (N), and systemic involvement or metastasis (M) for prognostic implications. There are other staging systems that can also be applied to specific types of cancer, such as blood, skin, or colon cancer.
- Prevention focuses on reducing the risk of developing cancer. There are three levels of prevention: primary, secondary, and tertiary. Primary prevention promotes healthy lifestyle choices. Secondary prevention involves detecting cancer with screenings when treatment has the best chance of a desired outcome. The focus of tertiary prevention is reduction of symptoms and complications related to the disease process including getting the correct treatments, symptom management, emotional and social supports, and maintaining or regaining physical and emotional health after treatment has ended.

31.3 Care of the Patient with Cancer

- To assist the patient in managing complications, the nurse must evaluate physiological, psychological, and situational factors. Holistic assessment is required. Specific assessment will depend on the type of cancer and the patient's current treatment plan. Generally, the nurse will look for signs of cachexia, and assess skin color to determine proper perfusion, good oxygenation, and any evidence of jaundice or bleeding. Treat fatigue, pain, gastrointestinal issues, hematological complications, altered nervous system functions, and any skin impairments.
- An oncological emergency, which includes metabolic emergencies, hematologic emergencies, and structural emergencies, is an acute issue that may cause mortality or morbidity.
- Nursing care for individuals with cancer addresses physical, psychosocial, cultural, and spiritual needs. Nurses look for cues in abnormal test results, new symptoms, and changes in the patient's condition that indicate additional testing or intervention is needed. Nurses must also manage side effects and complications. To evaluate outcomes, nurses assess often for the patient's understanding of their condition, treatment plan,

and self-care instructions, adjusting whenever the patient's outcomes are not being met or when there are changes to the plan of care.

- Treatment options vary widely based on individual patient factors, including age, overall health, type of cancer, and stage of progression. Medical therapies may include surgery to remove tumors or affected tissues, targeted therapies that attack specific molecules, hormone therapy for hormone-driven cancers, stem cell transplants to replace diseased bone marrow, and genetic profile-specific medicine. The most commonly used therapies are external or internal radiation, chemotherapy, and immunotherapy drugs. Nurses play a key role in administering radiation, chemotherapy, and immunotherapy drugs, monitoring for side effects, and managing symptoms to improve quality of life.
- Cancer care requires a truly comprehensive coordination of care among interdisciplinary team members. The complex and ongoing nature of cancer care often requires specialized providers that are unique to patients with cancer.

31.4 Survivorship

- Survivorship in cancer care recognizes that many individuals continue to live after their initial diagnosis and treatment. Some survivors are completely cancer-free whereas others are living with cancer. Anyone with a history of cancer is considered to be in survivorship. Challenges faced by cancer survivors may be psychological, social, emotional, spiritual, or physical.
- Remission signifies a period when cancer is not detectable or actively growing. Recurrence indicates that the cancer has resurfaced and is no longer under control or stable. Secondary cancer can arise from factors that contributed to the initial cancer or develop because of previous cancer treatments. The risk of cancer tends to increase with age, irrespective of an individual's cancer history.
- The primary responsibilities of the nurse in survivorship care are health promotion and symptom management. The nurse also reinforces teaching about follow-up appointments, diagnostic testing for surveillance of ongoing remission or recurrence, medication adherence, side effect management, and when to seek medical attention.
- Providing a range of support options in collaboration with health-care providers, services, and support groups is crucial for comprehensive survivorship care.

Key Terms

acquired genetic factor change that develops from exposure to risk factors
apoptosis cell death
brachytherapy type of radiation treatment in which a radioactive source is placed in or near a tumor; it can be a wire, seed, disc, capsule, or implant
cancer disease caused by uncontrolled division of abnormal cells
carcinogen substance or agent that can cause cancer
carcinoma cancer that creates solid tumors
carcinoma in situ cancer confined to the layer of cells where it began and has not spread to surrounding tissues
chemoreceptor trigger zone area of the brain that detects toxins in the blood and cerebrospinal fluid and sends signals to the vomiting center of the brain
chemotherapy cancer treatment that uses drugs to kill cancer cells or stop them from growing and dividing
differentiation how mature or immature cancer cells look and behave compared to normal cells
external beam radiation noninvasive method using high-energy radiation beams to destroy cancer cells
grading process used to classify cancer cells based on how abnormal they appear when examined under a microscope
hyperviscosity syndrome oncologic emergency in which the blood is so thick it will not flow properly
immunosurveillance body's monitoring process by which cells of the immune system detect and destroy premalignant of malignant cells
immunotherapy type of cancer treatment that uses the body's immune system to fight cancer; involves stimulating the immune system to attack cancer cells or using antibodies to target specific cancer cells
innate genetic factor mutation that is inherited
late effect health problem that occurs months of years after treatment of cancer was completed
leukemia cancer of the blood-forming tissues

lymphoma cancer that begins in the lymphatic system
mucositis inflammation and ulceration of the mucous membranes lining the digestive tract; common side effect of chemotherapy and radiation therapy
neuropathy condition characterized by damage to the nerves, often causing pain, numbness, tingling, or weakness
neutropenia condition in which there is a low count of immature white blood cells called neutrophils
oncological emergency serious and often life-threatening complication of cancer or its treatment that requires immediate medical attention
radiation therapy (also, radiotherapy) cancer treatment that uses radiation to kill cancer cells or shrink tumors
recurrence new occurrence of something (cancer diagnosis) that has occurred, happened, or appeared in the past
remission period when an illness is less severe, or manifestations of the illness are not actively affecting the person
sarcoma malignancy of connective or nonepithelial tissue
staging system used to describe the extent and spread of cancer in the body
stomatitis inflammation and ulceration of the mouth and lips; common side effect of chemotherapy and radiation therapy
survivorship state of surviving something that might have resulted in death; it applies to an individual from the time a cancer diagnosis is made throughout the remainder of their life
TNM system method used for staging to describe the extent and spread of cancer based on the size of the tumor, whether or not the cancer has spread to nearby lymph nodes, and whether or not there is metastasis to distant organs or tissues
tumor suppressor gene type of gene that normally inhibits cell growth and division, helping to prevent the development of cancer

Assessments

Review Questions

1. What characteristic best defines a cell as cancerous?
   a. demonstrates uncontrolled growth
   b. alters all cell metabolism
   c. results in fatigue and weight loss
   d. produces special hormones

2. What type of cancer affects the lymph nodes, spleen, and bone marrow?
   a. sarcoma
   b. carcinoma
   c. leukemia
   d. lymphoma

3. What diagnostic test is used to assess the presence of a tumor?
   a. electroencephalogram
   b. magnetic resonance imaging
   c. complete blood cell count
   d. ultrasound guided biopsy

4. What does tumor grading assess?
   a. the size of the tumor
   b. the extent of the metastasis
   c. the degree of tumor cell differentiation
   d. the number of lymph nodes involved

5. What is an example of secondary prevention of cancer?
   a. mammography
   b. smoking cessation

c. maintaining a healthy weight
d. HPV vaccination

6. A patient with cancer is experiencing chemotherapy-induced nausea and vomiting. What nursing intervention is most appropriate?
   a. Administer an antiemetic such as ondansetron.
   b. Provide foods that are soft and warm.
   c. Ask the patient to eat more at the next meal.
   d. Limit fluid intake until the nausea has passed.

7. A patient with cancer is at risk for impaired skin integrity due to radiation therapy. What action does the nurse include?
   a. Apply lotion to the skin before radiation therapy.
   b. Use only paper tape on the patient's skin.
   c. Inspect the skin before each radiation treatment.
   d. Take measures to keep the radiation site dry.

8. How can a nurse evaluate the effectiveness of pain management?
   a. Assess the patient's vital signs.
   b. Monitor the patient's sedation level.
   c. Observe the patient performing activities.
   d. Ask the patient about their pain.

9. What therapy is commonly used to treat cancer?
   a. nutritional therapy
   b. chemotherapy
   c. psychotherapy
   d. acupuncture

10. What is the primary focus of survivorship care?
    a. early cancer detection
    b. constant surveillance
    c. health promotion
    d. palliative care

11. What is the definition of a cancer survivor?
    a. anyone who has received a cancer diagnosis
    b. someone who was screened for cancer occurrence
    c. individuals who have achieved a cancer cure
    d. a person scheduling a prophylactic mastectomy

Check Your Understanding Questions

1. What risk factors are related to increased development of malignancy?
2. Name three risk factors for cancer occurrence that are considered modifiable.
3. Describe ways to support someone who is at high risk of recurrence.
4. Explain how cancer recurrence and secondary cancers might affect a survivor.
5. Outline strategies to improve coordination of survivorship care.

Reflection Questions

1. Reflect on a situation where you were part of interdisciplinary care team. Imagine that the patient had a cancer diagnosis. How would the collaboration among different health-care professionals (e.g., nurses,

doctors, social workers, pharmacists) affect the patient's care and outcome?

2. What teaching might you include when discussing fatigue with a patient?
3. Reflect on a time when you were part of a team providing care. How could that team focus on improving the quality of life for cancer survivors?

What Should the Nurse Do?

Sarah completed her treatment for lung cancer. She underwent surgical removal of the diseased lung followed by chemotherapy and radiation treatment. Sarah requires teaching and support for the next phase of survivorship.

1. What guidance should you give Sarah about sexual health and physical intimacy?
2. What specific emotional assessments would you prioritize during Sarah's follow-up visits?
3. How would you teach Sarah about recognizing and reporting late effects of lung cancer and treatment?

Competency-Based Assessments

1. Provide examples of how cancer survivorship applies to experiences beyond diagnosis and completion of cancer treatment.
2. Role-play a teaching session that is unique to someone who had a solid tumor of any kind you choose, surgery to remove the tumor, and chemotherapy treatment.

CHAPTER 32
Palliative Care

FIGURE 32.1 It can be a privilege to care for patients as they approach the end of life. Alongside a special team of health-care professionals, the nurse provides the compassion and knowledge to aid the patient and their family. During this special time, the nurse might use the art of music, playing soothing melodies that offer comfort and solace. This act of blending the art and science of nursing demonstrates a deep empathy, providing a serene and supportive environment as the patient transitions. (credit: Bart Harris/National Guard, Public Domain)

CHAPTER OUTLINE

INTRODUCTION Palliative care is an essential and evolving field within nursing practice that focuses on providing compassionate, holistic care to individuals with life-limiting illnesses. This chapter serves as a resource for nurses to deepen their understanding of palliative care and develop the skills necessary to deliver high-quality end-of-life care. By combining evidence-based practices, clinical expertise, and a patient-centered approach, this chapter aims to equip nurses with the knowledge and tools needed to address the physical, emotional, and spiritual needs of patients and their families during this delicate phase of life.

The practice of palliative care embodies the values of comfort, dignity, and respect, recognizing that every person's end-of-life journey is unique and should be approached with sensitivity and empathy. Nurses play a pivotal role in facilitating the provision of comprehensive palliative care, serving as advocates, educators, and caregivers. This chapter offers a comprehensive overview of the principles, theories, and practical considerations in palliative care, with a particular emphasis on the nursing perspective. From symptom management and communication strategies to ethical dilemmas and grief support, nurses should be empowered to deliver compassionate care and support

patients in achieving the highest possible quality of life until the end of life.

32.1 Palliation

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Define palliative care
- Identify settings where palliative care is provided
- Discuss the importance of collaborative teamwork in palliative care
- Differentiate between do-not-resuscitate (DNR) and do-not-intubate (DNI)

A critical concept in health-care, **palliation** centers on alleviating suffering and enhancing quality of life for patients with serious, often progressive, illnesses. Unlike curative treatments that aim to eradicate disease, palliative care embraces a holistic approach, prioritizing relief from symptoms, pain, and stress. It acknowledges the profound intersection of physical, emotional, and spiritual needs that arise as patients navigate the complexities of their conditions.

Understanding palliation and its core principles is essential for delivering compassionate and effective care. Grasping what palliation entails ensures that health-care providers are dedicated to relieving suffering and improving patient quality of life. Recognizing the various settings where palliation is offered—such as hospitals, hospices, and home environments—allows for the adaptation of care to fit the specific resources and challenges of each context. Effective palliation often depends on a interdisciplinary approach, with health-care professionals collaborating to meet the multifaceted needs of patients and their families. Additionally, understanding critical decisions and distinctions—for example, between do-not-resuscitate (DNR) and do-not-intubate (DNI) orders—is vital for aligning care with patients' wishes and goals. This section aims to highlight how palliation provides comfort and dignity during challenging times, emphasizing its integral role in supporting patients through their illness and end-of-life journey.

Palliative Care

Person- and family-focused care to relieve or reduce symptoms associated with terminal illnesses or diseases that are no longer responding to treatment is considered **palliative care**. This type of care is meant to bridge the gap between curative care and **hospice care**, which is care provided when a patient is approaching the end of life. The goal is to provide the patient with the greatest quality of life while maintaining their dignity as the disease progresses.

Evolution of Palliative Care

Palliative care evolved from the hospice movement in the late 1960s, which focused on end-of-life care, and has developed worldwide in a variety of cultures. However, Roman Catholic traditions dating back to the eleventh century recognized the concept of “hospice” as a place of hospitality for the sick and dying. These early hospices are believed to have been established during the Crusades. While hospices were widespread in the Middle Ages, their prevalence decreased as religious orders became more widespread.

The modern usage of hospice as part of the philosophy of end-of-life care originated with the work of Dame Cicely Saunders, who began working with terminally ill patients in London around 1948. Saunders began her work as a nurse but acquired a medical degree in 1957. While working at Yale University in 1963, Saunders discussed the idea of specialized care for the dying, centering on palliative care; she also shared pictures that showed remarkable differences in patients who were receiving palliative care. For instance, patients in hospice care appeared more relaxed and content, often surrounded by family and engaged in meaningful activities, whereas those in traditional hospital settings often looked distressed and isolated. Saunders’s efforts led to a broader discussion in the United States about the need for specialized hospice care at the end of life, emphasizing the importance of providing a supportive and compassionate environment for patients as they approach their final stages. In 1967, Saunders founded the first hospice for terminally ill patients in the United Kingdom, known as St. Christopher’s Hospice (Hospice of Holland, 2023).

Two years later, Elizabeth Kübler-Ross published a book, *On Death and Dying*, which contained over 500 interviews with dying patients (Kübler-Ross, 1969). Kübler-Ross discussed how everyone deserves the right to make their own

decisions related to their end-of-life care. Kübler-Ross testified in 1972 before the U.S. Senate Special Committee on Aging to declare that dying with dignity included one's right to make their own decisions, including the right to die at home. Kübler-Ross's findings, combined with Saunders's earlier work, led to the founding of the first hospice in the United States, in Branford, Connecticut, in 1974. In 1982, Congress created a provision for a Medicare hospice benefit, and in 1986 the Medicare Hospice Benefit was enacted, giving states the option to include hospice services in their Medicaid programs.

LINK TO LEARNING

Today, many cultures view quality palliative care as a human right. The World Health Organization (WHO) discusses how palliative care (https://openstax.org/r/77Palliativecare) relieves suffering and improves the quality of life for patients.

Settings for Palliative Care

Utilizing an interdisciplinary team of health-care professionals to manage symptoms, palliative care can be provided in a variety of settings, such as hospitals, nursing homes, and specialized clinics; often, it is performed within the patient's home. The location of treatment is dependent on the patient's desires, the acuity of care that is needed, and health insurance coverage.

Institution-Based

Palliative care can be institution-based when a patient requires a high level of care. This could include a patient in the intensive care unit, oncology unit, or medical-surgical unit of a hospital. Palliative care can also be utilized in long-term care facilities for a population of patients who are too ill to return home and require skilled care outside of the hospital setting.

Outpatient-Based

Palliative care can also be provided on an outpatient basis for patients who are well enough to remain at home but who may need skilled care in certain settings, such as clinics or a provider's office. Examples of outpatient-based care might include treatments for pain management, radiation, or infusions.

Community-Based

Palliative care can also be received in the patient's home from a home health agency. Other examples of community-based care might include intravenous infusion therapy or peritoneal dialysis treatment, with patients receiving IV fluids, medications, or feeding tubes at home. As the goal is not curative, chemotherapy treatments may be discontinued, but nutrition and hydration may be continued.

Palliative Care Team Members

Palliative care requires collaboration. The palliative care team is made up of several different health-care professionals who work closely with the patient and their family and provider (Table 32.1). Typically, the team includes palliative care providers, nurses, social workers, nutritionists, and chaplains. However, the team members may vary based on the patient's level of care and needs. Consider a patient with chronic obstructive pulmonary disease (COPD) who needs help performing their activities of daily living (ADLs), maintaining their mobility, and managing their pain. Which health-care professionals would likely be on this patient's interdisciplinary team for palliative care?

Provider	Role in Palliative Care
Primary Care Provider (PCP) Advanced Practice Registered Nurse (APRN) Nurse Practitioner (NP) Physician Assistant (PA)	• Provides orders for the patient to receive services through home care or home health agency. • Refers the patient to a pain management clinic. • Receives updates from the interdisciplinary team to provide optimal patient care.
Pain Management Clinic	• Treats and manages the patient's pain. • Communicates with the PCP to collaboratively provide patient-centered care.
Home Care Agency	• Provides a health aid to help the patient with their ADLs such as bathing, dressing, grooming, light housekeeping, preparing a meal, and running errands. • The frequency of the aid visits will vary depending on the patient's needs: ◦ Example 1: A patient with early-onset COPD who has experienced a slight decrease in endurance but who requires no assistive device for mobility may need only two visits per week. ◦ Example 2: A patient with advanced COPD who has experienced a significant decline in endurance and who uses a walker for ambulation and supplemental oxygen during the day and night may need three to five visits per week. • Patient care is supervised by a nurse who writes a plan of care and directs the health aides' delivery of care to meet the patient's needs. • The nurse also advocates for the patient and communicates with each provider to discuss changes in condition and obtain new orders as needed to promote continuity of care.
Home Health Agency	• Assesses the home for any specialized equipment or community needs, including resources that may assist with care. • Provides physical therapy to help the patient maintain strength and mobility. • Offers occupational therapy, dietary consultations, social work services, chaplains, and speech therapy as needed. • Provides updates to the interdisciplinary team to report the patient's progress for continuity of care.

TABLE 32.1 The Palliative Care Interdisciplinary Team

Nursing Management

Nursing management is a key component of patient care. With palliative care, the nurse may take on the role of case manager and become the hub of communication. As case manager, the nurse is on the front line, speaking with patients and their families to determine the efficacy of care, coordinating care, and updating the plan of care. When communicating with patients and their families, the nurse should always:

- allow the patient and family adequate time to reflect and provide an answer to each question.
- avoid the impulse to fill in the silence during the communication process; it is more appropriate to simply pause and listen than to interject during the "empty space."
- be sensitive and ask if more time is needed to think about a specific topic or question.
- avoid the impulse to give advice.
- ask questions, including open-ended questions.
- assess understanding by restating, summarizing, or reviewing what was said, both for yourself and the patient. When family members are participating in the patient's care, have them re-demonstrate with a verbal walkthrough of the specific care.

An example of effective nursing management can be seen in the following example. A patient in a skilled nursing facility is receiving palliative care for the pain associated with cancer; the nurse observes several things during assessments:

- The patient is having difficulty swallowing pills and may need an order for crushed or liquid medications.
- The pain medication that is currently prescribed lasts only four hours instead of six hours.
- A certain position creates more pain for the patient compared to an alternative position.
- The patient has difficulty participating in physical therapy when the pain medication is not administered thirty minutes to an hour before the therapy session.

As the hub of communication, the nurse has taken on a role managing the patient's case and should communicate all these issues to the specific providers involved in the patient's care. For this case, the nurse may obtain a new order from the provider to administer the pain medication every four hours, increase the medication's strength, change its delivery method, or switch to a different medication. The nurse should communicate to the nurses on opposite shifts as well as the physical therapy team that the pain medication needs to be administered before a physical therapy session, and should ensure the other nurses, nursing assistants, and members of the physical therapy team are aware that certain positions cause more pain for the patient. These items should be well documented as well as communicated to each service line for quality care and patient safety. It is important to note that while this example relates to a skilled nursing facility, the nurse's role would be similar if this example pertained to a patient receiving palliative care through a home health agency with physical therapy in their home.

Communication in Palliative Care

Communication skills are essential to providing continuity of care. Frequent communication is key to ensuring that the palliative care team remains informed. Often, this is achieved through regularly scheduled interdisciplinary team meetings, which may also include the patient and their family. It is equally important to listen to the patient and their family to understand their expectations, family dynamics, and communication style, all of which will help create a comprehensive plan of care.

Table 32.2 gives an example of an interdisciplinary team meeting to discuss a patient who had a stroke several months ago and was recently hospitalized for an exacerbation related to congestive heart failure (CHF); the patient is now scheduled for discharge to home, where he lives with his wife.

Team Member	Role in Palliative Care
Primary Care Provider (PCP) Advanced Practice Registered Nurse (APRN) Nurse Practitioner (NP) Physician Assistant (PA)	• Actively listens for changes in condition. • Asks questions for clarification. • Obtains data related to the patient's inpatient needs as well as upcoming needs related to the discharge. • Writes the orders needed to address the items discussed by the team. • Ideally, provides comprehensive documentation for the patient's primary care provider (PCP), which will likely be obtained through a record request from the PCP's office, to ensure continuity of care after discharge.

TABLE 32.2 Communication within the Palliative Care Team

Team Member	Role in Palliative Care
Nurse	• Notices the patient has experienced difficulty swallowing and asks the provider for an order to obtain a swallow study prior to discharge to prevent choking and aspiration of fluids or food into the lungs. • Explains to the dietitian that the patient has experienced difficulty chewing and is in need of a soft diet, while also asking the provider for an order for a soft diet. • Discusses the need for new orders for crushed or liquid medications. • Explains the need to obtain services from a home care agency to help the patient at home with their ADLs, which will also help with patient safety at home. • Will continue to follow the outcome of the patient's swallow study to ensure the patient's dietary needs are met. • Reinforces with the family the dietitian's suggestions to prevent weight loss by providing frequent, smaller meals. • Will update the plan of care as needed. • Is available to answer the patient's and family's questions as the discharge date approaches. • Provides updates to the interdisciplinary team related to changes in condition, responds to patient and family questions or concerns, and obtains new orders as necessary. • Discusses the patient's medications, including possible side effects observed, to educate the family and ensure continuity of medication administration after discharge. ◦ For example, Seroquel could cause dizziness or weakness, which could contribute to a fall. The nurse educates the family about warning signs to look for and asks the provider if the medication needs to be decreased in strength, administered less frequently, or even discontinued. • Reinforces the physical therapist's explanation of decreased endurance and the need for frequent rest periods with both the patient and family. • Educates the patient and family about the patient's increased risk of falls, suggests interventions that could prevent falls, and advises that activities such as bathing, dressing, and grooming be performed during peak times when the patient has more energy. • Educates the family to weigh the patient regularly to monitor for fluid overload related to the CHF and reinforce the treatment plan when this should occur. • Discusses the discharge instructions and medications with the patient and family on the date of discharge to ensure that the patient has prescriptions for the prescribed medications and that everyone understands the patient's needs and agrees with the plan of care.
Physical Therapist (PT)	• Discusses the increased weakness related to the CHF, including how it impacts the patient's ability to meet their ADLs. • Discusses the patient's continued right-sided weakness, which impairs his mobility and increases the risk of falls. • Explains the benefits of continued physical therapy after discharge with a home health agency of the patient's choice, and asks the provider for an order. • Explains to the family what decreased endurance is and why the patient may need frequent rest periods to recover from activity.

TABLE 32.2 Communication within the Palliative Care Team

Team Member	Role in Palliative Care
Occupational Therapist (OT)	• Confirms with the social worker and family that the patient has adaptive utensils to feed themselves after discharge. • Discusses with the social worker and family the need for the following durable medical equipment (DME) at home due to the patient's increased weakness and impaired mobility: a shower chair and a wheelchair for medical visits. • Ensures everyone is aware that the patient has a walker that was used prior to admission for ambulation in the home and explains why, for safety reasons, the patient should always use the walker when ambulating. • Actively follow the results of the patient's swallow study to collaborate with the dietitian for the patient's dietary needs.
Social Worker	• Actively listens to determine the patient's anticipated needs at home. • Coordinates the DME services to ensure a shower chair and wheelchair is ordered for the patient to use at home. • Educates the family about community services that would be beneficial: ◦ Example 1: Adult day care can promote socialization and provide some rest for the patient's primary caregiver in the home. ◦ Example 2: A Meals on Wheels program can deliver meals to the patient's home during the day, while the patient's wife is working outside the home.
Dietitian	• Actively listens to determine the patient's needs. • Follows up on the patient's swallow study in the event thickened liquids need to be ordered. • Collaborates to ensure an order for a soft diet is obtained. • Explains to the patient and family that the patient's CHF and increased weakness can make eating a major task that requires a lot of energy, which could result in difficulty consuming large meals. • Discusses how smaller, more frequent meals may benefit the patient. • Educates the patient and family about the importance and components of a proper diet.
Family Members (Wife and Daughter)	• Actively listens to the team's observations. • Ideally, asks questions related to things they do not understand. • The inclusivity of being a part of the team provides education for the family to understand how their loved one's diagnosis affects daily living and patient outcomes. • The meeting provides the family with the opportunity to participate in and coordinate the care that their family member needs before and after discharge.
Chaplain	• Provides emotional and spiritual support to the patient and family. • Addresses any spiritual or existential concerns related to illness or end-of-life issues. • Facilitates discussions on advanced care planning and patient's wishes. • Coordinates with the team to address any specific spiritual needs or requests.

TABLE 32.2 Communication within the Palliative Care Team

Medical Management

In a hospital-based setting or skilled nursing facility, serious situations may arise that require the use of cardiopulmonary resuscitation (CPR) or mechanical ventilation to sustain life. It is crucial to discuss with the patient and their family the options of CPR and mechanical ventilation, including what each procedure involves and under

what circumstances it might be used. This discussion is a key component of patient-centered care, ensuring that patients and their families fully understand and can make informed decisions about these life-sustaining interventions. This conversation is important regardless of the patient's stage in their end-of-life journey.

In addition to understanding the procedures themselves, patients and their families should be aware of specific medical orders that outline their preferences for end-of-life care. A **do-not-resuscitate (DNR)** order indicates that a patient does not want CPR to be conducted if their heart stops. A **do-not-intubate (DNI)** order indicates that a patient does not want to be placed on a ventilator if they are unable to breathe independently. If a patient does not wish to have life-saving interventions, it is important to have them sign a DNR or DNI order and place it in their file.

Medical Orders for Life-Sustaining Treatment (MOLST) is a program with a goal of improving quality of care for patients at the end of life (Basset Healthcare Network, 2024); some states refer to this program as **Physician Orders for Life-Sustaining Treatment (POLST)**. While the intent of these programs is the same, the applicable forms vary from state to state. Regardless, completing the forms helps patients specify their goals and preferences for their end-of-life care, including:

- resuscitation instructions when there is no pulse
- intubation and ventilation instructions when breathing has stopped
- instructions for hospitalization and transfer
- comfort care expectations
- treatment guidelines
- preferences for the use of antibiotics

The benefit of using a MOLST or POLST form is that it is transferrable among all care settings such as hospitals, nursing homes, and community settings.

The type of medications used in palliative care depends on the patient's diagnoses and associated symptoms. One of the most common symptoms is pain. The severity and type of pain determine the appropriate medication needed. For mild to moderate pain, acetaminophen is often prescribed. For moderate to severe pain, providers may add narcotics such as codeine to acetaminophen to manage pain. For pain associated with inflammation, such as arthritis, a nonsteroidal anti-inflammatory drug (NSAID) such as ibuprofen or naproxen might be appropriate.

There are many other difficult decisions that a patient and their family will face during their end-of-life care. The nurse should be prepared to offer advice and answer a variety of questions, including:

- What is the most effective method of pain management?
- When is the right time to begin morphine administration?
- Do the benefits of morphine administration outweigh the disadvantages?
- Should a feeding tube be ordered when the patient can no longer eat?
- Will the use of a feeding tube prolong life and prevent suffering or merely prolong the patient's suffering?
- Should intravenous fluids be provided when a patient can no longer drink and appears dehydrated?
- Will the use of intravenous fluids prolong life and prevent suffering or merely prolong the patient's suffering?

Ultimately, for any decision involving palliative care, the key question is how it will impact the patient's quality of life and relieve their suffering.

32.2 End-of-Life Care

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Describe the differences between hospice care and palliative care
- Identify the nurse's role in hospice care
- Discuss the importance of communication during end-of-life care
- Analyze the impact and implications of medically assisted dying as an end-of-life care option

End-of-life care is designed to provide relief of symptoms for someone who has received a terminal or incurable diagnosis and has chosen not to receive treatment for the condition. It is not necessary to wait until hours, days, or even weeks prior to a person's passing to implement this care. In fact, the sooner end-of-life care begins, the more opportunities there are to provide physical, spiritual, and emotional comfort for both the patient and their

family—processes that may happen over many months.

End-of-Life Care

End-of-life care encompasses the time frame leading up to a person's death. It is compassionate care designed to assist both the family and patient during this major season of life. Palliative care is introduced when a patient's disease is no longer responding to treatment and focuses on the person's physical comfort. In contrast, hospice care is utilized when a person is nearing the end of life (fewer than six months to live) and focuses not only on comfort care but also on the physical, psychological, emotional, and spiritual needs of both the patient and their family (American Psychological Association, 2024).

Hospice

Hospice care can be provided in the patient's home, enabling the patient to die at home if they choose; however, some patients may prefer to seek hospice care in a hospital or specialized facility until the very end. Regardless of the setting, the goal of hospice is to provide comfort versus curative care. Hospice services are intended to bring comfort to the patient through physical, psychological, emotional, and spiritual care, as well as provide supportive services for the family during the dying and bereavement processes.

Hospice Team Members

Hospice care is provided by an interdisciplinary team, typically consisting of a provider, nurse, certified nursing assistant, social worker, and chaplain, who work together to provide a comprehensive plan of care (Table 32.3). Each team member holds a piece of the puzzle for the patient's care plan; thus, it is vital that the team communicates frequently.

Team Member	Role in Hospice Care
Primary Care Provider (PCP) Advanced Practice Registered Nurse (APRN) Nurse Practitioner (NP) Physician Assistant (PA)	• Oversees the patient's care. • Writes the orders for the care team to follow. • Provides prescriptions and medication orders for the patient. • Communicates within the interdisciplinary team to promote optimal patient outcomes.
Nurse	• Is the front-line provider for the patient's care. • Conducts assessment of the patient's condition each visit. • Communicates changes in condition to the provider. • Writes the plan of care and revises as needed. • Coordinates the patient's care within the interdisciplinary hospice team. • Coordinates care with the medical equipment provider. • Coordinates prescription needs with the pharmacy. • Communicates pertinent information to the CNA, social worker, and chaplain throughout the patient's care. • Supervises patient- and family-centered care to promote patient safety and optimal outcomes.
Certified Nursing Assistant (CNA)	• Helps the patient with ADLs such as bathing, dressing, and grooming. • Maintains cleanliness in the patient's environment. • Ensures needed items are within the patient's reach. • Prepares small meals such as breakfast, lunch, or snacks. • Communicates within the interdisciplinary team to promote continuity of care.

TABLE 32.3 The Interdisciplinary Hospice Care Team

Team Member	Role in Hospice Care
Social Worker (SW)	• Provides counseling for the patient and family. • Assists with education needs. • Provides assistance with paperwork. • Assesses challenges and risks for the patient, coordinating solutions for each. • Connects patients with services. • Communicates within the interdisciplinary team to promote continuity of care.
Chaplain	• Visits and socializes with the patient. • Meets spiritual and emotional needs. • Communicates within the interdisciplinary team to promote continuity of care. • Continues to visit the family after the patient's death.

TABLE 32.3 The Interdisciplinary Hospice Care Team

Settings of Care

Hospice care is commonly provided in the patient's home. However, hospice care can also be provided in hospital settings, independent facilities, and long-term care facilities. The setting of the patient's care is dependent on the patient's wishes, facility policies, the geographic location of independent facilities, and health insurance coverage. The health of the caregiver and their ability to care for the patient as their illness progresses may also dictate the setting of care.

Hospice agencies typically also have **respite care** arrangements with skilled nursing facilities. Respite care provides short-term relief or some time off for the person providing care.

The hospice nurse will coordinate the arrangements to provide the caregiver with a temporary rest period during which the patient will briefly reside in a nursing facility, and then return home.

LINK TO LEARNING

Review this page of resources and fact sheets about palliative and end-of-life care (https://openstax.org/r/77APAEndofLife) from the American Psychological Association.

Nursing Management

The nurse takes on the role of case manager to coordinate care, advocate for their patient, and teach the family how to provide care as their loved one dies. The nurse typically visits the patient in their home to assess for any changes or worsening of condition, as well as to monitor for any necessary medication and treatment changes. The visits will likely increase each week as the patient's condition deteriorates. As the patient advocate, it is important that the nurse communicates their assessment findings to each team member to ensure the patient's needs are being met effectively; it is especially important to communicate with the provider to determine if new orders are needed for the patient's care.

LINK TO LEARNING

The End-of-Life Nursing Education Consortium (ELNEC) (https://openstax.org/r/77ELNEC) project is a national and international education initiative to improve palliative care.

Communication in End-of-Life Care

Communication can be difficult during end-of-life care. During this time, there are a variety of sensitive topics that many people do not feel comfortable discussing; however, it is important to engage in these conversations to ensure the patient's wishes are followed.

The nurse should plan to answer many questions from the patient and their family while discussing the patient's needs and terminal diagnosis, conversations that will happen multiple times throughout the care process. It is as important to actively listen as to provide information. The nurse who listens empathetically with compassion and remains sensitive and nonjudgmental is a source of emotional support and an invaluable asset for the patient and family during this difficult time.

When end-of-life care begins, it is important to discuss with the patient and family the necessity of having essential legal documents, such as an advance directive and durable power of attorney. An advance directive enables the patient to outline their wishes for their end-of-life care while they are still of sound mind and able to make these kinds of decisions. A **durable power of attorney (DPOA)** enables the patient to list specific individuals whom they entrust to make financial and health-care decisions when they are no longer able to do so. If the patient desires to address only health-care matters during end-of-life care, they can choose to utilize a durable power of attorney for health care only.

One of the most difficult conversations to have with a hospice patient concerns their DNR/DNI status. This conversation is typically brought up during the admission to hospice. The patient and family may want to defer this decision until a later time; however, it is vital to establish the patient's desire regarding this matter at the beginning of their end-of-life care. Once they have confirmed their decision, the patient will sign the DNR/DNI order, or the MOLST/POLST form, to be placed in their record. There are some hospice organizations that do not require their patients to have a DNR status, while others make DNR status a requirement.

Along with securing the patient's overall wishes for their end-of-life care, it is equally important to discuss the patient's needs and wishes with each member of the medical team on a regular basis. This will ensure the comprehensive plan of care is revised and updated accordingly, which will ultimately keep the team functioning in unison with the patient's needs and desires.

Medical Management

The goal of medical management during end-of-life care, especially hospice care, is symptom management. When a patient's symptoms cannot be relieved completely, it is important to decrease them to a tolerable level and maintain comfort. Symptoms may be related to the terminal diagnosis or to other chronic illnesses or comorbidities. The treatment methods during end-of-life care are both pharmacological and nonpharmacological. While some symptoms may require medications, other symptoms may require interventions such as positioning, guided relaxation, or the use of DME such as a CPAP, BIPAP, or supplemental oxygen.

Common symptoms to be addressed during end-of-life care include pain, shortness of breath, nausea and vomiting, anxiety, weakness, decreased appetite, dehydration, and incontinence. A list of key symptoms in different stages of dying can be found in Table 32.4. Oxygen is often used to relieve shortness of breath and its associated symptoms, such as anxiety, weakness, and confusion. When oral medications become ineffective for pain relief, sublingual or subcutaneous morphine is typically prescribed; morphine is also effective in relieving shortness of breath and associated anxiety. It is important to educate the family to expect symptoms such as weight loss, decreased appetite, cognitive decline, and decreased urinary output; doing so can help prevent excessive worry or panic during end-of-life care.

Stage	Symptoms	Management Tips
Early	• Decreased appetite • Increased fatigue • Changes in sleep patterns • Decreased interest in surroundings	• Offer small, frequent meals or favorite foods • Ensure comfort with appropriate bedding • Provide a calm, quiet environment
Mid	• Weakness and increased sleep • Decreased urine output • Cool and mottled skin • Changes in breathing patterns (e.g., irregular, shallow)	• Maintain warmth with blankets • Use skin moisturizers to prevent dryness • Monitor and adjust position frequently for comfort
Late	• Cheyne-Stokes breathing (alternating between slow, heavy breaths and periods of apnea) • Possible "death rattle" (noisy breathing) • Unresponsiveness	• Position the patient for optimal comfort and breathing • Consider medications to reduce noisy breathing • Ensure a supportive environment for the family
Final	• Marked decrease in consciousness • Unresponsiveness to stimuli • Irregular heart rate • Final cessation of breathing and heartbeat	• Provide emotional support and comfort care • Reassure and support the family • Contact hospice care team for final arrangements

TABLE 32.4 **Key Symptoms in Different Stages of Dying**

The hospice agency may provide the patient's caregiver with a comfort care kit to address and relieve the common symptoms associated with end-of-life care. Common medications found in the kit will vary, but typically include an antiemetic for nausea and vomiting, an antidiarrheal, a stool softener for constipation, acetaminophen for breakthrough pain and fever, and morphine for pain and symptoms associated with shortness of breath.

As the patient nears death, they will not be able to clear respiratory secretions, resulting in a change in breathing pattern. Suctioning or atropine will be utilized to minimize the excess secretions and decrease the noisy, gurgling type of breathing. It is important to discuss this with the family before it occurs to prevent panic and alarm at the onset of this change. At this point, the patient is typically unresponsive and unaware of the change, but the family often has difficulty believing the patient is not in distress. Providing reassurance for the family is essential.

It is noteworthy to mention discharge from hospice care. Some patients improve while receiving hospice care, at which time they are discharged. This can be a joyous experience, as it gives the family more time with their loved one. During this time, the hospice team will periodically check in on the patient. When the patient has a recurring decline and is again eligible due to physical needs, they can be readmitted into hospice.

Ethics and End-of-Life Care

It is the nurse's responsibility to provide care that is in alignment with the patient's moral principles, values, and spiritual and cultural beliefs, while also maintaining professional and ethical standards of care, especially as the patient's condition deteriorates. One of the most difficult decisions during end-of-life care is whether to withhold or withdraw medical interventions. This is why advance directives are critical during end-of-life care; difficult decision-making should be avoided during this time.

Medically Assisted Dying

A patient with terminal illness or severe chronic condition may seek to end their life in order to prevent pain and suffering, due to loss of autonomy, or for similar reasons. While certain terms and methods are often considered to be the same, there are deep distinctions between them. A **provider-assisted death** typically involves a provider providing a written prescription for a lethal dose of medication for the patient to administer themselves to end their life. This practice is designed for patients with terminal illnesses who are experiencing unbearable suffering, allowing them to control the timing and manner of their death. Currently, provider-assisted death is legally permitted in several U.S. states and jurisdictions, including California, Colorado, Hawaii, Maine, Montana, New Jersey, New Mexico, Oregon, Vermont, Washington State, and Washington, DC. In contrast, **euthanasia** involves an act by a separate individual to cause death (e.g., directly administering the medication); it is illegal throughout the United States. A nurse is ethically prohibited from administering medical aid in dying, but they must be informed and comfortable supporting patients and families in end-of-life situations.

The choice to pursue medically assisted dying generates a spectrum of emotions and ethical dilemmas. It offers a way for individuals to avoid prolonged suffering and assert control over their end-of-life experience. With patients legally having autonomy to control all other end-of-life decisions, it is reasonable to ask why the decision to choose medically assisted dying should be any different. However, it also conflicts with traditional medical ethics, as health-care providers are trained to preserve life rather than end it. This creates a challenging dynamic for health-care providers, who must balance their professional duties with personal beliefs about the morality of ending life. It is crucial for healthcare professionals to conduct self-assessments, maintain professional objectivity, and respect patients' autonomy and decisions, whatever their personal views.

REAL RN STORIES

Nurse: Laura, RN
Years in Practice: Fifteen
Clinical Setting: Home care
Geographic Location: Georgia

I had been caring for Mr. Hampton when he experienced a significant decline in kidney function. Mr. Hampton's provider informed him that he needed to begin dialysis treatment to maintain his quality of life. However, Mr. Hampton, being 75 years of age, felt he had lived a good life and did not want to pursue dialysis.

During one of my home care visits, Mr. Hampton shared the details of his last office visit with his provider and the provider's recommendations to begin dialysis. I had been caring for Mr. Hampton for quite some time and had developed a trusting, nurturing relationship with him. I listened empathetically to Mr. Hampton, presenting a professional, nonjudgmental demeanor, as he explained that he had chosen not to pursue dialysis.

Mr. Hampton lived with his daughter after losing much of his mobility, but his cognitive abilities remained intact. I knew that without dialysis, Mr. Hampton's physical condition and sharp cognition would deteriorate in a short amount of time. While I respected Mr. Hampton's decision, I knew I needed to inform Mr. Hampton and his daughter about what to expect moving forward to ensure that a well-informed decision was being made.

I proceeded to help Mr. Hampton and his daughter with additional end-of-life care decisions, including completing an advance directive and durable power of attorney, to ensure that Mr. Hampton's needs and desires would be carried out. I assisted them with their admission to hospice care. I remained attentive to their needs, provided emotional support, and continued to coordinate Mr. Hampton's care until his passing. For several weeks afterward, my agency remained in contact with Mr. Hampton's daughter to ensure she received emotional support as she transitioned through the bereavement process. The importance of end-of-life care was personified as Mr. Hampton passed with his dignity intact, and his daughter was emotionally supported throughout the entire process.

32.3 Assessment

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Describe the purpose of assessment during end-of-life care
- Identify expected physiological changes with end-of-life care
- Discuss the parameters for identifying the time of death for a patient

Assessment is the first part of the nursing process; it includes collecting objective data and a thorough medical history. It enables the nurse to obtain a holistic view of the patient to identify their needs and formulate an individualized plan of care. The initial assessment provides the patient's baseline information, which is then utilized to monitor for changes, worsening of a condition, or periods of exacerbation. Regular assessments are vital to ensure that the patient receives the right care, at the right time, and in the right setting, and that care aligns with the patient's desires.

Assessment for End-of-Life Care

The initial assessment for a new patient is a vital component of ensuring the patient's directives are followed during their end-of-life care. Not only is the nurse conducting a physical assessment, but they are also assessing the patient's final wishes and the family's dynamics and communication style. Including the family during end-of-life conversations is crucial so they are also aware of their loved one's wishes. The nurse must be observant and detail-oriented and initiate open-ended questions to formulate an individualized plan of care aligned with the patient's directives.

Each assessment is different, and the process of gathering information needed for the patient's comprehensive plan of care will be ongoing. With each follow-up visit, the nurse will continue to gather additional information that will likely necessitate changes to the initial plan of care. Topics of conversation with the patient and family during the initial assessment can be found in Table 32.5.

Category	Consideration	Examples
Disclosure	How does the family discuss very sensitive information?	• Are there any topics that the patient and family are uncomfortable discussing? • Who is the point of contact to disclose critical information to? • What kind of information can be disclosed to the children? To the family or extended family?
Decision-Making Style	How are decisions made in the family?	• Who is the primary decision maker? • Are decisions individual, family-centered, or completely provider-based? • Is there a designated **health-care proxy** who will make decisions when the patient is no longer able to decide?

TABLE 32.5 Topics to Discuss During an Initial Assessment

Category	Consideration	Examples
Symptom Management	How does the patient want their physical symptoms managed?	• How is a specific symptom affecting the patient's life (e.g., physical functioning, mobility, comfort)? • What makes the symptoms worse or better? Are the symptoms worse at a particular time of day? • Which medications are acceptable for relief of symptoms? • What are the patient's and family's expectations or goals for managing the symptoms? How is the patient coping with the symptoms? • What are the patient's beliefs regarding their care? • To what degree does the patient desire their care to be managed?
Life-Sustaining Treatment	Has the patient thought about the care they want as the end of life draws near?	• Do they have an advance directive or durable power of attorney? • What are their desires for nutrition and hydration? • Does the patient want to receive CPR or be connected to a ventilator? • Are antibiotics acceptable if an infection develops? • Would the patient want dialysis if their kidneys begin to fail?
Desired Location of Dying	Does the patient want to pass at home, or is there a preference for an alternate location?	• Who does the patient want as their primary caregiver? • Is the patient more comfortable with a female or male caregiver?
Spiritual/ Religious/ Cultural Practices	Is there anything specific that the patient needs the care team to know regarding their beliefs?	• Are there any practices that need to be observed as death nears? • Is there anything specific the care team needs to know about the care of the patient's body after death? • How does the family express grief? • Are there expected beliefs or practices that are important to the family during the grief/ mourning process?

TABLE 32.5 Topics to Discuss During an Initial Assessment

Expected Physiological Changes

Physiological changes will vary in a palliative care patient compared to a hospice patient with an anticipated life expectancy of six months or less. However, both palliative care and hospice patients seek end-of-life care to reduce or relieve their symptoms and maintain their quality of life and dignity. The care provided is dependent on which stage of the end-of-life process each patient is in.

Not everyone who is nearing death experiences pain, but it is a common symptom of both patients receiving

palliative care and hospice care. Pain can be draining and cause irritability, making it difficult to communicate with the patient. For a patient experiencing confusion, dementia, or a decreased level of consciousness, it may be difficult for them to express their pain level. Clues to watch for may include moaning, difficulty sleeping, or increased agitation or crying; patients in pain may also guard a specific site or extremity. It is also important to note that it is easier to treat pain at the initial onset, before it becomes extreme.

Another symptom that may be common in both populations of patients is shortness of breath or a feeling of breathlessness. The discomfort of not being able to catch one's breath may also lead to increased anxiety and agitation. Interventions that may help reduce shortness of breath include elevating the patient's head, opening a window, or using a fan to circulate air in the room. Patients with a respiratory diagnosis may have prescribed medications or therapies, such as an inhaler, nebulizer breathing treatments, or supplemental oxygen.

CLINICAL SAFETY AND PROCEDURES (QSEN)

Palliative Nursing Interventions for Shortness of Breath

Decrease anxiety

- Administer medication prescribed for anxiety or panic related to shortness of breath.
- Suggest relaxation techniques.
- Assist patient with a means to call for assistance, such as a call bell.

Treat underlying pathology

- Administer prescribed medications such as inhalers or nebulized breathing treatments.
- Administer prescribed diuretics and monitor fluid balance.

Alter perception of breathlessness

- Administer prescribed oxygen.
- Administer oral, low-dose opioid, such as morphine.
- Utilize a fan to provide air movement in the patient's environment.

Reduce respiratory demand

- Utilize energy conservation techniques, such as pursed-lip breathing, frequent rest periods, or attempting difficult tasks during the mornings when the patient has more energy.
- Ensure needed items are within the patient's reach, such as the phone, television remote, fluids, and snacks. (For hospitalizations or skilled facilities, ensure the call bell is within reach.)
- Utilize medical equipment such as a bedside table/tray, bedside commode, shower chair, or hospital bed to elevate the patient's head.

As a person nears death, their breathing pattern will eventually change to Cheyne-Stokes breathing. This is a breathing pattern that may alternate between slow, heavy breathing and shallow, rapid breathing, with possible intermittent delays (apnea) between each breath. The patient may also develop a noisy type of breathing sometimes called a "death rattle." While this may be alarming to the family, it usually is not upsetting to the patient. However, repositioning the patient will sometimes help, as will administering certain medications.

LINK TO LEARNING

Watch this video to hear an example of Cheyne-Stokes breathing (https://openstax.org/r/77CheyneStokes) and a description of its causes and treatment.

Digestive problems can become a common issue for both palliative care and hospice patients. Constipation is quite common for patients with decreased fluid intake; it is also an associated side effect of pain medications. Nausea, vomiting, and loss of appetite are also common at the end of life, and treatments will vary depending on the cause. For patients with decreased appetite, it might be helpful to offer favorite foods or serve frequent, small meals rather

than three large meals each day. Offering a high-calorie drink with a meal, such as brand names Boost or Ensure, may also be helpful. If the patient is weak or tired, the caregiver might find the patient is willing to eat if they feed them. It is important to note that a dying patient should not be forced to eat. Going without food and water can be unsettling to the family, but it is not painful for a dying patient.

LINK TO LEARNING

Specifics will vary with each patient, but knowing the signs and symptoms to watch for as well as the interventions for each situation (https://openstax.org/r/77ELNECSupp) will ensure you are prepared for a patient who is actively dying.

Time of Death

Often family members will ask how much time their loved one has left. It can be difficult to answer this question because each patient and the associated disease processes are different. However, as the end of life draws closer, symptoms such as decreased appetite, decreased fluid intake, decreased urine output, decreased level of consciousness, increased temperature, and changes in breathing pattern will be observed. It is important to discuss these changes with the family so that they are not alarmed when they occur. Education by the nurse can truly make a difference in decreasing the panic experienced by a family as they watch their loved one go through the stages of dying.

Additionally, it is important to prepare the family in advance for what they need to do if their loved one passes without a hospice caregiver present, especially if the patient has elected to pass at home. While family members may instinctively want to call 911, they should instead immediately call the on-call number of their hospice agency so that the nurse can come to their home to conduct the pronouncement of death, assist the family with the funeral home process, and provide comfort, compassion, and support.

LINK TO LEARNING

This article reviews common end-of-life signs (https://openstax.org/r/77WebMDEOL) for family members with a loved one approaching death.

Nurses are an invaluable support for the family of a deceased person. Simply being available to listen to the family is a crucial part of healthy grieving and coping. The nurse will answer questions or concerns about the circumstances surrounding the death and preparations for viewing the body, as well as assist in helping to contact support people such as the coroner, clergy, or relatives. There may also be times when the nurse assists the family with decision-making regarding a funeral home, transportation, and removal of a loved one's personal belongings. Utilizing sensitive, interpersonal skills at this time is essential.

Patients and families may wish to review these resources for experiencing palliative care (https://openstax.org/r/77PallCareRs) from the Palliative Care Resource Center.

32.4 Psychosocial Support

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Identify the role of hope in end-of-life care
- Examine grief, mourning, and bereavement as part of the end-of-life process
- Discuss ways to provide culturally competent care during the end-of-life process
- Examine resources available to support culturally and spiritually competent care

Patients suffer needlessly when they do not receive adequate care for symptoms associated with their serious illness. Not only is care needed for their physical problems, but it is also important to give attention to a patient's psychosocial and spiritual needs. This will enable the nurse to have a more comprehensive understanding of how the patient and their family have been impacted by their illness, while also ensuring that the nurse develops a holistic plan of care to meet everyone's psychosocial and spiritual needs.

Providing Psychosocial Care at the End of Life

Psychosocial care involves providing psychological and social support. This requires the nurse to use sensitivity and compassion to understand the patient's feelings, thoughts, behavior, health, well-being, and quality of life. Often this can involve discussing difficult topics. Nurses have a responsibility to discuss the possibilities and probabilities related to a patient's diagnosis and its impact on quality of life. The nurse also provides support as the patient reviews their life, values, and treatment decisions and seeks end-of-life closure. Simultaneously, nurses need to be culturally aware and exercise cultural competence when discussing death with patients and their families. The nurse must set aside their own prejudices or personal preferences to explore the type and amount of disclosure that will be most beneficial for the patient and family within their unique belief systems.

CULTURAL CONTEXT

Culture, Religion, and End of Life

Cultural and religious beliefs significantly shape an individual's perspectives on death and their end-of-life practices. Recognizing these diverse beliefs is essential for providing respectful and empathetic care. Each religion or cultural group has its own unique practices and principles surrounding death, which can impact medical decisions, funeral arrangements, and grieving processes. Table 32.6 summarizes how major religions around the world view death.

Religion	Major Beliefs about Death
Catholicism	• Beliefs: The soul of the deceased is believed to spend eternity in heaven, hell, or purgatory. Dying individuals should receive sacraments administered by a church leader. • Practices: Autopsies, organ donations, and cremation (post-1963) are permissible. A vigil is held before the funeral mass, which includes the Eucharist and can be led by a priest or deacon. Internment requires a rite of committal. • Nursing Implications: Nurses should ensure that sacraments and last rites are arranged if requested and learn the family's preferences for autopsy and organ donation.
Protestantism	• Beliefs: Various denominations believe in an afterlife. Beliefs about death and the afterlife can vary significantly across denominations. • Practices: Autopsies, organ donations, and cremation are generally allowed. Funerals may be led by a minister or chaplain. • Nursing Implications: Nurses should respect the family's wishes regarding funeral arrangements and be prepared to coordinate with clergy if needed.

Note: Beliefs may vary within each religion, and the information here represents general beliefs of each religion.
TABLE 32.6 **Religious Beliefs about Death** (Lowey, n.d.)

Religion	Major Beliefs about Death
Judaism	• Beliefs: Life is highly valued, though death is not seen as tragic. Beliefs about the afterlife vary among denominations. • Practices: Autopsies, embalming, and open caskets are not permitted. Funerals are held as soon as possible after death, excluding Sabbath or festival days. Mourners wear dark clothing and observe mourning periods, including shiva for the first seven days. • Nursing Implications: Nurses should facilitate timely funeral arrangements and adhere to practices around autopsies and caskets. Support for mourners during the grieving process may also be needed.
Buddhism	• Beliefs: The goal is a peaceful death within the cycle of life, death, and rebirth. A statue of Buddha may be present at the bedside. • Practices: Organ donation is not allowed. The room may be scented with incense, and the body is prepared by the family. Cremation is common; if buried, the body is dressed in regular daily clothes. Chanting by monks may occur at the funeral. • Nursing Implications: Nurses should be aware of the need for incense and body preparation and the family's preference for cremation or burial. Coordination with monks for chanting may be requested.
American Indian	• Beliefs: Beliefs and practices vary widely among communities. Death is often seen as a journey, with ancestors guiding the deceased. Sickness may signify an imbalance with nature. • Practices: Each community has distinct beliefs and customs. Family members may prepare the body, even if they were not present at the time of death. Organ donation is generally not supported, and natural burials are preferred. Healers and medicine persons may play a significant role, conducting ceremonies to honor the deceased and guide their spirit on its journey. These ceremonies can include prayers, songs, and rituals meant to restore balance and provide spiritual support to the community. • Nursing Implications: Nurses should respect community traditions and practices regarding body preparation, burial, and ceremonies led by healers or medicine men. Understanding and facilitating these practices helps to provide culturally sensitive care and honor the family's spiritual needs.

Note: Beliefs may vary within each religion, and the information here represents general beliefs of each religion.
TABLE 32.6 Religious Beliefs about Death (Lowey, n.d.)

Religion	Major Beliefs about Death
Hinduism	• Beliefs: Reincarnation and karma are central beliefs. Peaceful dying and death are desired. • Practices: Organ donation and autopsies are permitted. The body must be bathed daily after death and attended at all times until cremation (which should occur within twenty-four hours). Ashes are traditionally scattered in sacred rivers. • Nursing Implications: Nurses should facilitate body care and attend to religious practices surrounding cremation and the handling of ashes.
Islam	• Beliefs: Belief in an afterlife is central. The soul is considered freed after burial, which must occur promptly. • Practices: Embalming and cremation are not permitted; autopsies may be performed for medical or legal reasons. The body is shrouded and positioned to face Mecca (or the East). A person of the same gender should prepare the body, and there is separate seating for men and women at the funeral, with minimal flowers and mourning. • Nursing Implications: Nurses should facilitate timely burial and respect practices related to body preparation and gender-specific care. Awareness of cultural sensitivities related to mourning and funeral arrangements is also crucial.

Note: Beliefs may vary within each religion, and the information here represents general beliefs of each religion.

TABLE 32.6 Religious Beliefs about Death (Lowey, n.d.)

Understanding and respecting these diverse beliefs and practices is fundamental for nurses to provide compassionate, culturally competent care. Tailoring care to accommodate these needs ensures that patients and their families experience dignity and respect during the end-of-life process.

Hope

Hope is as much an integral part of end-of-life care as it is a part of curative care. In the medical community, hope is usually associated with finding a cure. However, in end-of-life care, hope is equated with prolonging life and maintaining one's quality of life and dignity. Patients receiving end-of-life care still have hope for things they want to accomplish.

According to psychologist C. R. Snyder (1994), there are three conditions for hope to thrive: goals, pathways, and agency. A goal is a desire, and a pathway is the means to obtain the goal. Agency refers to the beliefs that motivate us to strive for our goals. Agency can also be uplifted by the love, care, and support provided by those around us. While serious illnesses can easily make us feel hopeless, it is important for nurses to be a support network for patients and families, helping them navigate the pathways and nurture the agency necessary to achieve their goals during end-of-life care.

CLINICAL SAFETY AND PROCEDURES (QSEN)

Patient-Centered Care: Fostering Hope

It is important for a nurse to foster hope. Here are some methods a nurse can use:

- Make time to listen.
- Encourage patients to share their feelings.
- Provide accurate feedback and information.
- Support patient control over their circumstances, choices, and environment.
- Assist the patient in finding meaning in their life.
- Encourage realistic goals.
- Facilitate communication within the family.

- Assist with creating and developing networks within the family or community.
- Follow up with the social worker and chaplain to coordinate visits for the patient.

Grief, Mourning, and Bereavement

The emotions that a person feels internally after the loss of a loved one is called **grief**, while the outward expression of grief, such as wearing black, conducting a funeral or memorial, or journaling, is called **mourning**. The time frame following the loss, in which grief is experienced and mourning is expressed, is called **bereavement**. In 1969, Elisabeth Kübler-Ross categorized five stages of grief, as seen in Table 32.7. It is important to note that everyone grieves differently and at their own pace. Thus, the five stages of grief are cycles that may be repeated for an indefinite amount of time. A patient will also experience these various stages as coping mechanisms at the end of their life.

Stage	Description
Denial	The person may have difficulty accepting the circumstances are true. They may experience feelings of isolation or seek another health-care professional's opinion.
Anger	The person may wonder, "Why me?" They may feel resentment, rage, or envy directed at family members, health-care professionals, caregivers, or God.
Bargaining	The person may bargain for the patient to see a specific event, like a grandchild's birth or graduation, or plead for more time to reach a specific goal. This process might include making promises to God.
Depression	The person may feel a deep sadness about the loss. The patient may fear that a loved will struggle to get along after their passing.
Acceptance	The person is no longer angry or depressed and can acknowledge that the patient has lived a good life.

TABLE 32.7 Stages of Grief (Kübler-Ross, 1969)

LINK TO LEARNING

Watch this humorous video to see the Kübler-Ross stages of grief (https://openstax.org/r/77KRGrief) in action.

Patient and Family Concerns

Families may feel powerless or experience increased guilt related to their feeling of powerlessness. A helpful intervention is to involve the family in the patient's treatment and care. Families may also have learning deficits or inadequate coping mechanisms or communication skills; they may feel off balance with the impending death of their loved one. Nurses are exemplary teachers who quickly find themselves in a case manager role, coordinating and implementing the patient's plan of care and becoming the patient's and family's most utilized resource during end-of-life care.

It is also important to note that the family's method of coping may not coincide with the values and beliefs of the nurse or other members of the interdisciplinary team. Regardless, it is imperative that the patient's and family's wishes be respected to the greatest extent possible. The nurse's role throughout is to help the family members obtain the knowledge and tools they need to care for their loved one and process their death. This help could be as simple as teaching the family techniques for conserving their energy. Knowledge deficits can also relate to:

- a lack of understanding related to the patient's diagnoses, treatment regimen, or plan of care.
- an inability to anticipate a medical crisis.
- inexperience with end-of-life care and the protocol to follow for emergent care outside of the hospital.

However they are needed, nurses provide a strong foundation of support as they help and guide the patient and family through the end-of-life period.

Providing Culturally Competent Care

A portion of the nurse's role during assessment is to gather information related to the values, preferences, and practices of each patient. Sharing the patient's and family's cultural beliefs and practices with the care team is essential. This information, including the details of the patient's end-of-life care, preparation for death, and after-death rituals, should be included in the plan of care.

An important component of providing culturally competent care within the family is to use discretion as to the appropriate time and setting for sensitive conversations to be conducted. For example, in some cultures a designated family member speaks for the patient regarding treatment decisions. Several conversations during several patient visits may be necessary to ascertain the full context of the patient's end-of-life beliefs, preferences, and practices; this can give the nurse time to formulate appropriate questions for the next visit.

Providing context for these discussions is also helpful. For example, the nurse might preface a conversation by saying: "We want to ensure that we provide care that best addresses your needs. Honoring and supporting your wishes is of the utmost importance to us. We welcome any feedback that you may have as to how we are doing and what we could do better. If you do not mind, I would like to ask you a few questions to help me better understand and support what is most important to you. You don't have to answer anything that might make you feel uncomfortable, or if you need to time to think about your answer to share during our next visit, that is fine too."

As a new nurse, discussing sensitive information of this nature might feel uncomfortable at first, but it will become easier with time. Partnering with an experienced nurse for the first few assessments can be helpful. The bottom line is that patients and families will appreciate and respect the nurse for being forthright in initiating conversations that prioritize them, especially their cultural beliefs and practices.

Spiritual Care

When nearing the end of life, spiritual needs can become as important to a patient as physical concerns. While spiritual assessment is a key component for a terminally ill patient, spirituality is much broader than a patient's religious preference, affiliation, or beliefs. Spiritual needs may include the presence or absence of a sense of peace, purpose in life, or harmony with loved ones; it may require making amends with someone to resolve unsettled issues or offering reassurance that certain items will be taken care of (Swihart, Yarrarapu, & Martin, 2023).

Patients will often express their questions or concerns to a nurse before openly discussing them with their provider or family. However, the social worker and chaplain on the care team are also instrumental in helping with the patient's and family's spiritual care. It is important to sharpen your listening skills to bridge the communication gap within the family, helping to begin difficult conversations. Active listening and a heart of compassion go a long way in end-of-life care.

Some patients find solace in their faith and will ask to read a religious text or listen to religious music; other patients may derive equally spiritual benefits from reading secular texts or listening to secular music. Spiritual comfort can also be found when family and friends talk with their loved one about the importance of their relationship or when they reminisce about fond memories and good times. However it happens, optimal spiritual care provides holistic healing for a patient and their family.

The Library for Spirituality and Healthcare (https://openstax.org/r/77SpiritHealth) provides an opportunity to expand your learning on a variety of topics related to spirituality and its influence on the delivery of health care and patient outcomes.

Resources to Support Cultural and Spiritually Competent Care

Many communities are culturally diverse. To ensure cultural and religious competence in clinical practice, it is important to have an understanding of various religions and their beliefs associated with clinical issues, death, and

dying. Palliative and end-of-life care should always consider why culture is important, how culture influences end-of-life care, what barriers to effective communication exist, and what role the family should play. To provide the best care to patients, the nurse should utilize cultural resources and examine their own personal cultural beliefs to better understand the effects of culture on nursing care.

LINK TO LEARNING

The 2023 article "Cultural Religious Competence in Clinical Practice" (https://openstax.org/r/77NBK493216) by Diana L. Swihart, Siva Naga S. Yarrarapu, and Romaine L. Martin provides an overview of key tenets of major religions the nurse may encounter in patient care.

32.5 Special Considerations

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Analyze how caring for the dying patient affects the health-care provider
- Evaluate the health-care provider's attitudes toward death and dying
- Discuss options to support the caregiver during the end-of-life process

To develop a level of comfort with patients who are seriously ill, the nurse and other clinicians should consider their own experiences and values related to illness and death. Taking time to reflect, read, and talk with others is helpful when examining one's own beliefs about death and dying. Talking with individuals with different cultural beliefs will give nurses greater insight and ability to see things "through a different lens," making them more sensitive to other cultures' death-related beliefs. Finally, talking with other nurses and colleagues can help the nurse to gain a broader perspective on the diverse values shared by other health-care workers and the patients in their care.

Special Considerations for the Health-Care Team

Nurses and their health-care teams encounter death and loss daily, making grief a common experience. This can result in unresolved sadness, which Smith-Stoner and Frost have referred to as **shadow grief**. Everyone may possess a bit of shadow grief, but health-care providers tend to have a great deal. If left unresolved, the negative impacts of working with the dying—and the associated grief, unresolved anxiety, or denial—can lead to illness and burnout.

It is important to face our emotions, to stop pretending that we do not experience grief and the associated suffering of caring for the dying. Common defenses to avoid confronting our grief include suffering in silence, remaining "strong," staying busy, and taking care of others. Talking with other members of the care team is important for processing the intense emotions associated with caregiving of the dying (Smith-Stoner & Frost, 1998).

The Nurse's Attitudes Toward Death and Dying

The nurse's attitude toward death and dying can be a barrier to providing **holistic care** during end-of-life care. Holistic care includes the care of the whole person—their body, mind, spirit, and emotions. While death and dying tend to be difficult conversations for both health-care providers and patients, such conversations may be welcomed by the patient. In fact, as nurses enter the patient's world to discuss death and dying, the nurse can find healing through the patient's struggles and strengths. Conversations of this nature also help the patient find acceptance, enabling them to let go of related anger or depression. Communication can be healing for everyone involved, especially when the topic is a difficult one.

LIFE-STAGE CONTEXT

Children and Hospice

Death and dying do not discriminate by age. As difficult as it may be to accept, children die, too. To come to terms with this reality, you may need to accept the child's medical condition in your mind before you can accept it in your heart.

Dying children need our honesty. Protecting a child from the truth will likely result in them feeling alone and isolated. Children can cope only with what they know, making it crucial to create open, honest communication. Follow the child's prompting to determine what they do or do not want to know. Do not be surprised if they wax and wane between these two things. If you do not know the answer to a question, admit this to the child. Simply reassure them that together you will find out.

It is important to use language the child will understand as they slowly come to terms with the fact that they are dying. A young child may never fully comprehend the circumstances, but being honest with them will enable the child to think through the situation to formulate questions and develop more understanding. Never try to protect children by lying. It will lead to confusion, frustration, and anger because they will notice the emotions of their loved ones do not fit with the story they have been told.

While we should encourage communication, we should not force it. Children will process the reality of their situation in small doses over time as they are able to cope with it. Only answer what the child asks. Be careful not to overrespond.

Be mindful that children tend to make statements rather than directly articulate their thoughts or feelings. Be observant of cues or behaviors that may reflect unspoken needs and give insights into the child's awareness of things. Allow children to experience their feelings. Do not try to help them get over their feelings; instead, help with validating them.

Understand that despite the situation, children still want to live as happily as possible, laughing and playing as much as they can. Do not deviate from normal routines, as they help children to remain comfortable, in control, and protected. However, it is also appropriate to create special moments as you help the child make each day count to its fullest.

Handling difficult situations such as a child dying will always have better results and outcomes when honesty, love, and respect are utilized during all communications among the child, family, caregivers, and friends.

Caring for the Caregiver

Providing comfort care at the end of life can be physically and emotionally draining. The nurse may notice that the primary caregiver is exhausted. Encourage the caregiver to ask for help and assist them in obtaining it. Often other people want to help but simply do not know what to do. Help could be as simple as allowing a visiting relative or friend to pick up a portion of the load so the primary caregiver can rest for a bit.

Small gestures can go a long way when helping a caregiver. For example, offering to sit with their loved one for an hour or two, volunteering to walk the dog, asking if they need something from the store, offering to watch any children, delivering a meal, or coordinating efforts among a small group of helpers are all ways to support a person who is in a caregiving role. Share this with the caregiver, encourage them to accept help, and remind them that it is equally important to care for themselves so they can provide ongoing, compassionate care for their loved one.

Effective support to help caregivers cope includes:

- Simply being available to listen.
- Answering questions and providing information related to the patient's care, disease, and dying process.
- Formulating plans for after the patient dies.
- Helping the caregiver understand that it is all right to ask for help and to accept help when it is offered, and suggesting how to request or recommend help from others.

Ultimately, nurses, health-care professionals, families, and caregivers must make self-care a priority to provide quality, ongoing, compassionate care for dying patients.

Professional Caregiver

A professional caregiver, such as a certified nursing assistant or home health aide, is an excellent resource for primary caregivers. Having the help of a professional caregiver will free up time for the primary caregiver, often a family member, to attend to personal business or needs, spend time with their family, or simply rest. Working together with tasks such as bathing, dressing, and grooming can help decrease physical demands. There is no

shame in admitting that we are human and need time to rest, replenish, and nurture ourselves. The caregiver may find that their loved one welcomes spending time with other people, making this a win-win for everyone.

Supporting Health-Care Colleagues and Ourselves

To cope with one's own grief, effectively process the death and dying of patients, and deal with the anxiety of working with grieving patients and families, health-care professionals need support, education, and assistance. This should include a focus on ways to seek support and provide support for coworkers. Suggested ways to cope include:

- Taking time to cry with and for patients.
- Doing something physical such as walking, running, riding a bike, or hiking.
- Being outside in nature.
- Asking for help from the team. Do not try to shoulder everything on your own.
- Participating in employee-provided self-care resources, counseling, or classes.
- Visiting a place of worship and praying.
- Turning small pleasures into sources of joy in your personal and professional life.
- Remembering that laughter is also good medicine and healing.
- Creating a support group or small circle of friends to meet with.
- Journaling or listening to music.

LINK TO LEARNING

Providing resources to help caregivers (https://openstax.org/r/77NIAFamily) is a simple way to provide patient and family education. Caregiving is a stressful job, but introducing topics such as how to share caregiving responsibilities, what strengths and weaknesses caregivers should consider, how to support a long-distance caregiver, and how to help a parent who is a primary caregiver can help relieve caregiver stress.

Summary

32.1 Palliation

- Palliation and palliative care are designed to reduce or relieve symptoms for patients with serious illnesses that are no longer responding to treatment.
- Curative care or life-prolonging treatments can be continued along with palliative care.
- Palliative care is performed in a variety of settings, including hospitals, long-term nursing facilities, specialized clinics, and home environments.
- Collaborative care by a team of health-care providers—such as primary care providers, nurses, social workers, dietitians, and social workers—is part of safe and effective palliative care.
- Frequent communication among the team members ensures continuity of care as well as quality care.
- As a case manager, a nurse should follow up on the efficacy of treatment, coordinate care with the interdisciplinary team, and regularly update the patient's plan of care.
- A do-not-resuscitate (DNR) order means the patient does not want CPR as a life-saving measure; a do-not-intubate (DNI) order means the patient does not want to be placed on a ventilator.

32.2 End-of-Life Care

- End-of-life care includes palliative care, which relieves or reduces symptoms related to a serious illness to preserve a patient's quality of life, and hospice care, which provides comfort measures during the last six months of life.
- The nurse often takes on the role of a case manager to coordinate with the patient, family, and the care team to provide safe and effective end-of-life care. Communication is essential to ensure the patient and their family are supported and informed through the entire process.
- Provider-assisted dying is legal in some states and jurisdictions; it involves a provider prescribing a lethal dose of medication for the patient to use to end their life.
- Euthanasia involves an act by a separate individual to cause death; it is illegal in the United States.
- Providers may find the use of medically assisted dying to present an ethical or moral dilemma. The nurse should conduct their own self-assessment to separate their personal beliefs from the care they provide to a patient in this situation.

32.3 Assessment

- An end-of-life assessment is an important time for the nurse to talk with the patient and family, while also observing and collecting physiological information, reviewing the treatment plan and directives, noting the family dynamics and conversation styles, determining the decision makers and caregivers, and ensuring spiritual, religious, and cultural beliefs are respected.
- Palliative care and hospice care patients may have pain, shortness of breath, fatigue, constipation, nausea, vomiting, loss of appetite, loss of cognition, and decreased level of consciousness (LOC).
- As death draws near, the nurse should observe for additional physiological changes and ensure the family understands what the changes signify and what to expect after the end of life.

32.4 Psychosocial Support

- Hope is an integral part of end-of-life care; it prolongs life and maintains quality of life, as patients still have hope for things they want to accomplish.
- According to psychologist C. R. Snyder, there are three conditions for hope to thrive: goals, pathways, and agency.
- Grief is the emotional state that follows the loss of a loved one, while mourning is the outward expression of grief. Bereavement is the time frame following the loss in which grief is experienced and mourning is expressed.
- The five stages of grief are denial, anger, bargaining, depression, and acceptance. However, everyone grieves differently and at their own pace.
- Families may also have learning deficits, inadequate coping mechanisms, and gaps in communication skills that cause them to feel off balance with the impending death of their loved one.
- The family's method of coping with death may not coincide with the values and beliefs of the nurse and the

care team, but it is imperative that the patient's and family's wishes be respected to the greatest extent possible.
- An important component in providing culturally competent care within the family is to use discretion about the appropriate time and setting for sensitive conversations to be conducted. It is also important to provide context for the discussion.
- Spiritual assessment is a key component for a terminally ill patient. A patient's spirituality encompasses much more than their religious preference, affiliation, or beliefs.
- The nurse's role is to teach the family members and assist them with obtaining the knowledge and resources they need to care for their loved one.

32.5 Special Considerations

- Nurses and other members of the health-care team encounter death and loss daily, making shadow grief and related anxiety common experiences.
- The negative impacts of working with the dying—such as associated grief, unresolved anxiety, and denial—can lead to illness and burnout among health-care workers, as well as create a barrier to effective patient care.
- Caregiver support is an essential part of end-of-life care, and nurses must encourage self-care measures for the primary caregiver so they can better provide effective and compassionate patient care and manage their own feelings about the patient's end of life.
- Health-care professionals need support, education, and assistance to deal with the anxiety of working with grieving patients and families as well as to effectively process the death and dying of patients in their care.

Key Terms

bereavement period of time when one mourns a loss
do-not-intubate (DNI) order stating the patient does not want to be placed on a ventilator if they are unable to breathe independently
do-not-resuscitate (DNR) order stating the patient does not want CPR conducted if their heart stops
durable power of attorney (DPOA) document enabling the patient to list a specific individual whom they entrust to make financial and health-care decisions when they are no longer able to do so
euthanasia act by an individual to cause death, such as directly administering a lethal dose of a medication; illegal throughout the United States
grief emotional state that follows a loss
health-care proxy person designated in a durable power of attorney document to make health-related decisions for a patient who is no longer able to make their own decisions
holistic care care for the whole person, including body, mind, spirit, and emotions
hospice care specific type of palliative care for patients nearing the end of life, encompassing physical, psychological, emotional, and spiritual needs and desires
Medical Orders for Life-Sustaining Treatment (MOLST) program with a goal of improving quality of care for patients at the end of life by enabling them to specify their goals and preferences via a transferrable form; known in some states as POLST
mourning external actions taken to express one's grief, such as wearing black
palliation effort to alleviate suffering and enhance quality of life for patients with serious, often progressive, illnesses
palliative care comfort care provided when a serious illness is no longer responding to treatment
Physician Orders for Life-Sustaining Treatment (POLST) program with a goal of improving quality of care for patients at the end of life by enabling them to specify their goals and preferences; known in some states as MOLST
provider-assisted death use of pharmacological agents prescribed by a health-care provider to hasten death; legal in certain US states and jurisdictions
respite care period of rest for a caregiver in which the patient temporarily resides in a skilled nursing facility before returning home
shadow grief unresolved sadness

Assessments

Review Questions

1. After discussing the terms DNR/DNI with a patient, the patient has expressed they do not want to receive CPR or be placed on a ventilator. What is the nurse's top priority to ensure the patient's desires are honored?
    a. Share this information with the patient's family.
    b. Have the patient sign a DNR/DNI or MOLST/POLST form to be placed in their record.
    c. Post a sign in the patient's room of their DNR status so that all health-care providers will honor the patient's wishes.
    d. Have the patient tell their provider directly.

2. Once a patient confirms they do not wish to receive life-saving measures when their heart stops, the nurse should direct them to sign what document?
    a. advance directive
    b. power of attorney
    c. do-not-resuscitate order
    d. last will and testament

3. Mr. Smith's illness is no longer responding to treatment. His prognosis is poor, with fewer than six months to live. What course of care should the nurse recommend to Mr. Smith?
    a. hospice care
    b. palliative care
    c. respite care
    d. end-of-life care

4. What legal document outlines the specific health-care decisions for a patient when they can no longer make decisions for themselves?
    a. advance directive
    b. durable power of attorney
    c. do-not-resuscitate order
    d. informed consent

5. What legal document designates the trusted individual who can make health-care decisions for a patient when they can no longer make decisions for themselves?
    a. informed consent
    b. durable power of attorney
    c. advance directive
    d. living will

6. The nurse is discussing palliative care with a patient who has metastatic lung cancer. The patient has indicated that they wish to continue their cancer treatment. What is an appropriate response from the nurse?
    a. "You can continue your cancer treatment while receiving palliative care."
    b. "Palliative care is utilized when a patient's illness is no longer responding to treatment."
    c. "Do you not understand that your cancer has spread?"
    d. "I will let the doctor know that you do not wish to receive palliative care."

7. A palliative care patient with Alzheimer disease has lost a significant amount of weight during the last few weeks. The family member asks the nurse about nutritional shakes. What is an appropriate response by the nurse?
    a. "Prescribed nutritional supplements can be used to replace meals."
    b. "Prescribed nutritional supplements are wasted calories and not helpful."
    c. "Offering a prescribed nutritional supplement with a meal could be helpful."
    d. "Prescribed nutritional supplements help with weight loss."

8. What distress symptom is most common when a patient is nearing death?
    a. anxiety
    b. depression
    c. pain
    d. withdrawal

9. The hospice nurse visits a patient dying of lung cancer. During the visit, the patient says, "If I could live long enough to see my grandson graduate from college, I'd be ready to die." What phase of coping is the patient expressing?
    a. bargaining
    b. anger
    c. denial
    d. acceptance

10. The nurse is caring for a terminally ill teenager who is receiving palliative care. The nurse explains the purpose of palliative care to the teen's mother. The need for additional instruction is recognized by the nurse when the mother makes which statement?
    a. "Palliative care will provide relief or reduction of symptoms."
    b. "Palliative care will include pain management."
    c. "My child will die sooner by receiving only palliative care."
    d. "Optimal functioning will occur while receiving palliative care."

11. A family member of a terminally ill patient steps out of their loved one's room in tears. They tell the nurse, "I don't know how I will make it when Momma is gone." What is the nurse's best response?
    a. "Don't worry, everything will be all right."
    b. "Things will get easier with time."
    c. "This must be very hard for you."
    d. "You need to stay strong and not cry."

Check Your Understanding Questions

1. What is the goal of palliative care?
2. Can a patient continue to receive curative care or life-prolonging treatment while receiving palliative care?
3. Who can receive palliative care?
4. List some common symptoms associated with end-of-life care.
5. What is meant by medically assisted dying?
6. List the common physiological changes for palliative care and hospice patients.
7. Explain the terms grief, mourning, and bereavement.
8. What are three strategies you can use to help a caregiver manage their stress and exhaustion while providing end-of-life care?

Reflection Questions

1. Why is it necessary to have an interdisciplinary team to provide hospice services?
2. Why is important for the hospice patient to have an advance directive and durable power of attorney?
3. List different topics that a nurse might discuss during the initial assessment with the patient and family.
4. How can a nurse incorporate cultural sensitivity when discussing end-of-life care with patients and families?
5. Take time to reflect on your personal attitudes toward death and dying.

What Should the Nurse Do?

1. Charles, an 80-year-old patient with congestive heart failure, has been a home care patient for six months; during this time, a personal care assistant has helped Charles with bathing, dressing, and grooming. This care enables Charles to live at home independently. However, several months ago Charles had a stroke, and he still has not regained use of his dominant right hand and arm. Recently, he has been experiencing severe pain in his right arm and shoulder, as well as decreased endurance and shortness of breath. The provider has informed Charles that his pain will likely not improve and in fact might worsen due to the decreased mobility in his right arm and hand. Notwithstanding his recent decline, Charles still believes that he has several good years left and looks forward to seeing his grandson graduate from college.

   What type of care would be most appropriate for Charles's nurse to recommend at this time? Where would this care be provided?

Chris, a palliative care patient, has recently had a second stroke, leaving him unable to walk. He has not recovered the use of his right arm and hand from his first stroke last year. Chris's congestive heart failure has worsened, resulting in a significant decline with a poor prognosis. Chris has a documented ejection fracture of less than 20%, is symptomatic at rest, and has uncontrolled edema that has resulted in a total inability to complete his ADLs independently. Due to his significant decline, Chris will be discharged to a long-term care facility.

2. With Chris's decline and poor prognosis related to his congestive heart failure, what type of care would be most appropriate for him at this time?
3. Due to Chris's present health status, what types of legal documents should his nurse suggest Chris complete to ensure that his health-care directives are followed?
4. At this juncture in Chris's care, while discussing his end-of-life care and directives, what is another very important item that Chris needs to decide?

Charles has been in a nursing home for a few months following two strokes and worsening congestive heart failure that have significantly impaired his mobility. Now, he is unresponsive and can no longer communicate his wishes. The family has been informed that medical tests, physical therapy, and vital signs monitoring will be stopped as they are no longer providing a benefit to Charles's comfort or health status. Most recently, Charles has developed pneumonia. His family is asking about having him admitted to the hospital.

5. What is the best response for the nurse to provide to his family?
6. The family asks the nurse when Charles will die. How should the nurse respond?
7. Mimi was diagnosed with pneumonia a few days ago. Her family has been vigilant since her recent diagnosis, visiting frequently and ensuring that she is not left alone. What are some things the nurse can do to ensure the family is also cared for during this time?
8. You are working with a team that includes members with varying attitudes toward death and dying. How would you foster a collaborative environment that respects diverse perspectives and supports effective communication about end-of-life issues?

Competency-Based Assessments

1. Create a patient handout that explains the differences between palliative care and hospice care.
2. Create a patient handout that can be used to teach patients and their families about the expected physiological changes during end-of-life care, as well as supportive interventions that can be used to provide comfort.
3. You are a nurse working in a hospice setting, and you are assigned to care for Mrs. Patel, a terminally ill patient from a South Asian background. Mrs. Patel's family is highly involved in her care decisions, as it is a significant cultural value for them to make collective decisions regarding her treatment and end-of-life care. The family practices Hinduism, which includes specific rituals and preferences regarding death and dying. Outline how you would ensure that the family's preferences and cultural practices are respected while coordinating the patient's care.

CHAPTER 33
Emergency Care

FIGURE 33.1 An interdisciplinary team cares for a newly admitted patient with traumatic injuries after an accident. (credit: Brooke Army Medical Center Public Affairs/Joint Base San Antonio, Public Domain)

CHAPTER OUTLINE

INTRODUCTION Consider a nurse triaging a patient who was in a car accident involving alcohol; the patient has sustained multiple traumatic injuries. As the nurse is receiving a report from the emergency medical services, the patient becomes unresponsive. What should be the nurse's next steps in caring for this patient? A triage nurse should follow the airway, breathing, circulation, disability, and exposure (ABCDE) triage assessment method and provide continuing support and care for such patients. This systematic approach ensures that life-threatening conditions are identified and addressed promptly, maximizing the patient's chances of survival. For the nurse, this could involve monitoring and maintaining the patient's airway, controlling bleeding, assessing neurological status, and ensuring that a patient can be closely examined from head to toe for any less obvious injuries. Throughout this process, the nurse should remain aware of the need to protect the patient's privacy and dignity. The nurse must also maintain an awareness of the possibility that the patient could decompensate and thus should be on the alert for signs of decline or complications. To prevent these outcomes, the nurse may need to perform specific stabilizing tasks, such as administering fluids or blood products.

There are many avenues to becoming an experienced emergency department (ED) nurse. Some examples include specialized certifications, workshops, and continuing education in trauma care. This chapter discusses the steps to

take during emergency situations.

33.1 Triage and Assessment

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Define triage and the nursing responsibility related to triage
- Discuss the ABCDE assessments utilized in triage
- Use prioritization findings to guide nursing care
- Define components of effective documentation in the emergency department
- Explain patient consent in the event of an emergent event

Nurses should be prepared to respond to an emergency at any time. Most emergent conditions are treated by emergency department nurses in the hospital's emergency rooms. In addition to working in a fast-paced, ever-changing environment, ED nurses need exceptional assessment, prioritization, and critical thinking skills. The Joint Commission (2023) seeks to increase the quality of patient care in the ED and improve patient outcomes. This is achieved through accurately assessing and triaging patients, which reduces time spent waiting and being treated in the ED.

CLINICAL JUDGMENT MEASUREMENT MODEL

Recognizing Cues in a Patient in the ED

The nurse in a busy ED is assessing a fifty-six-year-old male patient who reports chest pain radiating to the left arm. The nurse asks the patient to rate the pain on the numerical pain scale, documenting a rating of 8/10. The nurse also notes that the patient is diaphoretic and appears anxious. The nurse records the patient's vitals at intake: BP: 148/90; HR: 111 bpm; RR: 23; and O_2 sat: 96 percent on RA. It is important for the nurse to identify the cues from the patient assessment, such as the chest pain, BP, and HR, that indicate there is a problem and then analyze those cues to determine the next steps.

Triage

The term **triage** refers to the process of assessing and prioritizing patients' care based on initial assessment findings. Nurses must be able to effectively and efficiently triage patients, especially in emergency situations. For example, a person who has chest pain would be prioritized before a patient with an ankle injury. Nurses understand that chest pain could be indicative of a myocardial infarction (MI) or heart attack, and while an ankle fracture is painful, it is not as life threatening as an MI. Triage occurs during initial intake phase, whenever there is a change in a patient's condition, and during situations with mass casualties.

During the triage phase, the nurse has several responsibilities. The first is to complete an assessment to determine immediate concerns. This involves asking questions, using clinical judgment to recognize cues, analyzing cues, and prioritizing findings. The nurse will also review the patient's medical history, if possible, to determine if any current concerns are related to previously identified conditions or comorbidities. Based on the severity of findings, the nurse will then prioritize care and take action, implementing interventions to address any identified concerns. The nurse will also follow any provider orders, such as administering medications or collecting blood samples for diagnostic testing. While conducting triage, the nurse should remember to ensure that the patient's privacy is protected.

CULTURAL CONTEXT

Respecting Modesty and Privacy

When undergoing a comprehensive assessment in the emergency department, the patient will need to have their clothing removed. The ED nurse will need to be respectful of the privacy and modesty of all patients, whether they are conscious or unconscious. In addition, the nurse should always be aware that modesty can have an important role in many religions and cultures. For example, modesty is greatly emphasized in the Muslim religion. A Muslim patient may prefer to be treated by a provider of the same sex, when possible (Attum et al., 2023). In an emergency

situation, it may not be possible to accommodate provider preference. In this case, the nurse can advocate for the patient by ensuring that a same-sex staff member or, if possible, a family member, is present during the exam. If the patient's clothing must be removed and modesty cannot be maintained, providers should try to expose as little of the patient's body as possible and restore coverage as soon as possible.

Additional steps that the nurse can take to preserve the modesty and privacy of all patients include closing patient curtains and doors before removing any clothing. If the patient is unconscious or unable to respond, politely ask anyone other than health-care staff to leave the room before assessing the patient. If the patient is alert and can respond appropriately, ask if they feel comfortable disrobing with others present in the room. When performing the assessment, provide a gown, drape, or blanket to cover private areas when the patient is not being assessed. Emergency departments tend to be very busy, and sometimes simple gestures such as these get lost in the shuffle. Before anything else, nurses are patient advocates, and they need to make sure respect is always a priority.

Airway, Breathing, Circulation, Disability, and Exposure (ABCDE)

One of the most utilized method for triaging patients in emergency situations is the **airway, breathing, circulation, disability, and exposure (ABCDE) triage assessment** (Althobity et al., 2024). Each letter represents a step of the assessment, performed in alphabetical order:

- A: Airway
- B: Breathing
- C: Circulation
- D: Disability
- E: Exposure

When using the ABCDE triage method, the airway is assessed first regardless of underlying cause or patient age (Althobity et al., 2024). Emergency airway conditions are always treated first before moving to other areas or body systems.

Airway

The airway is the most important system, because without an adequate airway, the patient's lungs cannot supply vital oxygen to the rest of the body (Althobity et al., 2024). To be skillful at airway management, the nurse must first understand the structural, physical, and pathological aspects related to the airway (Avva et al., 2024). When assessing the airway, the nurse first checks for patency. This can be done by asking the patient questions and listening to their response. If their voice sounds normal, without obstruction, their airway is patent. If their voice sounds muffled or crackled, there may be an obstruction. In some cases, a decline in level of consciousness can lead to airway obstruction caused by the tongue. The easiest way to open the airway for an unconscious patient is to use the head-tilt and chin-lift method (Figure 33.2). Determining airway patency enables the nurse to either move on to breathing or request the provider initiate an artificial airway.

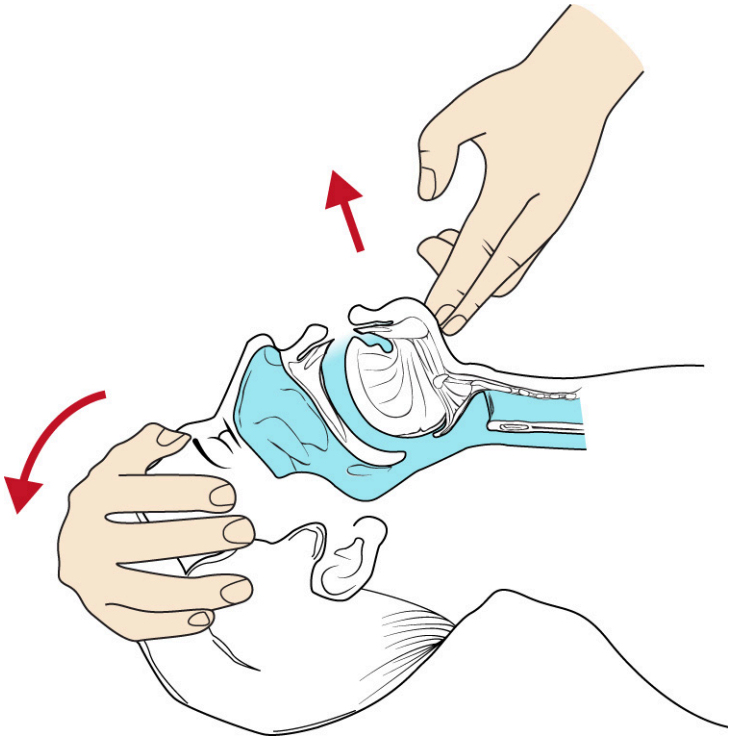

FIGURE 33.2 The head-tilt and chin-lift maneuver is the easiest way to open a patient's airway. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Breathing

The next step in the ABCDE triage assessment is to assess the patient's breathing. This can be achieved by counting the patient's respiratory rate. The nurse should assess whether the patient's chest rises symmetrically and whether the trachea is midline. The nurse will also determine how much effort it takes for the patient to breathe. This means noting if the patient is using accessory muscles or is displaying pursed lip breathing. Recognizing signs of respiratory distress is critical when assessing breathing status (Avva et al., 2024).

Next, the nurse will auscultate the lungs and apply a pulse oximeter to measure oxygen saturation. If the patient is in respiratory distress, the nurse will utilize emergency equipment, such as a crash cart, bag-mask for ventilation, suction, and an emergency intubation kit, to help stabilize the patient's breathing. Recommendations for compromised breathing include positioning the patient, providing supplemental oxygenation, and implementing an artificial airway, such as an endotracheal tube for airway management (Raveendra et al., 2020).

Circulation

The third step in the ABCDE triage assessment is circulation. Once the patient's airway and breathing are stable, assessing for circulation to determine adequate perfusion is critical. First, the nurse should confirm the patient's apical pulse with a stethoscope. Then, the nurse should check capillary refill time and for any signs of cyanosis or color change of the skin. Systemically assessing all pulse points will help identify any differences among the extremities. The nurse will also collect data, such as the patient's blood pressure, assessing for hypotension or hypertension. The patient is also placed on an electrocardiogram monitor to assess their cardiac rhythm. At this stage of the triage, intravenous (IV) line access is usually placed if the patient does not already have one. In emergency situations, choose a larger gauge IV in case the need arises for fluid boluses or blood replacements (Verhoeff et al., 2018).

LINK TO LEARNING

Often, the emergency room nurse places a patient's first IV. Watch this video for an overview of different IV gauges (https://openstax.org/r/77IVgauge) and their most common uses.

Disability

The next phase of the ABCDE triage assessment is to assess for disability. In this triage method, disability refers to a patient's level of consciousness. The Glasgow Coma Scale (GCS) is the most widely used assessment tool for assessing level of consciousness in emergency cases. The GSC assesses eye-opening, verbal, and motor responses to stimuli and provides a range of possible responses to help providers assess neurological deficits (see Table 15.4). There are many factors that can cause a decreased level of consciousness, and the health-care team will need to rule these out before attempting to treat the disability. A few such causes include decreased oxygenation to the brain or hyperventilation from pain, which can result in decreased oxygenation to the central nervous system; too much perfusion to the brain, as in the case of internal hemorrhaging; or a recent administration of analgesics, including prescribed and nonprescribed medications.

Exposure

The final step in the ABCDE triage assessment involves assessing for exposure. Being exposed in this instance can refer to being vulnerable to elements in the environment (such as extreme temperatures) or to harmful substances (chemicals, smoke inhalation, or drugs). The first step is assessing the patient's body temperature. An extreme hyper or hypo body temperature can be a sign of shock or infection. The nurse needs to assess for signs of underlying bleeding or trauma and skin abnormalities. Make sure to inspect the whole body, including the back and groin for any injuries or rashes. The nurse should initiate any cooling or warming measures if indicated.

Prioritizing Findings of the Triage Assessment

After the recognizing and analyzing of cues has taken place, it is time for the nurse to prioritize the findings. Prioritization can be achieved through many simple steps. The nurse will use a process of elimination—sort of like an algorithm—with each finding of the triage assessment. The following are the basic steps for prioritizing which findings must be addressed first:

- Airway, breathing, circulation (ABC): A patient's airway, breathing, and circulation must be assessed and prioritized before any other interventions.
- Acute versus chronic signs or symptoms: Acute symptoms (those that are current/recent) take precedence over chronic, long-term symptoms or health conditions. However, the nurse will remain aware of how chronic conditions could affect the patient's acute problem.
- Expected versus unexpected findings: The nurse needs to assess for expected findings on an exam but also monitor and pay attention to any unexpected findings—particularly if they could be harbingers of complications.
- Does this finding need further assessment, or can an intervention be applied?: The nurse needs to be able to assess whether a finding needs to be explored more or if it's appropriate to provide an intervention.
- Maslow's hierarchy of needs: The nurse should be aware of how a patient's needs, according to Maslow's hierarchy, influence care. At the most basic level, all patients need to have their physiological needs for food, water, and pain relief met. At the same time, emotional needs, like feeling safe, are also an integral part of patient-centered care.

Any identified immediate needs will be discussed with the provider for collaboration on next steps. After addressing the patients' immediate needs, the registered nurse will complete a more in-depth, comprehensive assessment.

Components of Effective Documentation

Documentation in the emergency department or during an emergency situation can be challenging. Despite this, it is still crucial for nurses to abide by documentation standards to validate the providing of timely, accurate, and quality care. Documentation involves recording assessment findings. Symptoms, or **subjective assessment findings**, are those findings that the nurse does not directly observe and are only reported by the patient. These findings can include how the patient feels. By contrast, **objective assessment findings**, or signs, are aspects that the nurse directly observes and that can be measured. Examples include vital signs, diagnostic tests, physical findings, and the patient's mental state.

In addition to featuring assessment findings, effective documentation includes past medical and social history, medications, a review of systems, and order acknowledgment. Nurses should also document any communication of the health-care team with the patient or family members, such as nursing education provided, discussion of

advance directives, language preference, and performance of medication reconciliation. Nurses must also document plans of care, along with their assessment and evaluation of nursing interventions performed, implementation, and responses and outcomes to patient care.

Documenting timely, accurate, and complete assessments ensures that the information shared among health-care professionals is factual. Many decisions among the interdisciplinary team are based on documentation of every patient encounter. Information written in the patient's chart should clearly convey the encounter and leave no gaps for assumptions (Lorenzetti et al., 2018). Documentation should also be organized, meaning that the timing of documentation should be in order and be completed as close as possible to the real time of the encounter.

Consent in an Emergency

When patients come into the emergency room and are able to sign documents, the first document they sign is a **consent**, which gives medical professionals the authority to treat the patient with the most competent and highest quality of care. If a patient is brought to the emergency room and is unable to sign at that time, life-sustaining measures are still provided under **implied consent**, which means approval is presumed though not obtained during an emergent situation due to the life-threatening nature of the situation.

Treating Minors

Minors, or those under eighteen years of age, are often brought in by parents or legal guardians to be seen in the emergency department. The Emergency Treatment and Labor Act requires that all minors and patients receive a medical screening (American College of Family Physicians, 2023). This law was enacted to determine if a minor's condition is life-threatening and whether they need emergency care even if they were brought in by a relative or friend instead of a parent or legal guardian. During an emergency, verbal consent from the parent or guardian via the telephone may be obtained. Two witnesses must be listening simultaneously and will sign the consent form, indicating that consent was received via telephone. If the minor needs immediate medical attention and the provider cannot obtain consent from a parent or legal guardian, then they can proceed with treatment. Health-care professionals should be knowledgeable about their individual state laws for treating minors in the emergency department.

LIFE-STAGE CONTEXT

Exceptions to Parental Consent

In some states, a mature minor may give consent for certain medical treatments. The provider can make a determination that the adolescent (usually over fifteen years of age) is suitably mature enough and has the appropriate intelligence to make the decision for treatment. The provider will also weigh the severity of the treatment, the risks and benefits of completing the procedure now versus waiting before obtaining consent from a mature minor.

An example of this situation might involve a family taking their child's sixteen-year-old friend on vacation with them. Suppose the friend trips while ice skating and gets hurt. The parents take the sixteen-year-old minor to the local emergency room for treatment. The minor's parents are at work and unable to be reached via phone. The health-care team has determined the minor has sustained a broken arm that requires the application of a cast. The minor can give consent on their own behalf for the cast if the provider has deemed the minor mature and knowledgeable enough to provide consent.

33.2 Types of Emergency Care

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Recognize types of traumas often seen in the emergency department
- Discuss forms of abuse often seen in the emergency department
- Identify psychiatric emergencies often seen in the emergency department
- Explain substance use disorders often seen in the emergency department

Many different types of traumas are seen daily in the emergency department. It is important for nurses to

understand that not all traumas are treated the same way. Nurses must work within the interdisciplinary team to provide timely, competent care for each unique situation. Most emergency departments throughout the United States are staffed with a wide range of specialists that are able to treat any situation that might be encountered.

Types of Traumas

Before arriving at the hospital, emergency medical services (EMS) call ahead to inform the ED staff about the patient's initial condition and any life-threatening injuries. The ED nurse then works with the health-care team to anticipate the patient's needs by setting up any equipment, gathering supplies, and preparing the patient's room. After the patient arrives at the hospital, the nurse performs the initial assessment. At this point, EMS gives a more in-depth hand-off report. The gold standard for report hand-off involves using the ISBAR method (Dalky et.al., 2020).

CLINICAL SAFETY AND PROCEDURES (QSEN)

QSEN Competency: Maintaining Quality and Safety During an Emergency

Disclaimer: Always follow the health-care facility's policy for triaging during an emergency.

Definition: Maintain safety and quality care to patients during an emergent response.

Knowledge: The nurse will assess and triage patients using the ABCDE triage method and appropriately prioritize care, escalating care to the appropriate facility when necessary.

Skill: Demonstrate effective triage strategies. The nurse will:

- Utilize the ABCDE triage method when assessing trauma patients.
- Escalate patient care to the appropriate level of care during the trauma event.
- Stabilize the patient before transport.
- Complete a secondary survey of the patient after they have been stabilized.
- Utilize the SBAR communication tool during handoff.

Attitude**:** The nurse will adhere to the ABCDE triage method and use the SBAR handoff tool for effective communication when transferring care.

(QSEN Institute, n.d.)

After the patient is stabilized, the nurse performs a secondary, more comprehensive assessment. If additional diagnostic testing is indicated, it is performed at this stage as well. If the current facility lacks the specialized care needed by the patient, they will be transferred to another facility to meet the identified needs. Some specialty facilities include burn units, stroke centers, or mother-baby care. Many kinds of trauma come through the emergency room, regardless of whether it is a small rural facility or a big metropolitan emergency room.

Crush Injuries

Emergency department nurses often encounter patients with crush injuries resulting from motor vehicle accidents or other catastrophic events. A **crush injury** occurs from prolonged pressure to an area of the body. Many crush injuries result in the loss of a limb or even patient death. Nurses must understand the potential health complications that can develop and recognize any cues of early and/or late deterioration. While these injuries most often occur with a traumatic event, they can also result from prolonged immobilization or anesthesia. Pressure sustained can block the return of the blood to the affected body area causing swelling and damage to muscle tissue and nerves. The muscles then release myoglobin into the bloodstream, along with other cellular components like potassium, magnesium, phosphates, and other chemicals, which can accumulate in toxic levels in the bloodstream. Crush injuries often result in life-threatening diagnoses like compartment syndrome, rhabdomyolysis, and other serious health conditions (Usuda et al., 2023).

Upon initial assessment, the nurse should assess the patient's skin color, especially the area distal to where the crush injury occurred. The nurse should observe the skin for signs of cyanosis and palpate pulses distal to the area of injury. If pulses are not palpable, the nurse can use a Doppler ultrasound to locate the patient's pulse. The nurse

should also check the patient's capillary refill time, which should ideally be less than three seconds. In addition, the nurse should ask the patient to move the affected body area, if possible, and ask the patient what they feel when the nurse applies sensation to the affected area (Long et al., 2023).

Nurses should perform neurovascular checks frequently on patients with crush injuries. If there are any notable deviations, this may indicate a worsening of the patient's condition. The nurse must immediately notify the health-care provider.

Rhabdomyolysis

One potential complication of crush injuries is rhabdomyolysis, the breakdown of skeletal muscle tissue that is often the result of sustained pressure or crushing of the muscles. Nurses will assess for early symptoms of this condition, which include pain, muscle weakness, and tea- or dark red–colored urine (myoglobinuria). The hallmark sign of rhabdomyolysis is significantly elevated CPK levels in the blood. Late symptoms include confusion, malaise, vomiting, and fever (Stanley et al., 2023). If any symptoms of rhabdomyolysis begin to develop, the nurse must alert the health-care provider immediately. In addition, nurses must continuously monitor the patient's diagnostic labs, such as CPK, CRP, and ESR.

Compartment Syndrome

Compartment syndrome leads to sustained pressure within a muscle compartment. Pressure increases within the muscle compartments to the point that circulation and oxygenation are restricted, and this results in muscle anoxia and necrosis. Permanent functions could be lost if this condition persists for longer than six hours (Torlincasi et al., 2023). The frequency of acute compartment syndrome is estimated to be 7.3 per 100,000 in males and 0.7 per 100,000 in females, with the majority of cases occurring after a crushing trauma (Torlincasi et al., 2023). Diligent and frequent assessment of the patient's neurovascular system, ideally every 30 minutes, can reduce the occurrence of compartment syndrome. Neurovascular assessment includes checking the patient's circulation, ability to move extremities, and loss of sensation.

Nursing Care for Crush Injuries

Crush injuries can result in severe complications, such as cardiac arrhythmia, compartment syndrome, internal hemorrhaging, and rhabdomyolysis. Fluid and electrolyte imbalances (e.g., hyperkalemia, hypocalcemia, hypovolemia) are common with crush injuries. It is vital that the nurse recognizes that rapid fluid resuscitation is key to improved outcomes. Recognizing cues for decline in status, prioritizing care, and taking swift action are the keys to providing competent, quality patient care. Nurses will need to perform frequent focused assessments such as the following (Long et al., 2023):

- Neurovascular checks that involve looking for cues, such as severe pain, pallor, decreased or absent pulses, numbness or tingling, and decreased sensation
- Monitor diagnostics, such as CPK, EKG, and urine samples, that involve looking for signs of improved vascularization in the affected area
- Monitoring of intake and output levels to check for balances or shifts

READ THE ELECTRONIC HEALTH RECORD

Caring for the Patient with a Crush Injury

A nurse is caring for a patient admitted to the surgical intensive care unit after receiving an open reduction and fixation of the right femur (ORIF) following a car accident. Review the patient's electronic medical record and answer the questions that follow.

Nurse's note (0247):

- Patient brought to SICU from OR following ORIF of right lower leg after being ejected from car, un-restrained.

Vital signs (0250):

- BP: 88/62
- O_2 saturation: 95 percent, sedated and ventilated
- HR: 110

- Temp: 99.5°F
- RR: 16

Nursing Assessment:

- Gen/Neuro: Sedated, multiple ecchymotic areas on face, right lower leg, and chest
- CV/Pulm: S1S2, RRR, tachycardic, lungs diminished throughout
- Skin: Cool to touch

1. What information in the EHR is the most concerning?
2. What other assessments should the nurse perform?
3. What action by the nurse would you anticipate?
4. What complications is this patient at risk for?

Poisoning

In 2021, more than two million calls to Poison Control were made in the United States (NCPC, 2023). This translates to approximately one call of reported exposure every fifteen minutes. In the emergency department, nurses are required to stay up to date on current poisoning protocols, as well as be responsible for understanding diagnostic testing related to **poisoning**, which refers to exposure to substances, drugs, or chemicals. They will also need to implement medical therapies to reverse poisoning, while providing appropriate nursing care and preventing further complications.

Specifically, **accidental poisoning** occurs when a person unintentionally exposes themselves to a substance that is harmful, while **intentional poisoning** can be caused by a person purposely exposing themselves to toxic substances or another person intending harm. Poisoning can occur through inhalation, ingestion, or absorption through the skin. It can happen through any form of a substance, whether a solid, liquid, or gas. Many chemicals around the household, such as fertilizers and cleaning supplies, can cause poisoning. Poisoning can also occur at the workplace. A common non-drug poisoning is from carbon monoxide, a poisonous gas that is inhaled (Centers for Disease Control and Prevention [CDC], 2018a).

The provider will order diagnostic testing as soon as possible if they suspect or confirm poisoning. Typically, this involves the nurse collecting bloodwork, such as CBC, CMP, ABGs, LFTs, and serum blood levels. Toxicology screening and urine samples may also be ordered to identify the substance. When a patient enters the emergency department with suspected or confirmed poisoning, the nurse is obligated to notify Poison Control (Mukherji et al., 2023).

LINK TO LEARNING

Poison Control is a valuable resource that nurses can use. It has a national number, 1-800-222-1222, that enables callers to speak with a representative that can provide guidance about conditions to watch for and even offer treatment recommendations for patients with acute poisoning. Explore Poison Control (https://openstax.org/r/77poisoncon) for additional information.

Depending on the poisoning substance and mechanism of action, different reversal agents or antidotes can be administered. For most poisonings, activated charcoal. For opioid overdoses, naloxone is administered, and for benzodiazepines, flumazenil. N-acetylcysteine (NAC) is another common reversal agent, and it is used for salicylate or acetaminophen poisoning (Chacko & Peter, 2019). Nurses can utilize Poison Control as a resource for information about the correct reversal agents to choose. Additional medical therapies include fluid resuscitation, the administering of anti-epileptic medications, and the facilitating of other supportive measures, such as inducing vomiting.

Nurses use the ABCDE triage assessment for assessing patients with potential or confirmed poisoning. Depending on the severity of the poisoning and the status of the patient, mechanical ventilation, supplemental oxygen, and/or medical sedation may be necessary. The patient should be placed on cardiac monitoring. Frequent assessment of

the patient's vital signs is also needed to recognize hypotension, hypertension, bradycardia, or tachycardia. Fluid resuscitation will be dependent on the patient's condition. The nurse assesses the patient's neurological status and may administer anti-epileptic medications, if they are prescribed, to prevent or control seizure activity (Chandran & Krishna, 2019). Depending on the substance, nurses should ensure the use of proper personal protective equipment (PPE) to protect against potential cross-contamination.

LINK TO LEARNING

The CDC published a resource for PPE use (https://openstax.org/r/77PPE) that includes types of PPE as well as proper use and disposal.

Nurses should also monitor bloodwork for electrolyte imbalances and administer appropriate electrolytes, as ordered. If the patient is hyperthermic, the nurse can apply a cooling blanket and administer antipyretics, as indicated. The nurse should administer any antidotes or reversal agents to the patient and provide frequent updates to the Poison Control Center. In addition, the nurse may employ elimination techniques, which include urine alkalinization, hemodialysis, or continuous renal replacement therapy as outlined in Chapter 20 Genitourinary and Reproductive Systems (Chandran & Krishna, 2019). Nurses will also provide supportive care for the patient and family.

Abuse

Abuse, neglect, and maltreatment can happen to anyone, anytime, and at any age. Often, the emergency department is the place of discovery. It is important for an ED nurse to be able to recognize cues of abuse and be prepared to take action for appropriate reporting and education on available resources. The nurse must understand the different types of abuse that can occur and the appropriate nursing interventions for each type. Nurses are legal mandatory reporters of abuse (Einboden et al., 2019). Every practicing nurse should follow their state and federal guidelines on reporting abuse.

The term **maltreatment** refers to the poor quality of care an individual receives. Neglect and abuse are types of maltreatment. The term **abuse** means harming another person physically, sexually, or emotionally. The term **neglect** means failing to supply a person with basic needs, such as food, shelter, or clothing. This can also pertain to emotional needs or failure to seek medical treatment. There are different types of abuse that can occur, such as a child, elder, sexual, and domestic partner abuse. Abuse can be emotional, physical, neglect, substance, and others.

Child Abuse

Nurses must be able to recognize potential cues of child abuse. Abuse should be suspected when there are unexplained injuries or injuries that do not match the described situation. For example, a spiral fracture of a child's wrist may indicate they were forcefully grabbed. A child may also exhibit aggressive or disruptive behavior, or alternatively, be withdrawn or emotionless. Upon discharge, an abused child may express fear of returning to the home with the abuser (Einboden et al., 2019). A nurse should recognize injuries on both sides of the head or around both eyes, unexplained bruising, bite marks, limping, or burn marks, as these can potentially indicate abuse. In the case of neglect, the victim may appear unkempt and have clothing or shoes that are beyond normal wear and tear. They may also show signs of malnutrition or have developmental delays (Adigun et al., 2023). Nurses should immediately report suspicions of abuse through the proper channels, like state departments and health-care organization protocols.

REAL RN STORIES

Nurse: Amanda, MSN
Years in Practice: Four
Clinical Setting: Emergency department
Geographic Location: Atlanta metropolitan area

In Atlanta, we serve a very diverse patient population and care for patients of all ages and backgrounds. One day, a

father brought his daughter into the emergency department for left arm injury and pain. He reported that his six-year-old daughter had fallen while rollerblading at home earlier that day. The girl was very withdrawn and shy when I was admitting her, not speaking much. After a while, she lightened up when I brought her warm blankets and stickers. When the physician came into the room to examine her, the father told the provider the same story. This time, however, the daughter mentioned in the middle of his story how she "hurt all last night but my dad wouldn't listen to me."

It seemed a little odd at first since the timeline of the story didn't match what the father said about being injured earlier that day. My red flags didn't go up at first, but then the x-ray came back showing she has a spiral fracture of her left humerus. I sensed something was off with the timeline of events. I notified the physician of my concerns, and he went and spoke to the father again, but this time confronting him more about the story. He again said it was from his daughter falling while rollerblading. This time his daughter interrupted to say that her arm didn't hurt until he pulled her up from the ground.

The provider and I both stepped out of the room. Together, we decided to report this to Child Protective Services. The girl interjecting her dad's story and her story not matching, and the spiral fracture was concerning. I called Child Protective Services and notified them of our concerns and findings. To my surprise, they were able to show up quickly while we were casting the patient. CPS called the mother of the child, who was actually separated from the child's father. So, CPS was able to interview the father and daughter separately. We learned later that the father had actually injured the daughter by yanking her off the ground when he was mad. The child's mother mentioned this wasn't the first "outburst" he's had. This was a lesson learned by me to listen carefully to your patients, including children, because you never know what they might say that can change your course of action.

Older-Adult Abuse

Older-adult abuse is maltreatment of a person who is over sixty years old. The term *older-adult abuse* encompasses neglect, physical, financial, sexual, or psychological abuse (CDC, 2021). Signs of abuse can include the person who provides care showing frustration or hostility. They can even have a lack of awareness about the older person's care. The older adult may be disengaged, fearful, and have a different account of events than the caregiver. There may be a lack of adherence with medications and treatments or multiple visits to the emergency department. Sometimes there are unexplained or frequent injuries or a lack of proper medical attention (Rosen et al., 2018).

Sexual Abuse

Signs of sexual abuse in children can present as nonspecific medical complaints or symptoms (e.g., incontinence), or the signs may be more obvious (e.g., genital bruising and bleeding). Children may exhibit inappropriate sexual behavior or language that is not age-appropriate, or have personality changes (Adigun et al., 2023). Signs of sexual abuse in older adults may look a little different. They may have recently received a diagnosis of a sexually transmitted disease. Physical examination may reveal genital or rectal bruising or redness (Rosen et al., 2018). If abuse is reported, a SANE nurse (discussed further in Forensic Nursing) examines these patients.

Domestic Partner Abuse

Domestic partner abuse is also called intimate partner abuse. In cases of physical abuse, the patient often will cover injuries by wearing clothing over the injury sites. They may have wounds or burns on their hands and forearms (Huecker, 2023). Some victims of abuse exhibit psychological symptoms, such as fear or poor self-esteem (Rosen et al., 2018). Others may have anxiety or depression or present with chest pain, complaints of painful intercourse, or even nonspecific symptoms. The nurse should attempt to talk to the patient privately and provide safety. If violence or assault is suspected, ask for a forensic nurse to participate in the care of the patient.

Nursing Responsibilities for Abuse

If abuse is suspected, a comprehensive history and assessment are required. This should be conducted away from the abuser if possible. The nurse should document the patient's general posture, demeanor, affect, and mental status. During the physical examination, the nurse should look for signs of poor hygiene, previous trauma, current injuries, or pressure injuries. Potential signs of injuries sustained from abuse include burn marks, broken jaw bones or teeth, lacerations, or bruising. If a genital assessment needs to be performed for suspected sexual assault, ensure a chaperone is present and recruit a specialized SANE nurse. Nurses should initiate a referral for a social worker to ensure the provision of proper follow-up care. The nurse should document findings thoroughly, and notify

the appropriate authority of the potential abuse (Adigun et al., 2023).

Psychiatric Emergencies

A psychiatric emergency occurs when a patient's behavior is or can become harmful to themselves or others. These incidents are sometimes referred to as mental health crises. There are different types of psychiatric emergencies; examples include suicide attempts, acute psychosis, intoxication, and delirium episodes. Consequently, some psychiatric emergencies are induced by the treatment plan for the patient's condition or diagnosis. Serotonin syndrome and neuroleptic malignant syndrome can result from to high levels of the prescribed psychiatric medication (Maktabi et al., 2024). The nurse should be knowledgeable about different types of psychiatric emergencies and be familiar with interventions for each.

When a patient is at risk for harming themselves or others, the provider will order a psychiatric hold, also called involuntary hold. A **psychiatric hold** is when a patient is involuntarily admitted to a health-care facility under law. These types of mandates do not require patient consent and are usually 72 hours in length (Morris, 2020). Each state has its own laws regarding psychiatric hold guidelines.

When assessing a patient with a psychiatric emergency, there are several factors the nurse must consider. First, the nurse must make safety a priority for themselves, the patient, and the other members of the health-care team. The nurse should remove any unnecessary items from the patient's surroundings and have the patient change into a gown, if possible. Please note that some patients may require sedation before they are able to be assessed. If the patient is having a medical emergency in addition to psychiatric emergency, the nurse should follow the ABCDE triage assessment method when performing the initial assessment. The nurse should ensure that the patient is medically stable before proceeding to the neurological assessment. The nurse should then check the reaction time of the patient's pupils and assess the patient's mental status. As part of the neurological assessment, the nurse should verify the patient's orientation to person, place, and time, and check their reasoning, memory, and attention (Newman, 2020). All assessment details should be thoroughly documented in the patient's chart.

In addition, the nurse should use evidence-based suicide and violence risk screening tools to evaluate the patient. The nurse should document a thorough health history, including any past violent behaviors or acts. If unsure of the patient's psychiatric status or if there are any concerns, the nurse should always request an order for referral for a psychiatric evaluation.

In some cases, a urine drug screen is ordered, so the nurse should anticipate completing this as soon as possible (Stellpflug et al., 2020). Not all psychiatric emergencies are caused by substances or mental health conditions. Organic causes, such as encephalopathy, electrolyte imbalance, or infection, can also cause psychiatric symptoms. In these cases, the nurse should anticipate additional bloodwork and diagnostic tests to discover the primary cause.

Safety is the nurse's top priority when caring for a patient with a psychiatric emergency. When speaking with the patient, the nurse should set clear boundaries and permit choices when possible. The nurse should utilize de-escalation techniques, and only use restraints as a last resort with a provider's order. If restraints are required, the nurse must follow all legal and institutional guidelines, and the patient should be continuously monitored.

Substance Abuse

According to the Centers for Disease Control and Prevention, in 2016, around one in five emergency department visits was associated with misuse of prescription drugs or alcohol. Additionally, in 2021, it was reported over 100,000 drug overdose deaths occurred in the United States (CDC, 2022a). Considering these alarming statistics, nurses in the emergency department will encounter many substance abuse cases over the course of their careers. It is critical for nurses to know the different types of substance abuse, intoxication, and withdrawal symptoms. Nurses must also be able to perform rapid nursing assessments and implement appropriate interventions while caring for patients with substance abuse disorders. According to the 2021 Substance Abuse and Mental Health Services Administer (SAMHSA) report, the most common drug-related emergency department visits were caused by the use of opioids, alcohol, methamphetamine, cocaine, and marijuana (Substance Abuse and Mental Health Services Administer, 2022).

High-Risk Intoxication and Withdrawal

It is critical that ED nurses recognize cues of high-risk intoxication, potential overdose, and withdrawal. Opioid and

heroin abuse cause respiratory and nervous system depression and can potentially lead to patient death if not reversed. Patients abusing these drugs often present as lethargic, dysphoric, and unable to answer questions. Their respirations may be shallow, and their respiratory rate is low. Because opioids release histamine, urticaria is another common finding. The same drugs can also have opposite neuropsychiatric effects, like agitation and violent behaviors in some patients. Pupil dilation, hypotension, and seizure activity are also common signs (Schiller et al., 2023).

Patients will also present to the ED with symptoms of alcohol withdrawal. If a patient has long-term alcohol dependence, withdrawal symptoms will occur if the substance is abruptly stopped. Symptoms range from mild to severe, depending on the length of alcohol use and the average amount consumed. Mild symptoms include elevated blood pressure, anxiety, and hyperreflexes, while hallucinations and seizures are more moderate symptoms. The most severe stage of alcohol withdrawal is called **delirium tremens**, which entails seizures and hallucinations, along with tachycardia, hypertension, and hyperthermia (Newman et al., 2022).

LINK TO LEARNING

Nurses use the Clinical Institute Withdrawal Assessment for Alcohol (CIWA) tool (https://openstax.org/r/77CIWA) to assess symptoms of alcohol withdrawal in patients.

Nursing Responsibilities for Substance Abuse

When assessing patients with substance abuse disorders, it is important to obtain a thorough history, including what drug was taken and the time the patient last took the substance. If the patient is having trouble breathing or is unconscious, the nurse should follow the ABCDE triage assessment method to do an initial assessment of the patient's respiratory, cardiovascular, and neurological systems. The nurse should then administer any reversal medications, if indicated, for the determined substance and follow the appropriate protocols. If the patient has an opioid overdose, administer naloxone to the patient (Schiller et al., 2023). If the patient is having alcohol withdrawal symptoms, use the Clinical Institute Withdrawal Assessment for Alcohol (CIWA) to assess the severity of symptoms. Alcohol withdrawal symptoms can become severe, and the nurse's role is to prevent the worsening of these symptoms. Benzodiazepines, such as diazepam and lorazepam, are administered to alcohol withdrawal patients to control their symptoms and progression. The nurse should also prepare to administer medications such as phenytoin for seizures and chlordiazepoxide for withdrawal symptom prevention (Newman et al., 2022).

INTERDISCIPLINARY PLAN OF CARE

Interdisciplinary Care for Patients with Alcohol Abuse Disorder

Nurses work with an interdisciplinary team and coordinate care for patients with alcohol abuse disorders. The following professionals may be part of the team:

- Neurologist: Patients with severe withdrawal symptoms, or delirium tremens, may have seizures and require referral to a neurologist.
- Pulmonologist and critical care intensivist: These providers may be necessary if withdrawal is so severe that the patient requires sedation and intubation to maintain their airway.
- Physical and occupational therapist: Once the patient is able to come off ventilator support, physical and occupational therapy will need to be ordered, ensuring the patient is able to complete the activities of daily living.
- Psychiatrist: Patients with alcohol use disorders often have underlying mental health conditions.
- Case manager: These professionals coordinate outpatient rehab facility care or other options once the patient is able to be discharged.

When caring for a patient with opiate withdrawal, nurses commonly utilize the Clinical Opiate Withdrawal Scale (COWS). This scale assigns points for a patient's symptoms by each body system, with scores totaling five or more, indicating withdrawal symptoms are present (National Institute on Drug Abuse, 2015). Nurses must also manage the patient's hydration status by administering IV fluids and electrolytes as ordered (Baandrup et al., 2017). They

will also administer anti-emetic medications, such as promethazine, to control nausea and/or vomiting. To help with withdrawal from opioids, methadone or buprenorphine can be administered and dosage titrated. Because opioid use is linked to psychiatric disorders, the nurse should collaborate with the health-care provider and request a psychiatric referral for inpatient and outpatient services (Shah et al., 2023).

LINK TO LEARNING

The Clinical Opiate Withdrawal Scale (COWS) (https://openstax.org/r/77COWS) is a useful tool for assessing signs and symptoms of opiate withdrawal and monitoring these symptoms over time.

33.3 Managing Risk Exposure

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the risk assessment tools and recognize potential violence in an emergency department patient
- Identify the common health risks and risks of exposure encountered in the emergency department
- Identify strategies for stress management for nurses working in the emergency department

While violence can occur at any workplace, health-care workers and nurses are particularly at risk for acts of violence (Stafford et.al., 2022). A recent study of emergency department nurses concluded that 89.9 percent had experienced at least one form of workplace violence in the previous year (Li et al., 2019). According to the Emergency Nurses Association, 56 percent of emergency nurses indicated that they had been verbally assaulted, threatened with violence, or physically assaulted within the last three years (Emergency Nurses Association, 2024). To help with violence prevention, nurses must receive training to recognize potentially violent behaviors, use proper screening tools, and employ de-escalation strategies.

Risk Assessment Tools and Strategies to Mitigate Violence

There are many available risk assessment tools that nurses can use to determine the likelihood of a patient becoming violent or dangerous (Kim et al., 2022). One commonly used evidence-based tool is the Triage Tool. The **Triage Tool** assesses a patient's potential for becoming violent to others or harming themselves. This is a five-question survey where the patient answers questions about any history of violence and thoughts of hurting themselves or others. Another commonly utilized evidence-based tool is the **Danger Assessment Tool**, a reliable tool providing a baseline score to assess an emergent situation. The Danger Assessment Tool is a scale from one to five and helps nurses assess the risk of a potentially violent patient or a patient who is in a violent situation (National Institute for Occupational Safety and Health, 2020). The Danger Assessment Tool is easy to use and provides immediate results to help nurses determine the next course of action.

LINK TO LEARNING

The Centers for Disease Control and Prevention has several tools, such as the Danger Assessment Tool (https://openstax.org/r/77DAT), that can be used to screen for violent behaviors.

It is imperative that nurses recognize potentially violent behaviors to prevent harm or violent acts. Potential behavioral cues include making inappropriate statements, verbal or written threats, and asking about hospital security. Some behaviors a nurse may witness include pacing, restlessness, and jaw clenching, all of which can indicate future potentially violent behavior (Cybersecurity & Infrastructure Security Agency, 2021). The Centers for Disease Control and Prevention (CDC) recommends utilizing the **STAMP method**, a quick, focused assessment for identifying signs of immediate potential violence (CDC, 2024a). STAMP stands for:

- (ST) staring/eye contact
- (T) tone and volume of voice
- (A) anxiety
- (M) mumbling

- (P) pacing.

LINK TO LEARNING

The Centers for Disease Control and Prevention has created an indicator for violent behavior tool (https://openstax.org/r/77violentbehav) called the STAMP method.

An important strategy for mitigating violence begins with understanding the factors that contribute to it. Workplace violence can come from patients, staff members, or visitors. Nurses should create a culture of respect and honesty and work to implement a zero-tolerance policy that prohibits any act of workplace violence. To report acts of violence, organizations should set up a framework for easy reporting to ensure accountability. Metrics need to be tracked and a complete risk analysis report created to evaluate strengths and opportunities for improvement. Nursing leadership should focus on providing violence prevention training, including recognition techniques, screening tools, and de-escalation strategies to all staff (American Organization for Nursing Leadership, 2022).

LINK TO LEARNING

The Joint Commission outlines steps to use when there is an active shooter present (https://openstax.org/r/77activeshoot) in its Quick Safety Guide.

If a violent situation does occur, there are many strategies nurses can utilize to de-escalate the scenario. One effective strategy, according to The Joint Commission (2019). is verbal de-escalation, a method that involves the following:

- Use clear, calm, and nonconfrontational communication.
- Ensure you are not using medical jargon.
- When a patient expresses concerns, be supportive.
- Respond in an appropriate tone and offer explanations.
- Use nonthreatening body language, such as avoiding crossing arms.
- Set clear expectations and limits with patients upfront.

Nurses can implement other safety interventions to protect themselves and others against violence. They should always be aware of their surroundings, have a clear exit path from the room, and keep their back towards the door and not the patient. If a violent situation arises, nurses should know how to call for help and where a safe room is located. To promote a calming environment in the patient's room, minimize lighting and noise as much as possible. Nurses need to dress for safety by always wearing their name badges and by not carrying items that can become weapons like keys, lanyards, or jewelry (Occupational Safety and Health Administration, 2016).

Common Health Risk Exposure

According to the Centers for Disease Control and Prevention (2024), there are over 22 million health-care workers in the United States. The health-care industry poses its own health risks, where nurses can be exposed to a variety of potential hazards, including diseases and workplace injuries. As a nurse, it's important to understand these hazards and learn ways to avoid them. Due to the fast-paced environment of the ED and because ED nurses are oftentimes the first line of patient care, they are particularly at risk for exposure.

Exposure risks can occur anytime during patient care, but there is an increased risk in the emergency department because ED nurses often encounter a patient before a diagnosis has been made. It is uncommon for a patient's contagious illness to not be identified for 24 to 48 hours after they arrive at the emergency department (Liang et al., 2018). In this period, ED nurses could potentially be exposed to illnesses such as viral meningitis, tuberculosis, COVID-19, and hepatitis. Thus, it is important for nurses to use infection control prevention techniques with every patient encounter. For instance, they must wear **personal protective equipment (PPE)**, which includes gloves, masks, gowns, and face shields, during all encounters with patients with a suspected illness (CDC, 2024b).

CLINICAL SAFETY AND PROCEDURES (QSEN)

Nursing Interventions: Safety

When caring for any patient, nurses must wear the proper personal protective equipment (PPE) to prevent disease and bloodborne pathogen transmission. Never enter a patient's room without wearing the PPE that is appropriate for the patient's confirmed diagnosis, even in an emergency. If a patient is placed on precautions, ensure that there is a sign outside of their room and document this in their chart. Patients can be on multiple precautions, such as contact and airborne, so pay attention before entering a patient's room. If unsure, follow the Centers for Disease Control and Prevention PPE guidelines.

Wearing the correct personal protective equipment is the best way to prevent exposure to chemicals, drugs, and communicable diseases. When utilizing liquid chemicals or handling medications that can splash, it is important to wear safety goggles, a mask, and a face shield to prevent the liquid from getting on the face, mouth, or eyes. However, there are still cases when exposure occurs, and nurses must understand the appropriate next steps. If any liquid enters the eyes, the nurse should not rub their eyes and should use the eye wash station immediately to flush the eyes. They should remove any contact lenses and seek additional medical attention.

Nursing Stress Management

Stress can be harmful to nurses and take a toll on their physical and mental well-being. Exposure to high-paced emergency situations over and over in particular can be stressful. It is important for nurses to be able to recognize and manage their own stress. Symptoms of stress can vary with each individual but can sometimes present as fatigue, exhaustion, or anxiety. Many health-care systems promote self-care activities like exercising, walking outside during breaks, meditation, and wellness routines within the workplace. Most health-care facilities have a culture of safety and offer employee assistance or workplace assistance programs. It is crucial for nurses to be able to self-reflect and assess themselves for signs of burnout. Talking about stress with fellow nurses or health-care professionals is another coping mechanism.

LINK TO LEARNING

Studies have found that mindfulness exercises can help reduce workplace stress or nurse burnout (Mayo Clinic, 2023). Explore mindfulness exercises (https://openstax.org/r/77mindful) to learn new techniques for how to incorporate mindfulness into your daily habits.

33.4 Forensic Nursing

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the role of the forensic nurse
- Examine methods for evidence preservation and collection in the emergency department
- Define the role of a sexual assault nurse examiner (SANE)

According to the Centers for Disease Control and Prevention (2022), more than 1.5 million people were treated for assault-related injuries in the emergency department in 2021. Violent crimes occur daily, so ED nurses must ensure that the proper protocols are followed when a patient who is a victim of violence enters the emergency department. Post-licensure certifications are available in specialty fields that focus on such situations. The roles and responsibilities of these nurses are crucial to preserving evidence for law enforcement and civil and criminal cases. This section will discuss the specialty field of forensic nursing.

Role of the Forensic Nurse

The specialty of forensic nursing trains nurses in health concerns and conditions related to acts of violence or abuse. A **forensic nurse** can work in many fields and handle various types of cases, including child abuse, sexual assault, and maltreatment of older adults. Continuing education beyond the NCLEX exam is required to become a forensic

nurse. These professionals receive training in evidence collection, chain of command for evidence, and emotional support for victims of violence. They provide compassionate care to survivors of violence while performing the physical exams required to collect forensic evidence. Given this background, the forensic nurse may be called upon to provide testimonies and expert opinions for civil and criminal cases relative to their nursing practice.

Methods for Evidence Preservation

Forensic nurses must be able to properly preserve evidence from survivors of violence and prevent any cross-contamination. They are trained to collect all types of evidence, such as biological specimens, and to document injuries. In addition, forensic nurses search for trace evidence, such as dirt and gravel, on clothing or the patient's body. When collecting, preserving, and documenting evidence, forensic nurses abide by set protocols. They must begin by documenting and taking photographs of the patient, clothing, and injuries. They must place the trace evidence, clothing, and specimens they collect into individual envelopes or the proper collection containers. Forensic nurses should carefully change their gloves between collecting each specimen and avoid coughing or sneezing to prevent contamination. When collecting biological specimens, they should always use the appropriate collection tools and separate every sample to prevent contamination. Swabs should be allowed to dry completely and should not be placed in plastic to preserve the specimen as much as possible (SAFE TA, 2024).

After sealing the individual items of evidence, nurses need to label each item with the patient's information and then sign, date, and time the envelope. Then they must complete a chain of custody form, which identifies any person who has come into contact with the evidence until it is released to law enforcement (Kleypas & Badiye, 2023).

Sexual Assault Nurse Examiner Nurse

A **sexual assault nurse examiners (SANE)** is a forensic nurse specifically trained in evidence collection and examination of victims of sexual assault. They typically work in emergency departments, but can also work in other facilities, like OB-GYN offices. SANE nurses abide by set protocols for collecting evidence, completing consent forms, and utilizing the Sexual Assault Evidence Collection Kit (SAECK) (Figure 33.3). They gather a detailed history from the patient about the assault and collect DNA evidence with swabs, hair combings, fingernail scrapings, etc. After examining the patient's entire body for additional injuries or evidence, they complete the required SAECK forms and seal all evidence. An examination by a SANE nurse can take upwards of six hours, and the examination should, as a standard, be completed within 72 hours of the sexual assault (Ladd & Seda, 2023).

FIGURE 33.3 The SAECK kit is used by SANE nurses to collect evidence from sexual assault victims. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

LINK TO LEARNING

The International Association of Forensic Nurses (https://openstax.org/r/77SANE) is a great resource to learn more about the process of becoming a Sexual Assault Nurse Examiner (SANE).

33.5 Transferring from the Emergency Department

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Describe the framework for optimal discharge planning from the emergency department
- Discuss components for effective patient education and hand-off communication for discharge planning
- Identify care coordination of the services needed by the patient being discharged from the emergency department

According to the Centers for Disease Control and Prevention, a survey across the United States revealed that more than 35 million people are discharged yearly from emergency departments. Emergency department nurses can discharge or transfer several patients a day. With nurses delivering the majority of discharge instructions and educating patients and families, it is imperative that they communicate effectively and provide comprehensive teaching. To avoid long wait times and diversions, health-care organizations must implement strategies to improve patient transfer and develop effective handoff communication (Institute for Health Improvement, 2023). Nurses

should abide by a framework, understand the components for effective patient education, and identify any areas of need with respect to care coordination.

Framework for Discharge from the Emergency Department

One of the measures implemented by the Centers for Medicare & Medicaid Services is to track 30-day hospital readmission rates. Some patients return to the ED due to a lack of adherence or a lack of available resources after discharge. Following an optimal framework for discharge planning can potentially help reduce hospital readmission rates. Discharge planning should begin upon initial assessment, where the nurse utilizes screening tools that apply to the patient. For example, some patients may need to be screened for fall risk before discharge. Regardless of the patient's time in the hospital, coordination of care should begin after initial assessment and should be an ongoing process. Nurses and health-care providers must continuously assess patient discharge readiness, available resources, and follow-up appointments. Post-discharge follow-up calls by the nurse are an integral part of the discharge framework as well (Yam et al., 2012).

Reducing Transfer Time

By implementing effective strategies, nurses and health-care team members can also work to reduce the transfer times to other departments within the same health-care system. Strategies should be implemented on a daily basis and across the facility to maximize patient flow. A few suggestions for reducing transfer time include the following:

- Evaluation of patient flow processes, from the moment of entry at the front desk, through registration, and into discharge.
- Properly triage patients according to the acuity assigned to them upon arrival to ED. The term **acuity** represents how the health-care team determines the severity of a patient's status (Managed Healthcare Executive, 2020).
- Admission decisions should be identified in a timely manner to allow for quicker placement into the appropriate unit.

Nursing Responsibilities for Transfer from ED

Under the Emergency Medical Treatment and Labor Act (EMTLA), patients must be stable prior to being transferred to any other unit or health-care facility. In an emergency, the health-care team must work diligently to stabilize the patient prior to any transfer. When initializing and stabilizing the patient, nurses should follow the ABCDE triage assessment method. Prior to transfer, the nurse should confirm that all vital signs are stable, and all provider orders have been implemented. This includes administering any medication, starting continuous IV infusions, and emergent diagnostic testing. When completing patient transfers, the nurse must communicate any outstanding orders or patient care concerns to the nurse taking over the patient's care.

Effective Communication between Departments

The gold standard for reporting hand-off is using the SBAR method (Dalky et.al., 2020). SBAR stands for Situation, Background, Assessment, and Recommendations. When the SBAR communication handoff tool is implemented, nurses communicate using a standard set of objectives related to the patient's condition. When reconsidering information about the situation, the nurse first details the patient's current medical condition or identified problem. Next, the nurse discusses background information relevant to the situation. This includes information about any comorbidities, past surgeries, or treatments for the same condition. The nurse then reports any related or significant assessment findings about the patient. For example, the nurse may recognize cues, such as bilateral coarse breath sounds, for the patient who is being admitted to the intensive care unit for pneumonia. Lastly, the nurse provides any recommendations for care, such as future interventions, testing, or care coordination needed (Shahid and Thomas, 2018). SBAR communication will look different at each point in the patient's transfer process. For instance, if the nurse is communicating with the MRI technician, the SBAR report will include more information about the provider's orders and the problem that was identified. If the nurse is transferring the patient to another inpatient unit within the same facility, however, the SBAR report will be more comprehensive, including items, such as past medical history, drains, lines, and other information.

LINK TO LEARNING

Johns Hopkins Medicine provides a great SBAR tool (https://openstax.org/r/77SBAR) with examples nurses can use when communicating amongst health-care team members.

Patient Education and Communication

When discharging a patient, nurses should provide education to patients and their families. Health-care education can be difficult to comprehend at times. Nurses need to ensure discharge information is conveyed in a clear, concise, easily understood format, keeping in mind the patient's preferred language and educational level. The nurse should use an interpreter for patients who do not speak the same native language. Nurses should review information, such as diagnoses, completed and pending diagnostics tests, referrals, medications with timing of future dosages, and the dates and times for follow-up appointments. If the patient has a new diagnosis, the nurse should print out and review any information relevant to the new condition. Additionally, the nurse should review any new medications, along with potential side effects, dosages, timing, and compliance. Signs and symptoms of a worsening condition and when to return to the emergency department should be reviewed as well. If possible, ensure that follow-up appointments or additional diagnostic tests are scheduled prior to discharge. Moreover, if a patient has received sedation, aftercare activities are reviewed with a companion to safely discharge the patient.

Care Coordination with Providers and Services

Care coordination is a vital component of patient care in any setting but can be especially important (and challenging) in fast-paced acute care settings. Effective coordination starts as soon as the patient arrives and continues with the end goal of ensuring the patient experiences a seamless transition through different phases of care and is, ultimately, able to leave the facility safely.

Care coordination should begin as soon as possible to ensure a seamless discharge, whether the patient is going home or to another facility. Assessment of readiness is a team effort by all providers involved in a patient's care, making communication of the utmost importance. This exchange of information should be efficient and accurate and may take the form of shared notes in an electronic record, phone consultations, or other means of communication. Nurses and providers will verify patient readiness and decide whether additional care at another facility, such as long-term care or rehabilitation, is needed or if the patient can be discharged home.

Coordinating with providers who will be receiving the patient at another facility or those in the community who will be supporting the patient when they are recovering at home is critical to ensuring the best possible outcomes and preventing any important information for follow-up from "falling through the cracks."

Before a patient leaves, education about what will happen next needs to be provided and the nurse must confirm that the patient understands and feels ready for the next step. It is also key to assess the patient's support system and ensure that they will have the resources they need upon discharge. The nurse will document these steps in the patient's discharge plan and ensure that they have a clear path forward once they leave the facility.

Read this report detailing factors that can affect the discharge process (https://openstax.org/r/77discharge) from the Agency for Healthcare Quality and Research.

Summary

33.1 Triage and Assessment

- The ACBDE assessment method is utilized to triage patients. The patient's airway is assessed first, then breathing, circulation, neurological disability, and exposure.
- Emergency department nurses use triaging to guide the implementation of care for their patients. ED nurses must triage and stabilize patients with the most life-threatening conditions first.
- Components of effective documentation include assessment findings, medical histories, and communication with patients, families, and other members of the health-care team. Nurses should also document medications appropriately and provide updates to the patient's plan of care and outcomes.
- Subjective assessment findings, or symptoms, are those aspects of the patient's condition that the patient feels or tells the nurse about and that cannot be directly observed or measured.
- Objective assessment findings, or signs, are those conditions that the nurse can directly observe or measure.
- In the event of a life-threatening emergency where the patient is unconscious or unable to communicate, implied consent is warranted.
- Minors who come to the emergency department must receive an initial medical screening for emergency conditions. If there is a life-threatening injury, then the health-care team may proceed with care. It should, however, first exhaust all efforts to obtain consent from the minor's parents or legal guardian.

33.2 Types of Emergency Care

- The ABCDE triage assessment is best practice when performing an initial assessment on trauma patients.
- Crush injuries occur from prolonged pressure to an area and can either be traumatic or nontraumatic. Subsequent muscle injury releases myoglobin and other components into the bloodstream causing health complications.
- Rapid fluid resuscitation is key with crush injuries to prevent complications, such as rhabdomyolysis, shock, and acute kidney injury. Nurses must promote outcomes, such as improving revascularization, treating electrolyte disturbances, and maintaining patient stability.
- Accidental poisoning occurs when a person accidentally exposes themselves to toxic levels of a substance. Intentional poisoning can be caused by a person intentionally exposing themselves to toxic substances or by another person intending harm.
- Nurses provide support care, such as monitoring vital signs and promoting hemodynamic stability. They administer antidotes and anti-epileptic medications as ordered.
- Maltreatment is poor treatment or care of an individual and encompasses abuse and neglect.
- Types of abuse include child, elder, sexual, and domestic partner abuse.
- Nurses must perform a complete history and physical assessment when abuse is confirmed or suspected, thoroughly documenting findings and reporting to the appropriate channels immediately.
- As mandated reporters, nurses are required by law to report suspected or confirmed abuse of any type or to any person.
- Examples of psychiatric emergencies range from suicide attempts to acute psychosis, and from intoxication and drug overdose to delirium tremens.
- When a patient is involuntarily admitted to a health-care facility under law, this is a psychiatric hold. State laws governing psychiatric holds vary.
- Safety is a nurse's top priority when caring for patients with psychiatric emergencies.
- Examples of drugs frequently encountered in the emergency department include opioids, alcohol, methamphetamine, cocaine, and marijuana.
- Opioid and heroin overdoses cause respiratory and nervous system depression and potentially lead to death.
- Patients withdrawing from alcohol can develop delirium tremens, a severe condition that can present with seizures, and can sometimes lead to death.
- The CIWA scale is used for alcohol withdrawal and the COWS is for opioid withdrawal. Nurses provide supportive measures to control withdrawal symptoms, prevent dehydration, and collaborate with psychiatric care.

33.3 Managing Risk Exposure

- Nurses utilize risk assessment tools, such as the Triage Tool or Danger Assessment Tool, to readily identify potential violent patient behaviors.
- Methods for mitigating violence include establishing a workplace culture of respect, receiving violence prevention training, implementing zero-violence workplace policies, and developing a framework for outcome reporting.
- Some safety actions nurses can take include dressing safely, always being aware of their surroundings, and following de-escalation techniques, like establishing a calm environment or not using medical jargon when they speak.
- Wearing proper personal protective equipment when there is potential exposure to chemicals, drugs, or communicable disease is the first step to preventing disease and bloodborne pathogen transmission.
- Stress management strategies include promoting self-care and safety and seeking support from others or employee assistance programs.

33.4 Forensic Nursing

- Forensic nurses often work in the emergency department and are specifically trained to examine patients who are victims of acts of violence or abuse.
- A forensic nurse follows set protocols for collecting and preserving evidence.
- Evidence collection involves collecting a thorough history, taking photographs, gathering samples, and completing the required documentation and a chain of custody form.
- A SANE nurse is a forensic nurse who is trained in sexual assault examinations and gathering evidence and uses a SAECK to collect evidence samples from the patient.

33.5 Transferring from the Emergency Department

- The framework for optimal discharge planning is an ongoing process, including initial screening, care coordination, and post-discharge follow-up.
- Health-care organizations must continuously re-evaluate their best practices for patient transfers. ED team members and nurses must appropriately triage patients and assign their acuity level.
- Nurses must ensure that patients are stable prior to transfer. Vital signs should be stable, orders and diagnostic tests should be completed, medications should be administered, and continuous infusions and drains/lines should be inserted, as needed.
- The SBAR tool is the recommended tool for nurses to utilize during patient transfer to communicate effectively and concisely.
- Nurses should review follow-up instructions with patients about their discharge care and signs and symptoms of worsening conditions.
- Determining the patient's social determinants of health that can affect the patient's care after discharge.

Key Terms

abuse harming another person physically, sexually, or emotionally
accidental poisoning when a person accidentally exposes themselves to a substance that is harmful
acuity represents how the health-care team determines the severity of a patient's status
airway, breathing, circulation, disability, and exposure (ABCDE) triage assessment method patients in emergency situations
consent gives medical professionals the authority to treat the patient, providing them with the most competent and highest quality of care
crush injury prolonged pressure to an area of the body
Danger Assessment Tool reliable assessment tool that provides a baseline score to assess an emergent situation
delirium tremens seizures and hallucinations, along with tachycardia, hypertension, and hyperthermia
Emergency Medical Treatment and Labor Act (EMTLA) federal law enforcing that patients must be stable prior to transferring to any other unit or health-care facility
forensic nurse nurse trained in health concerns and conditions related to acts of violence or abuse
implied consent approval is presumed and not obtained during an emergent situation due to the life-threatening

nature of the situation

intentional poisoning can be caused by a person intentionally exposing themselves to toxic substances or by another person intending harm

maltreatment poor quality of care an individual receives

neglect when a person or caregiver fails to supply a person's needs, such as food, shelter, clothing, or emotional support

objective assessment findings (also: *signs*) aspects of the patient's condition that the nurse directly observes and can be measured

personal protective equipment (PPE) includes gloves, masks, gowns, and face shields

poisoning exposure to substances, drugs, or chemicals

psychiatric hold when a patient is involuntarily admitted to a health-care facility under law

sexual assault nurse examiner (SANE) forensic nurse who receives specialized training in performing examinations and collecting evidence from victims of sexual assault

STAMP method method used for identifying signs of danger such as staring or eye contact, tone and volume of voice, anxiety, mumbling, and pacing

subjective assessment findings (also: *symptoms*) aspects of the patient's condition that the nurse does not directly observe and are only reported by the patient

triage process of prioritizing patients' care based on initial assessment findings; life-threatening conditions are prioritized over less severe or non–life-threatening conditions

Triage Tool evidence-based assessment of a patient's potential to become violent to others or harm themselves

Assessments

Review Questions

1. A nurse is assessing a patient's neurological status using the ABCDE triage assessment. What area is the nurse assessing?

a. airway
b. breathing
c. circulation
d. disability
e. exposure

2. When is implied consent obtained?

a. when a minor is seeking treatment
b. during an emergency situation that can lead to potential harm
c. during an emergency situation that is life-threatening
d. before a surgical procedure is performed

3. What is the hallmark sign that a patient has developed rhabdomyolysis from a crush injury?

a. elevated CRPB
b. elevated ESR
c. elevated CPK
d. elevated WBC

4. A patient is in the emergency department with intentional acetaminophen poisoning. What medication would the nurse plan to administer?

a. naloxone
b. flumazenil
c. N-acetylcysteine
d. There is no reversal agent.

5. What substance abuse disorder is commonly encountered in the emergency department? Select all that apply.

a. opioids
b. alcohol
c. suboxone
d. benzodiazepine
e. dextromethorphan

6. For how long is a psychiatric hold generally valid?
a. 24 hours
b. 48 hours
c. 72 hours
d. 96 hours

7. What term refers to poor treatment or care of an individual and encompasses the other terms?
a. abuse
b. maltreatment
c. neglect
d. violence

8. What is an example of a behavior that is not assessed in the STAMP risk assessment tool for recognizing violence?
a. soft tone of voice
b. pacing
c. mumbling
d. staring.

9. What is an example of a way to mitigate workplace stress?
a. walking outside during an assigned break
b. volunteering to eat lunch later in the shift
c. volunteering for extra work shifts
d. skipping a meal to help a coworker

10. What is the optimal timeframe for completing a sexual assault examination?
a. 24 hours
b. 36 hours
c. 48 hours
d. 72 hours

11. When collecting evidence, nurses should do what to swabs to preserve specimens as much as possible?
a. Place them in plastic.
b. Let them dry completely.
c. Store them together.
d. Soak them in water.

12. A nurse is giving a report on a patient who is being transferred to the surgical unit. The nurse tells the surgical nurse that the patient is scheduled for left hip surgery in the morning. What portion of the ISBAR communication is this?
a. situation
b. background
c. assessment
d. recommendation

13. What is an adequate method for delivering patient discharge education? Select all that apply.
a. verbalizing new information

b. providing written medication side effects
c. providing pamphlets with additional instructions
d. instructing the patient to use the internet to search for new information
e. using an interpreter if the patient speaks a different language

Check Your Understanding Questions

1. When caring for a patient who is under eighteen years old in the emergency department, what are the consent protocols, and what elements must the nurse document in the EMR?
2. Explain the triage process, and detail the method used when triaging patients.
3. What cellular changes occur during a crush injury?
4. What are examples of older-adult abuse?
5. Which methods could a nurse employ to mitigate violence?
6. Describe ways you can incorporate mindfulness into your daily routines.
7. Describe appropriate steps involved in the transfer of patients from the emergency department to an inpatient unit within the same facility.

Reflection Questions

1. Consider and discuss how the concept of triage contributes to efficient emergency department operations.
2. Give examples of some specific situations where the ABCDE triage assessment might be particularly crucial and explain why.
3. What trends would the nurse assess in the patient's clinical condition to see a resolution of rhabdomyolysis?
4. You are caring for a pediatric patient and notice bruise marks around their wrists and cuts on their forearms. What is your role as a nurse?
5. A nurse is caring for a patient with a psychiatric emergency. What types of psychiatric emergencies are there, and which measures should you implement when caring for this patient?
6. A nurse in an emergency room was assaulted by an intoxicated patient. During incontinence care, the patient grabs the nurse's stethoscope and attempts to strangle the nurse. The ED staff assisted the nurse, freeing her from the patient. What are some debriefing activities the nurse manager can take to mitigate the risk? Reflect on what the nurse could have done differently.
7. When caring for a patient with a history of violent outbursts who begins pacing the room and acting agitated, what are some effective verbal de-escalation strategies you can use? When would you need to place this patient in restraints? What strategies can you implement to ensure your safety while caring for this patient?
8. Describe the differences between a forensic nurse and a SANE nurse.
9. You are discharging a seventy-year-old patient who has bilateral wrist fractures because of a fall. What would you anticipate needing to consider to design an optimal discharge and care coordination plan before this patient goes home?
10. Describe potential challenges in implementing an effective discharge plan for patients from diverse cultural backgrounds. How would you address these challenges?
11. A patient arrived in the emergency department with a complex medical history and limited understanding of their conditions. How would you ensure effective communication and education during the discharge planning process?

What Should the Nurse Do?

1. A trauma patient in the emergency department was in a motor vehicle accident. They are unconscious and have a crush injury to the chest. Their vital signs are BP: 98/55; HR: 121; RR: 35; SpO_2: 84 percent, and

temperature: 95.9°F. How would the nurse assess this patient, and in what order would they address the patient's vital signs?

2. A sixteen-year-old female patient enters the emergency department. The patient is having abdominal pain and fever, but she is alert and not disoriented. She is diagnosed with an ectopic pregnancy requiring an emergency D&C. How should the nurse obtain consent for this procedure? What elements are subjective and objective?

Jay K. arrives by ambulance to the emergency room complaining of nausea, vomiting, and abdominal pain. He works as a construction worker and mentions that he was exposed to various chemicals at a worksite earlier today. He reports no significant medical history other than occasional episodes of acid reflux. Vital signs are as follows: BP: 140/90 mm Hg; HR: 100 bpm, RR: 20 breaths/min; and temperature 99.2°F (37.3°C). John appears pale and diaphoretic. He expresses concern about the possibility of serious chemical exposure and is anxious about his health and ability to continue working.

3. What physical examination findings might indicate potential chemical exposure in this case?
4. What immediate interventions would you implement to address both the patient's symptoms and concerns about potential chemical exposure?

5. A nurse goes into an emergency room bay to assess a patient who experienced a fall down the basement stairs. The patient is seen sitting in the chair, guarding her arm, with her partner standing in the corner, pacing. He is staring at her and does not maintain eye contact.
   The nurse suspects domestic partner abuse. What should the nurse do?

Tonya W., a thirty-two-year-old female, arrives at the emergency department after being brought in by law enforcement due to concerns about her safety and the safety of others. She presents with agitation, disorganized speech, and paranoid delusions, expressing the belief that she is being followed by unknown individuals. Tonya W. has a history of schizophrenia and noncompliance with medication. On assessment, her vital signs are as follows: temperature: 98.6°F (37°C); BP: 140/90 mm Hg; HR: 110 bpm; RR: 20 breaths per minute; and oxygen saturation: 98 percent on room air. The nursing staff recognizes the potential for violence given Tonya W.'s behavior and history and implements measures for her safety and the safety of others in the emergency department.

6. What behavioral cues suggest that Tonya W. may pose a risk of violence in the emergency department?
7. How would you prioritize the interventions needed to address Tonya W.'s safety and the safety of others in the emergency department?

Competency-Based Assessments

1. Develop a presentation for your peers that considers some potential consequences of inadequate documentation in the emergency department.

2. Develop a pamphlet describing a scenario where implied consent may be ethically justified, and explain why.

3. Research current treatment protocols for common crushing injuries. Develop a 10-minute presentation for your peers that covers the nursing interventions, assessments, and outcomes they might come across when caring for a patient with a crush injury.

4. Develop guidelines identifying how a nurse might differentiate between accidental ingestion of a toxic substance and intentional self-poisoning in the emergency department based on a patient's history and presentation.

5. Create a pamphlet explaining how nurses can ensure the safe and effective administration of antidotes to patients who have experienced poisoning while minimizing the risk of adverse reactions or medication errors.

6. Create three slides presenting the interventions and assessment tools a nurse can use when caring for a patient with alcohol withdrawal.

7. Conduct a search of recent nursing literature and identify a current article that discusses stress management strategies for nurses who cared for patients during the COVID-19 pandemic.

CHAPTER 34
Disaster and Recovery

FIGURE 34.1 Environmental disasters, like the destruction of a tornado, can be devastating. Nurses need to be aware of the role they play in disaster response. (credit: "Picking up the pieces" by Staff Sgt. Mike Meares/U.S. Air Force, Public Domain)

CHAPTER OUTLINE

INTRODUCTION In any profession, in any walk of life, the environment and the way it behaves affects all people. Environmental disasters can cause unimaginable damage to life and property. As a nurse, it is important to understand these disasters, how they come about, how they affect individuals and communities, and how to respond to of them. Whether a disaster is meteorological (from the atmosphere), geological (from within the earth), or water-related, it can cause significant devastation and loss of life. Nurses are an integral part of disaster response. They must be prepared to protect their current patients from the disaster and handle an influx of new patients in the immediate aftermath. Knowledge of these disasters and how to respond to them is essential to all nurses.

34.1 Environmental Disasters

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Describe examples of environmental water disasters
- Describe examples of environmental land disasters
- Summarize the roles and responsibilities of the nurse during environmental disasters

Water Disasters: Storms, Snow, Floods, and Tsunamis

Disasters involving water are some of the deadliest and most widespread disasters that can devastate the human race (Puryear & Gnugnoli, 2023). As nurses, the level of preparedness and understanding must be high in order to carry out duties properly. According to the **National Weather Service (NWS),** flash floods are the second-highest cause of death from meteorological disasters in recent years (NWS, 2022). Understanding how these disasters occur and what areas are most prone to them is paramount. For example, in Virginia, where heat-related ailments can be common in the summertime, 400 additional outpatient visits are required to care for heat-related illness along with seven thousand additional emergency department visits and two thousand hospital admissions each summer due to heat (Center for American Progress, 2023). Virginia hospitals use this information to ensure additional resources are ready each summer.

Thunderstorms are especially common in the United States. The United States experiences more thunderstorms than many other regions due to its unique geography (Borenstein, 2023). The country's geography channels warm, moist air from the Gulf of Mexico to collide with cool, dry air from the Rocky Mountains, creating unstable atmospheric conditions that are conducive to thunderstorms. The geography also serves as a mechanism to lift unstable air and cause thunderstorms to form. The entire United States can experience thunderstorms and the hazards that come with them, such as lightning, torrential rain, flash flooding, hail, damaging winds, and tornadoes. An important aspect of being prepared for such threats is listening to the information and guidance from the NWS and local meteorologists. Understanding the threat level on a given day and what can come with it is the first step in planning a response to such an event. This information is readily available on cell phones and on the NWS websites, such as the Storm Prediction Center. A battery-operated weather radio is essential for staying informed during severe weather. This information could be placed on a board so nurses have an idea what the threat is for the day on a regional level, and a television can be left on the local news.

Knowing when an area is under a watch or a warning for a particular hazard is also important. The difference between a watch and a warning is whether the hazard is imminent. For example, a **tornado watch** would be issued if the environmental conditions are favorable for tornadic development throughout the time period the watch is in place. A tornado warning would be issued if there is a storm with radar-indicated rotation or an observed tornado moving its way into the area.

Tropical storms and hurricanes can also cause immense and widespread problems. These storms not only have extremely strong winds and rain but can also spawn tornadoes and cause floods due to both heavy rain and **storm surge**, which is when water from the ocean is pushed ashore by heavy winds.

Snow and floods are similar in that the NWS and its partner agencies provide guidance and often establish command centers to coordinate communication for areas at risk from these hazards. Large amounts of snow can cause roadways to be blocked, making travel impossible. When the snow melts, there will be added risk because all the water can now cause flooding. Heeding expert advice and professional guidance is the best way to prepare for such disasters.

Floods can be caused by a multitude of factors. Floods can come in the **flash flood** variety, which is typically caused by an excessive amount of rain in a short time frame. Flash floods are dangerous due to how fast they come about (Roudbari et al., 2024). Floods can also come from a lot of precipitation being funneled into an area by high terrain. Understanding the terrain and susceptibility of the area to floods is another factor in being prepared. Floods can also be caused by geologic hazards such as landslides and tsunamis. Nurses in these areas should be prepared for the need to move patients to higher floors and to protect electrical equipment.

A **tsunami** is a geologic hazard that usually comes from shallow underwater earthquakes. Even weak earthquakes can cause devastating tsunamis. Knowing the course of action in an earthquake-prone area near a coast, such as the

American West Coast, is paramount to keep people as safe as possible. Tsunamis can also be caused in smaller bodies of water by landslides. The largest theorized tsunami came from a landslide triggered by a massive earthquake, causing the face of a mountain to plunge into a lake, displacing a massive amount of water and forming a massive wave.

Weather disasters severely disrupt access to hospitals and can be life-threatening for at-risk community members. Hospitals may sustain physical damage that limits their ability to provide care, and facilities can become inaccessible due to blocked roads. Nurses should be aware of potential emergency staffing needs. This means the need to ensure coverage for all shifts, which may mean sheltering in place at the hospital. Staff are often trying to work under overwhelming resource strain, including loss of crucial resources like electrical power. People with pre-existing medical conditions can be in grave danger if their necessary medications, equipment, or home care are interrupted during a disaster. Patients should be educated on preparing a "grab-and-go" emergency kit for such situations.

Nurses should be aware of their organization's emergency plan, including evacuation routes and shelter locations, and ensure windows and doors are secured (Puryear & Gnugnoli, 2023). Evacuation can be challenging for people with limited mobility. Even if people who are immobile are moved, many shelters are not able to accommodate complex medical needs. Evacuation drills are required by the Occupational Safety and Health Administration (OSHA) primarily for fire emergencies and other workplace hazards. States may have additional requirements for evacuation drills related to various emergencies, including severe weather and hazardous material spills, but these state-specific rules can vary.

Communication breakdowns further isolate the people who are in most need of help during a disaster, and the disruptions may have serious long-term consequences. Delayed care can lead to severe medical complications or even death. All of these effects and consequences will be amplified in populations with lower incomes and in medically underserved areas. Roads can be blocked or completely swept away, especially in these underserved areas where road quality may already be diminished. Food supplies can be tainted and leave communities at risk for starvation and the people affected can be hampered long term with emotional health problems and economic crises.

Land Disasters: Earthquakes, Landslides, and Wildfires

Earthquakes, landslides, and wildfires pose significant threats to life and property, often resulting in widespread damage. An **earthquake** is a geological disaster caused by collisions of tectonic plates. There are several regions of the world that are prone to earthquakes; however, they can happen anywhere. Earthquakes are very hard to predict, so it is difficult to predict when an area may be under threat. Understanding the regional threat of earthquakes determines the preparedness level required. Having an established disaster plan in place is one way to be prepared at all times for an earthquake. Being indoors in a sturdy building can mitigate any harm. When an earthquake occurs, a subsequent smaller and often weaker earthquake, called an **aftershock**, often happen.

Preparedness any time after the initial earthquake is crucial. Sometimes, earthquakes can trigger large landslides that can sweep away small buildings, trees, and large rocks into a running "river" of earth. If an area with high terrain experiences an earthquake, it is very likely that the shaking will dislodge rocks and create a **landslide**. The course of action when there is a landslide is to get to higher ground as quickly as possible. When an earthquake occurs or if heavy rainfall is forecasted, a landslide could be possible, and preparations should take place.

Wildfires can cause some of the most widespread damage of any natural disaster. A **wildfire** is most common in areas of drought and dry conditions where vegetation is present. Wildfires flourish in very dry and windy conditions; for example, in Alaska, the valleys of California, the Texas panhandle, and parts of the Southeast (Insurance Information Institute, 2020). The drier the vegetation is, the more likely it is for fire to start and spread. Windy conditions exponentially increase how fast and how far the fire spreads. Wildfires can spread hundreds to thousands of square miles in very short periods of time. Evacuation is the only way to escape these fires. The best way to be prepared is to listen for guidance from the NWS and local news agencies and be aware of a particular area's risk for wildfires. In case of fire, nurses should be prepared for any evacuation orders and the course of action to protect patients.

LINK TO LEARNING

The National Weather Service continuously keeps track of weather-related fatalities (https://openstax.org/r/77weathrdeath) in the United States.

Nursing Roles and Responsibilities

Nurses have many responsibilities when natural disasters strike, and must play a pivotal role in mitigating the impact on individuals and communities. Nurses are integral in disaster preparedness efforts. Nurses collaborate with interdisciplinary teams to develop and refine emergency response plans tailored to the specific risks posed by natural disasters. They assess community vulnerabilities, identify at-risk populations, and devise strategies to ensure swift and effective action when disaster strikes.

During the acute phase of an environmental disaster, nurses serve as frontline responders, providing immediate medical care and triage services. They possess the clinical expertise to assess and prioritize injuries, administer life-saving treatments, and stabilize patients for evacuation or transfer to higher levels of care. Nurses also fulfill critical roles in establishing and managing temporary medical shelters. They set up triage areas, organize medical supplies, and coordinate with other health-care professionals and emergency responders to streamline patient care, providing continuous monitoring, treatment, and emotional support to patients, and addressing the physical injuries, psychological trauma, and emotional distress that often accompany environmental disasters.

In the aftermath of an environmental disaster, nurses continue to play a vital role in long-term recovery efforts. Nurses collaborate with public health agencies, community organizations, and government entities to assess the health needs of affected populations and implement targeted interventions. Nurses advocate for at-risk groups, ensuring equitable access to health-care services, medications, and support systems. They also contribute to ongoing surveillance and monitoring efforts to detect and mitigate potential health threats arising from environmental hazards, such as contaminated water sources or infectious disease outbreaks. Importantly, nurses need to be aware of their own needs and make sure they take care of their mental health during an environmental disaster. Nurses can deal with trauma and burnout from these disaster events and it is important they take care of themselves so that they can take care of patients as effectively as possible. From proactive preparedness initiatives to hands-on clinical care and community advocacy, nurses' unwavering commitment to serving humanity during times of environmental disaster embodies the core values of the nursing profession and underscores the indispensable contributions of nurses to public health and safety.

REAL RN STORIES

Nurse: Nicole, RN
Years in Practice: Two
Clinical Setting: Medical ICU
Geographic Location: Joplin, Missouri

The tornado that struck Joplin, Missouri on May 22, 2011, was one of the deadliest tornadoes in U.S. history. As the ominous clouds darkened the sky over Joplin, I felt a sense of unease. Tornado warnings had been issued, and the atmosphere was tense. Little did I know, the hospital was about to face one of the most challenging days in its history.

When the tornado sirens began to wail, my coworkers and I sprang into action. Nurses hurriedly moved patients away from windows and into interior rooms, following the hospital's established tornado protocols. Some patients were too ill or immobile to move, so nurses stayed by their sides, shielding them from potential harm.

As the tornado descended upon the city with ferocious power, the hospital shook from the force of the winds. Windows shattered, debris flew, and the sound of destruction filled the air. Despite the chaos, we remained calm, and focused on our duty to protect and care for our patients.

In the aftermath of the tornado, we emerged as a beacon of hope amid the devastation. Despite suffering damage to parts of the facility, the hospital continued to operate, providing lifesaving care to those in need. We worked tirelessly, treating injuries, comforting survivors, and supporting our colleagues in the face of overwhelming adversity.

34.2 Biological and Technological Disasters

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Describe examples of biological disasters
- Describe examples of technological disasters
- Summarize the roles and responsibilities of the nurse during biological and technological disasters

In the field of nursing, preparedness and an understanding of biological and technological disasters is important. The intersection of health care and disaster management presents unique challenges that demand specialized knowledge and skills. From infectious disease outbreaks to technological failures like computer hacking to electrical malfunctions of machines, nurses play a crucial role in both the prevention and response to these events. This section explores the intricacies of biological and technological disasters, exploring their causes, manifestations, and the nursing interventions necessary to mitigate their impact on individuals, communities, and health-care systems.

Biological Disasters

Biological disasters pose significant challenges to the field of nursing, requiring a multifaceted approach to prevention, mitigation, and response. A **biological disaster** encompasses a wide range of events, such as an infectious disease outbreak, a pandemic (widespread epidemic of infectious disease), and a **bioterrorism** incident (deliberate release of harmful biological agents with the intent to cause illness or death). Throughout history, there have been many notable biological disasters ranging from deadly disease outbreaks to acts of terrorism. Some examples include:

- The influenza pandemic of 1918–1920, which killed more than 50 million people around the world, is one of the most devastating infectious disease outbreaks in modern history (Britannica, 2024).
- The 2001 anthrax attacks in the United States were an act of bioterrorism that took place at a particularly sensitive period of American history, just after the terrorist attacks of September 11 (Federal Bureau of Investigation [FBI], n.d.).
- The COVID-19 pandemic, starting in late 2019, has had profound global impacts, leading to millions of deaths, overwhelming health-care systems, and causing significant social and economic disruptions worldwide (World Health Organization, 2024).

Nurses were among the key players in response to these disasters and managing their aftermath. Nurses play a critical role in identifying early warning signs, implementing infection control measures, and providing care to affected individuals. In the face of biological disasters, nurses must be equipped with knowledge of epidemiology, pathophysiology, and public health principles to effectively assess, triage, and treat patients. Additionally, they serve as educators, helping communities understand the importance of vaccination, hygiene practices, and other preventive measures. By working collaboratively with interdisciplinary teams and remaining vigilant in monitoring for emerging threats, nurses can help mitigate the impact of biological disasters and safeguard the health and well-being of populations worldwide.

Influenza

Commonly referred to as the flu, **influenza** remains a significant public health concern globally, affecting millions of individuals each year (Gaitonde et al., 2019). This highly contagious respiratory illness is caused by influenza viruses that infect the nose, throat, and sometimes the lungs. Influenza viruses are notorious for their ability to mutate rapidly, leading to the emergence of new strains and seasonal outbreaks. Nurses play a vital role in influenza prevention, diagnosis, and treatment, particularly during flu season. They advocate for vaccination, educate the public on hygiene practices to reduce transmission, and provide care to those who become ill from the virus.

In health-care settings, nurses implement infection control measures to prevent the spread of influenza among patients, staff, and visitors. Additionally, they closely monitor patients with influenza-like symptoms, administer

antiviral medications when appropriate, and offer supportive care to alleviate symptoms and prevent further complications. The most important intervention is handwashing. Through their expertise in infection prevention and patient care, nurses contribute significantly to reducing the burden of influenza and safeguarding public health.

LIFE-STAGE CONTEXT

Considerations for Older Adults with Influenza

When considering older adults and their exposure to influenza, there are important factors to take into account due to their increased vulnerability to severe complications from the virus. Older adults are at higher risk of developing complications from influenza, such as pneumonia, exacerbation of chronic medical conditions (e.g., heart disease, diabetes), and hospitalization. Health-care providers should closely monitor older patients with influenza for signs of complications and provide appropriate treatment promptly (National Foundations for Infectious Disease, 2023).

The **H1N1 influenza virus**, commonly known as swine flu, emerged as a global health concern in 2009, triggering a pandemic that swept across continents. A subtype of the influenza virus, H1N1 was characterized by its rapid spread and ability to infect individuals of all ages. H1N1 presented unique challenges to health-care systems worldwide. The virus caused severe respiratory illness and, in some cases, led to fatal complications, particularly among at-risk populations (Centers for Disease Control and Prevention [CDC], 2019). The high morbidity and mortality associated with H1N1 underscores the devastating and lasting effect that biological disasters can have on public health.

Nurses play a pivotal role in response efforts, providing care to affected individuals while implementing stringent infection control measures to limit transmission. The H1N1 pandemic highlighted the importance of preparedness, collaboration, and adaptability in the face of emerging infectious diseases. Nurses were at the forefront of vaccination campaigns, community outreach initiatives, and patient education efforts, helping to mitigate the impact of H1N1 and protect at-risk populations. Through their expertise in epidemiology, patient care, and public health, nurses continue to play a crucial role in monitoring for potential outbreaks, advocating for vaccination, and ensuring swift and effective responses to infectious disease threats like H1N1.

Anthrax

Caused by the bacterium *Bacillus anthracis*, **anthrax** is a rare but potentially deadly infectious disease that can affect humans and animals. While naturally occurring anthrax infections in humans are uncommon, the bacterium has been weaponized in bioterrorism attacks, leading to heightened concerns about its potential use as a biological weapon. Anthrax can infect humans through inhalation, ingestion, or direct contact with infected animals or contaminated animal products. Common animal vectors (carriers) for anthrax include livestock such as cattle, sheep, goats, and horses, as well as wild animals like deer and other herbivores. Inhaled anthrax, the most lethal form, presents with flu-like symptoms initially but can rapidly progress to severe respiratory distress and systemic illness. The average fatality rate of the different forms of anthrax is approximately 44.75 percent (Manish et al., 2020). Nurses collaborate with public health authorities to educate communities on recognizing the signs and symptoms of anthrax, implementing appropriate infection control measures, and administering prophylactic antibiotics or vaccines when indicated. Nurse should educate the community on vaccines and therapeutic antibodies as the most crucial components of anthrax prophylaxis (pre- and post-exposure) and treatment (Manish et al., 2020). Signs and symptoms of anthrax include:

- Cutaneous anthrax
  - Painless skin sore with a black center, often appearing after the blisters or bumps
  - Small blisters or bumps that may itch
  - Swelling around the sore
- Inhalation anthrax
  - Body aches
  - Chest pain
  - Cough
  - Extreme fatigue
  - Fever and chills

    - Headache
    - Nausea and vomiting
    - Shortness of breath
    - Sweating (usually drenching)
- Gastrointestinal anthrax
    - Diarrhea or bloody diarrhea
    - Fever and chills
    - Hoarseness
    - Nausea and vomiting, especially bloody vomiting
    - Painful swallowing
    - Sore throat
    - Stomach pain
    - Swelling of neck, neck glands, and/or abdomen (stomach)
- Injection anthrax
    - Fever and chills
    - Itchy blisters or bumps where the drug was injected
    - Skin sore and/or abscess with swelling and a black center, appearing after the blisters or bumps

In the event of a bioterrorism attack involving anthrax, nurses are on the front lines of emergency response efforts, triaging and treating affected individuals while coordinating with interdisciplinary teams to contain the spread of the disease. Through their expertise in infection control, emergency preparedness, and patient care, nurses play a vital role in mitigating the impact of anthrax and protecting public health.

Nursing Roles and Responsibilities

Nurses play indispensable roles in biological disaster preparedness, response, and recovery efforts. With their diverse skill sets and frontline presence, they are integral to the health-care system's ability to effectively address the complexities of such crises. In the preparatory phase, nurses contribute to developing and implementing emergency response plans, conducting drills, and ensuring health-care facilities are equipped with the necessary supplies and protocols. These supplies include personal protective equipment (PPE) such as masks, gloves, gowns, and face shields; medical supplies such as bandages, antiseptics, and medications; emergency medical equipment such as defibrillators, ventilators, and first aid kits; and logistical supplies including communication devices, backup power sources, and sufficient stock of essential medicines and medical consumables.

Nurses need to remember cultural diversity impacts disaster preparedness and response efforts by influencing communication styles, belief systems, and help-seeking behaviors within communities. Having a strong understanding of the community's cultural norms and values is essential for developing culturally sensitive plans and interventions that effectively reach and support diverse populations.

During a biological disaster, nurses are often among the first responders, providing immediate medical care, triaging patients, and implementing infection control measures to prevent further transmission. They play key roles in surveillance, rapidly identifying and reporting cases to public health authorities to facilitate early intervention. In the aftermath of a biological disaster, nurses continue to support recovery efforts, offering ongoing medical care, psychological support, and community health services. Their resilience, adaptability, and commitment to patient-centered care are essential in navigating the challenges posed by biological disasters and ensuring the well-being of affected individuals and communities.

Technological Disasters

A **technological disaster** encompasses a broad range of events, with far-reaching implications for public health and safety. Examples include an industrial accident, a transportation incident, an infrastructure failure, and a **cyberattack**, defined as deliberate, malicious attempts to disrupt, damage, or gain unauthorized access to computer systems, networks, or electronic devices. Chemical, radiological, and nuclear disasters also fall under the broader category of technological disasters. Throughout history, there have been many notable technological disasters. Some examples include:

- The Minamata disease outbreak in the 1950s in Japan, caused by industrial mercury poisoning, led to severe neurological damage in thousands of people, raising awareness about industrial pollution and its impacts on

human health (National Institute for Minamata Disease, 2024).
- The Chernobyl nuclear accident in 1986 and the Bhopal gas tragedy in 1984 were chemical disasters that had both short- and long-term consequences (Britannica, 2024; World Nuclear Association, 2024).
- The Flint water crisis, beginning in 2014, exposed thousands of residents to lead-contaminated water, causing widespread public health concerns and highlighting issues of environmental injustice (EPA, 2024).

Chemical Hazards

A **chemical hazard** encompasses a diverse array of substances that can pose risks to human health and the environment. Toxic chemicals include substances such as pesticides, heavy metals, and industrial solvents. Exposure to toxic chemicals can lead to acute or chronic health effects, ranging from irritation and respiratory problems to neurological damage and cancer (such as mesothelioma, which is commonly caused by chemical exposure) (CDC, 2023).

Another category of chemical hazards are corrosive chemicals, which have the potential to cause severe damage to skin, eyes, and respiratory tissues upon contact. Examples include strong acids, alkalis, and oxidizing agents commonly found in industrial settings. Additionally, there are flammable and combustible chemicals, which pose fire and explosion risks if mishandled or improperly stored. These substances include fuels, solvents, and gases that can ignite when exposed to heat, sparks, or open flames.

Finally, there are reactive chemicals, which can undergo spontaneous reactions or produce hazardous byproducts when exposed to other substances or conditions. Examples include peroxides, oxidizers, and unstable compounds commonly used in laboratory and manufacturing processes. Understanding the characteristics and hazards associated with these types of chemicals is essential for effective risk assessment, mitigation, and emergency response efforts.

Radiation Emergencies

Radiation emergencies include several types radioactive exposure, which vary by source and damage. A **radiological disaster** encompasses a range of events involving the release of radioactive materials into the environment, posing risks to human health and the ecosystem. These disasters can be categorized into several types based on their sources and impacts. First, there are nuclear accidents, which involve the release of radioactive materials from nuclear power plants or research facilities due to equipment malfunctions, human error, or natural disasters. Examples include the Chernobyl disaster in 1986 and the Fukushima Daiichi nuclear disaster in 2011. Second, radiological terrorism involves deliberate acts to release radioactive materials with the intent to cause harm or create fear. This may include the use of radioactive sources in explosive devices or dispersal devices such as "dirty bombs." Third, radiological incidents can occur in health-care settings, such as accidental exposure to radiation during medical procedures or the mishandling of radioactive materials in laboratories during x-rays, radiation therapy, chemotherapy, and radioactive medication creation. Finally, environmental contamination from historical activities such as mining, waste disposal, or military testing can lead to long-term radiological hazards in communities. Ecosystems that support human society can experience devastating contamination, as radioactive particles can permeate soil, water, and food chains. When animals and plants are exposed to radiation, they become rendered unsafe for human consumption, which can have negative effects on agriculture and food supplies (Obrador et al., 2022).

Although the effects are not always readily or immediately visible, radiological disasters can pose significant harm to the environment and human health. The effects of radiological disasters are also not just an immediate concern, as they are often felt for decades. In terms of morbidity and mortality, radiation can penetrate the body, damaging cells and DNA, leading to acute conditions such as radiation sickness (characterized by nausea, vomiting, skin burns, and even death in severe cases). There are also long-term risks associated with exposure, including increased cancer rates (e.g., leukemia, thyroid cancer), genetic mutations, and birth defects in future generations (CDC, 2018).

A **nuclear disaster** (or nuclear incident) refers to the catastrophic release of radioactive materials, typically the result of a detonation or explosion. The most dangerous type of nuclear disaster is nuclear weapons detonation, involving the deliberate use of atomic bombs or other nuclear devices, resulting in devastating immediate and long-term consequences, as seen in the atomic bombings of Hiroshima and Nagasaki during World War II. Nuclear terrorism poses a significant threat, with the potential for malicious actors to acquire or construct improvised nuclear devices or dirty bombs, dispersing radioactive materials to cause harm and instill fear.

Nursing Roles and Responsibilities

In these crises, nurses play critical roles in both immediate response efforts and long-term recovery. During the acute phase of a technological disaster, nurses are often among the first health-care providers to arrive at the scene, triaging and providing emergency medical care. They collaborate with interdisciplinary teams to coordinate evacuations, manage mass casualties, and address environmental hazards. Nurses also play key roles in communicating with affected populations, providing reassurance and guidance on protective measures. In the aftermath of a technological disaster, nurses continue to provide essential health-care services, addressing both physical and psychological needs. They contribute to assessing and treating injuries, monitoring for potential health effects from exposure to hazardous materials, and supporting individuals and communities as they rebuild and recover. Through their expertise in emergency response, disaster management, and compassionate care, nurses serve as pillars of strength and support in times of technological crisis, helping to mitigate harm and promote resilience in affected populations. If the cyberattack happens to a facility, the nurse must assist with immediately shutting down any computer or electronic patient charts. This action can help mitigate a data breach.

Radiological disasters require coordinated response efforts to mitigate exposure risks, provide medical care to affected individuals, and minimize environmental contamination. Effective preparedness, training, and collaboration among health-care professionals, emergency responders, and government agencies are essential to effectively manage the complexities of radiological disasters and protect public health.

Nuclear disasters require comprehensive emergency response strategies, including evacuation, decontamination, medical treatment for radiation exposure, and environmental remediation efforts. In a health-care setting, this plays out as follows:

- Preparedness and training: Health-care facilities must ensure that staff are well-trained in radiation emergency protocols, including the use of personal protective equipment (PPE) and decontamination procedures.
- Triage and treatment: Hospitals and clinics must be prepared to triage and treat patients with radiation exposure. This includes having the necessary medical supplies, such as potassium iodide tablets, and equipment to monitor radiation levels.
- Evacuation plans: Clear evacuation plans should be in place for both patients and staff to ensure safe and orderly movement in the event of a radiation emergency.
- Decontamination units: Establishing decontamination units within or near health-care facilities to treat individuals exposed to radiation before they enter the main health-care environment.
- Communication systems: Robust communication systems are essential to coordinate with emergency services, public health authorities, and other health-care providers to ensure a unified response.
- Psychological support: Providing mental health support for both patients and health-care workers affected by the trauma and stress of a nuclear disaster.
- Public education: Educating the public on the signs and symptoms of radiation exposure and the importance of following evacuation and decontamination instructions.
- Resource allocation: Ensuring that adequate resources, including staff, medical supplies, and equipment, are available and can be rapidly deployed in response to a nuclear disaster.

By implementing these strategies, health-care settings can effectively manage the complex challenges posed by nuclear disasters and minimize the impact on human health. Effective international cooperation, stringent safety regulations, and ongoing research are also crucial in mitigating the risks associated with nuclear disasters and ensuring the safety and well-being of populations worldwide.

34.3 Epidemics and Pandemics

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Define the terms *epidemic* and *pandemic*
- Describe the example of the Ebola epidemic
- Describe the example of the COVID pandemic
- Summarize the roles and responsibilities of the nurse during an epidemic and a pandemic

Epidemics and pandemics represent profound challenges to global health and health-care systems, having significant effects on individuals, communities, and societies worldwide. Infectious disease outbreaks, which are characterized by the rapid spread of pathogens across geographic regions and populations, demand heightened vigilance, preparedness, and coordinated response efforts from health-care professionals.

In the field of nursing, understanding the dynamics of epidemics and pandemics is a crucial foundation for taking action, as nurses are at the forefront of care delivery, infection prevention, and public health promotion. This chapter explores the complexities of epidemics and pandemics, investigating their causes, transmission dynamics, clinical manifestations, and the essential nursing interventions necessary to mitigate their impact. By examining historical outbreaks and emerging infectious diseases, nurses can gain insights into the evolving landscape of epidemic and pandemic response, equipping themselves with the knowledge and skills needed to effectively address these formidable challenges and safeguard the health and well-being of individuals and communities.

Epidemic

An **epidemic** is the occurrence of a disease in a population or geographical area at a higher frequency than expected. It often refers to a sudden and significant increase in the number of cases of a particular illness within a defined period. Epidemics can be caused by infectious agents such as bacteria, viruses, or parasites, as well as non-infectious factors like environmental toxins. There are several types of epidemics, each characterized by distinct patterns of disease transmission and spread. Common types include a **point source epidemic**, where a large number of individuals are exposed to the infectious agent at the same time and develop symptoms within a relatively short period. A **propagated epidemic** occurs when the disease is transmitted from person to person over an extended period, leading to sustained transmission within the population. A **mixed epidemic** involves a combination of both point source and propagated transmission patterns. Understanding the different types of epidemics is critical for health-care professionals, as it informs strategies for disease surveillance, outbreak investigation, and control measures to mitigate the spread of illness and protect public health.

Ebola

Ebola virus disease (EVD), commonly known as Ebola, is a severe and often deadly illness caused by infection with the Ebola virus. Originally transmitted from wild animals to people, Ebola spreads through human-to-human transmission, and first appeared in two simultaneous outbreaks in 1976 in Nzara, Sudan, and Yambuku, Democratic Republic of Congo. The latter occurred in a village situated near the Ebola River, for which the disease was named. Since then, several outbreaks have occurred in Central and West African countries, with varying degrees of severity.

Ebola virus disease is characterized by symptoms such as fever, severe headache, muscle pain, weakness, diarrhea, vomiting, abdominal pain, and unexplained bleeding or bruising. The disease has a high mortality rate, with up to 90 percent of infected individuals dying from the illness (Whitmer et al., 2018). Health-care workers, family members caring for sick individuals, and people who have direct contact with the bodies of people who have died from Ebola are at the highest risk of infection.

Nurses play a crucial role in the prevention, detection, and management of Ebola outbreaks. Infection control techniques such as using gloves, gowns, N95 respirators, and face shields are critical to stopping the spread of the virus. Nurses provide care to infected patients while implementing strict infection control measures, such as avid handwashing and isolation of suspected patients to prevent further transmission. Nurses also play key roles in community education and outreach efforts to raise awareness about Ebola prevention strategies and promote early detection of cases. This can be achieved by hosting community health fairs and educational workshops. Through their expertise in infection control, patient care, and public health, nurses contribute significantly to containing Ebola outbreaks and protecting the health and well-being of affected communities.

Nursing Roles and Responsibilities

Nurses play indispensable roles in the response to epidemics, leveraging their expertise in infection prevention, patient care, and public health to mitigate the spread of infectious diseases and safeguard the well-being of individuals and communities. In the preparatory phase, nurses contribute to the development and implementation of epidemic preparedness plans, ensuring health-care facilities are equipped with necessary supplies, protocols, and training to effectively respond to outbreaks. During an epidemic, nurses are often among the first health-care providers to assess and treat affected individuals, implementing infection control measures to prevent further transmission. They play pivotal roles in triaging patients, conducting screenings, and providing care to those

infected, while also offering support and guidance to worried individuals seeking information and assistance. Additionally, nurses play critical roles in community outreach and education efforts, disseminating accurate information about the disease, promoting preventive measures such as vaccination and hygiene practices, and addressing misconceptions and fears. Nurses also collaborate with interdisciplinary teams to track and monitor disease transmission, identify emerging hotspots, and implement containment strategies. Furthermore, nurses provide essential care and support to at-risk populations, including older adults, children, and those with underlying health conditions, who may be at increased risk during epidemics. Through their dedication, expertise, and compassion, nurses serve as frontline heroes, working tirelessly to protect public health and mitigate the impact of infectious disease outbreaks on individuals and society as a whole.

Pandemic

A **pandemic**, a global outbreak of infectious disease, represents some of the most challenging public health crises. Unlike epidemics, which are localized outbreaks, pandemics spread across international borders, affecting populations worldwide. These events, often caused by novel viruses or pathogens to which humans have little to no immunity, can result in widespread illness, death, and societal disruption. Throughout history, pandemics such as the influenza pandemic of 1918, the HIV pandemic, and more recently, the COVID-19 pandemic, have shaped societies, economies, and health-care systems. Pandemics highlight the interconnectedness of our world and the importance of coordinated global responses. Nurses are at the forefront of pandemic response efforts, providing essential care to those affected, implementing infection control measures, and supporting public health initiatives.

COVID-19

COVID-19, caused by the novel coronavirus SARS-CoV-2, rapidly emerged as one of the most significant global health crises in modern history. Since its identification in December 2019 in Wuhan, China, the virus has spread rapidly across continents, leading to millions of infections and significant loss of life. COVID-19 presents with a wide range of symptoms, from mild respiratory illness to severe pneumonia, acute respiratory distress syndrome (ARDS), and multi-organ failure, particularly affecting older adults and those with underlying health conditions. The pandemic has profoundly affected societies, economies, and health-care systems worldwide, leading to widespread disruption, lockdowns, and social distancing measures to mitigate transmission.

LINK TO LEARNING

Read more to understand the impact COVID-19 had on nurses around the world (https://openstax.org/r/77COVIDimpact).

Nursing Roles and Responsibilities

Nurses have been on the frontlines of the pandemic response, working to provide care, implement infection control measures, and support overwhelmed health-care systems. They have demonstrated extraordinary resilience, adaptability, and compassion in the face of unprecedented challenges, risking their own health and well-being to save lives and alleviate suffering. As frontline health-care providers, nurses have played multifaceted roles in caring for COVID-19 patients, providing essential medical care, and implementing infection prevention and control measures to mitigate transmission. They have been responsible for assessing and managing the symptoms of COVID-19 patients, administering treatments, and monitoring their progress. Since COVID-19 can be transmitted through both airborne droplets and contact with contaminated surfaces, nurses must be vigilant in infection control management, such as handwashing and isolation precautions. Additionally, nurses have been instrumental in supporting overwhelmed health-care systems by triaging patients, coordinating care, and collaborating with interdisciplinary teams to ensure optimal patient outcomes (Figure 34.2).

FIGURE 34.2 A nurse cares for a COVID-19 patient in proper protective equipment. (credit: "COVID-19 Nurse" by Specialist 2nd Class Sara Eshleman/U.S. Navy, Public Domain)

Beyond direct patient care, nurses have been leaders in public health promotion and education, disseminating accurate information about COVID-19 prevention measures, the administration of investigational antiviral therapies, and vaccination efforts. Nurses have played crucial roles in COVID-19 testing, conducting screenings, collecting samples, and providing education on quarantine and isolation protocols. Nurses have played critical roles in administering COVID-19 vaccines, providing education and support to patients and communities, and advocating for equitable access to health-care resources. They have served as advocates for patient rights and equitable access to care, particularly for at-risk populations disproportionately affected by the pandemic. Throughout the COVID-19 crisis, nurses have exhibited extraordinary professionalism, adaptability, compassion, and embodied the core values of the nursing profession and making invaluable contributions to the global effort to combat the virus.

34.4 Community Response to Disaster

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Define the phases of community response to disaster
- Describe a culture of preparedness
- Summarize the roles and responsibilities of the nurse during a community response to disaster

In times of disaster, communities often emerge as resilient and cohesive entities, rallying together to address the challenges that result from natural or human-made crises. Whether facing the aftermath of a hurricane, wildfire, pandemic, or other emergencies, the collective response of community members plays a pivotal role in mitigating the effects of disasters and facilitating recovery efforts. This section explores the dynamics of community response to disasters, examining the diverse ways in which individuals, organizations, and local authorities collaborate to provide assistance, support, and resources to those affected. From volunteer efforts and mutual aid networks to emergency shelters and community-based organizations, communities mobilize their strengths and resources to meet the needs of their members and rebuild in the aftermath of devastation.

Phases of Community Response to Disaster

Disaster response includes several phases through which the nurse will progress along with colleagues to ensure effective action in response to a disaster. The phases exist as part of a continuous cycle:

- Mitigation includes actions taken to reduce potential harm before a disaster occurs.

- Preparedness focuses on shoring up capacity and developing response plans.
- Response is how immediate needs are addressed during a disaster.
- Recovery encompasses the long-term process of rebuilding communities and restoring normalcy or working together toward a "new normal."

Nurses contribute their unique skills and knowledge at every phase to protect patients, manage crises, and promote resilience.

Mitigation

During the **mitigation phase** of community response to disaster, the focus is on proactively reducing the risk and effects of future disasters. This phase involves comprehensive planning, implementation of strategies, and ongoing efforts to mitigate potential hazards and vulnerabilities within the community.

Community leaders, emergency management agencies, and other interested and impacted groups collaborate to identify and prioritize areas of concern, such as flood zones, earthquake-prone areas, or wildfire risk areas. Mitigation measures may include land-use planning, building codes and regulations, infrastructure improvements, ecosystem restoration, and public education initiatives. By investing in mitigation efforts, communities can minimize the loss of life, property damage, and economic disruption caused by disasters.

Moreover, mitigation activities help to enhance community resilience and sustainability, ensuring that the community is better prepared to withstand and recover from future disasters. Through proactive mitigation measures, communities can significantly reduce the human, social, and economic costs associated with disasters, ultimately fostering safer and more resilient communities for current and future generations.

Preparedness

The **preparedness phase** of community response to disaster is a crucial period characterized by proactive planning, coordination, and training to enhance readiness for potential emergencies. During this phase, community members, emergency responders, and local authorities collaborate to develop comprehensive emergency plans tailored to the specific hazards and risks facing the community. These plans outline roles and responsibilities, communication protocols, evacuation procedures, and resource allocation strategies to ensure an effective response in the event of a disaster.

Community members are encouraged to participate in preparedness activities, such as disaster drills, first aid training, and emergency supply kits, to enhance their ability to respond effectively during emergencies. Additionally, partnerships with neighboring communities, government agencies, nonprofit organizations, and private sector entities are forged to facilitate coordinated response efforts and resource sharing.

By investing in preparedness measures, communities can reduce the impact of disasters, protect lives and property, and enhance overall resilience in the face of adversity. The preparedness phase serves as a foundation for effective disaster response and recovery, empowering communities to mitigate risks and better withstand the challenges posed by natural or human-made emergencies.

Response

The **response phase** of community response to disaster is a critical period characterized by immediate actions in response to the event and ensuring the safety and well-being of affected individuals by establishing a command center, to coordinate communication for areas at risk from these hazards. During this phase, emergency responders, including firefighters, law enforcement, medical personnel, and volunteers, mobilize rapidly to provide lifesaving assistance, evacuate at-risk populations, and stabilize the situation. Communication networks are activated to disseminate timely information and instructions to the public, while emergency shelters are established to provide temporary housing and support for individuals who are displaced.

Coordination among local, state, and federal agencies, as well as community organizations and private sector partners, is essential to effectively manage resources, deploy personnel, and prioritize response efforts. Community members also play a crucial role in the response phase, aiding neighbors, providing first aid, and supporting emergency operations.

As the initial chaos subsides, responders shift their focus to performing damage assessments, conducting search and rescue operations, and addressing immediate needs such as food, water, and medical care. The response phase

is characterized by rapid decision-making, flexibility, and collaboration, as communities work together to mitigate the impacts of the disaster and begin the process of recovery.

Recovery

The **recovery phase** of community response to disaster marks the transition from immediate response efforts to long-term recovery and rebuilding. During this phase, communities focus on restoring essential services, infrastructure, and social networks to pre-disaster conditions, as well as addressing the physical, emotional, and economic effects of the event.

Recovery efforts are guided by comprehensive plans and involve collaboration among government agencies, non-profit organizations, businesses, and community members. The recovery process may include debris removal, infrastructure repairs, housing assistance, financial support for affected individuals and businesses, and psychosocial support services to address trauma and mental health needs.

Community resilience and social cohesion are key factors in successful recovery, as individuals come together to support one another, share resources, and rebuild stronger communities. The recovery phase is often a prolonged and challenging process, requiring patience, perseverance, and ongoing commitment from all parties. By investing in recovery efforts and leveraging lessons learned from past disasters, communities can emerge stronger and more prepared to withstand future challenges.

LINK TO LEARNING

The Federal Emergency Management Agency (FEMA) (https://openstax.org/r/77FEMA) is responsible for organizing the nation's efforts to prepare for, respond to, and recover from the effects of natural disasters and terrorist attacks.

Culture of Preparedness

A **culture of preparedness** in community response to disaster refers to the recognition and integration of cultural considerations into emergency planning, response, and recovery efforts. It involves understanding the diverse cultural backgrounds, beliefs, values, and practices within a community and incorporating this knowledge into disaster preparedness strategies.

Culturally competent emergency planning ensures that response efforts are inclusive, respectful, and effective for all members of the community, regardless of their cultural backgrounds. This may include translating emergency communications into multiple languages, accommodating dietary restrictions in emergency shelters, respecting cultural practices related to mourning and burial, and engaging community leaders and cultural organizations in disaster preparedness activities.

By incorporating cultural considerations into emergency planning, communities can foster trust, cooperation, and resilience among diverse populations, ensuring that everyone receives the support and assistance they need during times of crisis. Additionally, cultural preparedness creates a sense of belonging and empowerment within communities, enabling individuals to actively participate in disaster response and recovery efforts and contribute their unique knowledge and skills to the collective response.

Nursing Roles and Responsibilities

In community response to disasters, nurses play indispensable roles in providing essential health-care services, promoting public health measures, and supporting the overall well-being of individuals and communities. Nurses are often among the first responders during disasters, offering immediate medical care to those affected, triaging patients based on severity of injuries or illnesses, and facilitating evacuation efforts when necessary. They also collaborate with other health-care professionals and emergency responders to establish and operate emergency medical shelters, providing care for displaced individuals and addressing their health-care needs. Additionally, nurses play key roles in disease surveillance and control, monitoring for outbreaks of infectious diseases, implementing infection control measures, and administering vaccinations to prevent the spread of illness. Facilitating culturally competent preparedness is a crucial aspect of nursing during disasters. Nurses must be aware of and sensitive to the diverse cultural beliefs, practices, and communication styles of their communities.

34.5 Hospital Preparedness for Disasters

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Describe methods of training and evaluating hospital employees for disaster preparedness
- Discuss examples of emergency policies and procedures hospitals implement for preparation for disasters
- Identify examples of how hospitals administer disaster preparedness drills
- Summarize the roles and responsibilities of the nurse for hospital preparedness for disasters

Hospital preparedness for disasters is a critical component of emergency management, ensuring that health-care facilities are equipped to respond effectively to a wide range of emergencies, including natural disasters, infectious disease outbreaks, mass casualty incidents, and terrorist attacks. In times of crisis, hospitals serve as the frontline of medical response, providing lifesaving care to those injured or affected by the disaster. This section explores the essential elements of hospital preparedness, including emergency planning, surge capacity, resource management, communication systems, and staff training. By examining best practices and lessons learned from past disasters, health-care providers can enhance their readiness to effectively manage the challenges posed by disasters and safeguard the health and safety of patients, staff, and the community. Through comprehensive preparedness efforts, hospitals can ensure continuity of care, mitigate the impact of disasters, and contribute to the resilience and recovery of communities in times of crisis.

Training and Evaluation

Training and evaluation of hospital employees during disaster preparedness are essential components of ensuring a robust and effective response to emergencies. Regulatory agencies such as Occupational Safety and Health Administration (OSHA) and The Joint Commission (TJC) require all hospitals to use yearly practice drills to ensure emergency preparedness and response (FEMA, 2022). Hospital staff undergo comprehensive training programs to familiarize themselves with emergency protocols, procedures, and roles during disasters. These training programs often include tabletop exercises, simulation drills, and hands-on workshops to simulate real-life scenarios and enhance preparedness. Through these exercises, employees practice critical skills such as patient triage, communication, and resource management, allowing them to become proficient in responding to various types of emergencies. Additionally, ongoing education and refresher courses are provided to keep staff updated on best practices and changes in protocols.

Evaluation of hospital employees during disaster preparedness involves assessing their performance and competency in executing emergency procedures. After training exercises and drills, debriefings are conducted to review the response, identify strengths and areas for improvement, and lessons learned. Performance assessments, such as competency checklists and skills evaluations, provide objective feedback on individual and team proficiency in disaster response tasks. Feedback mechanisms, such as surveys and focus groups, allow employees to provide input on training effectiveness and suggest areas for enhancement.

By systematically training and evaluating hospital employees during disaster preparedness, hospitals can ensure that staff are well-prepared and competent to respond effectively to emergencies. These efforts help to enhance the overall readiness of the hospital and contribute to the delivery of high-quality care to patients during times of crisis.

Emergency Policies and Procedures

Emergency policies and procedures are crucial components of hospital disaster preparedness, providing a structured framework for responding to emergencies and ensuring the safety and well-being of patients, staff, and visitors. These policies outline protocols and guidelines for various aspects of emergency management, including incident command, patient care, communication, resource allocation, and staff responsibilities, which are created by committees of providers, nurses, and others. For example, hospitals establish an **incident command system (ICS)** to provide a standardized framework for coordinating emergency response efforts and facilitating communication among key parties. Within the ICS, roles and responsibilities are clearly defined, ensuring efficient decision-making and resource allocation during emergencies.

A critical component of disaster response is **mass casualty triage**, which is a systematic way of prioritizing patients

by survivability. The system enables health-care providers to effectively prioritize care and allocate resources in situations where the number of patients exceeds the available capacity. During mass casualty incidents, such as natural disasters, terrorist attacks, or mass shootings, health-care facilities may become overwhelmed with large numbers of injured individuals requiring immediate medical attention. Mass casualty triage systems help to quickly assess and categorize patients based on the severity of their injuries and the likelihood of survival, ensuring that those with the greatest need receive timely treatment and resources.

Various triage systems, such as the Simple Triage and Rapid Treatment (START) system or the JumpSTART system for pediatric patients, provide standardized algorithms for rapid assessment and classification of patients. A **triage tag**, color-coded based on the severity of injury, is often used to quickly identify and prioritize patients for treatment (Figure 34.3). A **red tag** is assigned to patients with life-threatening injuries requiring immediate intervention, a **yellow tag** for those with significant injuries but a stable condition, a **green tag** for patients with minor injuries or nonurgent medical needs, and a **black tag** for those who are deceased or beyond help.

FIGURE 34.3 Patient triage in action. Each tag represents a critical assessment to prioritize care during emergencies. (credit: "633rd Medical Group prepares for air show" by Airman 1st Class Kaylee Dubois/U.S. Air Force, Public Domain)

Health-care providers, including nurses, play crucial roles in mass casualty triage by conducting rapid assessments, assigning triage tags, and initiating life-saving interventions for critically injured patients. Effective communication and teamwork are essential for coordinating triage efforts and ensuring that patients are directed to the appropriate level of care. Additionally, ongoing training and drills help to ensure that health-care providers are prepared to assess patients, make triage decisions under pressure, and adapt to rapidly changing circumstances during mass casualty incidents quickly and accurately (Table 34.1).

Triage Under Usual Conditions	Triage Under Mass Casualty Conditions
Emergent An immediate threat to life	Emergent or class I: Red tag Immediate threat to life
Urgent Major injuries that require immediate treatment	Urgent or class II: Yellow tag Major injuries that require treatment

TABLE 34.1 Triage Under Usual Conditions versus Mass Casualty Conditions

Triage Under Usual Conditions	Triage Under Mass Casualty Conditions
Nonurgent Minor injuries that do not require immediate treatment	Nonurgent or class III: Green tag Minor injuries that do not require immediate treatment
Does not apply	Expectant or class IV: Black tag Expected and allowed to die

TABLE 34.1 Triage Under Usual Conditions versus Mass Casualty Conditions

Black-tagged patients might have spinal cord injuries, head traumas, or extensive body burns. While the decision to label a patient as a black tag is very difficult, the limited resources available during a disaster must be allocated to save as many lives as possible, rather than using more resources to save only a few.

In this system of triage, The Joint Commission recommends red-tagged patients have immediate life-threatening conditions that require immediate attention, such as shock or an airway obstruction. Patients with major injuries such as open fractures or large wounds that need treatment within 30 minutes to two hours would be yellow-tagged. Patients with minor injuries that can be managed after a delay, generally more than two hours, such as closed fractures, sprains, abrasions, or contusions would be green-tagged (The Joint Commission, 2023).

Green-tagged patients who are able to ambulate are often referred to as the "walking wounded" because they can leave the scene of the mass casualty on their own and seek their own medical assistance. In multi-casualty disasters, green-tagged patients usually make up the greatest number of patients (TJC, 2023). However, green-tagged patients who leave the scene may unknowingly carry contaminants from a nuclear, biological, or chemical incident into another environment with potentially disastrous consequences. Hospitals devise emergency response plans, including appropriate decontamination measures, to anticipate these kinds of needs during a disaster. By implementing systematic mass casualty triage protocols and training health-care providers in their use, hospitals can enhance their ability to effectively manage large-scale emergencies, prioritize care, and maximize the chances of survival for patients in times of crisis (TJC, 2023).

Additionally, hospitals develop surge capacity plans to expand capacity and accommodate an influx of patients during pandemics and disasters. Surge capacity means the hospital can take a larger than usual number of patients in a crisis. These plans outline procedures for opening additional patient care areas, mobilizing supplemental staffing, and reallocating resources to meet increased demand for medical services. Infection control policies are also critical for preventing the spread of infectious diseases within health-care facilities. These policies include guidelines for isolation precautions, personal protective equipment (PPE) use, environmental cleaning, and patient cohorting to minimize the risk of transmission among patients, staff, and visitors.

Furthermore, hospitals establish communication policies and procedures to facilitate timely and accurate communication during emergencies. These policies include protocols for internal communication among hospital staff, as well as external communication with patients, families, emergency responders, and community partners. By implementing comprehensive emergency policies and procedures, hospitals can enhance their readiness to effectively manage disasters and ensure the safety and well-being of all individuals within their care.

Hospital Emergency Preparedness Drills

Hospital emergency preparedness drills ensure that health-care facilities are ready to respond effectively to various emergencies. These drills simulate real-life scenarios and provide an opportunity for hospital staff to practice their roles and responsibilities in a controlled environment. One type of drill commonly conducted is tabletop exercises, which involve scenario-based discussions and decision-making exercises among FEMA and key stakeholders. During tabletop exercises, participants review emergency plans, identify potential challenges, and discuss strategies for addressing them.

Another type of drill is functional exercises, which simulate specific response actions, such as patient triage, decontamination procedures, or mass casualty management. These drills provide hands-on experience for staff to practice skills and procedures in a realistic setting. Full-scale exercises are also conducted, which simulate a

comprehensive response to a simulated disaster scenario from start to finish. These exercises involve multiple agencies, resources, and response elements and are designed to test coordination, communication, and decision-making across all levels of the organization. By conducting a variety of drills and exercises, hospitals can evaluate their preparedness, identify areas for improvement, and enhance their ability to respond effectively to a wide range of emergencies.

Nursing Roles and Responsibilities

Nurses play vital roles in hospital disaster preparedness by ensuring effective response and care delivery during emergencies. Their responsibilities span various stages of preparedness, response, and recovery. In the preparedness phase, nurses contribute by participating in training sessions, drills, and simulations to familiarize themselves with emergency protocols and procedures. They also play key roles in developing and updating disaster plans, ensuring that patient care considerations, such as triage protocols and medication management, are adequately addressed.

During the response phase, nurses serve on the front lines, providing immediate medical care, triaging patients, and mobilizing resources as needed. They collaborate closely with interdisciplinary teams to ensure coordinated and efficient care delivery. Nurses are often responsible for implementing infection control measures, managing patient flow, and providing emotional support to patients, families, and colleagues during stressful situations.

In the recovery phase, nurses continue to play critical roles in restoring normalcy and rebuilding services. They contribute to efforts to assess and address the physical and mental health needs of patients and staff affected by the disaster. Additionally, nurses may participate in community outreach and education initiatives, helping to promote resilience and preparedness for future emergencies.

Throughout all phases of disaster preparedness, nurses demonstrate leadership, adaptability, and compassion, ensuring that patient safety and well-being remain the top priorities. Their expertise in patient care, clinical assessment, and crisis management makes them invaluable assets in hospital disaster preparedness efforts, ultimately contributing to the resilience and effectiveness of health-care systems in times of crisis.

Summary

34.1 Environmental Disasters

- Storms, thunderstorms, hurricanes, snow, floods, and tsunamis are just a few examples of water disasters that hospitals must be prepared for.
- Land disasters like earthquakes, landslides, and fires can cause damage to facilities and make them inaccessible due to blocked roads.
- During a disaster, the nurse's role spans from being a frontline responder to contributing their skills to a community's long-term recovery.

34.2 Biological and Technological Disasters

- Biological disasters like influenza, pandemics, and bioterrorism attacks present unique challenges for nurses. In the face of biological disasters, nurses must be equipped with knowledge of epidemiology, pathophysiology, and public health principles to effectively assess, triage, and treat patients.
- During biological disasters, nurses serve as educators, helping communities understand the importance of vaccination, hygiene practices, and other preventive measures.
- Technological disasters, including chemical, radiological, and nuclear accidents, can have immediate effects and long-lasting consequences.
- In technological crises, nurses play critical roles in both immediate response efforts and long-term recovery. During the acute phase, nurses are often among the first health-care providers to arrive at the scene, triaging and providing emergency medical care. Nurses also play key roles in communicating with affected populations, providing reassurance and guidance on protective measures. In the aftermath of a technological disaster, nurses continue to provide essential health-care services, addressing both physical and psychological needs.

34.3 Epidemics and Pandemics

- Epidemics (the occurrence of a disease in a population or geographical area at a higher frequency than expected) and pandemics (global outbreaks of infectious diseases) are challenging situations for health-care personnel.
- Globally, outbreaks of Ebola have required nurses to both provide care and education about infection control.
- During the COVID pandemic, nurses were challenged to provide care in a time of both unprecedented strain on the health-care system and rapid scientific achievement.
- In both epidemics and pandemics, nurses are tasked with providing care, ensuring patient safety (as well as their own), promoting resilience, and prioritizing education and prevention efforts.

34.4 Community Response to Disaster

- Disaster response includes several phases and the phases exist as part of a continuous cycle: mitigation includes actions taken to reduce potential harm before a disaster occurs; preparedness focuses on shoring up capacity and developing response plans; response is how immediate needs are addressed during a disaster, and recovery encompasses the long-term process of rebuilding communities and restoring normalcy or working together toward a "new normal."
- A culture of preparedness in community response to disaster refers to the recognition and integration of cultural considerations into emergency planning, response, and recovery efforts. It involves understanding the diverse cultural backgrounds, beliefs, values, and practices within a community and incorporating this knowledge into disaster preparedness strategies.
- During a community's response to a disaster, nurses must collaborate with others to address the unique needs of the populations affected and adapt their approaches as needed. Additionally, nurses play key roles in disease surveillance and control, monitoring for outbreaks of infectious diseases, implementing infection control measures, and administering vaccinations to prevent the spread of illness.

34.5 Hospital Preparedness for Disasters

- Facilities and organizations can use established protocols to train and evaluate emergency preparedness among staff.

- Training sessions with real-world simulations, as well as hands-on skills and competency assessments, help staff build confidence and feel empowered to perform their work in times of crisis.
- Staff training sessions can be conducted on-site or led by experts in the community. Protocols and procedures can be developed from an interdisciplinary standpoint.
- The nurse is responsible for staying up-to-date on training, knowing where to find information about their facility's protocols and procedures, and clearly understanding their role in the event of a disaster.

Key Terms

aftershock smaller earthquake that follows the main shock of a larger earthquake
anthrax serious infectious disease caused by the bacterium *Bacillus anthracis*
biological disaster wide range of events, such as an infectious disease outbreak, a pandemic, or a bioterrorism incident
bioterrorism intentional release of a biological agent, such as bacteria, viruses, or toxins, intended to cause harm to individuals, populations, or economies
black tag patients with critical injuries who are not expected to survive given the available resources and medical priorities
chemical hazard diverse array of substances that can pose risks to human health and the environment
COVID-19 respiratory illness caused by the novel coronavirus SARS-CoV-2
cultural of preparedness proactive efforts made by individuals, communities, organizations, and institutions to understand, respect, and integrate diverse cultural perspectives, values, beliefs, and practices into disaster preparedness, response, and recovery efforts
cyberattack deliberate, malicious attempts to disrupt, damage, or gain unauthorized access to computer systems, networks, or electronic devices
earthquake sudden and violent shaking of the ground caused by the movement of tectonic plates beneath the earth's surface
Ebola virus disease (EVD) highly infectious and often deadly viral disease caused by the Ebola virus, commonly known as Ebola
epidemic occurrence of a disease in a community or region at a rate that exceeds what is normally expected
flash flood rapid and extreme flooding event characterized by a sudden onset of high water levels, often with little to no warning
green tag patients with minor injuries or those who require minimal medical intervention
H1N1 influenza virus subtype of influenza A virus that can cause respiratory illness in humans
incident command system (ICS) central hub for incident management activities, housing key personnel, resources, and equipment necessary for coordinating response efforts
influenza caused by influenza viruses, a contagious respiratory illness that affects the nose, throat, and lungs
landslide geological event characterized by the movement of a mass of rock, earth, or debris down a slope under the influence of gravity
mass casualty triage systematic process used by health-care professionals to prioritize and categorize injured individuals during a mass casualty incident based on the severity of their injuries and the likelihood of survival
mitigation phase stage in disaster management characterized by efforts to minimize or mitigate the impact of a disaster on individuals, communities, and infrastructure
mixed epidemic combination of both a point source epidemic and a propagated transmission epidemic pattern
National Weather Service (NWS) agency within the United States federal government that is responsible for providing weather forecasts, warnings, and other meteorological information to the public, businesses, and government agencies
nuclear disaster range of catastrophic events involving the release of radioactive materials, each presenting unique challenges and risks to human health and the environment
pandemic outbreak of a disease that affects a high proportion of the population across a large geographic location
point source epidemic type of epidemic where a large number of individuals are exposed to the infectious agent at the same time and develop symptoms within a relatively short period
preparedness phase stage in disaster management where proactive measures are taken to enhance readiness and response capabilities before a disaster occurs
propagated epidemic type of epidemic where a disease is transmitted from person to person over an extended

period, leading to sustained transmission within a population

radiological disaster range of events involving the release of radioactive materials into the environment, posing risks to human health and the ecosystem

recovery phase period following a disaster when efforts are made to restore affected communities, infrastructure, and economies to a state of normalcy or to a condition better than before the disaster occurred

red tag patients with life-threatening injuries who require immediate medical attention to survive

response phase immediate period following the occurrence of a disaster when emergency measures are activated to address the immediate needs of individuals, communities, and infrastructure affected by the disaster

storm surge water from the ocean pushed ashore by the heavy winds and can cause widespread flooding and bring ocean life inland

technological disaster broad range of events with far-reaching implications for public health and safety

tornado warning urgent message issued by the National Weather Service (NWS) when a tornado has been detected by radar or spotted by trained observers, and there is an imminent threat to life and property in a specific area

tornado watch alert issued by the National Weather Service (NWS) when weather conditions are favorable for the development of tornadoes in a specified area; it is issued in advance to provide early notice and allow people to prepare for possible tornado activity

triage tag color-coded or numbered identifiers used by health-care professionals during mass casualty incidents to categorize and prioritize patients based on the severity of their injuries or medical conditions

tsunami series of large ocean waves caused by the displacement of a large volume of water, typically as a result of an underwater earthquake, volcanic eruption, landslide, or meteorite impact

wildfire uncontrolled and often fast-spreading fire that occurs in forests, grasslands, or other wild land areas

yellow tag patients with serious injuries that are not immediately life-threatening and can wait for medical care without compromising their survival chances

Assessments

Review Questions

1. The nurse is conducting a community education session about preparing for severe weather emergencies. What statement by a participant indicates an understanding of the topic?

a. “We should evacuate our homes immediately when a tornado warning is issued.”
b. “I’ll stock up on perishable foods and water before a hurricane warning.”
c. “Having a battery-operated weather radio is essential for staying informed during severe weather.”
d. “It’s best to park my car under a tree for protection during a storm.”

2. During a tornado watch, what intervention should the nurse implement first for patients on the medical-surgical unit?

a. Assist all patients with ambulation to the basement
b. Move all patients to the hallways
c. Continue providing routine patient care
d. Notify the hospital administration of the tornado watch

3. What action should the nurse prioritize when handling a technological hazard, such as a chemical spill, in the health-care setting?

a. Donning personal protective equipment (PPE)
b. Evacuating patients immediately
c. Notifying the Environmental Services department
d. Documenting the incident in the patient’s chart

4. What is the priority action for the nurse if they suspect their computer has been hacked?

a. Disconnect the computer from the network
b. Notify the IT department
c. Shut down the computer immediately

d. Run antivirus software to scan for malware

5. What statement accurately describes the transmission mode of COVID-19?
   a. COVID-19 is primarily transmitted through airborne droplets.
   b. COVID-19 is transmitted only through direct contact with infected individuals.
   c. COVID-19 can be transmitted through both airborne droplets and contact with contaminated surfaces.
   d. COVID-19 is not transmitted between individuals, but rather through ingestion of contaminated food or water.

6. A nurse is caring for a patient suspected of having Ebola virus disease (EVD). What personal protective equipment (PPE) is essential for the nurse to wear when providing direct care to this patient?
   a. Gloves and gown
   b. Gloves, gown, and surgical mask
   c. Gloves, gown, N95 respirator, and face shield
   d. Gloves, gown, surgical mask, and eye protection

7. What is the correct order of the phases of disaster response?
   a. Preparedness, mitigation, response, recovery
   b. Mitigation, preparedness, response, recovery
   c. Response, mitigation, recovery, preparedness
   d. Recovery, response, preparedness, mitigation

8. A nurse is working on promoting a culture of preparedness in a community prone to natural disasters. What action best demonstrates this concept?
   a. Ensuring emergency kits are distributed to all community members
   b. Educating the community on the importance of disaster drills
   c. Integrating cultural considerations into emergency planning and response
   d. Establishing a clear communication plan for first responders

9. During the response phase of a disaster, a nurse must collaborate with others to address the unique needs of the populations affected. What action best exemplifies this responsibility during the response phase?
   a. Conducting a community-wide survey to assess the impact of the disaster
   b. Coordinating with local shelters to ensure culturally appropriate food is available
   c. Distributing blankets and first aid supplies to affected individuals
   d. Setting up a temporary medical clinic in the disaster area

10. In the context of disaster response, what is the primary goal of the mitigation phase?
   a. Prepare for potential disasters by training first responders
   b. Respond to immediate needs during a disaster
   c. Reduce the impact of future disasters through preventive measures
   d. Assist communities in recovering from the effects of a disaster

11. What action is most appropriate for a nurse to take during the recovery phase of a disaster?
   a. Evacuating residents from dangerous areas
   b. Providing immediate first aid and emergency care
   c. Developing long-term mental health support plans for affected individuals
   d. Conducting disaster preparedness drills

12. A nurse is triaging patients following a mass casualty incident. What is an example of a patient the nurse would prioritize for immediate medical attention?
   a. A patient with a fractured arm
   b. A patient with difficulty breathing and cyanosis
   c. A patient with a laceration on the leg

d. A patient with a minor abrasion on the forehead

Check Your Understanding Questions

1. What challenges can be faced by nurses working in the hospital during a tornado warning?
2. What are the primary nursing interventions for managing a patient with suspected anthrax exposure?
3. As a nurse, how would you describe Ebola virus disease (EVD) and your role in its management?
4. Why is it essential for hospital staff to have regular updates and refreshers on emergency policies and procedures? How does the hospital ensure these updates are effectively communicated?

Reflection Questions

1. How would you prioritize patient safety and maintain calm during a tornado warning? Reflect on any challenges you might face and the decisions you will make to ensure the well-being of both patients and staff. Consider what strategies will be most effective.
2. How does cultural diversity impact disaster preparedness and response efforts in our community or health-care setting?
3. Reflect on a recent training or drill you participated in that was focused on disaster preparedness in your hospital.

What Should the Nurse Do?

1. What should the nurse do during a wildfire emergency to ensure the safety and well-being of patients and staff?

Competency-Based Assessments

1. Describe how you would apply your knowledge and skills to ensure patient safety and provide effective care during a flash flood emergency. Provide specific examples of actions you would take to assess risk, prioritize patient needs, and collaborate with the health-care team and emergency responders.
2. Describe how you would provide holistic care for a patient diagnosed with H1N1 influenza, considering their physical, emotional, and educational needs. Include specific interventions you would implement to promote recovery and prevent transmission of the virus.
3. You are a nurse working in a hospital located in a region where an outbreak of Ebola virus disease (EVD) has been reported. As part of your role, you are responsible for managing patients suspected or confirmed to have EVD and implementing infection control measures to prevent the spread of the virus. Describe the key steps you would take to ensure the safety of yourself, your colleagues, and your patients while caring for individuals suspected or confirmed to have EVD. Please include specific actions related to personal protective equipment usage, patient isolation, and communication protocols. Additionally, explain how you would effectively educate patients, families, and staff about EVD prevention and control measures.

CHAPTER 35

Nursing Care of the Critically Ill Patient

FIGURE 35.1 A patient is cared for in an intensive care unit. The patient is intubated with multiple intravenous catheters. (credit: U.S. Navy, public domain)

CHAPTER OUTLINE

INTRODUCTION Critical care nursing is a specialty requiring astute assessment skills, clinical judgment, and critical thinking. Nurses who work in critical care settings are tasked with caring for extremely ill patients who are at high risk for death without life-saving medical intervention. Because of these patients' high acuity, critical care nurses in the intensive care unit (ICU) are typically assigned to care for only one or two patients at a time. A typical patient in the ICU is intubated, receiving ventilatory support, and receiving several continuous intravenous (IV) medications (e.g., sedation, vasoactive drugs) that must be monitored and adjusted frequently by the nurse because of their systemic effects on the patient's hemodynamics. In addition to managing the ventilator and medications, these patients also often have technological therapies in place, such as continuous renal replacement therapy or extracorporeal membrane oxygenation (ECMO), which the nurse is responsible for maintaining. Thus, critical care nurses must not only possess the technical skills to implement such complex therapies, they must also be able to think critically and make autonomous clinical decisions based on subtle changes in their patient's conditions. The

critical care nurse must be able to use all patient data—including assessments, medical histories, medications, and laboratory values—to determine real or potential complications the patient is currently experiencing or for which they are at risk.

Critical care is still a relatively new concept, with the first ICUs being established in the late 1950s to address the need for mechanical ventilation of patients with polio (Vincent, 2013). Over the next decade, ICUs were opened in many hospitals throughout the United States, Europe, and Australia. To assist with the education of nurses employed in these new intensive care settings, the American Association of Cardiovascular Nurses was established in 1960. The organization was renamed the American Association of Critical-Care Nurses (AACN) in 1970 to reflect the complex patient population more accurately (AACN, n.d.). As critical care units became more widespread in the 1970s, extensive research resulted in major advancements in medical technology. In present-day critical care units, these technological advancements are obvious. A wide variety of life-saving pharmacological and technological therapies have been developed and integrated into most ICUs worldwide. More recently, as telehealth has become more prevalent, electronic ICUs have been established in which critically ill patients are monitored remotely by critical care providers and nurses (Udeh et al., 2018).

The disease and financial burdens associated with critical care are already high, and several health-care trends continue to increase this burden. As patient life expectancy increases, so do the frequency of disease and resulting critical illness (Adhikari et al., 2010). Though technological advances have multiplied the available treatment options, they also bring an increased risk for treatment-associated complications, which can negatively affect the length of hospital stays and increase overall health-care costs. Additionally, incidence of burnout and post-traumatic stress disorder in bedside nurses and critical care providers has skyrocketed over recent years, largely related to the COVID-19 pandemic. This burnout has resulted in large-scale nursing and provider shortages that are likely to negatively affect critical care and health care in general for many years. According to the American Association of Colleges of Nursing (2022), there is a projected shortage of more than 200,000 nurses by the year 2031, and nursing school enrollments are not keeping up the pace to supply the workforce.

35.1 Assessment and Management of the Critically Ill Patient

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Identify admission criteria for intensive care
- Explain the required nursing skills and technological and pharmacological therapies that are unique to the critical care setting
- Describe the ethical and legal considerations of providing nursing care to critically ill patients

Critical care nurses are responsible for assessing, monitoring, and caring for high-acuity patients with multisystem disorders. These patients have complex medical conditions that require extensive medical intervention and nursing care. To provide optimal care to patients in the ICU, critical care nurses must skillfully display attention to detail, technical competence, and excellent communication skills. Caring for patients in these settings can be especially challenging because of the severity of their illness and the resulting stress and trauma experienced by patients and their families. Additionally, there are legal and ethical considerations that affect patients and their families in the critical care setting, often making this area of nursing even more challenging.

Admission Criteria for Intensive Care

Patients can be admitted to critical care settings for a variety of reasons, but most often there is a life-threatening medical condition that requires intensive monitoring and extensive medical and nursing care (Smith & Nielson, 1999). Some of the most common reasons for admission to the ICU are listed in Table 35.1.

Reason for Admission	Clinical Examples	Rationale
Requires interventions or therapies that are only available in critical care settings	• Continuous renal replacement therapy • Extracorporeal membrane oxygenation • Intra-aortic balloon pump therapy • Mechanical cardiovascular support using ventricular assistive devices • Mechanical ventilation • Noninvasive/invasive hemodynamic monitoring • Targeted temperature management • Titrating medications (e.g., vasopressors, sedation)	Critical care nurses have received extensive, specialized training and obtained certifications that qualify them to provide and manage complex interventions and therapies in the critical care setting.
Clinical instability	• Cardiac dysrhythmias • Hypoxemia • Severe hypotension • Shock	Admission to the ICU allows clinically unstable patients to be monitored closely and have easier access to life-saving therapies, should they be needed.
Postcardiac arrest	• Patients who experienced cardiac arrest, received cardiopulmonary resuscitation, and achieved return of spontaneous circulation	Patients experiencing cardiac arrest are at high risk for experiencing another cardiac event. Admission to the ICU allows for close monitoring and access to life-saving therapies.
Surgical recovery	• Craniotomy • Coronary artery bypass graft • Organ transplantation	Patients are admitted to the ICU after invasive surgical procedures because they are at high risk for hemodynamic instability and life-threatening postoperative complications.

TABLE 35.1 Reasons for Admission to Critical Care Setting

Risk Assessment Models

When a patient is admitted to the ICU, it is important to determine the severity of their condition because this information influences nurse staffing ratios and the allocation of other unit resources. This information also helps estimate the patient's survival rate, which is used to monitor and evaluate patient outcomes during and after their stay in the ICU. There are several risk assessment models that aid in determining the severity of the patient's medical condition. Two of the most widely used models are the Acute Physiologic Assessment and Chronic Health Evaluation (APACHE) II Scoring System (Medscape, n.d.) and the Sequential Organ Failure Assessment (SOFA). Both models evaluate several physiologic variables (e.g., temperature, heart rate), resulting in a score that reflects the severity of their condition. SOFA was originally used to determine the risk of organ failure in patients with sepsis (see Figure 23.7), but it is now used more broadly with patients admitted to the ICU. Scores from 0 to 4 are given in six key categories (e.g., respiration, renal); a higher score indicates a higher risk for organ failure and is associated with worse patient outcomes.

LINK TO LEARNING

This webpage provides information about the APACHE II Scoring system (https://openstax.org/r/77apache) and includes a template for calculating a score. A higher overall score indicates more severe disease and increased risk of hospital death.

Multisystem Organ Dysfunction

Though patients are often admitted to the ICU for one primary medical problem, it is common for critically ill patients to experience dysfunction of several body systems at once, contributing to the overall complexity of their care. This is known as **multiple organ dysfunction syndrome (MODS)** and is the leading cause of death for patients admitted to the ICU (Society of Critical Care Medicine, n.d.). Multiple organ dysfunction syndrome most often occurs in patients experiencing trauma-related events (e.g., motor vehicle accident) or systemic conditions such as shock or sepsis. When multiple body systems are affected, patient outcomes are negatively affected.

Required Skills for Critical Care Nurses

Working as a nurse in the critical care setting requires many skills, one of the most important being attention to detail. Because of the high acuity of patients in the ICU, it is important that critical care nurses can accurately assess and detect subtle changes in patient conditions that can quickly deteriorate and become life-threatening without appropriate intervention. Critical care nurses also must possess the technical skills and competence required to manage multiple IV medications and technological therapies at the same time. Critical care nurses need excellent communication skills to function well within a interdisciplinary team and to relay complex medical information to patients and their families. Additionally, it is imperative that critical care nurses be able to translate complex patient data into accurate and detailed documentation to be included in the patient's medical record as a resource for the rest of the interdisciplinary care team. The care of a patient in critical care commands a lot of time and detail; therefore, nurse-to-patient ratios are low in this setting; typically, one nurse cares for two critically ill patients during a shift.

Technological Supports Used in Critical Care

Critical care units are designed to provide life-sustaining care to critically ill patients while still maintaining a sense of comfort. Most ICUs consist of several single-bed rooms that are arranged for easy viewing from the nurses' station. Each patient room contains bedside equipment to monitor the patient's vital signs and other hemodynamic parameters, all of which are also in view of the nurse. There are usually several storage areas on the unit that contain medication-dispensing machines and other equipment such as ventilators and the crash cart. Storage areas should be easily accessible and located near patient rooms in case of medical emergency.

Though critical care units can be overwhelming for families and patients, especially when patients are hooked up to multiple IV pumps and other machines, they are usually designed to promote patient and family comfort. Some critical care units offer private family waiting rooms with couches as well as furniture in the patient rooms to support visitors' comfort when visiting the patient. Figure 35.2 shows a typical ICU room.

FIGURE 35.2 Patient rooms in a critical care unit room contain bedside equipment to monitor the patient's vital signs and other hemodynamic parameters. (credit: "An Intensive Care Unit in a Hospital" by R. Priseman/Wellcome Images, CC BY 4.0)

Critical care units use a wide range of technology and equipment to provide care to the critically ill. One of the most common pieces of equipment is the ventilator. Patients in the ICU are often unable to breathe effectively, indicating the need for **intubation**. This process involves the insertion of a flexible plastic endotracheal tube (ETT) through the mouth and into the trachea down to the airway; the ETT can then be connected to a ventilator. The ventilator is programmed by the respiratory therapist (RT) to provide effective control over the patient's breathing pattern when they are unable to adequately control it themselves. Another machine commonly used in critical care settings is the IV medication pump (IV pump). It is not uncommon to see patients in the ICU connected to multiple IV pumps at one time, receiving several different medications to maintain hemodynamic stability and comfort.

Pharmacological Supports Used in Critical Care

As mentioned, critical care patients being cared for in the ICU often receive multiple medications at one time. One of the most common classes of medications is vasopressors. These medications are used when patients cannot maintain adequate blood pressure on their own, which often is seen with conditions like shock. The critical care nurse is responsible for frequently adjusting the titration rate of these medications to keep the patient's blood pressure within the specific range prescribed by the health-care provider, which is why constant, detailed monitoring is an essential nursing skill. There are six major vasoactive medications used in this setting. The first five are vasopressors, which are indicated for blood pressure support, and include epinephrine, norepinephrine, phenylephrine, vasopressin, and dopamine. Another vasoactive agent, indicated for cardiac output (CO) support, is dobutamine.

Another medication class is sedatives. Patients who are connected to a ventilator or other invasive equipment often require sedation to ensure they stay calm and do not disconnect themselves from the life-saving machines. The

nurse is responsible for titrating these medications to maintain an appropriate level of sedation for the patient's condition. Patients may also receive opioid analgesic medications to mitigate pain, either via IV push or continuous infusion. Other common medication classes used in the critical care setting include anticoagulants, antidysrhythmic medications, and insulin. It is important to note that most of the medications given in the ICU must be administered intravenously (as opposed to orally) to deliver more immediate physiologic effects in critically ill patients.

Ethical and Legal Implications Confronted in Critical Care

Critical care nurses are often faced with ethical and legal issues in their day-to-day practice. Many of these issues are related to the complexity of the patients' conditions and the beliefs and values of the patients and their families. Dealing with highly emotional situations frequently can also have a profound impact on the critical care nurse, including feelings of depression and caregiver fatigue. It is important for nurses to be aware of their emotions and use resources such as counseling for their own mental health as needed. The two most common legal and ethical issues encountered by the critical care nurse include decision-making related to life-sustaining therapy and organ and tissue donation.

Life-Sustaining Therapy Decision-Making

As medical technology has advanced, there are more options for therapies that can be used to keep patients alive who previously would have died of their illnesses. Most of the legal and ethical issues surrounding life-sustaining care arise when there are questions relating to whether the patient would want particular interventions and what their anticipated quality of life would be. In some cases, the patient has proactively created an advance directive, which is a document that provides instructions for medical care if the patient cannot communicate their wishes. Often, patients who are on life-sustaining therapies are unable to convey their personal wishes. If they do not have an advance directive, medical decisions are made by their next of kin or a designated person via authorization called a durable power of attorney (DPOA), depending on state laws and/or previously identified wishes (e.g., the choice to withhold resuscitative measures) made by the patient. A person may be previously identified in a living will or advance directive as having DPOA for the patient. This may be an appointed family member, friend, or court-appointed attorney.

A related document is a do-not-resuscitate (DNR) order that indicates that the patient does not want cardiopulmonary resuscitation to be conducted if their heart stops. Do-not-resuscitate orders are discussed in are discussed in Chapter 32 Palliative Care.

If the patient has not previously explicitly written their health-care wishes, the designated person with DPOA or the patient's family is faced with determining what kind of care the patient would want to receive. This can be difficult to do, especially when there are multiple family members or legal decision-makers who have conflicting opinions, values, and beliefs. Ultimately, these decisions should be made based on knowledge of the patient's previous health status and determining whether the use of life-sustaining therapies could restore their quality of life to a level that would be acceptable to the patient. There are many moral and ethical considerations associated with these kinds of decisions and every patient situation is unique. Hospitals have developed ethics committees that can intervene and assist with decision-making if legal decision-makers and families are unable to determine the best course of action for the patient. Critical care nurses must be prepared to collaborate with these committees and advocate for their patients when necessary.

Organ and Tissue Donation

Although some critically ill patients make a full recovery, many others do not. Sometimes patients have experienced traumatic events or complications so great that they have lost all brain stem functioning, resulting in **brain death**, which is defined as the cessation of brain function, due to irreversible brain injury. In these situations, ethical and legal issues arise related to the potential for organ and tissue donation. Legal decision-makers or families may choose to continue life-sustaining therapy knowing that the patient will not recover neurologically, or they may choose to withdraw the life-sustaining therapies. If the decision is made to withdraw care, the potential for organ and tissue donation often becomes part of the conversation. Organ and tissue donation can be a difficult subject to discuss, and some families are not comfortable with having a loved one's organs harvested after death. The family or patient may have cultural or religious beliefs that affect whether they consider organ donation. Often, families also have fears related to misinformation or unknowns about the donation process that need to be addressed before the decision can be made to donate organs.

Because of the serious nature of these conversations, local organ procurement organizations should be called when death is anticipated, so that organ-donation nurses may come speak directly to the family. These professionally trained nurses have extensive experience with organ donation and can better speak to the process and provide details and emotional support to families. Most hospitals mandate that staff nurses not approach families about organ donation and instead wait for the organ procurement organization nurses to speak with them. This ensures that there has been no coercion or inaccurate information relayed to the family, minimizing the risk of future legal or ethical issues.

REAL RN STORIES

Narrative of a Nurse's Journey to Become an ICU Nurse

During nursing school clinical rotations, Alaina decided that she was most interested in critical care nursing. In her final semester of school, after completing a capstone rotation in the cardiovascular intensive care unit, she was certain that she wanted to become a critical care nurse after graduation. Though she was encouraged by many to start her career in a lower-acuity unit before pursuing critical care, Alaina was determined to enter the ICU right after graduation.

Sure enough, Alaina ended up securing a new graduate nursing position in a 28-bed trauma ICU. She knew that this would be a tough place to work, especially as a novice nurse. After every 12-hour shift, Alaina went home and spent at least two more hours studying the different conditions and medications she had encountered that day. After about a year of doing this, Alaina found that she was gaining more confidence in caring for critically ill patients. It was about this time in her nursing career when her unit manager approached her about being a preceptor for capstone students.

Over the next few years, Alaina served as a preceptor for nursing students and new employees and learned that she loved educating others about critical care. In addition to working in the ICU, Alaina started working part-time as a clinical instructor for a local nursing school, which allowed her to see other hospitals and ICUs and continue educating future nurses. After a few years in the ICU, Alaina studied for and obtained her Critical Care Registered Nurse (CCRN) certification, the highest level of competence in critical care nursing.

35.2 Cardiovascular Concerns

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiological changes to the patient's cardiovascular concerns when in the intensive care unit
- Describe the medical assessments and therapies that apply to the critical care patient's cardiovascular system
- Apply nursing concepts and plan associated nursing care for the critical care patient's cardiovascular system

The heart is arguably the most important organ in the body because it is responsible for providing perfusion to all other body systems and organs. Care of the critically ill patient with cardiac dysfunction and impaired CO is challenging because of the complex and invasive therapies required to maintain hemodynamic stability. Critical care nurses must possess the technical expertise to implement and monitor these interventions; they also need superior clinical knowledge and critical thinking skills. Though there are many different cardiovascular conditions experienced by patients in critical care settings, many of them will require the use of hemodynamic monitoring, pharmacological interventions, and invasive cardiovascular support, all of which are discussed in this section.

Pathophysiological Insult to the Critical Care Patient's Cardiovascular System

The underlying pathophysiologic mechanism of most critical cardiac conditions is a decrease in **cardiac output**, or the amount of blood the heart ejects each minute. A normal CO is 4–8 liters of blood per minute, illustrating the significance of the heart's function and the need for consistently maintaining an adequate CO. Bedside hemodynamic monitoring is often implemented in the ICU to assess CO and other parameters to determine the level

of functioning of the heart. See Table 35.2 for more information about hemodynamic parameters that are commonly monitored in the ICU.

Principles of Hemodynamic Monitoring

To understand the hemodynamic parameters being measured with invasive monitoring, it is important to become familiar with cardiac concepts that can directly influence heart function. As discussed in the chapter on the cardiovascular system, CO is calculated by multiplying the stroke volume, or the amount of blood ejected by the heart with each beat, by the heart rate, which is the number of heart beats per minute. Based on this formula, a decrease in heart rate will lower the patient's CO and an increase in heart rate will increase CO. However, it is important to recognize that although an increased heart rate can initially act as a compensatory mechanism to improve CO, eventually the heart will tire, resulting in a decreased CO.

In addition to heart rate, stroke volume also plays a significant role in the determination of CO and function. There are three main factors that influence stroke volume: preload, afterload, and contractility.

- The degree of stretch of the ventricle's cardiac muscles right before they contract is called preload. In other words, it is how much blood the ventricles can hold.
- The amount of resistance the ventricles must overcome to pump out blood with a contraction is called afterload. This resistance is influenced by several factors, including blood vessel tone and constriction, blood viscosity, and structural competency of the heart muscle.
- The strength of the contraction of the heart muscle itself is called **contractility**.

Changes to any one of these components can drastically affect the patient's stroke volume and overall CO.

Medical Assessments and Therapies

With knowledge of the mechanisms that influence CO, critical care nurses can assess and monitor hemodynamic parameters at the bedside with use of arterial catheters and pulmonary artery catheters. An **arterial catheter** is a small, flexible catheter that is inserted into either the radial or femoral artery and connected to monitoring equipment to reflect continuous blood pressure measurements. Figure 35.3 shows the different parts of an arterial line.

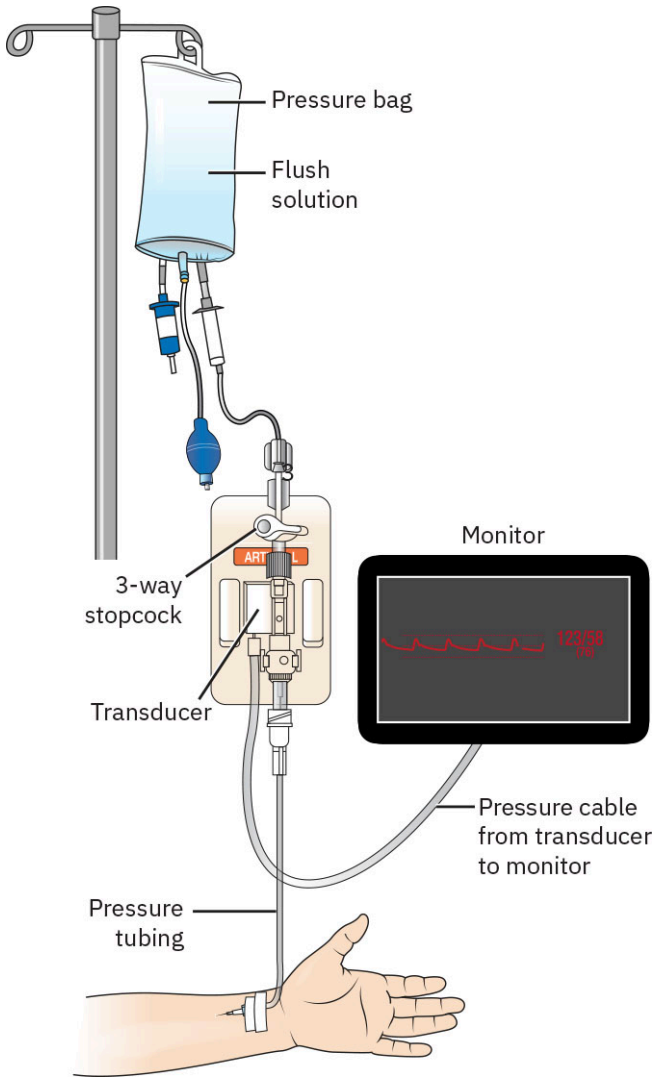

FIGURE 35.3 An arterial catheter is a small, flexible catheter that is inserted into either the radial or femoral artery and connected to monitoring equipment to reflect invasive blood pressure measurements. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

A pulmonary artery catheter, also known as a Swan-Ganz catheter, is a type of central venous catheter that is surgically inserted into the pulmonary artery and used to measure various pressures within the heart (Ziccardi & Khalid, 2023). Figure 35.4 shows the different parts of a pulmonary artery catheter. Pulmonary artery catheters assist with monitoring many different internal heart pressures, as listed and described in Table 35.2.

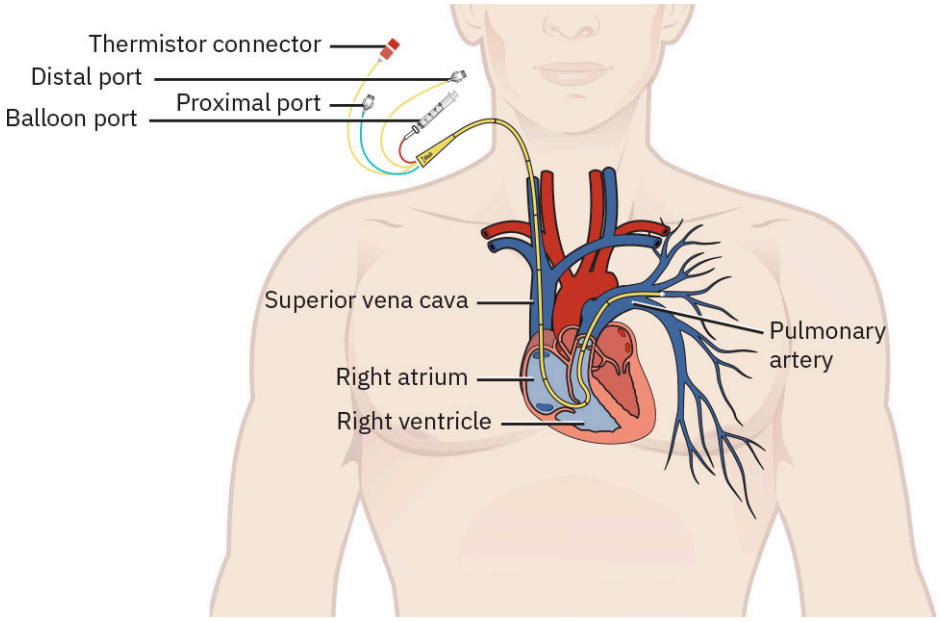

FIGURE 35.4 The distal end of the pulmonary artery catheter is placed in the pulmonary artery for pressure measurements. The other ports are connected to monitoring equipment and used to measure various internal heart pressures. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Hemodynamic Parameter	Description	Normal Range
Cardiac output (CO)	Amount of blood ejected from the ventricles each minute	4–8 L/min
Cardiac index	CO value that has been adjusted and personalized on the basis of the patient's body size and surface area	2.5–4.0 L/min/m^2
Stroke volume	Amount of blood ejected by the ventricle with each heartbeat	60–100 mL/beat
Right ventricular end-diastolic pressure	Reflects right ventricular preload	0–8 mm Hg
Left ventricular end-diastolic pressure	Reflects left ventricular preload	4–12 mm Hg
Right atrial pressure and central venous pressure	Interchangeable terms that reflect the pressure of the blood volume in the right side of the heart at the end of diastole	2–6 mm Hg
Pulmonary artery pressure	Pressure within the pulmonary artery	11–20 mm Hg at rest
Pulmonary artery occlusion ("wedge") pressure	Reflects the pressure in the left atrium; determined by injecting air into the balloon port, causing an occlusion or "wedge"	8–12 mm Hg
Systemic vascular resistance	Resistance that the left ventricle must overcome to pump blood to the body	800–1200 dynes/sec/cm^{-5}

TABLE 35.2 Commonly Monitored Hemodynamic Parameters and Their Normal Ranges

In addition to hemodynamic monitoring, there are several other diagnostic tests and procedures used in critical care settings to evaluate the function of the cardiovascular system. A description of these can be found in Table 35.3.

Diagnostic Test	Description	Clinical Significance
Chest radiography (X-ray)	Use of electromagnetic waves to produce images of the heart and surrounding structures	Used to evaluate the size and structure of the heart, heart positioning, abnormal fluid accumulation, and structural defects
12-Lead electrocardiogram	Noninvasive use of sticky leads placed on the chest and connected to a monitor to determine heart rate and rhythm by measuring internal electrical activity	Used to diagnose or rule out cardiac dysrhythmias and myocardial infarction
Echocardiogram	Noninvasive use of ultrasound waves to visualize the internal and external structure of the heart	Used to diagnose valve disorders, congenital defects, and cardiac tumors and to calculate ejection fraction
Cardiac catheterization	Invasive procedure that involves insertion of a catheter through the radial or femoral artery and advancing it up to the heart	Used to identify and determine the severity of blockages within the coronary arteries as the cause of the cardiogenic shock

TABLE 35.3 Common Diagnostic Tests and Procedures Used to Assess the Function of the Cardiovascular System

Pharmacological Supports

Medications used in critical care settings for cardiovascular support are called **vasoactive medications**, meaning they exert their effects on blood vessels and have the potential to significantly alter hemodynamics. Most of these medications are given intravenously and may only be administered in the ICU or progressive care unit (a.k.a., “stepdown units”), where there are more resources available for frequent hemodynamic monitoring. Additionally, doses of many of these drugs must be titrated by the critical care nurse according to standing orders and specific parameters set by the health-care provider to achieve optimal hemodynamic effects. A description of some of the most common classes of cardiovascular medications are presented in Table 35.4.

Medication Class	Examples (Example Brand Name)	Action	Side or Adverse Effects	Nursing Considerations
Beta-blockers	• Carvedilol (Coreg) • Metoprolol (e.g., Lopressor)	Block beta-adrenergic receptors, resulting in decreased heart rate, blood pressure, and heart contractility	• Asthma attacks • Bradycardia • Fatigue • Heart blocks Hypotension	• Consider holding a dose if heart rate is below 60 bpm. • Use caution in patients with diabetes, because these medications can mask signs of hypoglycemia.
Calcium channel blockers	• Amlodipine (Norvasc) • Diltiazem (e.g., Cardizem) • Nicardipine (Cardene)	Blocks flow of calcium into heart and blood vessels, resulting in muscle relaxation and a decreased workload on the heart	• Bradycardia • Dizziness • Headache • Heart blocks • Hypotension	• Consider holding a dose if heart rate is below 60 bpm. • If given orally, tablets cannot be crushed or chewed.
Inotropes	• Dobutamine (Dobutrex) • Dopamine (e.g., Intropin) • Milrinone (Primacor)	Improves CO by increasing heart contractility	• Extravasation and tissue necrosis at IV catheter site • Headache • Nausea/vomiting • Tachycardia • Ventricular ectopy	• Administer in a large vein, preferably through a central catheter. • Monitor heart rate, rhythm, and blood pressure closely. • Titrate dose to desired effects.

TABLE 35.4 **Common Classes of Cardiovascular Medications**

Medication Class	Examples (Example Brand Name)	Action	Side or Adverse Effects	Nursing Considerations
Nitrates	• Nipride • Nitroglycerin (e.g., Tridil)	Relaxation of smooth muscle in blood vessels, resulting in vasodilation and decreased workload of the heart	• Facial flushing • Hypotension • Lightheadedness • Severe headache	• Monitor blood pressure closely. • Titrate dose to desired effects.
Vasopressors	• Epinephrine • Norepinephrine (e.g., Levophed) • Phenylephrine (e.g., Neo-Synephrine) • Vasopressin	Vasoconstriction of blood vessels, resulting in an increased blood pressure	• Anxiety • Chest pain • Extravasation and tissue necrosis at IV catheter site • Hypertension • Tachycardia • Ventricular dysrhythmias	• Administer in a large vein, preferably through a central catheter. • Monitor heart rate, rhythm, and blood pressure closely. • Titrate dose to desired effects.

TABLE 35.4 Common Classes of Cardiovascular Medications

Nonpharmacologic Interventions

In addition to pharmacologic treatments, there are nonpharmacologic interventions that can be implemented in critical care settings to provide cardiovascular support. Most of these interventions are invasive and require complex medical equipment at the bedside, which must be monitored closely by the critical care nurse.

To decrease afterload and improve perfusion of the coronary arteries during diastole, **intra-aortic balloon pumps (IABPs)** are used. These devices are often used after invasive cardiac surgeries, with severe heart failure exacerbations, or after large myocardial infarctions (Khan & Siddiqui, 2023). The procedure involves the insertion of an introducer sheath into the femoral artery. The IABP catheter is then inserted into the sheath and advanced until the balloon part of the catheter is in the aorta. The IABP is often referred to as a counter-pulsation device, meaning that it inflates when the heart is not contracting (during diastole) and deflates during contraction (systole) (Figure 35.5.) When the balloon inflates during diastole, it pushes blood into the coronary arteries, which improves perfusion to the heart muscle and decreases cardiac workload. When the balloon deflates during systole, it reduces afterload, making it easier for blood to be pumped out to the rest of the body. IABPs are highly invasive and require specialized training to operate. Because they are inserted into a large artery, it is imperative that the ICU nurse monitor the patient closely for signs of bleeding or neurovascular changes such as a diminished pedal pulse, which may indicate thrombosis.

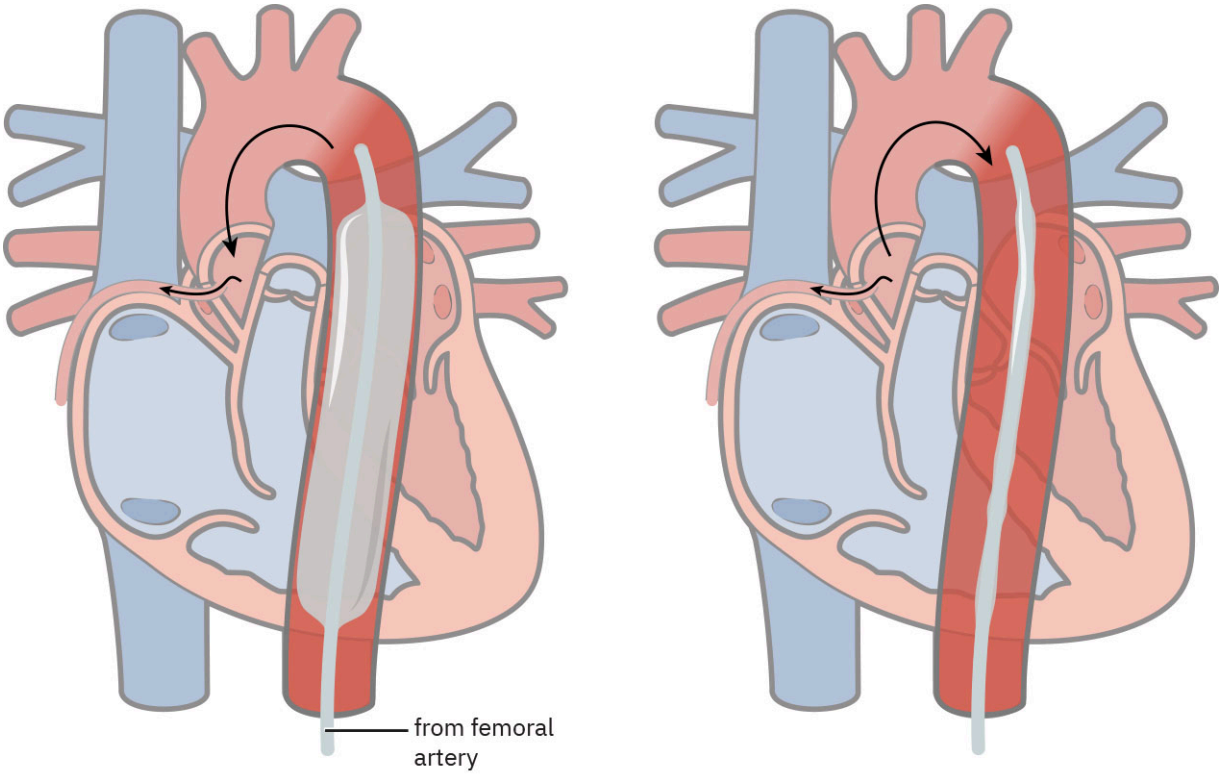

FIGURE 35.5 The intra-aortic balloon pump is inserted through the femoral artery and advanced to the aorta. (a) The pump inflates during diastole. (b) The pump deflates during systole. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Another invasive cardiovascular therapy that may occur in the ICU is **extracorporeal membrane oxygenation (ECMO)**. This procedure involves the use of a machine that acts as an artificial heart and lungs for the patient when their organs are not functioning at optimal levels. Blood is pumped from the right side of the heart to the ECMO machine, where it is oxygenated and warmed, and then sent back to the body (Figure 35.6.) Because the blood bypasses the heart and lungs, it gives them time to rest, which is important for patients who have experienced severe trauma or disease to these organs (Mayo Clinic, n.d.). ECMO is highly invasive and requires a high level of nursing skill to monitor and operate the equipment. Complications with ECMO are common and include bleeding, clotting, infection, and limb ischemia. Treatment of a patient receiving ECMO is interdisciplinary, inclusive of perfusionists who assist in the maintenance of the machine and a cardiologist who evaluates the response to the therapy.

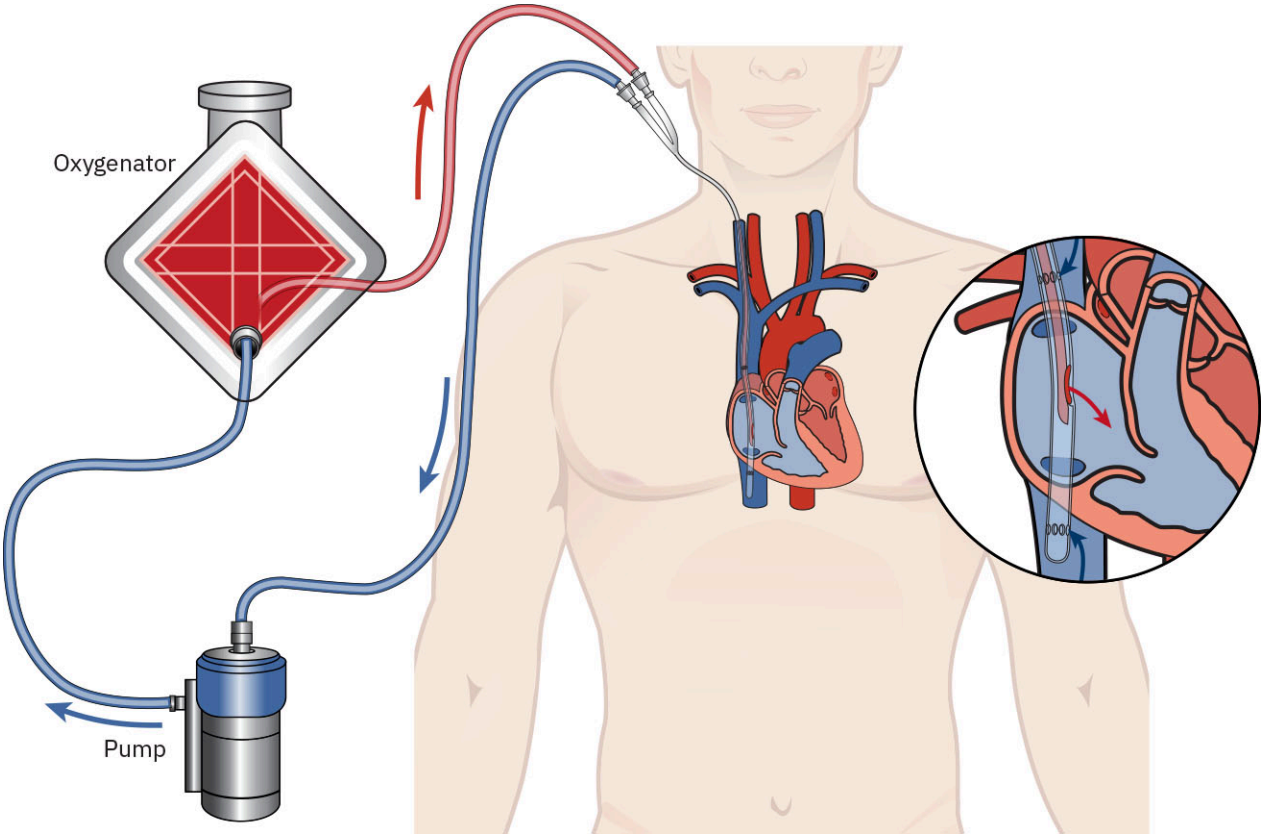

FIGURE 35.6 ECMO allows the patient's blood to bypass the heart and lungs. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

LINK TO LEARNING

Visit this overview of ECMO (https://openstax.org/r/77ecmo) provided by Yale Medicine.

External pacing, also called transcutaneous pacing, is another cardiovascular intervention that is performed in the ICU. This process involves the placement of electrode pads on the patient's chest to deliver shocks that keep the heart maintaining an adequate rate (Figure 35.7.) This procedure is performed when the patient is experiencing symptomatic bradycardia or some degree of heart block. This is only a temporary solution, however, and these patients will often need to be sent to the operating room quickly after initiation of the external pacing, to receive a permanent pacemaker.

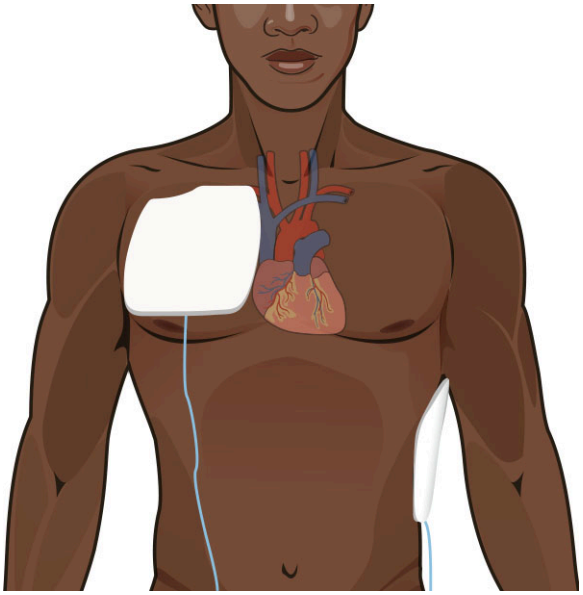

FIGURE 35.7 For transcutaneous pacing, electrode pads are placed on the patient's chest. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Exemplar: Cardiogenic Shock

Cardiogenic shock is a life-threatening cardiac disorder that may be experienced by patients in the ICU. Most often, this condition occurs secondary to a large **myocardial infarction (MI)**, or heart attack, but it can result as a secondary complication from many other disorders as well (National Heart, Lung, and Blood Institute. 2022).

Cardiogenic shock due to injury or death of the cardiac tissue causes the heart to stop pumping effectively. The inability of the heart to pump effectively results in severe hypotension and a lack of perfusion to all other body systems. This can lead to MODS.

When the heart is damaged, it loses some of its cardiac muscle strength and is unable to contract effectively. Without a strong heart contraction, less blood can be ejected, resulting in a decreased stroke volume and CO. The forward flow of blood backs up into the pulmonary system, resulting in fluid overload and hypoxia because the heart is no longer able to process the blood and pump it to other parts of the body. The heart will attempt to compensate for the decreased CO by increasing heart rate, but eventually the workload of the heart becomes too great and the body develops cardiogenic shock. Clinical manifestations of cardiogenic shock resemble those of left-sided heart failure, including

- crackles in the lungs
- diaphoresis
- hypotension
- S3 heart sound
- shortness of breath
- tachycardia

Treatment for cardiogenic shock focuses on determining and treating the underlying cause and decreasing the workload of the heart through both pharmacologic and nonpharmacologic interventions, some of which are discussed later in this section. Additionally, treatment involves providing supportive care to the rest of the body's organs and tissues that are negatively affected by decreased perfusion.

Nursing Concepts and Care

Nursing care of the critically ill patient experiencing cardiovascular dysfunction is complex and requires optimal clinical judgment and critical thinking skills. The nurse must be prepared to quickly intervene based on subtle changes in the patient's condition. These requirements are reflected within the Clinical Judgment Measurement Model, with each step of the model being explored further in the following sections.

Recognizing Cues and Analyzing Cues

First and foremost, critical care nurses must perform frequent assessments of the cardiovascular system. These assessments allow the nurse to detect subtle changes from baseline. Beyond physically assessing heart sounds and circulation (e.g., capillary refill, pulses), the nurse should closely monitor hemodynamic parameters such as CO and stroke volume and intervene as necessary on the basis of those findings.

Prioritizing Hypotheses, Generating Solutions, and Taking Action

Nursing care often involves administration of vasoactive medications that can significantly alter patient hemodynamics. Because of this, the nurse must have extensive knowledge of the mechanism of the medications and monitor and evaluate their effects closely. As with most medications administered in the ICU, frequent dose titrations, or adjustments, are based on the patient's hemodynamics and the physician's standing orders, requiring both careful assessment and attention to detail. Without proper attention to the effects of these medications, cardiovascular function may be greatly altered, resulting in systemic complications that could have otherwise been prevented. In addition to administering and titrating medications, the critical care nurse is responsible for maintaining invasive therapies such as IABPs and ECMO. These therapies present risks such as bleeding and thromboembolism, so the critical care nurse should be able to assess for these complications and intervene appropriately.

READ THE ELECTRONIC HEALTH RECORD

Caring for the Critically Ill Patient with Heart Failure

The nurse is caring for a patient admitted to the cardiac intensive care unit (CICU). Review the patient's electronic health record (EHR) and answer the questions that follow.

Nurse's note (0800):

- Patient brought to CICU from emergency department [ED]. ED nurse reports that the patient is exhibiting signs of biventricular heart failure. Pulmonary artery catheter was placed in the ED. Patient has been connected to the bedside monitor and vital signs are currently stable. Will continue to monitor.

Vital signs (0930):

- BP [blood pressure]: 90/52 mm Hg
- Cardiac index [CI]: 2–3 L/min
- CVP [central venous pressure]: 7 mm Hg

Vital signs (1030):

- BP: 82/52 mm Hg
- CI: 1–1.5 L/min
- CVP: 10 mm Hg

Current orders:

- Normal saline @ 100 mL/h (Widiarti et al., 2024)
- Dobutamine 5 µg/kg/min IV continuous infusion (titrate to maintain systolic BP >100 mm Hg)

1. What information in the EHR is the most concerning?
2. What other assessments should the nurse perform?
3. What action by the nurse would you anticipate?
4. What complications is this patient at risk for?

35.3 Respiratory Concerns

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiological changes to the patient's respiratory concerns when in the intensive care unit
- Describe the medical assessments and therapies that apply to the critical care patient's respiratory system
- Apply nursing concepts and plan associated nursing care for the critical care patient's respiratory system

One of the leading causes of ICU admissions is **acute respiratory failure (ARF)**, which is a sudden failure of the lungs that causes impaired gas exchange. The result is both hypoxemia, or low oxygen levels in the blood, and hypercapnia, or elevated carbon dioxide levels. In hypoxemia, body organs are not adequately perfused, leading to organ dysfunction and eventual failure. This highlights the importance of maintaining both a patent airway and adequate ventilation for patients in critical care settings. Without appropriate respiratory care, the patient's life is at risk and systemic complications may result.

Pathophysiological Insult to the Critical Care Patient's Respiratory System

Respiratory failure is common in critically ill patients, and the COVID-19 pandemic contributed to an increase in respiratory failure incidence over the last several years (Wilcox, 2020). There are two main types of respiratory failure: hypoxemic and hypercapnic (Mirabile, Shebl, Sankari, & Burns, 2023). These two types are briefly outlined in Table 35.5.

	Hypoxemic Respiratory Failure	Hypercapnic Respiratory Failure
Definition	The failure of the lungs and heart to provide adequate oxygen to meet the body's metabolic needs	The failure of the lungs to eliminate carbon dioxide (CO_2) from the body
Diagnostic criteria	Partial pressure of oxygen (PaO_2) <60 mm Hg without elevation of CO_2	Partial pressure of CO_2 ($PaCO_2$) >50 mm Hg (hypercapnia)
Causes	• Anemia • Diffusion defects • Hypoventilation • Intrapulmonary shunting • Low CO • Ventilation-perfusion mismatch	• Increased alveolar dead space • Increased CO_2 production • Intrapulmonary shunting • Pump failure (due to decreased respiratory drive or fatigue)

TABLE 35.5 Hypoxemic Versus Hypercapnic Respiratory Failure

Exemplar: Acute Respiratory Distress Syndrome

Acute respiratory distress syndrome (ARDS) is the most severe form of ARF, with a nearly 40% mortality rate (Siegel, 2022). Among other causes, studies have shown a direct correlation between severe COVID-19 cases and the development of ARDS. Other common causes of ARDS are listed in Table 35.6.

Direct causes	Fatty embolism Gastric aspiration Near-drowning Respiratory infection (e.g., COVID-19, pneumonia) Trauma resulting in chest or lung injury
Indirect causes	Burn injury Cardiopulmonary bypass Drug overdose Multiple blood transfusions Sepsis

TABLE 35.6 Common Causes of ARDS

The pathophysiology of ARDS is not well understood, but it appears to involve widespread lung inflammation after injury or insult, which results in an accumulation of fluid in the alveoli, or air sacs, of the lungs. Fluid-overloaded alveoli are not able to function effectively, which results in severely decreased gas exchange within the lungs and a decreased perfusion of oxygenated blood to the tissues. Assessment findings and diagnostic criteria associated with ARDS are listed in Table 35.7. Treatment for ARDS involves providing oxygenation, pharmacological interventions, and prone positioning, all of which are discussed in more detail later in this chapter.

Assessment findings	• Decreased level of consciousness • Dyspnea • Fine crackles in the lungs • Hypoxemia that does not improve with administration of oxygen • Restlessness or irritability • Tachypnea that results in respiratory alkalosis
Diagnostic criteria	• Acute onset (within 1 week) • Bilateral lung infiltrates on chest X-ray of noncardiac origin (ground-glass opacities) • Ratio of PaO_2 to the fraction of inspired oxygen <300 mm Hg

TABLE 35.7 Assessment Findings and Diagnostic Criteria for ARDS

Endotracheal Intubation and Mechanical Ventilation

Intubation refers to the placement of a flexible ETT through the patient's mouth or nose and into the trachea and airway. Most commonly, this is performed through the mouth and the tube is left in place so it can be connected to a ventilator to control the patient's respiratory efforts. At the end of the ETT is a distal cuff, or balloon, that is inflated with a small amount of air to keep the tube in place and seal off the trachea so that air passes through, and not around, the tube. An illustration of an ETT placement is shown in Figure 35.8. The ETT is secured with a harness that is threaded around the back of the patient's head and held in place with Velcro straps and padded stickers on the cheeks to prevent skin breakdown.

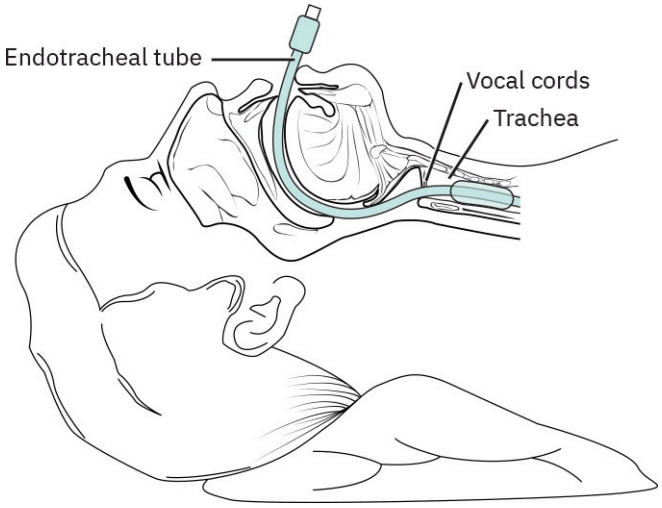

FIGURE 35.8 The endotracheal tube is placed through the trachea, with the end of the tube resting in the top portion of the airway. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Once the ETT has been placed, the nurse and RT collaborate to connect the tube to the ventilator. A ventilator provides mechanical ventilation that takes the place of the patient's own breathing and respiratory drive (Figure 35.9.) Successful placement of an ETT tube includes listening for air passage in all lobes, a chest X-ray to confirm placement, and end-tidal CO_2 measurements, which demonstrate appropriate ventilation. Ventilators are used for many conditions, some of which involve the patient being unable to adequately breathe on their own, such as ARF, or traumatic brain injury that interferes with the patient's respiratory drive. Ventilators provide several different modes and settings that can be adjusted according to the function of the patient's respiratory system. Some supplement the patient's initiated breaths; others deliver all breaths while the patient is sedated or pharmacologically paralyzed.

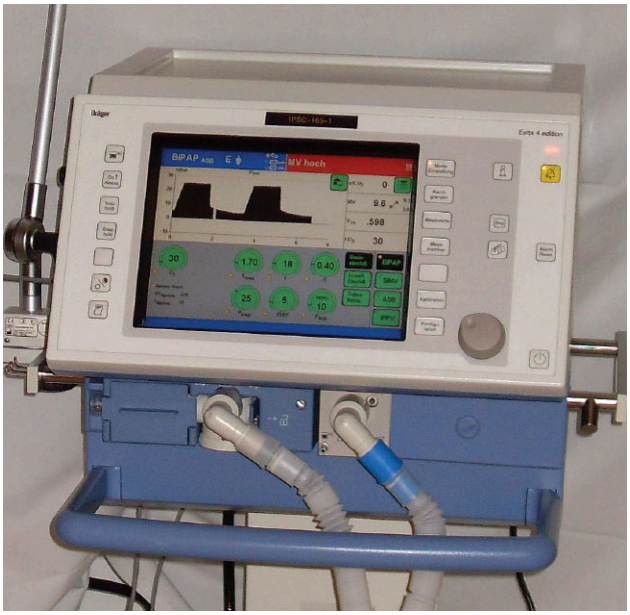

FIGURE 35.9 A ventilator provides mechanical ventilation that takes the place of the patient's own breathing and respiratory drive. (credit: "Respirator 'Evita4' on an ICU" by Blogotron/Wikimedia Commons, Public Domain)

Nurses work closely with the respiratory care team to ensure the correct ventilator mode is being used and that appropriate changes in settings are made on the basis of changes to the patient's condition. One of the main roles of the nurse when caring for patients connected to a ventilator is suctioning the airway as needed. Often, an in-line suction catheter is attached to the ETT, allowing for sterile suctioning of the airway at the bedside for patients with excessive respiratory secretions. Another role of the nurse when caring for a patient receiving ventilator assistance is communication with other team members, most notably the RT and provider, to ensure optimal functioning and management of the ventilator.

Exemplar: Ventilator-Associated Pneumonia

Though mechanical ventilators are necessary in many cases, their use increases the risk of aspiration and subsequent infection, which can result in ventilator-associated pneumonia (VAP), which is pneumonia that develops within 48 hours of the patient being intubated. The development of VAP has been linked to longer hospitalizations and increased health-care costs, indicating the important need for prevention measures in the critical care setting. Many ICUs have implemented intervention bundles that can help prevent the development of VAP. An example of one of these care bundles is presented in the following Quality and Safety Education for Nurses (QSEN) Feature Box.

CLINICAL SAFETY AND PROCEDURES (QSEN)

QSEN Competency: Evidence-Based Practice

Definition: integrate best current evidence with clinical expertise and patient and family preferences for delivery of optimal health care.

Evidence-Based Practice Strategies to Avoid VAP: VAP Practice Bundle.

The nurse will

1. maintain ETT cuff pressure,
2. keep the head of the bed elevated to at least 30°,
3. provide regular oral care with chlorhexidine swabs,
4. conduct daily awakening (“sedation vacation”) with assessment of need for continued intubation, and
5. administer prophylactic medications for stress ulcers and deep venous thrombosis.

Medical Assessments and Therapies

One of the most frequently used bedside diagnostic tests for assessing respiratory function and gas exchange in the ICU is arterial blood gas (ABG) measurement. This test involves obtaining a blood sample either by direct needle puncture of the radial artery (Figure 35.10) or from an arterial catheter. The sample is then processed and laboratory values reflect the patient’s oxygenation status. These values and their descriptions are listed in Table 35.8. Critical care nurses must understand the meaning of these values and collaborate with the respiratory therapy team to implement changes to the plan of care and interventions based on ABG findings.

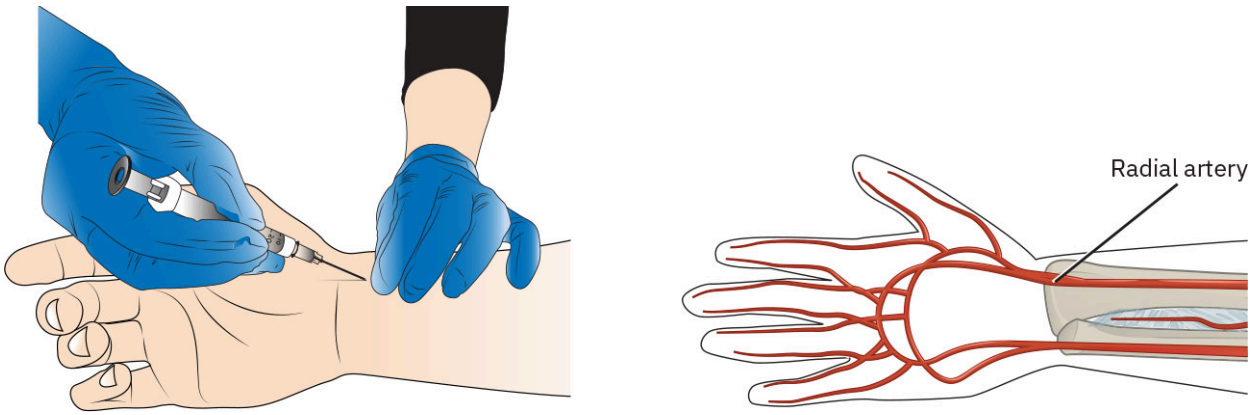

FIGURE 35.10 A direct needle stick to the radial artery obtains a sample for an ABG test. (a) The needle is inserted into the artery at a 45° angle. (b) The radial artery is located next to the radius of the arm. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

ABG Component	Normal Range	Description	Clinical Significance
PaO_2	80–100 mm Hg	The pressure of oxygen dissolved in the blood	• PaO_2 <60% indicates hypoxemia
pH	7.35–7.45	The concentration of hydrogen (H^+) ions in the blood	• pH < 7.35 indicates acidemia • pH > 7.35 indicates alkalemia
$PaCO_2$	35–45 mm Hg	The pressure of CO_2 dissolved in the blood	• $PaCO_2$ <35 mm Hg indicates respiratory alkalosis • $PaCO_2$ >45 mm Hg indicates respiratory acidosis
Bicarbonate (HCO_3^-)	22–26 mEq/L	A substance that acts as a base to neutralize acids in the body	• HCO_3^- <22 mEq/L indicates metabolic acidosis • HCO_3^- >26 mEq/L indicates metabolic alkalosis
Base excess or base deficit	−2 to +2 mEq/L	The sum of all buffer bases in the body	• Base deficit indicates metabolic acidosis • Base excess indicates metabolic alkalosis

TABLE 35.8 Components of an Arterial Blood Gas (ABG)

Pharmacological Supports

There are different classes of medications commonly given in critical care settings as part of care for the respiratory system. For patients receiving mechanical ventilation, use of sedatives and neuromuscular blocking agents (also called paralytics) may be indicated. These classes of medications are often used to minimize movement when patients are receiving ventilatory support; movement may potentially dislodge the ETT and compromise the patient's airway. It is important to temporarily pause these medications at least once per day to assess the patient's neurological status and continued need for intubation and mechanical ventilation. These periods are often called "sedation vacations," and they can be performed at the same time as spontaneous breathing trials (SBTs), which are discussed in the next section. In addition to sedation, patients receiving ventilatory support often receive IV opioid medications for pain relief. Placement of an ETT for long periods can cause pain, particularly when combined with immobility, so it is important for critical care nurses to frequently assess and treat patients for nonverbal signs of pain. This is especially important for patients receiving ventilatory support because they are unable to verbally communicate their pain level, requiring a degree of nursing assessment skills to determine pain level on the basis of body language and other nonverbal clues such as changes in vital signs.

Another class of medications used to treat severe respiratory conditions is corticosteroids. These are usually given through an inhaled nebulizer treatment or intravenously. The purpose of corticosteroids is to decrease the airway inflammation associated with many respiratory disorders. Use of corticosteroids poses some risks, including increased risk of infection due to immunosuppression, and episodes of hyperglycemia, so it is important for the critical care nurse to observe patients closely for adverse effects.

Prophylactic medications are usually given daily to patients receiving ventilatory support to prevent the development of stress ulcers and deep vein thrombosis (DVT), which are common in patients receiving mechanical ventilation. Medications for stress ulcers include sucralfate (e.g., Carafate), proton pump inhibitors (PPIs), and

histamine receptor blockers. DVT presents a risk for developing pulmonary emboli, which can result in respiratory complications and death. To prevent this, anticoagulants such as heparin or a low-molecular-weight heparin, such as enoxaparin (brand name, Lovenox), are administered subcutaneously.

Nursing Care

Most of the nursing care for patients in the ICU is related to care of the ETT and ventilator. First and foremost, critical care nurses are responsible for frequently monitoring ETT placement. If the tube becomes even slightly displaced, the ventilatory support being provided may not be efficient. Several times during the shift, the nurse should check the placement of the ETT to ensure it has not moved. Small markings on the ETT allow for easy visual assessment of placement at the lips. If the nurse determines that the tube may have migrated from its optimal position, it is imperative that they let the health-care provider know. It is likely that the patient will need an immediate X-ray to confirm tube placement.

Another aspect of nursing care for patients receiving mechanical ventilation is SBTs, which are overseen by the nurse and RT. SBTs involve switching the mode on the ventilator to a setting that allows for assessment of the patient taking breaths on their own. If the patient can breathe effectively in this mode and does not show any other signs of agitation or abnormal vital signs, they may be ready for removal of the ventilator and ETT. The main role of the nurse during this process is turning off the sedation and neuromuscular medications and paralytics so that the patient is fully awake and able to participate in the breathing trial process. Turning off the sedation can be startling to the patient who wakes up with an ETT in their throat, so the nurse must be present and able to communicate the process to the patient to ease their anxiety and prevent them from pulling out essential catheters and tubes. Current practices use risk assessment models such as the Richard Agitation Sedation Scale to gauge a patient's mental status when progressing on drug holidays (Sharma et al., 2024)

Finally, prone positioning has often been used in the ICU for patients with respiratory conditions, especially those with ARDS related to COVID-19. Prone positioning entails the patient lying on their abdomen, which enables gravity to improve perfusion to more parts of the lungs. This process is highly complex, especially when patients are connected to a ventilator and other invasive equipment. Proning a patient requires the assistance of several staff members to ensure the patient can be safely positioned without disruption of their equipment and catheterss. In the past several years, there have been developments in proning beds that provide protective padding for both the patient and their equipment, and make positioning much easier. A picture of one of these beds is shown in Figure 35.11.

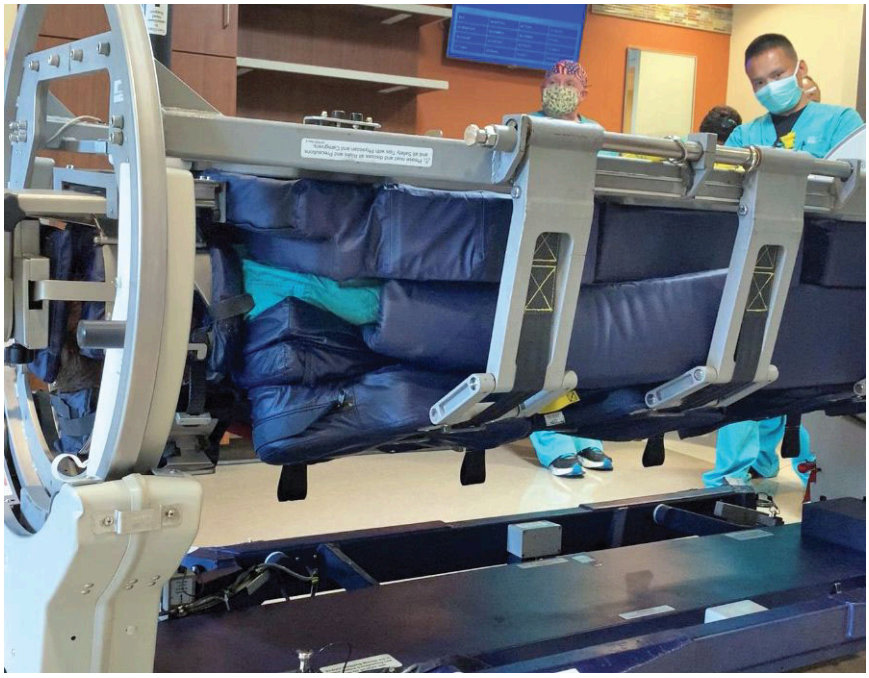

FIGURE 35.11 A padded proning bed in used in the ICU to safely position an intubated patient. (credit: Defense Visual Information Distribution Service, Public Domain)

35.4 Neurological Concerns

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiological changes to the patient's neurological system when in the intensive care unit
- Describe the medical assessments and therapies that apply to the critical care patient's neurological system
- Apply nursing concepts and plan associated nursing care for the critical care patient's neurological system

The neurological system is involved in consciousness and the control of physical movement and vital functions in the medulla, such as breathing, heart rate, and thermoregulation. Critically ill patients often have neurological system dysfunction that may result in serious systemic complications and permanent physical disabilities. For many patients, frequent neurological assessment and interventions are key components of nursing care in the critical care setting.

Pathophysiological Insult to the Critical Care Patient's Neurological System

The underlying pathophysiologic mechanism behind many neurological disorders observed in critical care settings is increased intracranial pressure (ICP). This pressure is normally between 1 and 20 mm Hg (Pinto, Tadi, & Adeyinka, 2023). Without intervention, sustained increased ICP can result in severe, permanent complications and death for the patient while in the hospital and upon discharge.

The cranium contains three main elements: the brain, CSF, and blood. The Monroe-Kellie Doctrine concludes that a change in one of these three components must be compensated for by another component (Teach Me Surgery, 2020). For example, if a patient is experiencing brain swelling, there needs to be a decrease in either blood or CSF volume to account for the extra space the swelling is now taking up. An elevation in ICP is observed when there is an increase in any one of the three components without adequate compensation from the other two. Some of the common causes of increased ICP are:

- brain tumors or hematomas
- cerebral edema (e.g., traumatic brain injury)
- increased CSF production (hydrocephalus)
- infections of the central nervous system (e.g., meningitis)
- structural abnormalities (e.g., stroke, aneurysms)

There are several key assessment findings that are indicative of increased ICP. The first sign, and one that is easy to miss, is a decrease in the level of consciousness (LOC). If the patient appears more drowsy than usual or slightly confused, it may indicate an early sign of increased ICP. The nurse can use the Glasgow Coma Scale (see Chapter 17 Nervous System and Chronic Diseases of the Nervous System) to observe neurological changes from the patient's baseline.

LINK TO LEARNING

For more information, go to this website about the Glasgow Coma Score (https://openstax.org/r/77glasgow) from First Aid for Free.

Another important assessment for patients at risk for increased ICP is the pupillary response. Pupillary dilation and lack of reactivity are associated with increased ICP and other neurological disorders. Another finding directly related to increased ICP is a combination of three factors, called Cushing's triad: (1) bradycardia, (2) irregular respirations, and (3) systolic hypertension with widening **pulse pressure**, or the difference between the systolic and diastolic blood pressures

Additional signs of increased ICP include headache, blurred vision, and projectile vomiting, often without nausea. Abnormal posturing is another sign: with decorticate posturing, the patient pulls their arms into their chest; with

decerebrate posturing, the patient's arms are flexed at the sides (Figure 35.12). If any signs of increased ICP are noted, quick intervention is necessary to prevent severe neurological complications.

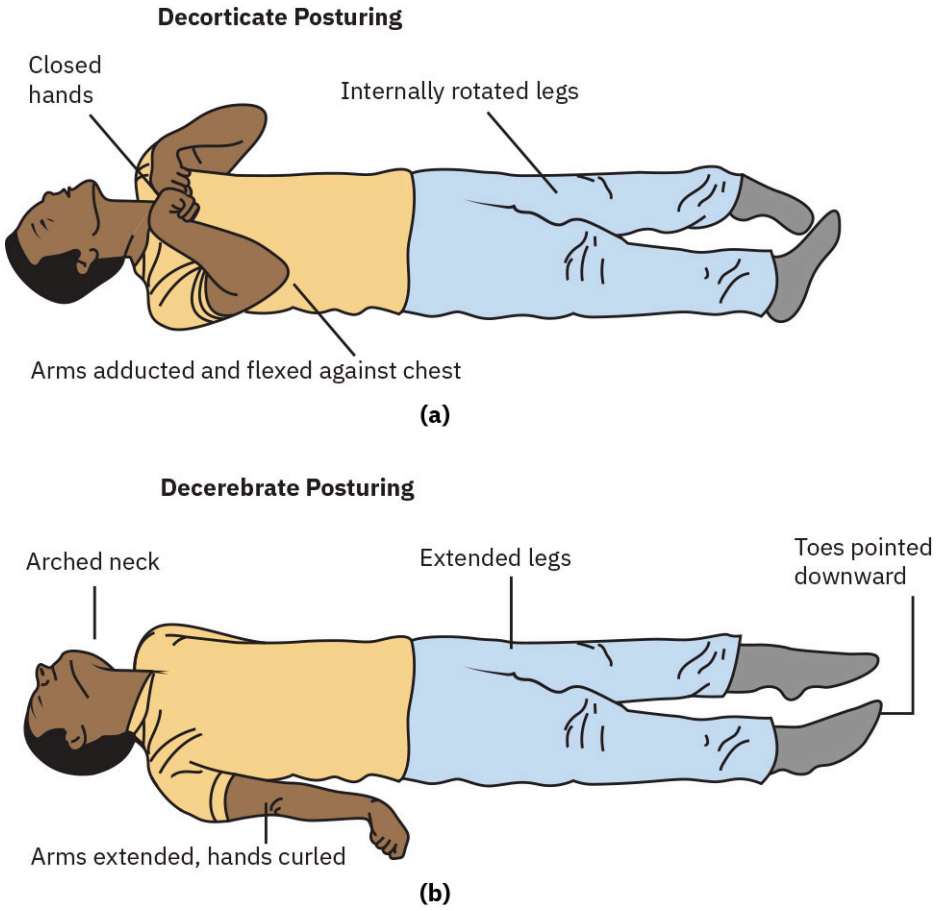

FIGURE 35.12 Both (a) decorticate positioning and (b) decerebrate posturing may be observed with increased ICP and brain injury. Decerebrate posturing indicates a more severe brain injury. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Exemplar: Traumatic Brain Injury

A common reason for admission to the ICU is traumatic brain injury (TBI). Annually, 2.8 million people in the United States will have a TBI, with more than 250,000 cases requiring hospitalization (Michael et al., 2023). Traumatic brain injury often occurs with trauma and can involve skull fractures, hematomas, and concussions, all of which have the potential to increase ICP. The treatment for TBI is similar to that for increased ICP, which is discussed in more detail in a later section.

Medical Assessments and Therapies

In addition to frequent neurological assessments, which are often a standard of care in the ICU, several other diagnostic tests are used to assess the function of the neurological system. These diagnostic tests and procedures are outlined in Table 35.9.

Diagnostic Test	Description	Clinical Significance
Computed tomography (CT) scan	Use of X-rays to create three-dimensional images of internal brain structures	A CT scan is often the first diagnostic test used to detect neurological issues. If abnormalities are noted, further testing is usually indicated. Contrast dye is used cautiously with patients who have existing allergies and renal impairment.
Magnetic resonance imaging (MRI)	Use of magnetic fields and radio waves to generate detailed images of internal brain structures	MRI is often performed after abnormality is noted on a CT scan. MRI provides more detailed images of the brain, allowing for easier diagnosis.
Electroencephalogram (EEG)	Use of small electrodes attached to the scalp that transmit electrical brain activity	An EEG is used to detect seizure activity or a lack of electrical activity that may indicate severe brain injury or death.

TABLE 35.9 Common Neurological Diagnostic Tests Used in the Critical Care Setting

Pharmacological Supports

Several different medications are commonly administered in the ICU to treat neurological disorders. The main medication used for increased ICP is mannitol, which is an osmotic diuretic. Mannitol works by pulling water out of the brain and back into the vessels. It is administered intravenously and should only be given when ICP can be closely monitored and frequent neurological assessments can be performed. If administered too quickly, mannitol can cause severe shifts in brain fluid status, which will worsen neurologic dysfunction. Other side effects of mannitol include: dehydration, electrolyte imbalances, hypotension, and rebound cerebral edema.

For cerebral edema and swelling, corticosteroids such as dexamethasone (e.g., Decadron) or methylprednisolone (e.g., Solu-Medrol) are often used. These medications decrease inflammation by suppressing white blood cells, which can improve brain swelling. Lastly, patients at risk for or who are having active seizures can be treated with an IV antiseizure medication such as levetiracetam (e.g., Keppra). Side effects to monitor for with use of levetiracetam include anemia, muscle weakness, and suicidal ideation or psychosis.

Nursing Care

Most of the nursing care for patients experiencing neurological dysfunction in the ICU centers around interventions to decrease ICP. In addition to pharmacologic interventions, there are several other ways critical care nurses can reduce the patient's ICP. First, the nurse should ensure the patient is receiving adequate oxygenation; if the brain is not receiving enough oxygen to function at its full capacity, hypoxia can make ICP worse. It may be necessary to change the settings on the mechanical ventilator to ensure adequate oxygenation and effective brain perfusion.

Another important aspect of nursing care for patients with neurological disorders and increased ICP is blood pressure management. It is vital that the nurse titrate medications or administer fluids as necessary to maintain an adequate mean arterial pressure (MAP). MAP must be between 70 and 90 mm Hg to ensure that cerebral perfusion pressure (CPP), or perfusion of oxygen and blood to the brain tissue, is adequate for optimal functioning. Lastly, the critical care nurse should implement interventions to decrease the body's metabolic demands. Decreasing these demands permits the body and brain to rest and heal accordingly. Table 35.10 lists key interventions for reducing metabolic demands and ICP.

Intervention	Description
Targeted temperature management (TTM)	• Body temperature is lowered to a state of hypothermia, which decreases the metabolic demands of the brain. • TTM may be performed noninvasively by placing cooling blankets or ice packs directly against the skin. • Target temperature varies by hospital protocol but is typically between 33 and 36 °C (91.4–96.8 °F). • Hypothermia is maintained for 24 hours, and then patient is slowly rewarmed to assess neurological function.
Sedation	• Sedative medications are administered to reduce pain, irritability, and movement, all of which can increase ICP. Sedation also reduces the increased risk of metabolic demand, because this makes ICP worse. Laxatives and stool softeners are administered to reduce straining and constipation, which also increase ICP.
Surgical intervention	• A craniectomy, or partial removal of the skull bone, can be used to improve brain swelling. • A ventriculostomy or shunt can be placed to remove excess CSF (based on parameters provided by the provider) and decrease ICP.
Maintain low-stimuli environment	• Limit visitors and procedures and keep room dim and quiet to allow patient to rest and prevent increased ICP.
Body positioning	• Keep patient's head midline, avoid hip flexion, and elevate the head of the bed to 30° to promote drainage of CSF and decrease ICP.

TABLE 35.10 Interventions and Protocols to Reduce Metabolic Demands and ICP (Teach Me Surgery, 2020)

35.5 Gastrointestinal Concerns

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiological changes to the patient's gastrointestinal concerns when in the intensive care unit
- Describe the medical assessments and therapies that apply to the critical care patient's gastrointestinal system
- Apply nursing concepts and plan associated nursing care for the critical care patient's gastrointestinal system

The gastrointestinal (GI) system is often overlooked for critical care patients because it may be viewed as less important than evidently life-sustaining body systems such as the cardiovascular or respiratory systems. However, the GI system plays an essential role in nutrient absorption, fluid and electrolyte balance, and provision of energy for the maintenance of overall body metabolism. Critically ill patients are at risk for adverse GI effects and complications if this system is not properly assessed and treated as part of the patient's plan of care while in the ICU. For these reasons, care of the GI system should be a nursing priority in addition to the care provided for all other body systems.

Pathophysiological Insult to the Critical Care Patient's GI System

The most common reason for admission to the ICU related to the GI system is acute bleeding. One of the main causes of GI bleeding is the presence of bleeding stress ulcers, usually in the stomach or intestines. These ulcers

often begin as peptic ulcer disease (PUD) and can quickly become life-threatening if they rupture and bleed.

Another common cause of GI bleeding is related to **esophageal varices**: small veins that form when portal hypertension is present, often due to alcoholic cirrhosis liver disease. Esophageal varices are only able to withstand low blood pressure, so they are prone to rupture and bleeding, especially in patients with chronic hypertension.

Common assessment findings for patients with acute GI bleeding are:

- abdominal pain or cramping
- anemia
- cool, clammy skin
- decreased LOC
- decreased urine output
- **hematemesis** (bloody vomitus)
- hypoactive bowel sounds
- hypotension
- **melena** (bloody stools) and/or dark tarry stools
- tachycardia

Medical Assessments and Therapies

A complete blood cell count (CBC) and comprehensive metabolic panel can be used to detect the presence of GI bleeding. Results may show hemoglobin and hematocrit levels to be normal at first but then decreasing. Platelet count may initially increase to maintain clotting and stop the bleeding, but it decreases as platelets are used up. Other common laboratory values that may indicate a GI bleed are:

- elevated blood glucose level
- increased blood urea nitrogen (BUN) and serum creatinine levels
- increased partial thromboplastin time or increased prothrombin time
- increased serum lactate level
- increased white blood cell count due to inflammation

If an acute GI bleed is suspected, the patient will likely be scheduled for an emergent endoscopy. This procedure involves the insertion of an endoscope through either the esophagus (for upper GI bleeds) or rectum (for lower GI bleeds) to enable direct visualization of the potential bleeding site. During this procedure, if bleeding is noted, the provider can use a laser on the end of the scope to cauterize the bleeding so that it stops completely or at least slows.

Pharmacological Supports

There are several medications that are indicated for a critically ill patient experiencing an acute GI bleed. First, use of antibiotics is often implemented because the development of stress ulcers has been linked to bacterial infections by *Helicobacter pylori* (Zhang et al., 2021). Patients are prescribed a2-week course of antibiotics to eradicate the bacteria completely and prevent the development of additional ulcers in the future. Most patients experiencing bleeding from stress ulcers will also be recommended to take a PPI such as omeprazole (e.g., Prilosec) or pantoprazole (Protonix) to decrease gastric acid secretion and allow for complete healing of the ulcer. If the bleeding originates from esophageal varices, octreotide (Sandostatin) can be used to stop the bleeding. This medication works by reducing pressure within the portal vasculature, which slows bleeding. It is important to note that these medications should all be administered intravenously, because patients with acute GI bleeds should not ingest anything by mouth; this allows their GI system to rest and heal.

Nursing Care

Patients presenting with acute GI bleeds are immediately placed on “nothing by mouth” (NPO) restrictions. Thus, all medications will be administered intravenously instead of orally, and the patient will not be allowed to eat or drink until the bleeding has resolved. This allows the GI system to rest and heal without the added stress of having to process food and medications.

The immediate priority when caring for patients with acute GI bleeding is maintaining hemodynamic stability. Gastrointestinal bleeds can quickly become life-threatening without medical intervention. It is important for the

nurse to closely monitor the patient's hemodynamic status and vital signs and intervene as needed. Patients with GI bleeding may require IV fluid replacement or multiple blood transfusions to restore lost blood volume (DiGregorio & Alvey, 2022). They may also require the use of vasopressor medications if they are experiencing severe hypotension from the loss of blood. For patients requiring blood transfusions, it is important to ensure that informed consent has been obtained from either the patient or the patient's DPOA agent if they are unable to give consent. Some patients will not be agreeable to receiving blood transfusions because of personal or spiritual beliefs.

The insertion of a nasogastric tube (NGT) is often indicated for patients with acute GI bleeding; therefore, nurses must be familiar with and comfortable performing this skill quickly at the bedside. After insertion, the NGT is typically connected to low, intermittent suction. This level of suction allows for blood and other gastric contents to be pulled out of the patient's stomach in a slow, controlled manner.

CLINICAL SAFETY AND PROCEDURES (QSEN)

QSEN Competency: Safety

Definition: Minimizes risk of harm to patients and providers through both system effectiveness and individual performance.

Skills Checkoff: NGT Insertion

1. Wash hands.
2. Don appropriate personal protective equipment.
3. Explain procedure to patient.
4. Ask patient about potential contraindications (e.g., deviated septum, facial trauma).
5. Check nostril patency. Have the patient occlude one nostril and assess breathing through the other nostril. Determine which nostril provides better airflow and should be left open.
6. Estimate length of tube to be inserted by measuring the end of the tube from the tip of the patient's nose to the earlobe and then down to the xiphoid process. Mark this spot on the tube with tape or a marker or note the correct black measurement marking printed on the tube.
7. Lubricate the tip of the NGT with KY jelly or petroleum-based lubrication.
8. Gently insert the tip of the NGT into the chosen nostril and slide it along the nasal cavity floor, aiming the tube down and back.
9. Have the patient take sips of water through a straw while you insert the tube to facilitate its passage down the esophagus. Continue advancing the tube until the predetermined length of tube has been inserted.
10. If the patient is severely gagging or has a hoarse voice, or if oxygen saturation is decreasing, remove the tube immediately because it may be located in the airway.
11. Use hospital protocol to check correct placement of NGT. This typically involves use of a chest X-ray or aspiration of gastric fluid to check pH.

35.6 Renal Concerns

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiological changes to the patient's renal system when in the intensive care unit
- Describe the medical assessments and therapies that apply to the critical care patient's renal system
- Apply nursing concepts and plan associated nursing care for the critical care patient's renal system

The kidneys play many major roles in the body, most notably the filtration of toxins and control of blood pressure and hydration status. Without optimal kidney functioning, perfusion to body organs will be decreased and there will be a resulting buildup of toxins and electrolytes that can result in life-threatening systemic complications. For that reason, it is imperative to prioritize care of the renal system for all critically ill patients.

Pathophysiological Insult to the Critical Care Patient's Renal System

Although some patients may be admitted to the ICU for a primary kidney issue, most often, patients are admitted for an issue within another body system but then experience acute kidney injury due to the nature of their illness or

from medical interventions. Certain medications administered in critical care settings are **nephrotoxic**, or capable of causing renal damage, and some procedures also pose the risk of causing acute kidney injury. Therefore, it is important to closely monitor renal function and intervene as soon as the patient is at risk of injury.

Exemplar: Acute Kidney Injury

We define **acute kidney injury (AKI)** as a sudden reduction in kidney function. It is caused by an insult to the nephron unit that manifests with alteration in laboratory values and decreased urine output. There are many etiologies for the development of AKI (Goyal et al., 2022), several of which are listed in Table 35.11.

Etiology	Causes
Hypovolemia	• Burn injury • GI fluid loss (e.g., vomiting, diarrhea) • Sepsis
Severe hypotension from decreased CO	• Cardiogenic shock • GI bleed • Massive pulmonary embolism • MI
Severe hypotension from widespread vasodilation	• Anaphylactic shock • Effects of general anesthesia • Septic shock
Renal vasoconstriction	• Nephrotoxic medications • Overuse of nonsteroidal anti-inflammatory drugs • Use of contrast media during imaging procedures

TABLE 35.11 Common Etiologies of Acute Kidney Injury (AKI)

AKI can be classified into one of three categories on the basis of its etiology. These three classifications are defined and described in Table 35.12.

Classification Category	Definition	Clinical Examples
Prerenal causes	Conditions that result in decreased perfusion to the kidneys	• Burn injury • Hemorrhage • Hypovolemic shock • Prolonged vomiting or diarrhea
Intrarenal causes	Conditions that result in direct damage to kidney tissue itself	• Nephrotoxic medications (e.g., aminoglycosides, contrast media) • Prolonged ischemia from prerenal causes
Postrenal causes	Conditions that block the outflow of urine	• Benign prostatic hyperplasia • Blood clots • Renal stones or tumors

TABLE 35.12 Classification of the Causes of AKI

Medical Assessments and Therapies

Diagnosing AKI involves close evaluation of serum laboratory values, especially creatinine and BUN. Serum creatinine is a breakdown product of skeletal muscle. It is made at a relatively stable rate and so is a good laboratory value to use for the diagnosis of AKI when alterations are noted. An increase in serum creatinine level may indicate an early sign of AKI: as renal function decreases, the kidneys are unable to filter out the excess creatinine at the same rate as when they are optimally functioning. Blood urea nitrogen is a breakdown product of protein metabolism, so elevations in this value may indicate the kidneys are unable to effectively excrete the excess protein byproducts. However, there are other conditions beyond AKI that can increase BUN level, such as dehydration or GI bleeding; therefore, although important, it is not the most reliable indicator of AKI on its own.

Trends in glomerular filtration rate (GFR) should also be monitored closely to determine the level of functioning of the kidneys. Glomerular filtration rate is a measurement of how quickly the kidneys can filter out toxins and other waste products. A decrease in GFR indicates the kidneys are unable to filter as quickly as they could when functioning at an optimal level. The trend of the GFR will also influence medication therapy selection and dosing to avoid toxic level accumulation.

Beyond laboratory values, several imaging procedures may be used to diagnose kidney injury. These include renal ultrasound, CT scans, and renal angiography. The main concern with these procedures is that they often necessitate the use of nephrotoxic contrast media for better visualization. It is important to weigh the risks versus benefits of performing these procedures with contrast, depending on the patient's current renal status (Davenport et al., 2020).

Pharmacological Supports

Most of the pharmacological interventions for AKI are focused on maintaining optimal fluid and electrolyte balance. Patients experiencing prerenal causes of AKI may require IV fluid replacement to restore renal perfusion. For patients experiencing intra- or postrenal causes of AKI, use of diuretics to remove excess fluid and toxins may be indicated. It is important to note that diuretics have some nephrotoxic qualities; they should be used cautiously, with the lowest dose, to avert further damage. The decision to give IV fluids or diuretics is based on the specific cause of the AKI and the patient's current renal status.

When the kidneys are not functioning at their highest level, they are often unable to excrete electrolytes effectively. This can result in a buildup of some electrolytes in the body, with hyperkalemia being a significant resulting electrolyte imbalance. Elevated levels of potassium can result in life-threatening cardiac dysrhythmias. Patients with hyperkalemia will require continuous telemetry to monitor for dysrhythmias. Often, these patients will require the administration of sodium polystyrene (e.g., Kayexalate) to help the body excrete potassium and maintain a normal electrolyte balance. Administration of dextrose with insulin assists with mobilization of excess potassium into the intracellular fluids. Another therapy, calcium gluconate, has been used emergently by stabilizing hyperexcitability of myocardial cells, which is caused by excess potassium. In some cases, emergency dialysis may be required to remove the potassium more quickly.

Another important consideration when caring for patients with AKI is limiting the use of medications that may further harm the kidneys. Many medications, most notably antibiotics, are nephrotoxic. The nurse should work closely with the pharmacist to ensure that patients with or at risk for AKI are receiving the lowest doses possible of these medications to prevent worsening of the kidney injury.

Nursing Care

Because of the kidney's role in the maintenance of fluid balance, a priority aspect of nursing care for patients with AKI is measuring and recording strict intake and output data. A decrease in urine output can be one of the first signs of AKI; hence, it is vital that the nurse be attentive to any changes in urination, even subtle ones. Additionally, weighing the patient at the same time daily and comparing measurements is important. Every pound of weight gain is associated with a liter of fluid accumulation; therefore, these measurements can show fluid retention that may indicate AKI. Other deviations the nurse may observe are hypertensive blood pressures, due to fluid volume excess, and irregular heart rates and alteration of mentation, due to electrolyte disturbance. Lastly, appropriate use of medications is essential. There are many nephrotoxic medications whose risks and benefits must be determined before administration. Some of these medications are:

- aminoglycoside antibiotics (e.g., gentamicin, tobramycin)

- antivirals (e.g., acyclovir, nirmatrelvir co-packaged with ritonavir [brand name, Paxlovid])
- diuretics (e.g., furosemide)
- NSAIDs (e.g., ibuprofen, naproxen)
- vancomycin

CULTURAL CONTEXT

AKI and Ethnicity

Nurses must be aware that certain ethnic groups and patients with chronic comorbidities are at risk for AKI. Black, Hispanic, American Indian, and Alaskan Native people carry the highest risk for kidney failure (National Institutes of Health, 2023). Comorbid conditions, such as uncontrolled diabetes, hypertension, and hyperlipidemia, and risk factors, such as smoking, obesity, and use of certain recreational drugs, also place patients at risk. Nurses must reconcile all active medications against the EHR to spot patterns for potential new nephrotoxic agents. If identified early, and with the proper assessment and implementation of treatment, AKI can be reversed.

35.7 Integumentary Concerns

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiological changes to the patient's skin when in the intensive care unit
- Describe the medical assessments and therapies that apply to the critical care patient's integumentary system
- Apply nursing concepts and plan associated nursing care for the critical care patient's integumentary system

The skin, which is part of the integumentary system, is the largest organ of the body. It serves several important purposes, including thermoregulation and protection of internal body structures from injury and infection. The most-encountered integumentary system issue in critically ill patients is the development of pressure injuries and ulcers. In fact, studies have shown that anywhere from 8% to 23% of patients in the ICU will develop a pressure ulcer during their hospital stay (Krupp & Monfe, 2015). Because the development of **hospital-acquired pressure injuries (HAPIs)**, or pressure ulcers that are acquired during an inpatient hospital stay, increases health-care costs and negatively affects patient outcomes, it is an area of nursing research that has received a lot of attention in recent years.

Pathophysiological Insult to the Critical Care Patient's Integumentary System

Nursing care in the ICU is usually focused on performing life-saving medical interventions, so taking care of the patient's skin is often not treated as a high priority. However, skin breakdown can lead to **necrosis**, or tissue death, and contribute to the development of life-threatening infections, increasing the overall length and cost of hospitalizations. As a result, it is important for the critical care team to prioritize patient skin care (Spader, 2018).

Exemplar: HAPIs

In addition to negatively affecting patient outcomes, the development of pressure injuries while in the hospital is especially concerning because the Centers for Medicare & Medicaid Services will not reimburse hospitals for their treatment. These factors have resulted in many hospitals conducting their own research and implementing unit-specific policies to promote the prevention of skin breakdown.

Although pressure injuries can occur in any area of the hospital, it is common to see the highest rates within critical care settings. There are many factors specific to critical care settings that increase the risk of skin breakdown and the development of pressure injuries, including

- fluid volume replacement and resulting fluid overload causing edema and tissue breakdown
- hemodynamic instability that worsens with immobility
- medical device placement that puts pressure on the skin surface
- poor nutritional status resulting in delayed wound healing
- prolonged periods of immobility

- urinary and fecal incontinence
- vasoactive IV medications resulting in decreased tissue perfusion

Integumentary System in Critical Care

Although a thorough skin assessment should be conducted by the critical care nurse at a minimum of once per shift, special attention should be given to the most common sites of skin breakdown. These sites, which are found over bony prominences, include the coccyx, buttocks, sacrum, and heels.

Risk Assessment Scales

The use of assessment scales to calculate the risk of skin breakdown can be helpful for determining who will benefit from more frequent interventions to prevent skin breakdown. The most-used skin risk assessment scale in critical care settings is the Braden Scale. This scale assesses risk factors for skin breakdown, including the patient's sensory perception, skin moisture, mobility level, and nutrition status, to calculate a score that indicates their risk level. A low score on the Braden Scale indicates the patient has an increased risk for skin breakdown and subsequent pressure injury development. Hospital and unit protocols will vary, but it is typical to perform and document this scale score at least once per shift. Given the propensity for a critically ill patient to be bed bound, use of the Braden Scale identifies risk for skin integrity issues (Kennerly et al., 2022).

LINK TO LEARNING

Visit this source from the Agency for Healthcare Research and Quality to see a copy of the Braden Scale (https://openstax.org/r/77bradenscale2) and to learn more about preventing pressure injuries.

Nursing Care for the Prevention of Pressure Injuries

Many critical care units have implemented care bundles—groups of related, evidence-based care interventions—designed to decrease the incidence of pressure injuries. The included interventions will vary depending on the specific hospital and unit, but they often involve manual turning, specialty beds, and prophylactic dressings.

Manual Turning Protocols

Most critical care units have adopted some kind of manual turning protocol in which the nursing staff physically turns and repositions patients in bed when the patient cannot do it themselves (Padula & Black, 2019).. This is especially important for patients who are immobile or have difficulty repositioning themselves. Protocols usually call for manual patient repositioning every 2 hours, alternating the side of the body that the patient is lying on by placing pillows underneath them and elevating their heels (Figure 35.13). This practice has been shown to improve the incidence of skin breakdown in the ICU, but it can be difficult for nursing staff to keep up with the frequent manual turns, indicating the need for other options such as specialty beds and mattresses. It is also important to note that some patients in the ICU are not hemodynamically stable enough to tolerate even slight turns, so these patients are at an even higher risk for skin breakdown.

FIGURE 35.13 Patients who are immobile should be manually repositioned every 2 hours to prevent skin breakdown. Pillows are used to maintain the patient's position. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Specialty Pressure Beds

Over the last 2 decades, there has been an increase in the development of specialty hospital beds to reduce the incidence of skin breakdown. These beds work by redistributing air pressure under different parts of the patient's body to keep them from always lying on one side. The main drawback of these beds is the expense: some hospitals are unable to afford more than a few, if any, for their critical care units. In these cases, use of the manual turning protocol will suffice, but it is important to note that the use of specialty beds has been shown to decrease the incidence of HAPIs in critical care settings (McNichol et al., 2020).

Prophylactic Dressings

In addition to manual turning protocols and specialty mattresses, many critical care units have implemented the use of foam dressings that can be used prophylactically to prevent skin breakdown. These dressings act as a thick barrier between the skin and the potential cause of the breakdown, which may be the bed itself or some kind of medical device that is lying against the skin. The dressings used in critical care settings are usually placed on the coccyx and heels, but there are many other dressing styles available for other body parts at risk for pressure injuries.

INTERDISCIPLINARY PLAN OF CARE

Interdisciplinary Roles and Plan of Care for a Patient with a HAPI

- Nurse: performs daily skin assessment; repositions patient manually every 2 hours; applies prophylactic dressings on bony prominences
- Physical and occupational therapists: perform range of motion exercises; assist with manual patient repositioning
- Wound care team: assesses, manages, and cares for pressure injury wounds
- Dietitian: develops and implements nutrition plans that help improve wound healing and promote new tissue growth
- Pharmacist: monitors dosage of vasoactive medications to limit risk of tissue breakdown and potential necrosis

35.8 Musculoskeletal Concerns

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the pathophysiological changes to the patient's musculoskeletal system when in the intensive care unit
- Describe the medical assessments and therapies that apply to the critical care patient's musculoskeletal system
- Apply nursing concepts and plan associated nursing care for the critical care patient's musculoskeletal system

When receiving medical care in critical care settings, patients are often confined to their hospital beds for long periods. Although these medical interventions are necessary for sustaining life, musculoskeletal complications may arise from prolonged periods of immobility. These complications include **muscle atrophy**, or the severe loss of muscle mass, and the development of contractures, resulting in short, stiff joints. Both conditions have the potential to negatively affect the patient's quality of life and ability to perform activities of daily living long after they are discharged from the hospital. For this reason, thorough musculoskeletal assessments should be performed frequently on critically ill patients, and early mobility is encouraged as tolerated and appropriate for the patient's condition.

Pathophysiological Insult to the Critical Care Patient's Musculoskeletal System

Many critically ill patients who survive their acute illness report lingering physical limitations after discharge from the hospital. These limitations often affect both personal and professional aspects of life and can contribute to an overall lower quality of life. Most often, these limitations stem from severe muscle atrophy and contractures caused by prolonged immobilization in the ICU.

When patients are confined to bed for long periods, they are unable to effectively use their upper and lower extremity muscles, resulting in overall loss of muscle tone and subsequent atrophy (Figure 35.14). Immobility may also result in contractures because patients are unable to adequately perform full range of motion and other exercises independently. When patient extremities are held in one position for long periods, a permanent contracture can result. Contractures are especially common in the hands and feet of critically ill patients because of the way they are positioned in bed. The high incidence of muscle atrophy and contractures in critical care settings highlights the need for frequent musculoskeletal assessment and the promotion of early mobility strategies.

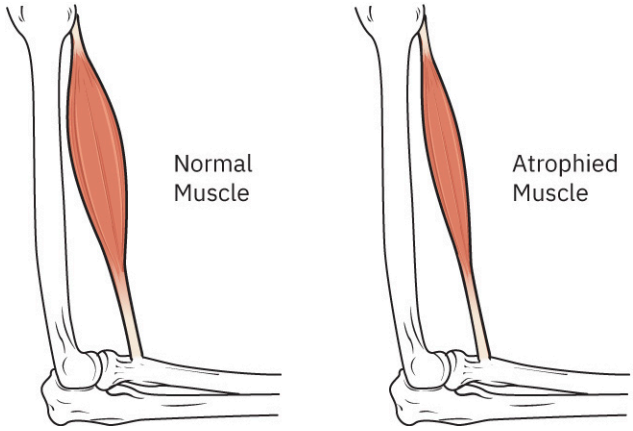

FIGURE 35.14 Muscle atrophy may occur in the legs of patients who are confined to bed for long periods. Compared with a normal muscle, the one with atrophy is much smaller. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Assessment and Early Mobilization

Prevention and treatment of muscle atrophy and contractures in the ICU should be a priority of nursing care to reduce the risk of permanent physical disability after discharge. Prevention and treatment strategies include frequent musculoskeletal assessment, promotion of early mobility, and physical and occupational therapies for critically ill patients. Additionally, other efforts such as optimal nutrition and fluid status help ensure the patient will be able to participate in early mobilization strategies.

Musculoskeletal Assessment

As part of the thorough physical assessment performed at least once per shift, the critical care nurse should assess the musculoskeletal system. This assessment provides baseline information about the patient's muscular function and can be compared with subsequent assessments to determine if the patient is at risk for developing atrophy or contractures. The components included in this assessment are listed and described in Table 35.13.

Assessment	Description and Rationale
Inspection and palpation	• Look at muscles and joints and observe for symmetry, color, and deformities. • Palpate muscles and joints for warmth or tenderness and deformities.
Range of motion (ROM)	• Compare bilateral joints to determine if one side has more-limited ROM. • May be active (patient initiated) or passive (nurse or other provider manipulates joint movement).
Muscle strength	• Compare strength of muscle groups bilaterally to determine if one side is weaker. • Grade muscle strength from 0 to 5, with 0 indicating no muscle contraction and 5 indicating full muscle strength

TABLE 35.13 Components of a Musculoskeletal Assessment in the Intensive Care Unit

Nursing Care for the Prevention of Musculoskeletal Declines

Although the acuity of the critically ill patient may deter progressive interventions to prevent musculoskeletal decline, the status of the patient will determine which interventions can be used. In addition to nutrition, the intent of early movement when clinically tolerated has demonstrated therapeutic effects on musculoskeletal decline of the critically ill patient.

Promotion of Early Mobility

Historically, critically ill patients were kept confined to bed; they were not ambulated or exercised at all for fear that it would negatively affect their healing process or increase their risk of falls. However, in recent years, earlier mobility during hospitalization in the ICU has been promoted. Studies have shown that the implementation of early mobility in critical care settings has greatly reduced the length of hospital stays and decreased the severity of physical disability experienced by patients after discharge (Bergbower et al., 2020).

Early mobilization of a critically ill patient requires collaboration among interdisciplinary teams, principally the nursing staff and physical and occupational therapists. It is important that the therapists have at least a basic knowledge of the invasive equipment the patient will be connected to while ambulating, such as a ventilator or chest tubes. Additionally, it is important that the nurse can effectively physically assist the therapists to help the patient ambulate or move as they are able. Hospitals and specific units will have varying protocols for early mobilization, but it is not uncommon to see critically ill patients walking in the unit hallways while still connected to life-saving medical equipment, to prevent future musculoskeletal complications. An interdisciplinary approach using input from physical and occupational therapists and case managers should guide the discharge planning. Anticipation of care needs is an ongoing evaluation and can be adjusted when the patient's acuity stabilizes. Above all, keep in mind that readiness to progress to a medical-surgical floor is an ongoing process.

Promotion of Nutrition on Musculoskeletal Health

Critical illness depletes necessary nutrients to combat illness. Because of increased metabolic demands, loss of muscle tone leads to muscle atrophy. A randomized control trial examined the role of nutrition and exercise on decreasing loss of muscle mass in the critically ill population (Chapple et al., 2022). With respect to nutritional modalities, parenteral nutrition consisting of amino acids and protein in that study was found to have prospective benefits of reduced incidence of muscle wasting in the critically ill patient. Ultimately, the benefits of early mobilization and addressing nutritional needs maximize positive outcomes on reducing muscle wasting and preserving caloric reserves. Nurses must advocate for these essential components when considering the musculoskeletal needs of the critically ill patient.

Summary

35.1 Assessment and Management of the Critically Ill Patient

- Critical care nursing is a specialty of its own, requiring astute clinical judgement and critical thinking, due to the complexity of the patient's medical challenges.
- Patients are typically admitted to critical care settings because they have a life-threatening medical condition that requires intensive monitoring and extensive medical and nursing care. Often, they are experiencing dysfunction of multiple body systems.
- Technological supports such as ventilators and continuous renal replacement, and pharmacological supports such as vasopressors and sedatives are commonly encountered in the care of the critically ill patient.
- Nurses caring for critically ill patients will confront ethical and legal dilemmas such as organ donation, end-of-life support, and integration of legal documents such as living wills to assist with navigation of goals of care.

35.2 Cardiovascular Concerns

- The underlying pathophysiologic mechanism of most critical cardiac conditions is a decrease in CO, which is calculated by multiplying the stroke volume by the heart rate. The three main factors that affect stroke volume are preload, afterload, and contractility.
- Assessment of cardiovascular insult typically requires the insertion of arterial catheters and pulmonary artery catheters, which monitor CO, cardiac index, and other hemodynamic parameters. Other diagnostic tests and procedures used in critical care settings to evaluate the function of the cardiovascular system include chest radiography, 12-lead electrocardiograms, echocardiograms, and cardiac catheterization.
- The care plan for a critically ill client with cardiovascular insult may include both pharmacological supports (typically vasoactive medications, which exert their effects on blood vessels) and technological therapies such as IABPs, ECMO, and external or transcutaneous pacing.
- Cardiovascular deviations in the critically ill patient may be complicated by cardiogenic shock, which commonly results from an MI, or heart attack.
- Nursing care of the critically ill patient experiencing cardiovascular dysfunction follows the Clinical Judgment Measurement Model, including frequent assessments of the cardiovascular system and close monitoring of hemodynamic parameters. The nurse is also responsible for administering and titrating medications and maintaining invasive therapies such as IABPs and ECMO.

35.3 Respiratory Concerns

- Respiratory failure and the development of ARDS is common in critically ill patients, with the incidence increasing over the past several years due to the COVID-19 pandemic.
- Pertinent assessments for critically ill patients with respiratory dysfunction include monitoring blood gases to determine CO_2 and oxygen levels, listening to lung sounds, and placing an ETT tube.
- Nursing interventions for ARDS include maintenance of the mechanical ventilator, prevention of VAP, and participation in SBTs.
- Effective care of the respiratory system and prevention of complications have the potential to significantly improve overall patient outcomes.

35.4 Neurological Concerns

- The underlying pathophysiologic mechanism behind many neurological disorders observed in critical care settings is due to increased ICP. Alterations in ICP can occur due to trauma, infection, or bleeds.
- Assessments require close monitoring of neurological findings such as LOC, pupillary response, posturing, or deviations in hemodynamics (i.e., abnormal respiration)
- Interventions for increased ICP include frequent neurological assessments; administration of medications, including steroids and diuretics; optimal patient positioning to promote drainage of CSF; and decreasing the body's metabolic demands.
- By intervening early and treating increased ICP, there is a better chance to prevent severe, permanent neurological disability.

35.5 Gastrointestinal Concerns

- The most common GI condition that results in ICU admission is the presence of acute GI bleeding, often related to ruptured stress ulcers or esophageal varices.
- Providers may observe hemodynamic instability, as evidenced by low blood pressure, active bleeding in the stools, or decrease in the CBC. The patient may report dizziness, abdominal pain, poor appetite, or bloody vomitus or stools.
- Interventions for acute GI bleeding include administration of medications, maintenance of hemodynamic stability, and NGT insertion.

35.6 Renal Concerns

- Physiological insult to the kidneys that is commonly encountered in critical care is AKI, which can have prerenal, infrarenal or postrenal causes. AKI reduces the kidneys' ability to filter toxins from the bloodstream and maintain fluid balance.
- Diagnosing AKI involves close evaluation of serum laboratory values, especially levels of creatinine and BUN. Trends in GFR should also be monitored closely to determine the level of functioning of the kidneys.
- Pharmacological interventions for AKI typically focus on maintaining optimal fluid and electrolyte balance. Hyperkalemia is a particular concern. Because many medications, most notably antibiotics, are nephrotoxic, patients should receive the lowest possible doses to prevent worsening of the kidney injury.
- When caring for patients with AKI, nursing interventions center around maintaining a normal fluid and electrolyte balance and administering appropriate medications to restore kidney function. Nursing assessments include monitoring vital signs, urine output, and weight.

35.7 Integumentary Concerns

- Integumentary pathophysiological insult results from multiple variables that place the critical care patient at risk, including nutritional problems, immobility, fluid shifts, and incontinence.
- Skin breakdown in critical care settings can contribute to necrosis and the development of life-threatening infections, increasing the overall length and cost of hospitalizations. Therefore, diligent skin care should be a high priority for critical care teams.
- Assessment of skin should occur every shift. Risk assessment models such as the Braden Scale help identify patients at risk, given their mobility, skin integrity, nutritional status, and skin moisture.
- Interventions for the prevention of skin breakdown in critical care settings include frequent manual patient repositioning and use of specialty beds and prophylactic skin dressings.
- The prevention of skin breakdown in the ICU involves an interdisciplinary care team to limit the risk of pressure injury development.

35.8 Musculoskeletal Concerns

- The most frequently encountered musculoskeletal problems in critically ill patients are muscle atrophy and contractures, both of which are related to prolonged immobility and bedrest.
- Prevention and treatment of muscle atrophy and contractures in the ICU should be a priority of nursing care to reduce the risk of permanent physical disability after discharge.
- Interventions for the prevention of muscle atrophy and contractures include frequent musculoskeletal assessments and promotion of early mobility.
- Implementation of early mobility in critical care settings requires interdisciplinary collaboration and knowledge about the complexity of the patient's medical condition and physical limitations.

Key Terms

acute kidney injury (AKI) sudden reduction in kidney function, usually related to another underlying condition or cause

acute respiratory failure (ARF) sudden failure of the lungs and respiratory system, resulting in hypoxemia and hypercapnia

arterial catheter small, flexible catheter that is inserted into an artery and connected to monitoring equipment to reflect continuous blood pressure measurements

brain death cessation of brain function due to irreversible brain damage that makes it impossible for the patient to remain alive without life-sustaining therapy
cardiac output amount of blood that the heart ejects from the left ventricle each minute
contractility strength of the cardiac muscles during a contraction
esophageal varices small veins that form as collateral circulation in the presence of portal hypertension
extracorporeal membrane oxygenation (ECMO) use of invasive equipment to serve as an artificial heart and lungs, allowing these organs to rest and heal
hematemesis blood in the vomit
hospital-acquired pressure injury (HAPI) pressure ulcers that are acquired during an inpatient hospital stay, most often related to pressure from medical devices or prolonged immobility
intra-aortic balloon pump (IABP) balloon pump inserted in the aorta that inflates during diastole to push blood into the coronary arteries and deflates during systole to push blood to the rest of the body.
intubation insertion of an artificial breathing tube into the airway to maintain patency and restore an effective breathing pattern, often with use of a mechanical ventilator
melena presence of partially digested blood in the stool
multiple organ dysfunction syndrome (MODS) syndrome often experienced by critical care patients that involves dysfunction of two or more body systems
muscle atrophy severe loss of muscle mass, most often due to prolonged immobilization or malnutrition
myocardial infarction (MI) occlusion of perfusion to the heart within the coronary arteries, resulting in eventual cardiac muscle death; also known as a "heart attack"
necrosis tissue death
nephrotoxic capable of causing renal damage
pulse pressure difference between systolic and diastolic blood pressures
vasoactive medication medication that exerts its effect on blood vessels
vasopressors medications that improve blood pressure and organ perfusion by constricting blood vessels

Assessments

Review Questions

1. The nurse is caring for a patient admitted to the ICU for hypovolemic shock. After assessing the patient, the nurse calculates the SOFA score to be 5. What statement accurately describes the significance of the calculated score?
   a. All assessment findings were within normal range.
   b. It is likely that the patient has a mild risk of organ failure.
   c. The patient is experiencing severe symptoms that result in high risk of organ failure.
   d. Based on the score alone, it is not possible to determine the patient's risk of organ failure.

2. The nurse is caring for a newly admitted patient in the ICU. Upon assessment, the nurse notes that the patient is breathing at a rate of seven breaths per minute and oxygen saturation is 84%. What action is most appropriate for the nurse to take at this time?
   a. Administer an opioid analgesic via IV push.
   b. Request an order for a vasopressor medication.
   c. Initiate a referral with the palliative care team.
   d. Prepare the patient for intubation at the bedside.

3. The nurse preceptor is explaining the function of an IABP to a new graduate nurse. What statement by the new graduate nurse would indicate understanding?
   a. "The balloon is inflated during systole."
   b. "IABPs work by increasing afterload."
   c. "The balloon helps perfuse the coronary arteries."
   d. "The IABP functions as an artificial heart for the patient."

4. What medication would the critical care nurse anticipate being ordered for a patient exhibiting severe hypotension?

a. carvedilol (Coreg)
b. furosemide (Lasix)
c. nitroglycerin (Tridil)
d. norepinephrine (Levophed)

5. What clinical condition would predispose the patient to cardiogenic shock?
a. congestive heart failure
b. acute respiratory distress syndrome
c. myocardial infarction
d. pleural effusion

6. What patient is most at risk for developing ARDS?
a. a patient with mild influenza
b. a smoker with a history of lung cancer
c. a survivor of a near-drowning experience
d. a person with a history of chronic obstructive pulmonary disorder

7. The nurse preceptor is educating a student nurse about prevention strategies for VAP. What statement by the nurse indicates an understanding of the teaching?
a. "I will keep the patient's head of bed at 20°."
b. "It is important to clean the patient's mouth with water only."
c. "Once per day, we need to turn off all sedative medications."
d. "The endotracheal cuff should be deflated daily to see how the patient tolerates it."

8. What laboratory value would be indicative of hypercapnic respiratory failure?
a. $PaCO_2$ 52 mm Hg
b. HCO_3^- 23 mEq/L
c. PaO_2 85 mm Hg
d. pH 7.40

9. The critical care nurse is taking care of a patient with traumatic brain injury who is receiving a continuous IV mannitol infusion. What is an example of a finding that would alert the nurse that the patient may be experiencing a side effect of the medication?
a. blood pressure of 125/86 mm Hg
b. decreased LOC
c. heart rate of 55 beats/min
d. bounding peripheral pulses

10. A patient is at risk of increased ICP. What might the nurse anticipate in the patient's medical history that contributes to this risk?
a. microcephaly
b. core body temperature of 37 degrees Celsius
c. meningitis
d. diabetes mellitus

11. The nurse is reviewing the patient's chart and observes the BUN level has elevated to 40 mg/dL and the creatinine level is 2.6 mg/dL, which is doubled from the day before. What order would most concern the nurse for this patient?
a. Diltiazem XR 320 mg daily.
b. Vancomycin 1,000 mg intravenously twice a day.
c. Warfarin 2 mg daily.
d. Normal saline 0.9% 100 mL/h intravenously.

12. What would likely be a prerenal cause for AKI?
    a. hemorrhage
    b. benign prostatic hypertrophy
    c. contrast media
    d. renal cell carcinoma

13. A preceptor is reviewing the graduate nurse's understanding of the critically ill patient's risk of muscular atrophy. What statement made by the graduate nurse would prompt the preceptor to provide more education?
    a. "Assessing the patient's range of motion can help determine their risk for muscle atrophy."
    b. "A muscle strength rating of 5 indicates the patient has no atrophy of that muscle."
    c. "It is important to keep the patient on strict bed rest because they are connected to a ventilator."
    d. "I will perform range of motion exercises often to prevent the patient from getting a contracture."

Check Your Understanding Questions

1. What challenges are often encountered by critical care nurses when working in an ICU setting?
2. You are the nurse caring for a patient who is about to receive ECMO therapy. How would you explain the procedure to the patient and their family?
3. What are examples of interventions that critical care nurses may take when caring for a patient with cardiogenic shock?
4. The patient's pH measurement comes back as 7.47 after being treated for acute hypercapnic respiratory failure. What acid or base pH would this represent?
5. The nurse observes that a patient's ETT tube has migrated forward. What intervention should the nurse anticipate next?
6. Briefly list three interventions nurses can implement to reduce ICP.
7. Describe how decorticate posturing differs from decerebrate posturing.
8. The critical care nurse has recently noticed an increase in pressure ulcers on their unit. What interventions should the nurse suggest to the unit manager and other staff nurses to decrease the incidence of skin breakdown on the unit?

Reflection Questions

1. Critical care nurses must possess many skills and traits to provide high-quality care to critically ill patients. What skill or trait do you think is most important for a critical care nurse to have, and why?
2. Discuss ethical considerations that a critical care nurse may encounter when participating in the care of a critically ill patient.
3. How would a nurse preceptor explain to a new graduate the pathophysiological insult from cardiogenic shock?
4. Discuss the role of the perfusionist in the collaborative care of a patient receiving ECMO therapy.
5. How would a nurse explain the benefits of proning a patient in the ICU to a family member?

What Should the Nurse Do?

The nurse is caring for a patient who presented to the ED with abdominal pain and fatigue for the past several hours. The patient reports a history of hypertension, PUD, and chronic obstructive pulmonary disorder. Laboratory values obtained include a hemoglobin of 7.8 g/dL and hematocrit of 24%.

1. Based on the patient's medical history and laboratory values, what condition should the nurse suspect?
2. Upon ambulating to the bathroom, the patient reports feeling lightheaded. The ED nurse takes the patient's vital signs, which reveal a blood pressure of 95/55 mm Hg and a heart rate of 117 beats/min. The patient is

able to sit on the commode; after wiping, they notice the presence of bright red blood in the stool. What actions are appropriate by the nurse at this point?

Sarah, a 55-year-old female, has been admitted to the ICU after a severe car accident resulting in multiple injuries, including fractures and internal bleeding. She presents with oliguria, indicating decreased urine output, and complains of generalized edema and discomfort in her lower back. Sarah has a medical history of hypertension and type 2 diabetes mellitus, both poorly controlled. On assessment, her blood pressure is 160/100 mm Hg, heart rate is 110 beats/min, respiratory rate is 22 breaths/min, and temperature is 37.8 °C (100.04 °F). Laboratory results reveal elevated serum creatinine and BUN levels, suggestive of AKI. Nurses prioritize assessing her fluid balance, monitoring electrolytes, and implementing measures to optimize renal perfusion.

3. What signs and symptoms indicate potential renal dysfunction in Sarah's presentation?
4. Considering Sarah's presentation and medical history, what are the primary hypotheses for the cause of her AKI? Consider prerenal, intrarenal, and postrenal causes.

Nikki, a 65-year-old female, is admitted to the ICU after a severe motor vehicle accident. She presents with multiple fractures, including a femoral fracture, and is intubated due to respiratory distress. Nikki reports severe pain in her left thigh and limited mobility. Her medical history includes hypertension and osteoporosis. Upon assessment, her vital signs reveal a blood pressure of 140/90 mm Hg, heart rate of 110 beats/min, respiratory rate of 24 breaths/min, and oxygen saturation of 92% with supplemental oxygen. Additionally, she exhibits signs of muscle wasting and decreased range of motion in her affected limb.

5. What physical examination findings might indicate potential musculoskeletal complications in a critically ill patient like Nikki?
6. What interventions would you implement to address Nikki's pain and limited mobility while minimizing the risk of further musculoskeletal complications in the ICU?
7. What would the nurse advocate for regarding nutritional support?

Competency-Based Assessments

1. Describe the nursing responsibilities associated with caring for a patient diagnosed with MODS. How does patient acuity influence these responsibilities?

2. There are numerous legal considerations associated with providing nursing care to critically ill patients. Provide an example of a legal issue that may arise in this context and explain how nurses can mitigate potential risks.

3. A patient admitted to the ICU after a TBI exhibits signs of ICP. Discuss the pathophysiological changes contributing to this patient’s neurological deterioration.

4. Place the following steps for NGT insertion in the correct order by letter:
    A. Estimate length of tube to be inserted by measuring the end of the tube from the tip of the patient's nose to the earlobe and then down to the xiphoid process. Mark this spot on the tube with tape or a marker or note the correct black measurement marking printed on the tube.
    B. Lubricate the tip of the NGT.
    C. Use hospital protocol to check correct placement of NGT. This typically involves use of a chest X-ray or aspiration of gastric fluid to check pH.
    D. Explain procedure to patient.
    E. Have the patient take sips of water through a straw while you insert the tube to facilitate its passage down the esophagus. Continue advancing the tube until the predetermined length of tube has been inserted.

5. Describe how the skin of patients in the ICU undergoes physiological alterations due to factors like extended periods of immobility, pressure, moisture exposure, and compromised blood flow.

6. When assessing a critically ill patient’s skin integrity in the intensive care setting, describe how you would recognize signs of pressure ulcers; evaluate skin elasticity, coloration, and temperature; and identify any indications of damage or infection.

CHAPTER 36

Home Health Nursing and Rehabilitation

FIGURE 36.1 Home health nurses can assist their patients outside of a traditional hospital setting. (credit: modification of "Nurse Advising Senior Woman On Medication At Home" by agilemktg1/Flickr, Public Domain)

CHAPTER OUTLINE

INTRODUCTION People often picture health care and nurses only in the context of a hospital, but many patients whose injury or illness is initially treated in a hospital are eventually discharged and managed in their own homes. Home health nursing and rehabilitation is an increasingly essential area in health care that allows nurses to provide compassionate care outside the traditional clinical hospital setting. Healing, support, and education are combined and designed to foster resilience and build wellness for improved life in diverse populations. Nurses are essential to restoring health and function and empowering people and families in the communities that they serve. Nursing services include personal care for long-term care residents, home care, and care at post-acute care centers, also called rehabilitation centers, which are unique centers for continuing care.

36.1 Home Health Care

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the nurse's role in a home health setting
- Explain the process of conducting a home health visit

A holistic approach, **community-based care** goes beyond typical medical treatments for specific conditions to

address broader factors affecting health outcomes in a community. It is centered on delivering patient-centered care, which includes cultural sensitivity and considers the emotional, physical, social, and environmental factors that impact an individual's health. Community-based care includes home health care, school nursing, prison health, and more. Best practices for each of these specialties are established by the Home Health Agency Center, the National Association for Home Care and Hospice (NAHC), and the U.S. Department of Health and Human Services' Centers for Medicare and Medicaid Services (CMS).

Providing community and health-care services within a home setting, often referred to as home health care or home-based care, offers numerous benefits for patients who require medical attention, rehabilitation, or ongoing support. This approach allows individuals to receive personalized, high-quality care in the comfort of their own homes, promoting a sense of familiarity and autonomy. Home health care encompasses both medical and nonmedical services to address various needs and provide peace of mind for individuals, particularly older adults and those who are chronically ill or recovering from surgery or illness.

Due to its advantages, home health care has grown increasingly common within modern health-care systems. The Cleveland Clinic declared that the use of home health after an inpatient hospitalization decreases the rate of readmission hospitalizations, complications, and even death (National Association for Home Care & Hospice, 2021). Further, it saves at least $6,500 per patient in government Medicare costs (National Association for Home Care & Hospice, 2021). In this module, we explore the essential elements and advantages of home health care, particularly its role in improving overall quality of life and health-care outcomes for patients.

The Nurse's Role in Home Health Settings

Nurses play an instrumental role in developing comprehensive home-care plans for their patients. An important step in transitions of care, these plans should outline health-care needs, goals, interventions, and strategies that address conditions for patient health.

To prepare for planning, nurses perform a detailed assessment of patient health status, which involves reviewing past medical histories and present conditions, medications, allergies, physical abilities, environmental factors such as home fall risks, and any support systems in place. This preparation enables care plans to be customized to each person's unique requirements. Based on assessment findings, nurses collaborate with patients, their family, and members of their health-care team to set realistic and obtainable goals that meet SMART (specific, measurable, attainable, relevant, and timely) criteria. Examples could involve food preparation, medication administration, wound-care services, patient education sessions, and rehabilitation exercises, as appropriate. Following is an example of a SMART goal that a nurse could set with an older adult patient to help with improved medication adherence:

- Specific: The patient will take their prescribed blood pressure medication every day at 8 a.m. without fail.
- Measurable: The patient will track their medication adherence using a pill organizer or a medication adherence app, accurately recording each instance of medication taken.
- Achievable: The patient will consult with their health-care provider to ensure that the prescribed medication schedule fits their lifestyle and does not conflict with any other medications or personal commitments.
- Relevant: Maintaining consistent medication adherence is crucial for managing blood pressure effectively and reducing the risk of complications associated with hypertension.
- Timely: The patient will achieve 90 percent medication adherence within the next three months, as evidenced by their medication adherence records and discussions with their health-care provider during follow-up appointments.

Recognizing the unique circumstances surrounding home care, nurses tailor care plans specifically to each patient's home environment, the resources available, and personal preferences. Nurses consider each patient's cultural background, beliefs, and values when creating care plans; this ensures care is culturally sensitive and respectful.

Nurses engage patients as active participants in care planning by including their input and preferences and acknowledging the patient has ownership over their own health care. This collaboration allows care plans to remain relevant over time. Nurses work collaboratively with health-care team members such as physicians, therapists, social workers, home health aides, and home-care aides, with each contributing their unique expertise toward patient care. A nurse educates both patient and family on their care plan, including its purpose, techniques for

performing self-care tasks, and potential signs of complications to watch out for.

A registered nurse documents the care plan, detailing goals, interventions, expected outcomes, and changes made at subsequent visits. Accurate documentation ensures continuity of care and communication within the team. Nurses understand that care plans may need to change with time due to patient progress, health status changes, and new developments. Once established, nurses share the plan with primary care doctors and other health-care providers involved with managing patient care, which ensures a cohesive approach toward improving health management for each patient.

Nurses also must consider ethical considerations when providing care plans or making health-related decisions on behalf of others. Nurses ensure the care plans they create respect the autonomy, values, and rights of home-care patients. Producing such plans requires an assessment of patient needs as well as collaboration from health-care teams to promote efficient communication with positive results for home-care patients.

The nurse's role in home health care clearly extends beyond medical treatment. Nurses provide comprehensive care, education, and emotional support, enhancing patients' well-being and promoting optimal recovery within the familiar and comforting surroundings of their own homes. The nurse plays a central role in coordinating and delivering these services effectively (Chen, 2022).

Home Health Visits

A home health visit is an opportunity to conduct a nursing assessment in the patient's home, documenting the patient's health, monitoring their progress, and making sure they receive the care and support needed. A nursing home health visit may include different components depending on the patient and the purpose, but they usually include the following activities:

- Assessment of home environment: Nurses assess the patient's living conditions and make recommendations for modifications or adaptations to ensure safety and accessibility.
- Medical assessment and monitoring: Nurses conduct thorough assessments of the patient's health status, including vital signs, and monitor wound care, medication management, and chronic conditions. Regular assessments help detect changes in health and ensure timely interventions.
- Medication management: Nurses educate patients and caregivers about medication regimens, administer medications as needed, and monitor for adverse effects or interactions. They play a critical role in ensuring medication adherence and preventing medication-related issues.
- Wound care: Patients with wounds or surgical incisions require specialized care to promote healing and prevent infections. Nurses assess the wound's progress, change dressings, and provide guidance on wound-care techniques.
- Pain management: For patients with acute or chronic pain, nurses work to assess the nature and intensity of pain, administer pain medications, and implement nonpharmacological pain management strategies to improve comfort and quality of life.
- Rehabilitation services: Physical therapists, occupational therapists, and speech therapists may visit patients at home to provide rehabilitation services after surgeries, injuries, or medical events like strokes. Nurses collaborate with these therapists to ensure comprehensive care.
- Patient and family education: Nurses educate patients and their families about the patient's condition, self-care techniques, and lifestyle modifications to promote recovery and prevent complications. This education empowers patients to actively participate in their care.
- Emotional and psychological support: Nurses provide emotional support and counseling to patients and their families as they navigate the challenges of illness, recovery, and lifestyle adjustments.
- Care coordination: Nurses serve as the point of contact between patients, their families, and other health-care providers. They coordinate appointments, facilitate communication among the care team, and ensure a seamless transition between different levels of care.
- Assistance with activities of daily living (ADLs): For patients who have difficulty with activities such as bathing, dressing, and grooming, nurses coordinate with home health aides to ensure the patient's personal care needs are met.
- Chronic disease management: Patients with chronic conditions such as diabetes, heart disease, or respiratory disorders require ongoing management. Nurses help patients understand their conditions, manage symptoms,

and adhere to treatment plans. Especially for older adults who deal with chronic conditions and polypharmacy, home health visits can be helpful in resource utilization (Cook et al., 2022).
- End-of-life care: Nurses play a vital role in providing palliative and hospice care at home, ensuring that patients with terminal illnesses are comfortable, pain free, and supported emotionally during their final days.

How Nurses Should Prepare for a Patient Home Visit

It is important to prepare for a home visit to ensure that the nurse is equipped to provide comprehensive and effective care to patients. The nurse should take the following steps to prepare for a visit to a patient's home to maximize effective time with the patient:

- Review the patient information: Review the patient's **medication regimen**, which lists all medications the patient is currently taking, including over-the-counter medications and home remedies. For each medication taken, the nurse should know what the dosage is, how often the patient takes it, and if there are any side effects. Additionally, examine the patient's medical information, including referral information and any notes made by the health-care provider who referred the patient. If possible, interview the patient about their health, including any symptoms, medical conditions, allergies, surgery, family history, and medical history.
- Verify appointment details: To avoid scheduling mistakes, double-check the time, date, and address for the home visit. If necessary, confirm the visit with the patient's caregiver or the patient themself. Plan the travel route in advance, particularly if the patient's house is located in an unfamiliar area. This will ensure that the nurse arrives on schedule and is familiar with the area. Make sure to plan the visit to allow for adequate time to assess, intervene, educate, and document. It is important to be organized to maximize the time allowed with the patient.
- Gather the necessary supplies: Gather all the equipment and medical supplies before the visit, including tools to record vital signs such as a stethoscope and blood pressure cuff. Make sure any medical equipment that will be used, such as a stethoscope, pulse oximeter, glucometer, or thermometer, is in working order. Be sure to have all the necessary documentation tools such as a notebook or tablet for recording your findings, recommendations, and interventions.
- Prepare educational materials: Prior to the visit, prepare any handouts or visual aids needed to explain concepts to patients and their families.
- Prepare mentally: Review the care plan ahead of time to know what to focus on during the visit in order to best assist the patient. Be patient and empathic when you approach the visit. Prepare to actively listen to your patient's concerns and adjust your care plan to their needs. Be flexible and adaptable to any unexpected needs or changes that may occur during your visit. Having this mindset will help you provide quality care, establish rapport with the patient and their family, and improve outcomes.
- Check communication devices: Make sure that all communication devices, such as a mobile phone or tablet, are fully charged. These devices may be used to communicate and access patient records as well as document the visit. Keep a list of emergency numbers handy in case an unexpected situation arises during your visit.
- Consider your personal presentation: Dress in professional clothing and ensure that your appearance is neat and clean. This will help establish professionalism and trust during the visit.

Personal Safety Precautions

Nurses who conduct home visits must also take care to ensure their personal safety. Personal safety is always a top priority. Trust your judgment if you feel your safety has been compromised during a visit to a patient's home. Take the appropriate steps to ensure your well-being, and make sure to proactively plan for your personal safety while on home visits.

Prior to your visit, make sure to tell your supervisor or colleague about the details of your visit, such as the address and the expected duration. Schedule home visits during daylight hours as much as possible. Doing this will improve visibility and reduce the risk of visiting unknown areas at night. Also before your visit, make sure to research the area and neighborhood where the patient resides. You should be aware of local safety issues or concerns that may affect your visit. Additionally, make sure to bring the right personal protective equipment (PPE) with you, especially when dealing with situations that involve infection control or dangerous substances.

If taking public transit to the location of your visit, make sure to thoroughly research your route to avoid delays, unanticipated detours, or potentially unsafe stops. If you are driving, parking your car in a well-lit area will help you

to feel safer. Avoid parking in driveways and alleyways that may obstruct your exit. Trust your instincts if something seems off or unsafe.

On arrival, assess the environment as you approach the home of the patient and be aware of the surrounding areas. Observe for hazards such as uneven pathways, poorly lit areas, or aggressive animals. Consider rescheduling your visit or asking for assistance if you are uncomfortable or have any concerns about entering the home. Wear the proper identification, such as a uniform or badge, to clearly identify you as a health professional. Secure your belongings and keep them out of sight. This is especially important if you are using a bag to carry equipment. Keep valuables locked and out of sight.

Identify possible exit routes for emergencies when entering the home of a patient. Be alert to doors and windows that could be used as escape routes. Once you are inside the home, keep a safe distance from unfamiliar pets or other animals that may be a danger. Ask the patient to restrain the animal if needed.

Unfortunately, taking proper safety precautions may not always be enough. It is smart to invest in critical personal safety skills, such as de-escalation techniques and self-defense classes, prior to starting your home visits. Learning how to de-escalate tense situations and defend yourself, if necessary, will help you handle potentially dangerous situations. Report any safety concerns you may encounter during your visit to your supervisor, and always document them in your report.

How to Conduct a Home Visit

As a nurse, you should understand what a typical home health visit entails so that you can plan your time accordingly. Your time is valuable, and there is often a lot to do during a visit. An example of a general overview for a nurse conducting a home visit is presented in the following Feature Box. Please be sure to adhere to individual state regulations and regulatory body procedures as appropriate.

CLINICAL SAFETY AND PROCEDURES (QSEN)

Conducting a Home Visit

1. Review the patient's history and care plan before the visit. (Revisit How Nurses Should Prepare for a Patient Home Visit for all the preparation steps you should take prior to a home visit.)
2. Confirm with the patient or caregiver the date, time, and address of your visit. Inform the patient of any special instructions or preparations they should make.
3. Arrive on time at the patient's house. Introduce yourself to the patient, showing your identification (badge and uniform), and explain the purpose of your visit.
4. Assess the patient's current health. Differentiate prior and new changes since your last visit. If necessary, perform a physical exam.
5. Check the patient's medications to ensure they are being taken correctly. Answer any questions or concerns the patient may have about their medication.
6. Perform any necessary interventions such as treating wounds, administering medication, or teaching patients to use medical equipment.
7. Educate the patient and any caregivers about the illness, treatment plan, self-care strategies, and recommended lifestyle changes. Evaluate their understanding through a return demonstration or correct verbal response.
8. Provide support to the patient or coordinate with a home health aide if they need assistance with ADLs, like bathing or dressing.
9. Work with the therapists if you are a part of a rehabilitation program or therapy to ensure that all exercises and treatments are being performed correctly.
10. Document all findings and recommendations, including interventions and patient feedback. Communication with other members of the care team is important to ensure coordination. Recognize the concerns of the patient and their family and offer reassurance.

At the end of the visit, provide a summary of the visit for the patient. Outline any actions to be taken and give clear instructions that the patient and any caregivers can follow until your next visit. Review your findings with your

supervisor or the health-care team. Reflect on your experience after the visit and complete all required documentation, including visit reports, assessments, and interventions. Decide if any follow-up visit is needed; if so, make an appointment and explain the plan to the patient and any caregivers.

A successful home visit is dependent on effective communication, clinical expertise, and a patient-centered approach. Every visit is different, so nurses need to be flexible and responsive.

REAL RN STORIES

Nurse: Lucy, RN
Years in Practice: Eight
Clinical Setting: Home health practice
Geographic Location: San Jose, California
Mr. Garcia had recently been discharged from the hospital, where he had been treated for severe pneumonia and COVID-19. As I approached his home for my initial home health visit, my emotions mixed between excitement and fear. This would be my inaugural appointment to assess his recovery and see how he was doing at home. At first, I noticed only crisp autumn air as I rang the doorbell; shortly thereafter, Sonia, Mr. Garcia's daughter, welcomed me inside, showing me around their cozy living room, where there was an uncomfortable hospital bed in one corner. It reminded me of the many recent health challenges the family had been enduring.

Mr. Garcia was resting comfortably in an armchair, wrapped up warmly and looking exhausted. We began discussing his medications as well as any concerns he might have about their effectiveness or adverse interactions. He expressed both relief at being back home as well as concerns regarding managing his medications and breathing exercises. Together we reviewed his medications, discussed his respiratory therapy plan, and identified any warning signs to watch out for. I took time to assess his vital signs, breathing, and overall well-being. At first sight, it was obvious that the hospitalization had taken a toll, yet I could sense his resolve to rebuild his strength. We discussed maintaining a nutritious diet, staying hydrated, and gradually increasing his physical activity. Sonia was eager to offer support in helping her father's recovery process. Our discussion turned toward mental health concerns, and Mr. Garcia expressed some anxiety and uncertainty regarding his future well-being. I assured him that these emotions were perfectly natural, and we discussed resources for him and confirmed he is not in any danger to himself or others. Before departing, I made sure he had access to all his medications and equipment as well as scheduled a follow-up visit so we could monitor his condition closely.

As I left, I felt an immense sense of fulfillment. Being a home health nurse means providing support, empathy, and education during sensitive moments for patients like Mr. Garcia. I knew his road ahead would be challenging, but I was determined to help him regain both health and independence within his own environment.

Initial Visit

To build trust, it is important to establish a respectful and friendly rapport with both the patient and their family, beginning with the first visit. A positive rapport will also make it easier for you to assess the patient's needs and develop a care plan that is tailored for them. A simple but crucial first step is to respectfully introduce yourself and clearly explain your role as an at-home nurse.

Before beginning any treatments or suggesting interventions, the nurse needs to evaluate and gather critical information on the patient. Assess any health concerns, take vital signs, and perform a complete physical exam, moving from head to toe (Figure 36.2). Gather information about allergies, current medications, and previous treatments. The nurse should also evaluate the patient's living environment for safety hazards and accessibility. Identify potential obstacles to the patient's health or well-being.

FIGURE 36.2 A home health nurse takes vital signs during an initial visit with a patient. (credit: "JTF-Bravo Medical Element provides care to local community" Tech. Sgt. Amber Carter/Joint Task Force-Bravo, Public Domain)

Once the initial assessments have been made, the nurse should sit down with the patient and their family, if applicable, and discuss next steps and a care plan:

- Set goals and preferences: Discuss with the patient their health goals and care preferences. Ask what they want to achieve from home health care and how they see their plan of care. Inform the patient and family of the importance of home health care, the role played by the nurse, the level of coordination with other health professionals, and the results the patient can expect. Get informed consent to treatment and services. Emphasize that communication with the primary care provider, referring physician, and any other specialists involved in patient care is essential. This will ensure seamless coordination and an understanding of patient needs.
- Establish the initial care plan: Together with the patient, develop an initial plan of care. This plan should include goals, interventions, and a timetable for achieving the desired outcome.
- Create an emergency plan: Talk to the patient's family about an emergency plan. Give emergency contact information and explain the steps to be taken in an emergency.
- Plan for a follow-up and next visit: Plan the next visit to the patient's home and explain the purpose of a follow-up visit. Be sure that your patient is aware of when you will be returning and what preparations are needed. Address any fears or concerns the patient might have regarding their health or home health. Reassurance and emotional support are important. Keep a professional demeanor during the entire visit. Communicate clearly and respectfully to make sure the patient is comfortable and understands their care plan. The first visit to the patient sets the tone of the experience the patient will have with the service. This is an opportunity to collect comprehensive information, build trust, and lay the foundation for effective care planning.
- Last, make sure to document any information relevant to the patient record, including the care plan discussion, assessment findings, and other pertinent information. Documentation is essential for communication and continuity of care within the health-care team.

LINK TO LEARNING

Although there is much to prepare before conducting a home health visit, the patient's perspective about the home health visit (https://openstax.org/r/77HomeHealth) should be considered by the nurse. There may be pets present and areas or rooms that are off-limits.

Assessing the Need for Continued Visits

Assessing patients for continued home health visits requires an in-depth evaluation of their health needs and progress to determine whether home health-care services are meeting goals effectively. Start by reviewing a patient's medical history, assessment findings, and care plan, which provide context for gauging progress and noting any changes in condition. Conduct a comprehensive assessment of their current health status. Take vital signs, perform physical assessments, and examine any symptoms or complaints the patient might be having. Review the medication regimen to ensure the patient is able to adhere to the prescribed medications and is experiencing no side effects or interactions. If a patient is not taking the prescribed medications, do not simply label them as "noncompliant"; instead, find out what the barriers are and work to help the patient overcome them. Sometimes, it is a poor understanding or financial constraints, which the nurse can help the patient navigate.

Evaluate patient progress toward meeting goals outlined in their care plan and identify any hindrances to progress. Ask the patient whether their needs are being fulfilled with the home health services provided to them, and encourage open dialogue about any concerns or suggestions that arise. As you discuss these topics, remember that you will need to communicate what you learn with the patient's primary care physician and any specialists involved in their care; note any changes to the patient's condition or care plan that you will need to mention and questions you may need to ask, including the extent to which future home health visits are needed as well as their frequency and duration.

Ending the Visit

Effective home health visits must end on a positive and professional note to ensure the patient and family members feel fully informed and supported by the health-care services provided during visits. Briefly recap the key points discussed during your visit, such as assessment findings, interventions conducted, and any changes to care plans.

Leave behind educational materials, handouts, or written instructions that reinforce what was discussed during your visit and that can easily be understood by recipients. Remind patients about self-care techniques discussed during their visit, and emphasize their role in managing their health and well-being. Provide your contact details should a patient or their family have questions or concerns or need anything else between visits. Reaffirm your dedication to their health, reassuring them of your support throughout their care journey. It is also important to address cultural sensitivity during these interactions, particularly for patients with different cultural backgrounds or communication preferences. Be certain that throughout their visit, the patient feels valued as an individual. Thank them for trusting in you to fulfill their health-care needs. Before concluding the visit, make sure you ask both the patient and their family members whether they understand all the information that was discussed during this appointment, including any lingering queries or uncertainties they have. Having them repeat back information provided is usually more effective than just asking them if they understand.

Document your visit as soon as it has taken place to keep details fresh in your mind and ensure important data do not slip by unnoticed. When documenting visits, you should use objective language without bias or judgment being applied toward those you visit. Stick with facts rather than make assumptions and include all relevant details, including the following:

- patient identification information such as name, birth date, and address
- date, time, and place of visitation
- interventions conducted, such as medications prescribed, wound care provided, and education offered
- aspects or topics regarding patient concerns discussed during the visit, such as safety precautions or instructions given directly to the patient or caregiver

When possible, include the patient's own words when describing symptoms, feelings, or concerns, as this provides more depth and context to documentation. The following is an example of a simple nurse's documentation following

a home visit to check on wound care. Be sure to adhere to the agency and state's policy and guidelines around specific requirements for nursing documentation.

CLINICAL SAFETY AND PROCEDURES (QSEN)

Documenting a Home Visit

Patient Name: John Doe
DOB: January 10, 1955
Location: Patient's residence
Visit Time: 10 a.m. to 11 a.m.
Subjective: Patient reports mild discomfort at the wound site but denies any significant pain. He states that he has been following the wound care instructions diligently.

Objective:

- Wound inspected and measured:
  - Length: 2 cm
  - Width: 1.5 cm
  - Depth: 0.5 cm
- Wound bed appears clean with no signs of infection.
- Minimal serosanguinous drainage noted on dressing, within expected limits.
- Surrounding skin intact; no signs of maceration or irritation.
- Patient's vital signs within normal limits:
  - blood pressure: 120/80 mm Hg
  - pulse: 78 bpm
  - respiratory rate: 16 bpm
  - temperature: 98.6°F (36.9°C)
- Patient demonstrates understanding of wound-care instructions and is able to verbalize the steps for dressing changes.

Assessment: Wound healing progressing as expected without signs of infection or complications. Patient is compliant with the prescribed wound-care regimen.

Plan:

- Continue with current wound-care regimen:
  - Clean wound with saline solution daily.
  - Apply prescribed antibiotic ointment to wound bed.
  - Cover with sterile dressing.
- Educate patient on signs and symptoms of infection and when to contact health-care provider.
- Schedule follow-up visit in one week for reassessment of wound progress and to reinforce wound-care instructions.

Provider Signature: [Name], RN

Date and Time of Signature: April 16, 2024, 11 a.m.

36.2 Rehabilitative Care

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Identify members of the rehabilitation team
- Summarize the principles of patient-centered, rehabilitation-focused care
- Describe the nurse's role in rehabilitative care
- Discuss the various specialties associated with rehabilitative care
- Explain the role of functional ability assessments in patient rehabilitation

The recovery and strengthening phase of nursing that a patient encounters following an acute illness, injury, or hospitalization is known as **rehabilitative nursing**. It forms the cornerstone of patient-centered health care, acting as an intermediary between medical interventions and a patient's recovery of health, function, and independence. Rehabilitative nursing draws inspiration from holistic healing principles, which recognize that recovering from an illness or injury often involves physical, emotional, and psychological modifications. Individuals undergoing surgery, managing chronic conditions, or recovering from injuries often face unique difficulties during their recovery that go beyond medical treatments alone. Psychological, emotional, and spiritual dimensions of health should be included in the nursing plan of care. Rehabilitative nursing serves as a multidimensional solution to recovery, merging clinical expertise with compassionate care to guide individuals toward health and self-empowerment.

Nurses play an essential role in aiding rehabilitation processes as facilitators, educators, and advocates who assist their patients throughout the complex rehabilitation journey. Rehabilitative nursing care encompasses an expansive spectrum of interventions designed to restore mobility and build mental resilience, ultimately empowering patients to retake control over their lives throughout the healing process. Rehabilitative nursing care stands as one of the cornerstones of modern health care, helping patients maintain quality of life throughout the various stages of healing and wellness.

The Rehabilitation Team

Rehabilitation can be defined as an interdisciplinary effort among health-care providers to address complex patient needs such as injuries, surgeries, or chronic conditions. Typically, rehabilitation teams include the following professionals, who collaborate to meet the physical, emotional, and functional needs of each patient during their healing journey.

- Physiatrist: A **physiatrist** is a medical doctor specializing in physical medicine and rehabilitation. Physiatrists lead rehabilitation teams, assess functional abilities of their patients, and develop comprehensive treatment plans to increase mobility, function, and overall quality of life for each person they treat. They also oversee patients throughout treatment plans for ongoing improvements to mobility, function, and overall quality of life.
- Physical therapist: Physical therapists (PTs) specialize in movement and function. They create exercise plans, administer manual therapy techniques, and employ various other strategies to assist their patients in rebuilding strength, flexibility, balance, and mobility.
- Occupational therapist: Occupational therapists (OTs) specialize in helping their patients regain independence in daily activities such as working or leisure activities by conducting assessments, devising plans, and providing training tailored specifically for self-care needs, work situations, or recreational pursuits.
- Speech-language pathologist: Speech-language pathologists (SLPs) specialize in diagnosing and treating communication and swallowing disorders. They assess and treat issues regarding speech, language, cognition, and swallowing for patients recovering from neurological conditions or injuries.
- Rehabilitation nurse: Rehabilitation nurses specialize in care management for individuals recovering from injuries related to motion and undergoing rehabilitation. They help with ADLs, medication administration, wound-care management, and patient education while working alongside other members of the rehabilitation team.
- Social worker: Social workers assess the psychosocial needs of patients and their families. They provide counseling, support, and resources that address emotional, financial, and practical obstacles encountered during rehabilitation processes.
- Case manager: Case managers oversee and facilitate patients' rehabilitation journey. They ensure effective communication among team members, manage care transitions smoothly, and help access necessary services for optimal care.
- Psychologist/psychiatrist: Psychologists and psychiatrists play an essential part in supporting team efforts by meeting patients' mental health needs. Through counseling, therapy, and interventions, they help individuals cope with emotional strain and mental illness issues.
- Orthotist/prosthetist: These members of the rehabilitation team offer customized orthotic/prosthetic solutions. An **orthotist** designs, fabricates, and fits orthotic devices—supportive equipment for bones—to assist patients in improving mobility and functionality. A **prosthetist** does the same for prosthetic devices, which augment or replace damaged or missing body parts. Working closely with rehabilitation teams, they ensure proper fit and function are in place.

- Respiratory therapist: Respiratory therapists specialize in respiratory care for those experiencing difficulty with breathing. Their services may include helping improve lung function through exercises and managing chronic respiratory conditions.
- Dietitian/nutritionist: Dietitians and nutritionists assess patients' nutritional needs and develop plans that support recovery and overall health while accommodating any special considerations related to a particular condition or circumstance. They are extremely helpful for patients with unique dietary and nutritional education needs, such as persons with diabetes, cystic fibrosis, Crohn disease, and more.
- Adaptive equipment specialist: This professional assesses the need for and provides **adaptive equipment** to help restore body functions to patients with disabilities. They also help patients who need an **assistive device** to perform activities they find challenging due to a health condition or limitation.
- Neuropsychologist: A **neuropsychologist** specializes in diagnosing and treating cognitive and behavioral issues related to brain injuries or neurological conditions, providing interventions designed to correct cognitive deficits and boost mental well-being.

Principles of Patient-Centered, Rehabilitation-Focused Care

Patient-centered, rehabilitation-focused care is an approach that places the patient at the forefront of their recovery journey. This has great value for community health, as it assists people in moving from an acute care hospital setting back home to lead meaningful lives (Stucki et al., 2005). An acute hospitalization is truly only a short time period, yet the process of rehabilitation can be ongoing, impacting the quality of the rest of the patient's life. Effective rehabilitation emphasizes tailoring care plans, interventions, and communication to the individual needs, preferences, and goals of the patient. Table 36.1 displays a list of core principles of patient-centered, rehabilitation-focused care. By embracing these principles, health-care providers create an environment that promotes patient engagement, well-being, and successful rehabilitation outcomes

Principle	Description
Individualized care	• Recognize that each patient has unique needs, goals, and preferences. • Develop care plans that are tailored to the individual, considering their physical, emotional, cultural, and psychosocial aspects.
Shared decision-making	• Engage patients as active participants in their care. • Involve them in discussions about treatment options, goals, and plans, allowing them to make informed decisions based on their values and preferences.
Empowerment and autonomy	• Encourage patients' sense of control over their rehabilitation journey. • Provide them with information, education, and support to make choices that align with their values and aspirations.
Goal setting	• Collaborate with patients to set achievable, measurable, and meaningful goals that reflect their priorities. • Regularly review and adjust these goals based on progress and changes in the patient's condition.
Holistic approach	• Consider the physical, emotional, cognitive, and social dimensions of a patient's well-being. • Address all aspects of the patient's health, thereby contributing to a more comprehensive and effective rehabilitation process.

TABLE 36.1 Core Principles of Patient-Centered, Rehabilitation-Focused Care

Principle	Description
Cultural sensitivity	• Respect patients' cultural backgrounds, beliefs, and values. • Adapt care plans and interventions to align with cultural preferences, ensuring that care is respectful and culturally sensitive.
Effective communication	• Foster open and transparent communication with patients. • Listen actively to their concerns, questions, and feedback, and address any uncertainties they may have about their care.
Collaboration among health-care professionals	• Work collaboratively with interdisciplinary teams to ensure seamless and coordinated care. • Address different aspects of the patient's recovery as each team member contributes their expertise.
Psychosocial support	• Recognize the emotional and psychological impact of illness or injury. • Provide emotional support, coping strategies, and resources to help patients manage the psychosocial challenges they may face.
Patient education	• Educate patients about their condition, treatment options, and self-care strategies, as well as the rationale behind interventions. • Empower them to actively participate in their care and make informed decisions.
Respect for patient preferences	• Prioritize patients' preferences and choices within the bounds of safety and evidence-based practice. • Consider each patient's comfort, values, and lifestyle.
Continuity of care	• Ensure that patients experience a smooth transition between different phases of care, from acute treatment to rehabilitation and beyond. • Coordinate care and information-sharing to prevent gaps in care.
Outcome-oriented care	• Focus on achieving meaningful outcomes that enhance the patient's functional abilities, quality of life, and overall well-being.
Regular assessment and evaluation	• Continuously assess the patient's progress and evaluate the effectiveness of interventions. • Adjust the care plan as needed to align with the patient's changing needs and goals.
Respect for dignity and privacy	• Treat patients with dignity and respect their privacy. • Create a safe and comfortable environment that fosters trust and openness.

TABLE 36.1 Core Principles of Patient-Centered, Rehabilitation-Focused Care

The Nurse's Role in Rehabilitative Care

The nurse's role in rehabilitation nursing is multifaceted and integral to facilitating the recovery, well-being, and functional independence of patients undergoing rehabilitation. In this specialized field, nurses work collaboratively

with an interdisciplinary team to provide comprehensive care that addresses the physical, psychological, emotional, and spiritual needs of patients (American Association of Rehabilitation Nurses, 2017). A rehabilitation nurse may work in a rehabilitation facility other than the patient's home, such as in a long-term acute care (or simply "rehab") center. Rehab centers serve the transition period following an acute hospitalization when a patient may still need skilled nursing care around the clock before they may return home (Figure 36.3). For example, a patient may be in postsurgery recovery but may still need help getting in and out of their wheelchair.

FIGURE 36.3 A rehabilitation nurse helps patients during their recovery phase. (credit: "Therapists help Iraqi patients gain independence" by Airman 1st Class Jason Epley/U.S. Air Force, Public Domain)

The nurse's role in rehabilitation nursing includes many of the same elements as in home health nursing:

- assessment and care planning
- collaboration
- medication management
- physical care and functional rehabilitation
- psychosocial care
- communication
- documentation of all care

However, rehabilitation nurses must also assist with transition planning: helping patients to prepare for transitions from rehabilitation settings back to their homes or communities by coordinating the necessary resources, support, and education.

REAL RN STORIES

Nurse: Margaret, RN

Years in Practice: Five
Clinical Setting: Acute care center
Geographic location: Raleigh, North Carolina

As a rehabilitation nurse, I had the honor of working with Hadia, a 35-year-old patient from India who experienced a major car accident that resulted in spinal cord damage. Her journey toward recovery has been difficult, yet her spirit and courage are inspirational. At one of our sessions together, I assisted the physical therapist with exercises. During one key moment, Hadia managed to take steps using a walker by herself. It was truly transformative. I found great satisfaction in seeing Hadia's infectious joy: it validated all our hard work and reminded me why I chose to pursue rehabilitation nursing. We share in all our patients' triumphs, setbacks, and ultimately transformation as their lives begin reassembling themselves in new ways.

Rehabilitation Case Management

Rehabilitation case management plays an essential part in providing patients undergoing rehabilitation with comprehensive care, from coordinated assessments and planning through delivery of interventions and resources that help achieve their rehabilitation goals. Table 36.2 summarizes nursing activities related to the various roles of a rehabilitation case manager.

Role	Nurse Activities
Advocate and planner	• Share plan of care with team. • Address legal concerns to patient care.
Collaborator	• Communicate with interdisciplinary team. • Assist with insurance coverage.
Coordinator	• Schedule and follow up on appointments. • Order durable medical equipment.
Educator	• Provide education on self-care strategies, medication management, and lifestyle modification.

TABLE 36.2 The Role of the Case Manager in Rehabilitation

Rehabilitation Specialties

Rehabilitation nursing encompasses a range of specialties that focus on addressing specific aspects of patients' recovery, functional independence, and quality of life. Rehabilitation typically involves a team of specialists all working together for the good of the patient (O'Sullivan & Schmitz, 2019). Examples of these specialties include orthopedic rehabilitation, neurological rehabilitation (including stroke, spinal cord, and traumatic brain injury rehabilitation), pulmonary rehabilitation, geriatric rehabilitation, and pediatric rehabilitation.

LIFE-STAGE CONTEXT

Rehabilitating Older Adults

Rehabilitation nurses must recognize that older patients frequently experience age-related functional decline. In these populations, rehabilitation programs that target improving mobility, balance, and ADLs can greatly increase quality of life. Older adults often present multiple chronic illnesses. Rehabilitation nurses must coordinate care and address polypharmacy concerns while considering all interplay of conditions when developing treatment plans. It is vitally important for older adult patients to undertake risk analysis to provide a safe rehabilitation environment. Understanding environmental and physiological factors that cause falls is one key for creating such an atmosphere. Many older adults may also experience cognitive impairments like dementia; rehabilitation nurses must tailor

communication techniques as necessary to safely accommodate cognitive deficits and ensure patient well-being.

Stroke Recovery

Stroke recovery is an involved and multidimensional process that must address physical as well as psychological difficulties. Nurses play an integral part in treating their stroke patients' individual issues, and they can aid the recovery process in myriad ways.

People who have been impacted by stroke typically experience physical, cognitive, social-emotional, and socioeconomic challenges. Some physical impairments may include weakness or paralysis on one side of their body (known as hemiparesis), changes to muscle tone, and issues with balance and coordination. Physical therapy plays an integral part of stroke recovery by improving mobility, strength, and motor control. Experiencing dysphagia, an increasingly prevalent risk after stroke, may impede nutrition and hydration, increasing the risks of aspiration pneumonia and complicating recovery efforts. Patients who experience stroke with aphasia can develop depression, frustration, and even suicidal ideation because of their inability to communicate clearly. Rehabilitation nurses help individuals adapt to these changes by finding ways to communicate and engage in meaningful activities.

Recovering from stroke is an interdisciplinary journey in which nurses, therapists, and psychologists all come together to help those who experienced stroke regain independence, enhance quality of life, and adapt to a new reality. It is important to assist patients in regaining functional independence in ADLs, such as dressing, grooming, and feeding themselves. Occupational therapy plays an invaluable role in providing adaptive techniques and strategies. Speech therapy helps people who have experienced stroke rebuild their skills to address aphasia as well as strengthen the muscles to safely swallow and eat.

Recovery from stroke can be emotionally exhausting for patients. Many experience depression, anxiety, frustration, and mood changes; these sudden changes to physical and cognitive capabilities, while simultaneously adapting to a new normal, can add another layer of emotional challenge. Patients impacted by stroke frequently experience fatigue, which may impede their participation in therapy sessions and daily tasks. Therefore, finding an equilibrium between rehabilitation efforts and rest is of utmost importance.

Medication management is another integral part of rehabilitation therapy. Patients who experienced stroke must often manage multiple medications for conditions like hypertension, diabetes, and anticoagulation; maintaining appropriate medication adherence is critical in avoiding future strokes and managing other health concerns.

Spinal Cord Rehabilitation

Spinal cord rehabilitation addresses the complex challenges faced by individuals experiencing spinal cord injuries (SCIs). An SCI may lead to various degrees of paralysis or loss of function depending on its level of severity and location on the body. Rehabilitation for such individuals aims at optimizing functional independence, improving quality of life, and offering support for physical, emotional, and psychosocial well-being. This type of rehabilitation is typically achieved through adaptive techniques, assistive devices, and mobility training programs.

Individuals living with SCIs often experience changes to sensation, including loss of sensation, altered perceptions, and neuropathic pain. Therefore, managing sensory changes and pain management are critical elements of rehabilitation. Spinal cord injuries may disrupt the autonomic nervous system's control of bladder and bowel function, necessitating rehabilitation interventions to manage bladder and bowel control, prevent infections, and preserve skin integrity.

Depending on the severity of the spinal injury, respiratory function can also become compromised. Individuals having more serious wounds may require respiratory support such as breathing exercises and techniques designed to minimize complications related to breathing issues. Spasticity (involuntary muscle contractions) is common after an SCI and should be managed through medications, stretching exercises, and physical therapy to increase comfort and mobility.

Additionally, individuals with limited mobility are at an increased risk for pressure ulcers (bedsores). Proper skin care and preventive measures must be implemented to mitigate such complications. Many individuals with SCIs rely on wheelchairs or other assistive devices for mobility purposes; training in their safe use forms an integral component of rehabilitation.

Spinal cord injuries may lead to emotional challenges such as depression, anxiety, grief, and body image concerns; addressing these challenges may require counseling services, peer support groups, and other forms of psychosocial support. It may also be helpful for nurses to collaborate with rehab teams specializing in treating sexual health concerns associated with spinal injuries; these specialists can provide education about options for sexual activity and family planning. Spinal cord injuries often have an overwhelming effect on family and other caregivers of an affected individual, necessitating support and training to ensure a safe home environment for everyone involved in the process.

Spinal cord rehabilitation emphasizes enhancing functional independence for everyday activities such as dressing, bathing, and grooming. Occupational therapy assists individuals to redevelop the necessary self-care abilities needed for self-sufficiency. Reconnecting individuals with their communities and engaging them in recreational and social activities are also integral parts of spinal cord rehabilitation, helping promote social inclusion and foster feelings of belongingness and acceptance. Adaptive sports and recreational activities provide individuals with SCIs an avenue to maintain physical fitness, build self-confidence, and have fun. Rehabilitation nurses also work to evaluate individuals' vocational goals and capabilities before providing necessary training and support to reintegrate them back into the workforce.

Cardiac and Pulmonary Rehabilitation

Cardiac and pulmonary rehabilitation programs are tailored to improve the health and well-being of those experiencing cardiac or lung conditions, respectively.

Cardiac rehabilitation programs focus on personalized exercises tailored specifically for individuals living with heart conditions. Balancing intensity with one's cardiovascular fitness level and health status is integral to improving cardiac function and endurance. Education, lifestyle modifications, and medication administration each play key roles in cardiac rehabilitation programs. Cardiac rehabilitation programs provide essential education on medication usage, including potential side effects and the importance of sticking with prescribed regimens. Cardiac rehab programs also offer psychosocial support services, which offer counseling services, stress-management techniques, and support groups.

Patient education is integral to a cardiac rehabilitation program. Cardiac rehabilitation programs often offer nutritional advice regarding low-sodium diets and portion-control strategies, as well as ways to manage weight and blood sugar. It is also important to educate the patient on heart anatomy and function, cardiovascular system design and performance, and the effects of exercise. The patient should understand that these strategies all play a role in avoiding future adverse heart events.

Pulmonary rehabilitation aims at increasing lung capacity by means of breathing exercises and other methods that maximize oxygen exchange. Individuals living with lung conditions frequently experience shortness of breath and reduced exercise tolerance, making pulmonary rehabilitation programs an essential way of strengthening respiratory muscle strength and endurance. Pulmonary rehabilitation offers individuals who experience conditions like chronic obstructive pulmonary disease, asthma, and pulmonary fibrosis the tools needed to effectively manage symptoms, avoid exacerbations of their condition, and optimize lung function.

Many individuals living with lung conditions require oxygen therapy and inhaler medications. Pulmonary rehabilitation educates participants on energy conservation techniques such as safe storage, proper use, and delivery methods of inhalers and other tools for oxygen therapy. Pulmonary rehabilitation offers techniques for conserving energy and managing daily tasks without straining one's respiratory system. Individuals living with lung conditions require techniques to clear mucus from their lungs and improve lung hygiene, including coughing and huffing techniques that work most effectively. Pulmonary rehabilitation includes instruction in these techniques as well as psychosocial support services for individuals needing rehabilitation services. Lung conditions can lead to feelings of isolation, anxiety, and depression. Pulmonary rehabilitation programs offer support and teach strategies that address the physical needs of a lung transplant as well as the psychosocial impact of lung disease.

Patient education around nutrition and dietary needs is critical for pulmonary rehabilitation too. Nutritional education centers on maintaining a healthy body weight and optimizing energy levels to support lung function. Nutritional strategies also play a crucial role in managing conditions like obesity-related hypoventilation.

Both cardiac and pulmonary rehabilitation programs emphasize education, support, lifestyle modifications, and

lifestyle management services to maximize patients' well-being and quality of life. These specialized rehabilitation approaches allow people to manage their conditions more easily while increasing functional capacity and leading healthier lives.

Assessment of Functional Ability

Functional ability assessment in rehabilitation is an integral part of the rehabilitation process. It entails accurately assessing patients' physical, cognitive, and psychosocial capabilities to establish current levels of independence and potential areas for development. Assessments provide valuable data for creating personalized care plans with realistic rehabilitation goals in mind. Activities of daily living are daily self-care tasks performed by individuals, including bathing, dressing, grooming, eating, and toileting. Measuring how effectively patients complete ADLs on their own or with assistance allows us to determine their level of independence with self-care tasks.

An **instrumental activity of daily living (IADL)** is a more complicated task that contributes to an individual's overall well-being and independence; they include preparing meals, managing medications and finances, and completing home chores. Assessing IADLs provides insight into a patient's ability to function within both home and community environments. Evaluating a patient's mobility and transfer abilities entails evaluating their capacity for safe movement from one location to the next: for example, moving between beds, chairs, toilets, and tables. Assessing mobility also allows health-care practitioners to determine any additional assistance, such as assistive devices, gait training, or strength-building interventions, that might be required for them.

Assessing a patient's ability to walk and stand independently or with assistive devices can give valuable insights into their overall mobility and help identify areas for intervention to enhance balance, coordination, and walking ability. Evaluating cognitive abilities such as memory, attention, problem-solving, and decision-making is vital in treating brain injuries or cognitive impairments, especially among patients residing in care homes or residential facilities. Cognitive assessments help guide interventions designed to tackle any challenges to functional independence that might impact daily activities. Assessing a patient's ability to communicate, either verbally or via alternative channels, helps establish whether the patient can effectively express needs, understand instructions, and interact with others.

Patients experiencing dysphagia require frequent assessments to ensure safe eating without aspiration; rehabilitation nurses can provide essential guidance for diet recommendations and interventions to minimize complications. Speaking and swallowing are helpful components of a respiratory assessment. Patients living with lung conditions benefit from having their lung function and endurance assessed to gauge the potential capacity for physical activity and exercise.

Consideration should also be given to the social supports, family dynamics, mental health issues, and emotional well-being of patients undergoing rehab therapy; these factors can influence a patient's motivation, engagement in therapy, and overall rehabilitation outcomes. Assessing the living environment for accessibility and safety features serves to inform recommendations for modifications or assistive devices that facilitate functional independence at home.

Functional ability assessments provide health-care providers with baseline data that allow them to track patient progress. Regular reassessments enable health-care providers to adjust interventions and goals as patients' abilities change over time. Including patients in goal setting helps ensure their rehabilitation plan reflects their preferences and values. Setting realistic and obtainable goals motivates patients to actively engage with rehabilitation activities. Interdisciplinary teams that may include nurses, PTs, occupational therapists, SLPs, and psychologists conduct functional ability assessments on patients to gain a comprehensive understanding of functional abilities and limitations so they can design rehabilitation interventions to promote independence while increasing overall quality of life for these individuals. For many years, the Functional Independence Measure has been the gold standard for assessing a patient's function in rehabilitation; it is required by CMS. The **Inpatient Rehabilitation Facility Patient Assessment Instrument (IRF-PAI)** is the assessment instrument that IRF providers use to collect patient assessment data for quality measure calculation and payment determination in accordance with the IRF Quality Reporting Program.

36.3 Additional Care Settings in the Community

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the nurse's role in different community care settings
- Discuss care and collaboration efforts when caring for those experiencing homelessness

Nurses play a central role in a variety of health-care settings, including hospitals and community care settings, and address diverse patient needs. As the health-care industry shifts toward preventive and holistic approaches, nurses may find themselves leading efforts to offer services far beyond hospital walls. These settings can include health-care homes, schools, clinics, shelters, and beyond.

The Nurse's Role in Community Care Settings

Nurses play vital roles in many community-based settings, providing health-care expertise and compassionate care beyond hospital environments. For example, nurses may work in community clinics to provide preventive care, health screenings, immunizations, and treatments for common illnesses, as well as health education to empower individuals and communities in making informed decisions about their well-being. Nurses may participate in community health initiatives focused on health promotion, disease prevention, and education. For instance, they might organize health fairs, workshops, or screening programs as an effort to engage and empower communities toward improving their own well-being. Rural and remote regions often rely heavily on nurses as primary health-care providers due to limited access to medical facilities, providing a full array of health-care services, such as assessment, treatment, medication administration, and emergency responses.

Nurses may also offer these services in correctional facilities. Correctional facilities employ nurses who offer health-care services for incarcerated people's acute and chronic medical needs, including administering medications, managing chronic conditions, conducting health assessments, and making health assessments to ensure incarcerated people's needs are being met within this special setting.

Nurses working at senior care facilities, such as assisted living centers or nursing homes, provide medical assistance for older adults in various forms. This may involve managing chronic conditions, administering medications, and overseeing overall well-being in these community-based environments. Furthermore, nurses also serve as advocates, educators, caregivers, and coordinators of care for individuals within this setting: their roles go well beyond simple medical duties by including activities to promote health, education, and emotional support and collaboration to increase well-being outcomes and enhance overall quality of life.

We cover some additional community care settings in more detail, including hospice care, ambulatory and outpatient services, occupational health programs, and school health programs.

Hospice Care

The **hospice** and palliative care settings offer compassionate nursing services for individuals living with life-limiting illness. Nurses provide pain management, emotional support, and education about end-of-life care, while assuring patient comfort and dignity.

Hospice nurses play an invaluable role in providing health care beyond hospital settings, ensuring that individuals receive comprehensive yet personalized attention in the comfort of their own environments. Hospice care, especially home hospice, can have a significant impact on individuals facing life-limiting illness and improving quality of life during its final stages. Community-based nurses are at the core of hospice care, offering compassion, expertise, and comprehensive support to both patients and their families. Beyond medical tasks alone, the nurse's role spans emotional support, pain management, symptom relief, and education. They work in close cooperation with interdisciplinary teams composed of physicians, social workers, spiritual counselors, and volunteers to deliver tailored treatment to meet a patient's specific needs. The hospice nurse focuses on the patient's needs and supports family members and loved ones during the death and dying transition. Palliative care and hospice care often overlap in nursing care, but Table 36.3 shows how they are distinct.

	Palliative Care	Hospice Care
What is it?	A focus on relieving the pain, symptoms, and stress of a chronic illness, which may not be terminal	A focus on providing care for patients at the end of life
What is the time frame of care?	No time frame	Generally lasting up to six months
What is the scope of service?	Interdisciplinary team may be involved for a variety of treatments	Interdisciplinary team is involved for pain management but not curative treatments
Where is care given?	Patient's home, skilled nursing facility, assisted living facility, hospital	Patient's home, skilled nursing facility, assisted living facility, hospital, hospice facility
Does Medicare pay?	Medicare Part B pays 80 percent of charges	Medicare Part A pays all hospice services
What other services are offered?	Telehealth, patient education, advance care planning	Complementary therapies, professional end-of-life care, telehealth

TABLE 36.3 Palliative Care versus Hospice Care

Ambulatory Services

Outpatient health care or **ambulatory services**, also referred to as "ambulatory care," refers to health-care services in which the patient receives care without needing hospital admission. Ambulatory care services aim to meet an array of medical needs, from preventive services such as routine exams to diagnosis, treatment, and management of various health conditions. Ambulatory services are typically found in clinics, medical offices, urgent care centers, specialty centers, and even prisons. These services are offered exclusively to those not needing hospitalization. Nurses working in outpatient settings conduct initial assessments and prioritize care according to urgency and necessity, gathering medical histories, performing vital sign measurements, and analyzing symptoms to guide appropriate interventions or referrals for each individual patient.

Ambulatory services cover an array of health-care needs, such as preventive services, diagnostic testing, imaging and laboratory analysis, vaccinations, physical therapy services, and minor surgery treatments, as well as follow-up visits for chronic disease management. Patients receiving outpatient services typically return home the same day after medical appointments or procedures performed at outpatient facilities.

Ambulatory services allow convenient access to health care without hospital admission being necessary. Appointments can often be scheduled at times convenient to patients, and services are designed to offer efficient and timely care without prolonged wait times. Whereas health-care facilities typically deliver outpatient services via scheduled appointments to manage patient flow more efficiently, ambulatory services provide flexible scheduling to make receiving care as painless and comfortable as possible without disrupting daily lives or routines. They play a pivotal role in provision of preventive services, early diagnosis of conditions, and effective management. Table 36.4 compares the various services offered in different health-care settings.

Outpatient Care Settings	Services Provided
Ambulatory care	Lab work
Urgent care	Lab work, diagnostics, x-ray, first aid for acute medical problems, suturing, wound care, physical assessment
Health-care clinic	Visit with provider, diagnostics, medication prescribing, small treatments such as respiratory medications, wound care; nurses monitor progress with chronic disease management
Telehealth	Simple acute illness that can be treated by an online provider and that does not require suturing, x-ray, or lab diagnostics

TABLE 36.4 **Services of Outpatient Care Settings**

Occupational Health Programs

The field of health care focused on improving and protecting employees in their place of work is called **occupational health**. Occupational health programs aim to promote employee well-being and safety in the workplace. They incorporate various strategies and interventions designed to create a safer and healthier work environment by avoiding injuries, illnesses, and hazards. Nurses are an essential part of occupational health management, playing both advisory and managerial roles. Their responsibilities extend far beyond direct patient care to include health promotion, injury prevention, educational programs for both employees and employers, and collaboration among both parties involved.

Working closely with occupational safety specialists, nurses develop and implement safety protocols. They educate employees on workplace health and safety practices, such as appropriate ergonomics, the use of PPE, health screenings, and strategies to avoid injuries and lead a healthy lifestyle. Nurses assess workplace hazards, such as exposure to hazardous materials or musculoskeletal issues, and recommend measures to mitigate risks.

Occupational health nurses specialize in injury management and first aid response plans in workplace settings. They often can offer immediate attention for workplace accidents or refer the individual to an acute care outpatient facility for treatment. They administer first aid, assess injuries' severity, and determine if further medical attention is required. Duties also include monitoring employees to ensure compliance with health safety standards: for example, checking N95 mask measurement, ensuring people are up to date on their vaccines, and administering flu or COVID vaccines. Occupational health nurses are also involved in health surveillance, performing periodic monitoring checks on workplace employees' physical conditions for potential issues that might require medical intervention.

Occupational health nurses routinely monitor employees working in high-risk environments, such as those working with potentially harmful chemicals or on construction sites. By conducting regular health assessments, occupational nurses can detect potential health concerns early and initiate effective solutions. They help workers follow specific protocols after an injury to file an insurance claim for additional medical attention. By keeping detailed health records for employees' medical histories and conducting regular assessments, occupational health nurses assist in tracking trends, pinpoint areas of concern, and support evidence-based decision-making processes. As a result, they can devise and implement wellness programs designed to promote healthier behaviors among employees, such as smoking cessation initiatives, weight management plans, stress relief techniques, and fitness activities. Nurses work collaboratively with employers and management to establish policies and practices to create a safe and healthy work environment, serving on safety committees while contributing their health-care knowledge in decision-making processes.

Nurses play an essential part in emergency response planning in the workplace. They educate employees on emergency procedures, conduct drills, and ensure medical supplies and equipment are readily accessible. Nurses also help employees who are returning to work after an injury by teaching them about emergency procedures, conducting drills, and ensuring medical supplies are quickly available should an incident happen. Nurses work

alongside health-care providers to develop return-to-work plans that consider employees' medical conditions and job demands, in cases of workplace injuries or illnesses. Nurses also serve as advocates and provide employee support services when workplace injuries or illnesses arise. Nurses play an essential part in developing an environment conducive to employee well-being by working alongside employers to create safe work environments that promote both physical and mental well-being.

School Health Programs

School programs, more commonly referred to as school health programs, are comprehensive initiatives created to support students' physical, emotional, and academic well-being within an educational setting (de Buhr et al., 2020). School programs encompass various services, interventions, and activities designed to meet the physical, mental, and social health needs of pupils and staff.

Nurses serve as health-care professionals who can offer expert clinical knowledge and health education within a school environment. School nurses conduct a variety of assessments to determine students' needs and detect potential health concerns. They conduct vision and hearing screenings, monitor growth and development, and assess overall health status. Nurses provide health education to students, staff, and parents on topics like nutrition, hygiene, sexual health prevention strategies, substance use reduction plans, mental wellness awareness campaigns, and safety precautions.

School health nurses may also administer immunization shots. Nurses take great care to record all necessary immunizations received by students, thereby helping to prevent contagious diseases from spreading within the school community and aiding efforts to manage chronic diseases. In an era of controversy regarding immunizations, school nurses help educate parents about vaccines, including criteria for exemption. School nurses also provide services for children experiencing chronic health conditions, such as diabetes, asthma, and allergies. They create individualized health plans, educate school staff about students' needs, and ensure emergency medications such as EpiPens are easily available, should an emergency arise. Nurses in school settings are trained to respond promptly to medical emergencies in school settings—for example, injuries, allergic reactions, and seizures—and offer immediate emergency assistance if necessary.

One essential job of the school health nurse is to assess mental health needs and offer support to individuals experiencing anxiety, depression, trauma, and other forms of mental distress (Markkanen et al., 2021). Nurses should be able to recognize signs of mental health concerns in students, offer immediate assistance when necessary, and refer them to mental health professionals for further evaluation and intervention. Nurses provide counseling and emotional support for students facing health-related or personal difficulties, offering a safe space in which students may discuss or share any worries that arise. Collaborating closely with school administrators and staff members as well as parents and community resources, nurses organize health promotion events at school, such as health fairs, wellness workshops, and awareness campaigns. They also advocate for policies that foster an environment conducive to well-being at school.

School health nurses keep accurate health records on students, including immunization records, health assessments, and medical histories. They provide essential input when crafting health policies at schools to prioritize student well-being with respect to nutrition, physical activity, and other related matters. Nurses also provide an **individualized care plan** that outlines care requirements for each student with specific medical needs, for example, a child with diabetes or seizures (Potts et al., 2018). These personalized care plans outline necessary accommodations, interventions, and communication strategies in order to support each student's well-being.

Caring for Persons Experiencing Homelessness

Caring for people experiencing homelessness requires a holistic and compassionate approach that recognizes the unique challenges and vulnerabilities affecting this population. Homelessness can result in physical, mental, and social health complications due to limited housing or resources, which must all be addressed simultaneously. Working with people without housing involves building trust, providing support, and helping them access resources that will improve their overall well-being.

Nurses play an invaluable role in meeting the unique health needs and vulnerabilities experienced by persons without housing, such as lack of access to basic health services and environmental conditions that exacerbate physical and mental illnesses. Nurses provide essential health-care services like wound care, immunizations, blood

pressure monitoring, and treatment for minor illnesses or injuries. Wound care in particular can be an important element of infectious disease prevention. Nurses educate individuals experiencing homelessness about ways they can prevent infectious diseases like HIV, hepatitis, and tuberculosis by offering vaccinations and disseminating hygiene supplies.

When working with a patient without housing, the nurse should conduct a health assessment to detect and address immediate health concerns and establish an evidence-based framework for ongoing care (de Buhr et al., 2022). The assessment should cover physical and mental conditions, substance use, and any chronic conditions. People experiencing homelessness face a higher risk for mental illness and substance use disorders than the overall population in the United States (Narendorf et al., 2022). The assistance of a nurse could include counseling sessions or referrals to professional mental health services as well as crisis intervention strategies. Nurses address substance use by offering counseling services and referrals to treatment programs for substance use disorders. Nurses also educate individuals on safe injection practices and risks of overdose.

Nurses provide individuals experiencing homelessness with access to community resources such as shelters, food services, clothing donations, and employment assistance programs, as well as housing programs and social services. Nurses can also advocate for improved health-care access and social services for populations without housing and help raise awareness about the unique health challenges faced when experiencing homelessness. By working to meet the complex physical, mental, and social needs of this population, nurses contribute greatly toward improving individuals' overall well-being as they journey toward stability through housing solutions.

36.4 Transition and Continuity of Care

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the process of discharge planning for patients requiring continued services
- Describe the role of nurse case managers in supporting patients through the care continuum
- Explain how collaborative care functions and supports positive patient outcomes

A change from one patient setting to another outside of a hospital setting is called **transitional care**. It could be a change from the emergency department to another medical-surgical department, or a transition from a hospital to a rehabilitation center and then back home. Transitions and **continuity of care** play a central role in health care's ever-evolving landscape and represent key moments on an individual patient journey. They focus on the process of helping patients move between health-care settings to ensure seamless health-care experiences that focus on patient needs and positive outcomes. Transitioning between care settings and changing treatment plans are critical junctures that must be handled carefully to avoid errors or disruption. Through an examination of strategies, challenges, and key roles in ensuring continuity, this section explores how health-care systems can integrate all their various components effectively to offer patients optimal care outcomes.

Discharge Planning for Community or Home Care Settings

In home and community-based care settings, **discharge planning** is an organized process designed to facilitate a safe transition for patients from health-care facilities, like hospitals or rehabilitation centers, back into their own home or a care setting of choice. This process aims to ensure patients receive all the support, resources, and follow-up care necessary for ongoing recovery and self-management of health outside the hospital setting. Effective discharge planning is essential in avoiding readmissions, improving patient outcomes, and supporting overall well-being in the home or community environment. Key components of discharge planning in an inpatient or home care setting include collaborative decision-making, the creation of a care plan, patient education, medication reconciliation, home safety assessment, and coordination of assessment, care, services, and follow-ups.

Discharge planning begins with a detailed evaluation of a patient's physical, psychological, and social needs. Health-care providers, such as nurses, case managers, and social workers, collaborate in this assessment to ascertain the patient's level of independence, support network, and required services. Together with the patient, the nurse will review the patient's health status, treatment plan, and medication management needs, as well as any lifestyle modifications required, before discharging the patient from health-care services.

Based on the assessment, an individualized care plan is developed and tailored specifically for each patient. The care plan may include details regarding medications, wound-care treatments, and equipment requirements as well

as diet restrictions, exercise routines, and follow-up appointments. Discharge planners collaborate with health-care providers, community resources, and home-care agencies to coordinate services and support needed upon discharge from hospital care, including home health nursing services, physical therapy services, occupational therapy treatments, medical equipment delivery, and social services for their patients.

Patient education is an important component of discharge planning. Both patients and caregivers need to receive education about their conditions, treatment plans, medications, signs, and complications, as well as self-care strategies, to actively manage their own health at home. Discharge planners need to ensure their patients understand their medication regimen, including dosages, frequency, and potential side effects. They may arrange prescriptions from community pharmacies as well as home delivery services.

Home environments will be assessed to ensure they meet patient safety needs and accommodate mobility difficulties or medical equipment, with modifications recommended as appropriate for safety and functionality. Lowered countertops in the kitchen, wider doors, and easier-to-manipulate door handles may be some of the modifications needed to ease the transition to a home setting. Appointments will be scheduled with the patient's care provider after initial assessments to provide any needed follow-ups and updates as appropriate. Follow-up appointments will then take place to review how treatment has gone so far and offer recommendations where needed. Discharge planners facilitate these follow-up appointments between patients, primary care physicians, specialists, and health-care providers to monitor patient progress and adapt the care plan as necessary. Effective communication among all members of the care team is of utmost importance, and discharge planners ensure medical records, care plans, and instructions are communicated accurately to home-care providers, caregivers, and the patient.

The Nurse's Role in Discharge Planning

Nurses play a crucial role in supporting patients through their transition from inpatient to outpatient services. This transition is a critical juncture in a patient's health-care journey, and nurses contribute significantly to ensuring a smooth, safe, and successful shift from the hospital to a less-intensive care setting. Nurses provide essential education to patients and their caregivers about the patient's condition, medications, treatment plan, and self-care strategies. This education empowers patients to actively participate in managing their health and follow recommended practices after discharge.

Nurse Case Management

The role of a nurse case manager in community or home care settings is multifaceted and essential for ensuring the provision of high-quality, patient-centered care to individuals who require ongoing medical attention, support, and coordination of services in their homes or within the community. Nurse case managers play a pivotal role in facilitating effective communication, coordinating care services, and advocating for the well-being of their patients. A nurse case manager functions in acute care settings as well as in managed care organizations, rehabilitation centers, and long-term settings.

Collaborative Care

Also referred to as interdisciplinary or interprofessional care, collaborative care is an approach to health care that stresses collaboration among multiple health-care providers from different fields to deliver comprehensive and holistic treatment to patients. This approach acknowledges that health conditions often involve complex interactions spanning various domains and require specialists from diverse fields to properly meet patients' physical, psychological, emotional, and social needs. Collaborative care aims to optimize patient outcomes, elevate quality care delivery, and create patient-centered experiences. It involves teamwork, effective communication, and shared decision-making as part of its approach toward health challenges. Key characteristics and components of collaborative care include interdisciplinary teams, effective team communication, coordination of patient care, and patient-centered care.

Depending on the patient's needs, a collaborative care team may include physicians, nurses, pharmacists, social workers, PTs, occupational therapists, and psychologists, all of whom collaborate closely for patient care. Each team member brings their unique expertise to address various aspects of patient health. All team members work toward common goals related to improving well-being, safety, and recovery for the patient. Goal setting should begin with knowledge of the patient, including their preferences and needs. Involvement from every member in this endeavor

is of vital importance for meeting goals effectively.

Collaborative care ensures that care interventions and services are coordinated to minimize duplication, address gaps in care delivery, and maximize resource use, thus improving patient experiences while preventing fragmentation of care services. In collaborative health care, patients' preferences, values, and goals are taken into consideration when making care decisions. This approach empowers patients to actively take part in their treatment plans. Health-care professionals collaborate closely with patients and their family members, helping them make well-informed decisions regarding treatment options, interventions, and care plans. Patients' input is considered when making these choices.

Referring patients to support groups or peer-led programs can provide emotional support, shared experiences, and a sense of community for individuals facing similar health challenges.

Referrals to dietitians or nutritionists support patients with dietary restrictions or those needing guidance for managing specific conditions through proper nutrition. Referrals to pharmacists or medication management programs help patients better understand and adhere to their medications and regimens, managing side effects as necessary and adhering to prescribed regimens.

Summary

36.1 Home Health Care

- Home health nurses serve an invaluable function within health-care systems, acting as intermediary communication channels between health-care providers, such as physicians and therapists, and patients.
- Home health nurses conduct in-person home visits, which can involve a lot of planning. There are a number of steps nurses should take to prepare for their visit.

36.2 Rehabilitative Care

- Rehabilitation nurses are one part of a larger team of rehabilitation specialists, which can include occupational therapists, SLPs, and PTs, among many others.
- Therapy plays an essential part in helping restore functional independence for patients, improving quality of life and supporting return to normal ADLs. Rehabilitation nurses provide expert, patient-centered care that covers physical, emotional, and psychological well-being.
- The role of the rehabilitation nurse is to manage complex medical conditions, therapeutic interventions, and coordination of care to produce improved patient outcomes, reduced hospital readmission rates, and an easier transition back home or to community-based settings.
- There are several different specialties within the rehabilitation nursing field. A rehabilitation nurse may specialize in stroke recovery, spinal cord rehabilitation, cardiac and pulmonary rehabilitation, or many other areas.
- Being able to assess patients for functional ability is a critical part of being able to move forward with care plans. Nurses should be able to accurately evaluate their patients in their ability to complete ADLs and IADLs.

36.3 Additional Care Settings in the Community

- Community health nurses may work in a variety of settings, including hospice centers, ambulatory and outpatient centers, work environments, and schools. They play vital roles in assuring the well-being and health of various populations.
- Nurses may also work extensively with people who are experiencing homelessness, extending far beyond traditional health-care facilities to bring essential services directly into communities across the country.

36.4 Transition and Continuity of Care

- Discharge planning involves coordination and communication between health-care providers to meet patients' needs during times of transition.
- Nurse case managers play an invaluable role in providing continuity of care by serving as liaisons between various health-care professionals and patients.
- By collaborating with the rest of the health-care team, nurses play an invaluable role in maintaining continuity of care while enhancing the overall experience of care delivery for each of their patients.

Key Terms

adaptive equipment medical equipment, such as hearing aids or cochlear implants, used to help those with disabilities adapt to full function

ambulatory services health-care services provided on an outpatient basis, wherein a patient receives care without needing hospital admission for an extended stay

assistive device type of medical equipment, such as a cane or wheelchair, used to make activities of daily living easier

community-based care holistic approach that considers the emotional, physical, social, and environmental factors that impact an individual's health

continuity of care seamless communication between health-care professionals when a patient is transferring to a new setting

discharge planning organized process designed to facilitate a safe transition for patients from health-care facilities, like hospitals or rehabilitation centers, back into their own home or a care setting of choice

hospice service that provides care for patients at the end of life

individualized care plan outline of a personalized health-care plan

Inpatient Rehabilitation Facility Patient Assessment Instrument (IRF-PAI) assessment instrument that IRF providers use to collect patient assessment data for quality measure calculation and payment determination in accordance with the IRF Quality Reporting Program

instrumental activity of daily living (IADL) task that contributes to an individual's overall well-being and independence but that are more complicated than ADLs

medication regimen list of all medications the patient is currently taking

neuropsychologist medical specialist who diagnoses and treats cognitive and behavioral issues related to brain injuries or neurological conditions

occupational health field of health care focused on improving and protecting employees in their place of work

orthotist specialist who designs, fabricates, and fits orthotic devices to improve patients' mobility and functionality

physiatrist medical doctor specializing in physical medicine and rehabilitation

prosthetist specialist who designs, fabricates, and fits prosthetic devices to improve patients' mobility and functionality

rehabilitative nursing recovery and strengthening phase of nursing that helps a patient begin to recover from acute illness, injury, or hospitalization

transitional care change from one patient setting to another outside of a hospital setting

Assessments

Review Questions

1. What are some of the roles of a home health nurse during a home visit? (Select all that apply.)
    a. providing emotional support
    b. performing limited outpatient surgery in the home
    c. reviewing laboratory results
    d. educating the patient and family
    e. administering medications

2. What is an essential goal of documentation in home health nursing?
    a. to include personal opinions and assumptions
    b. to use the nurse's subjective language to describe assessments
    c. to document only positive outcomes
    d. to provide accurate and objective information

3. What is a crucial step when ending a home health visit?
    a. Skim through the summary and provide a physical copy.
    b. Leave educational materials with the assumption the patient will read them.
    c. Review next steps and follow-up appointments.
    d. Omit the patient's questions and concerns.

4. What is one activity of rehabilitation nursing?
    a. order medications
    b. refer for physical therapy
    c. facilitate maximum patient independence and function for activities of daily living
    d. focus solely on psychological well-being

5. What is one key component of assessing functional ability in rehabilitation nursing?
    a. evaluating only physical capabilities
    b. concentrating exclusively on cognitive skills
    c. examining emotional well-being
    d. ignoring family input during assessment

6. Rehabilitation nurses address which aspects in caring for stroke survivors? (Select all that apply.)

a. cognitive impairments
b. cardiovascular surgery
c. mobility challenges
d. emotional support

7. What are the primary goals of nurses working in school health programs?
   a. administering medications directly to students
   b. offering therapy services directly to teachers
   c. promoting student health and academic success
   d. conducting research related to educational methods

8. What should be the primary responsibility of a nurse who cares for persons without housing?
   a. offering cosmetic treatments
   b. offering luxury medical services
   c. building trust and rapport
   d. addressing only physical health concerns

9. What is the primary goal of transition and continuity of care in health care?
   a. reducing health-care personnel needs
   b. getting rid of wait times
   c. ensuring seamless coordination during transitions of care
   d. doing away with patient education.

10. What does "continuity of care" refer to in health care?
    a. frequent readmissions
    b. discontinuation of medical treatments
    c. coordinated delivery of health-care services
    d. avoidance of preventive services

Check Your Understanding Questions

1. Summarize the process of preparing for an initial home health visit.
2. Explain the difference between a rehabilitation nurse and a rehabilitation case manager.
3. Explain the different types of services that are available in outpatient settings, including urgent care centers and clinics.
4. What are resources a nurse case manager can use to help a patient transition out of the hospital and back home?

Reflection Questions

1. Think about your future role as a rehabilitation nurse. What skills and qualities do you think are needed to become a successful rehabilitation nurse?

What Should the Nurse Do?

1. Upon entering a patient's home and conducting a preliminary environmental assessment, the nurse notices two dogs not crated and asks the patient to move the dogs. The patient says no. The dogs begin to growl. The nurse does not feel safe to conduct the visit with the dogs not safely crated. What should the nurse do next?

CHAPTER 37

Trends in Health-Care Technology

FIGURE 37.1 Health-care technology has revolutionized the delivery of individualized patient care, from robotic assistance in the operating room to the day-to-day patient care tools. (credit: modification of "Col. Lovette receives 81st MDG immersion tour" by Kemberly Groue/U.S. Air Force, Public Domain)

CHAPTER OUTLINE

INTRODUCTION Advancements in technology are significantly reshaping the landscape of health-care services, offering innovative solutions that enhance patient care and outcomes. Telemedicine has emerged as a transformative approach, enabling medical treatment to be delivered remotely, removing geographical barriers, and increasing access to health care for underserved populations. Artificial intelligence (AI) technologies have demonstrated the ability to perform human tasks, aiding in accurate diagnosis, personalized treatment recommendations, and efficient health-care management. Smart beds have revolutionized patient care by utilizing sensors and data analytics to monitor vital signs, optimize patient positioning, and prevent pressure ulcers, leading to improved patient comfort and health outcomes. Moreover, wearable devices have become increasingly popular for tracking health metrics, facilitating earlier disease detection, and empowering individuals to actively manage their well-being.

37.1 Telemedicine and Artificial Intelligence

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Define telemedicine
- Define artificial intelligence
- Explain how AI and telemedicine impact patient care
- Identify the challenges of integrating AI into telemedicine
- Describe the role of technology in nursing education
- Discuss the nurse's role in the evolution of telemedicine and AI

Imagine the convenience of connecting with your health-care provider through a video call during your lunch break at work, eliminating the need to take time off to seek medical care. What was once a futuristic idea has now become a reality with telemedicine. While telemedicine is not a new concept, recent advancements in technology—especially in the wake of the COVID-19 pandemic—have propelled its use, solidifying its place in modern health care. Embracing the power of artificial intelligence (AI) further enhances telemedicine's capabilities and creates endless possibilities for future developments. As nurses, it is important to be well-informed about the potential challenges posed by AI-based telemedicine and recognize the integral role we play in its evolution and successful implementation for safe and effective patient care.

The discipline of **informatics**, the science of information, plays a pivotal role in harnessing these technological advancements within health-care organizations. By incorporating informatics into their operational strategies, health-care providers can streamline workflows, enhance data-driven decision-making, and improve overall efficiency in delivering patient care. The Institute of Medicine's Healthy People 2030 objectives further emphasize the importance of health information technology for achieving enhanced access and effectiveness in health-care services, creating a strong impetus for health-care organizations to embrace technological innovations (National Academies of Sciences, Engineering, & Medicine, 2021). Due to all these factors, the total value of the health-care information technology market is projected to surpass $707 billion by 2032 (Acumen Research and Consulting, 2023).

As technology continues to transform the health-care landscape, it is critical for nurses to adapt effectively, understanding and embracing the uses and impact of health informatics and information technologies within their practice. High-tech devices are developed and implemented to improve patient care, but they will never replace the importance of human touch and compassion. Consequently, nurses must play a role in the digital evolution of health care, as they leverage new technologies to optimize workflows and achieve better patient health outcomes. In brief, nurses who stay abreast of technological advancements are best positioned to foster an environment of continuous improvement and patient-centered care.

What Is Telemedicine?

The remote diagnosis and treatment of patients by means of telecommunications technology is called **telemedicine**. Sometimes referred to as telehealth, telemedicine allows health care to be delivered from a distance using technologies such as computers, cameras, tablets, smartphones, videoconferencing, wireless communications, and the internet. Telemedicine may be used to provide care for a variety of situations, such as:

- postsurgical follow-up
- prescription management
- treatment of skin conditions
- delivery of lab or test results
- online counseling
- physical and occupational therapy
- remote monitoring of chronic or reoccurring conditions and urgent care issues

CLINICAL SAFETY AND PROCEDURES (QSEN)

Telemedicine for Stroke Assessment and Care

John, a sixty-year-old man, has a history of hypertension and is at risk for stroke. His health-care provider has equipped him with a telemedicine kit that includes a tablet, a high-resolution camera, and a connected blood pressure monitor. The telemedicine platform is designed to facilitate regular check-ins and immediate assessments in case of potential stroke symptoms.

- Remote monitoring: John uses the telemedicine kit at home to measure his blood pressure regularly. The data is transmitted securely to his health-care provider, who monitors trends and adjusts his medication as needed. Additionally, the tablet is equipped with an application that guides John through simple neurological assessments, such as checking for facial droop, arm weakness, and slurred speech.
- Regular telehealth check-ins: Every few weeks, John has scheduled video calls with his neurologist through the telemedicine platform. During these check-ins, the neurologist assesses John's overall neurological function using standardized stroke scales, such as the National Institutes of Health Stroke Scale (NIHSS). During the video call, the neurologist guides John through specific tasks to assess his neurological status, such as asking him to lift both arms, smile to check for facial symmetry, and articulate specific phrases. The neurologist scores each task based on the standardized scale, providing an objective measure of John's neurological health.
- Emergency assessment: One day, John experiences sudden weakness on one side of his body and difficulty speaking. Recognizing these potential stroke symptoms, John activates the emergency feature on his telemedicine platform. The neurologist is immediately notified and conducts a live video assessment. Using the tablet's camera, the neurologist observes John's physical symptoms in real time. The neurologist guides John through additional assessments to evaluate the severity of the symptoms. Based on the findings and the NIHSS scores, the neurologist determines that it's a potential stroke and activates the emergency response team.
- Timely intervention: Emergency medical services are dispatched to John's location, and he is taken to the nearest stroke center for immediate intervention. The early detection through telemedicine enables a faster response, potentially reducing the long-term impact of the stroke.

This example demonstrates how telemedicine, combined with stroke scale assessments, can be a powerful tool for continuous monitoring, early detection, and timely intervention in cases of stroke, ultimately improving patient outcomes.

While the delivery of virtual health care continues to increase in popularity and frequency, it may not be appropriate for all situations. For example, conditions that require the provider to physically assess the patient or perform diagnostic testing still require a face-to-face visit. Emergencies such as severe trauma, acute chest pain, or sudden neurological deficits demand immediate in-person evaluation to ensure timely and accurate treatment. Additionally, complex cases where multiple specialists need to collaborate or where nuanced physical examinations are crucial may also necessitate traditional office visits.

CLINICAL JUDGMENT MEASUREMENT MODEL

Take Action: Determining Appropriateness of Telemedicine Visits

While working the triage phone line, a nurse at a hospital receives a call from a patient reporting they woke up with their "eye crusted shut." The nurse asks the patient a series of follow-up questions, such as if the eye is red, if there is a foreign object in the eye, and if one eye or both eyes are affected (recognizing cues). From the patient's answers, the nurse determines there are no foreign objects in the eye, only the right eye is affected, and the eye is red. The nurse then analyzes the cues and suspects the patient may have conjunctivitis, or pink eye (prioritize hypotheses). The nurse determines the patient needs to be scheduled to see a provider to receive medical treatment (generate solutions). Recognizing that pink eye is contagious, the nurse determines it would be better to schedule a telemedicine visit. The nurse confirms the patient has access to the internet and a

mobile phone or computer, explains how the telemedicine visit will work, and schedules the appointment for later that day (take action).

Telemedicine allows for two-way telecommunications (Figure 37.2). The patient may be asked to supply the provider with their weight, vital signs, laboratory values, and symptoms. Additional documentation, such as images and medical records, may also be uploaded by the patient to ensure the provider has all information needed to accurately diagnose the problem. On the other hand, the provider may supply the patient with notifications or reminders related to their health, detailed instructions for home care, and encouragement for continuing with their treatment plan.

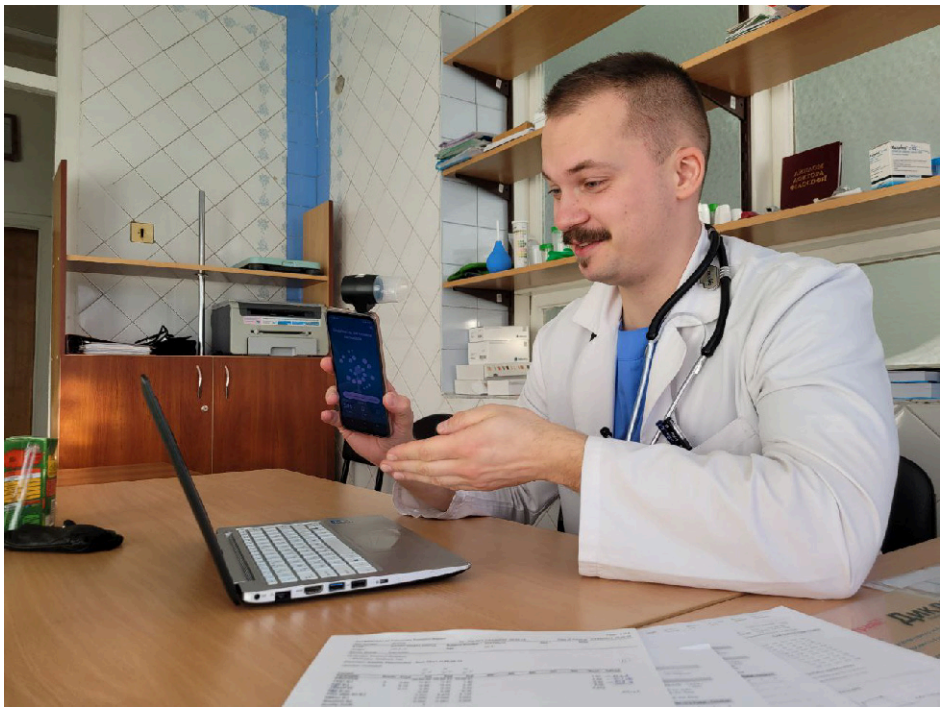

FIGURE 37.2 Telemedicine allows bidirectional audio and visual communication between patient and provider. (credit: "Оцінка ефективності телемедицини для навчання пікфлоуметрії пацієнтів із захворюваннями органів дихання" by Mariia Tsyben/Wikimedia Commons, CC0 1.0)

Utilizing telemedicine offers several benefits. It makes health care more accessible and affordable. Patients can conveniently access care from their current location, eliminating the need to travel, take time off work, or arrange childcare, thereby reducing associated costs. Additionally, telemedicine provides enhanced access to specialized providers, regardless of geographical constraints, while also minimizing wait times for appointments, lowering exposure to potential health risks, and increasing patient engagement and adherence to treatment (Vicente et al., 2022). For instance, patients can avoid exposure to contagious diseases such as influenza or COVID-19 by opting for virtual consultations instead of sitting in crowded waiting rooms. Research has shown that patients who participate in telemedicine visits experience lower hospitalization rates (Campion et al., 2023; Pande et al., 2015; Peters et al., 2021).

CULTURAL CONTEXT

Cultural Considerations of Telemedicine

Cultural considerations in telemedicine are crucial for providing effective and patient-centered care to individuals from diverse cultural backgrounds. When implementing telemedicine services, health-care providers should keep in mind the following variables:

- Language and communication: Language barriers can hinder effective communication between health-care

providers and patients. Telemedicine platforms should support multiple languages and use interpreters when necessary. When communicating with English as a Second Language (ESL) patients, it's important to use clear and straightforward language to ensure understanding. Avoiding slang can help facilitate effective communication.

- Cultural beliefs and practices: Each culture may have unique beliefs and practices related to health, illness, and treatment. Health-care providers must be culturally sensitive and respectful of these beliefs, as they can influence a patient's willingness to engage in telemedicine and adhere to treatment plans.
- Privacy and confidentiality: In some cultures, discussing personal health matters openly may be considered taboo. Providers must ensure that telemedicine consultations are conducted in a private and secure environment to respect patients' cultural norms and maintain confidentiality.
- Access to technology: Cultural factors can influence a patient's access to technology and willingness to use telemedicine services. Providers should be aware of potential disparities and work to ensure equitable access to telehealth services for all patients.
- Body language and nonverbal cues: In telemedicine, the inability to fully observe a patient's body language and nonverbal cues can pose challenges. Cultural differences in nonverbal communication, such as eye contact, should be considered, and providers should be sensitive to these nuances during virtual consultations.
- Family and community involvement: In some cultures, family and community members play a significant role in health-care decision-making. Providers should be open to involving family members in telehealth consultations if the patient desires and consents to it.
- Religious observances: Religious practices may impact a patient's availability for telemedicine appointments. Many religious traditions observe specific days or times for worship, rituals, or rest, which could conflict with standard telemedicine appointment schedules. For instance, in Islam, Muslims are required to pray five times a day at prescribed times. These prayer times could coincide with potential telemedicine appointments, making it challenging for patients to be available without interruption. Providers should be accommodating and flexible with scheduling to respect patients' religious observances.
- Health literacy: Cultural factors can influence a patient's health literacy level, affecting their understanding of medical information and treatment plans. Providers should use clear and simple language and patient education materials that are culturally appropriate.

By integrating these cultural considerations into telemedicine practices, health-care providers can ensure care is inclusive, respectful, and effective in meeting the diverse needs of their patients. This approach fosters trust, improves patient engagement, and leads to better health outcomes for individuals from different cultural backgrounds.

Influence of COVID-19 on Telemedicine

Because telemedicine limits the physical contact required to provide care, the prevalence of virtual care rapidly increased with the onset of the COVID-19 pandemic in 2020. Within the first three months of the pandemic, telemedicine encounters increased by 766 percent, from 0.3 percent to 23.6 percent of all encounters (Shaver, 2022). The widespread adoption of telemedicine played a crucial role in reducing disease transmission, facilitating triage care, ensuring uninterrupted access to health-care services, and safeguarding the well-being of patients, providers, and the entire community (Shaver, 2022).

Telemedicine not only enabled safer health-care delivery during the pandemic—it also played a pivotal role in driving progressive changes in reimbursement policies. Some of these policies were temporary, but others became permanent. For example, the federal government expanded coverage for reimbursable services, allowed reimbursement for care received at the patient's home, and expanded the number of providers eligible to provide telemedicine (Department of Health and Human Services [DHHS], n.d.). There has also been a rise in research studies providing evidence to support the use and effectiveness of telemedicine, which should further encourage policy changes as health care settles into a new "normal" postpandemic (Campion et al., 2023; Pande et al., 2015; Peters et al., 2021; Snoswell et al., 2023).

Artificial Intelligence

Encompassing computer science and comprehensive data sets, **artificial intelligence (AI)** focuses on leveraging technology to address and solve complex problems, enabling machines to perform tasks that typically require human intelligence. AI analyzes data by using algorithms and models that recognize patterns in data to emulate how humans learn, a process known as **machine learning**. AI has the potential to increase the efficiency, accuracy, and speed at which health care is delivered. While there are benefits to AI, potential challenges include data privacy concerns, risk of error, and the inability of AI to demonstrate wisdom or compassion—both of which are essential to the delivery of health care. As such, AI is not intended to replace the provider. Rather, AI is intended to complement the provider so care can be delivered more efficiently, allowing providers more time to spend with their patients.

Common applications of AI in telemedicine include practices relevant to telemonitoring, patient care, and chronic disease management. AI-powered chatbots and virtual assistants can interact with patients to gather information about symptoms, provide initial assessments, and offer guidance on health-care queries. AI is used to analyze medical images—such as x-rays, MRIs, and CT scans—to aid in the detection and diagnosis of conditions. Wearable devices equipped with AI algorithms can analyze physiological data such as heart rate, blood pressure, and glucose levels, providing real-time insights to health-care providers and triggering alerts for potential issues.

Telemonitoring and Patient Care

The practice of monitoring aspects of a patient's health from a remote location is called telemonitoring. It allows data such as heart rate, blood pressure, oxygen saturation, weight, and blood sugar levels to be entered or transferred into a portal that can be accessed by the provider. Telemonitoring has proven to be effective at monitoring both acute and chronic conditions. Research has shown telemonitoring to be particularly useful in improving patient outcomes for heart failure, stroke, COPD, asthma, and hypertension (Noah et al., 2018). By closely monitoring these data, providers can identify changes in a patient's condition more quickly and alter the plan of care accordingly. In addition, telemonitoring reduces the patient's travel time, frequency of visits, costs associated with seeking care, and risk of infection; it also frees up medical providers to attend to patient needs that cannot be monitored remotely.

Patient data management systems (PDMSs) are comprehensive software solutions designed to manage and organize patient-related data within health-care facilities. PDMSs automatically retrieve data from bedside medical equipment, such as vital sign machines, ventilators, and intravenous (IV) pumps. The integration of PDMSs and telemonitoring creates a more comprehensive and seamless health-care management approach. Patient data collected through telemonitoring devices can be directly fed into the PDMS, providing health-care providers with a holistic view of the patient's health status. This integration promotes data-driven decision-making, enhances care coordination, and supports more personalized and proactive health-care interventions. Benefits of PDMSs include their integration with clinical decision support systems that enhance clinical decision-making, decreasing charting time, increasing time to spend with the provider, reducing medical errors, and improving clinical outcomes.

Patient Diagnosis

AI can also be used to assist providers in identifying and diagnosing diseases with increased accuracy, speed, and efficiency (Figure 37.3). AI can use stored medical images from x-rays, MRIs, ultrasounds, and CT scans to analyze subsequent images, for example. AI can also use patient data such as imaging, vital signs, demographics, medical history, and laboratory results to predict accurate diagnoses that may be used to support provider decision-making. While AI may be used to help providers make more informed patient care decisions and reduce the likelihood of misdiagnosis, it should not be used in solitude to diagnose a patient. AI can generate predictions; however, it is the responsibility of the health-care provider to apply their clinical judgment and expertise to accurately interpret the predictions and arrive at a diagnosis.

FIGURE 37.3 A body scanner microscope uses AI to analyze images of spots on the skin and rate the severity to help with diagnosis. (credit: "Artificial intelligence makes its way to MacDill dermatology clinic" by Senior Airman Adam R. Shanks/U.S. Air Force, Public Domain)

CLINICAL JUDGMENT MEASUREMENT MODEL

Prioritizing Hypotheses: Using AI for Patient Diagnosis

Scenario: A patient named Emily presents with a persistent cough and shortness of breath. Her primary care provider orders a chest x-ray to investigate potential pulmonary conditions.

In the hospital's diagnostic workflow, an advanced AI system designed for pulmonary imaging analysis is seamlessly integrated. Trained on a diverse data set, the AI algorithm excels at identifying nuanced patterns and abnormalities related to respiratory health. Emily's chest x-ray undergoes meticulous analysis by the AI algorithm, which examines the image for indications of nodules, infiltrates, or other respiratory anomalies. The AI system generates a comprehensive report highlighting regions of interest and providing an assessment of potential conditions based on recognized patterns in the x-ray.

The AI-generated report is made available to the attending radiologist, who collaborates with the AI system in a synergistic approach. The radiologist, leveraging their clinical expertise, conducts a thorough analysis, considering both the AI insights and their own observations, and determines Emily has pneumonia. This scenario showcases the collaborative and complementary role of AI in pulmonary imaging, illustrating how technology supports health-care professionals in providing precise and timely diagnoses for better patient care.

Patient Treatment Plans

AI provides models for searching medical data to assist with the development of patient treatment plans. By collecting and analyzing data, computers can formulate treatment recommendations based on the patient's diagnosis, health history, risk factors, and medical condition. While trial and error have historically guided some treatment plans, AI offers valuable insights into identifying the most beneficial treatment plan for the patient right from the beginning.

AI can be utilized to deliver individualized treatment for patients, tailoring medical interventions to meet their unique needs and conditions. AI chatbots, for instance, can be used to provide customized, real-time recommendations to patients according to the patient's symptoms. Additionally, AI can be employed to provide patient education. By storing patient data, including medical history and preferences, these AI-powered technologies can effectively provide patient-centered care.

Robots

Robots are becoming increasingly integrated within treatment. For example, robots can be used to complete simple, repetitive tasks such as taking a patient's vital signs and assisting with hygiene. Utilizing robots to complete these

tasks reduces human workload and provides the nurse more time to focus on other, more complex duties. Robots can also be used to assist with mobility, provide medication reminders, and engage patients in opportunities for social interaction. They may also be used to help deliver medication, collect labs, and disinfect equipment. Artificial intelligence coupled with these robotic supports can produce powerful outcomes in data analysis and, in some cases, with diagnosis or alerts.

Additionally, robots can be used to perform surgical procedures. For example, the da Vinci Surgical System is a robotic surgical platform used for various procedures, including prostatectomies, hysterectomies, and colorectal surgeries (Figure 37.4). It consists of robotic arms controlled by a console, providing the surgeon with enhanced dexterity and precision. Used in spine surgery, the Mazor X and Renaissance systems assist surgeons in the placement of spinal implants with high precision. These robots enhance accuracy and reduce the risk of complications. In fact, surgical procedures are the most widely used application of robotics within health care due to the volume of procedures that can be conducted in comparison to the volume achieved by humans (D'Souza et al., 2019). AI is increasingly being incorporated into these systems to provide feedback after each surgery, potentially helping the surgeon improve their performance and improve the robotic products.

FIGURE 37.4 The Davinci Surgical System, a robotic surgical platform used for surgical procedures, is an example of how robots can enhance health-care delivery and patient outcomes. Artificial intelligence can help surgeons and equipment-makers analyze the performance on these machines and improve them over time. (credit: Air Force/Arnold Air Force Base, Public Domain)

Patient Engagement

The field of study and application that focuses on the use of information and communication technologies to empower individuals in managing their health and health care is called **consumer health informatics**. It involves the integration of technology, information, and communication tools to provide consumers (patients or individuals) with access to health information, support self-care, and facilitate communication with health-care providers. Consumer health informatics encompasses topics such as health literacy, consumer education, personal health records, and patient engagement and empowerment. Consumer health informatics addresses these areas by analyzing consumers' information needs, exploring methods to deliver accessible information, and implementing measures to cater to these needs. This includes integrating consumer preferences into health information systems and meeting the growing demands for internet-based health information.

Chronic Disease Management

AI technologies have the potential to bridge the gap between rising health-care costs and the increasing burden of chronic diseases, leading to reduced mortality rates. Algorithms offer the capability to identify individuals with an elevated risk of developing chronic diseases, predict the progression of existing conditions, and utilize health records to anticipate patient outcomes. Incorporating AI into chronic disease management holds the potential to lower costs, enhance outcomes, optimize resource utilization, expand access to care, improve quality of life, and alleviate the burden on the health-care system. It can also create personalized treatment plans based on each patient's individual needs, provide the right treatment at the right time, reduce the risks of complications and disease progression, and reduce side effects of unnecessary treatments.

AI telemonitoring may also prove beneficial to the treatment of chronic medical conditions. AI algorithms can analyze patient data in real time and produce alerts for abnormal readings or patterns, aiding in the detection of changes to a patient's health status and facilitating early interventions. Patterns can be identified to determine the effectiveness of a treatment plan and recommend adjustments as needed. Using real-time data, providers can then tailor the treatment plan to meet the individual needs of the patient, identify early warning signs, and provide personalized feedback.

Challenges with Telemedicine and AI

While telemedicine is associated with many benefits, there are also some notable challenges to be aware of. For example, telemedicine can be used to improve access to care, but providers must take caution not to inadvertently create or reinforce health disparities: preventable differences in the ability of socially disadvantaged populations to achieve optimal health. In particular, older adults, minorities, and those with lower socioeconomic status may not always have the necessary technologies, including internet access, needed for telemedicine. It is essential for providers to explore strategies for ensuring that patients who lack these key resources can still access telemedicine and to consider alternative approaches that reduce barriers to care for individuals who cannot access telemedicine.

Even when patients can access the internet and other necessary technologies, telemedicine adds a layer of complexity that may be difficult for some to understand. Patient education will be necessary prior to initiating telemedicine care. For this education to be effective, health-care professionals will need to receive training on how to use the technology and navigate potential challenges that may occur.

LINK TO LEARNING

The U.S. Department of Health and Human Services (HHS) maintains Telehealth.HHS.gov (https://openstax.org/r/77TelehealthGov), a great resource to help patients make and prepare for a telemedicine visit.

Telemedicine can also pose challenges when a provider is unfamiliar with the patient's medical history or unable to easily communicate with the patient's other providers. This may result in fragmented care, with each provider knowing only the conditions and prescribed medications that are directly relevant to their expertise. Additionally, some health conditions may not be suitable for virtual care, necessitating in-person provider visits and potentially duplicating care efforts.

Another significant challenge associated with the integration of AI and telemedicine is the potential for dehumanization in health-care interactions. As technology plays a larger role, there is a risk of diminishing the human touch and empathy traditionally associated with health care. Patients may feel a sense of detachment when engaging with AI-driven systems or virtual consultations, impacting the quality of the patient-provider relationship. Striking a balance between technological efficiency and the human aspects of care is essential to ensure that patients feel supported, heard, and cared for throughout their health-care journey. Addressing issues related to trust, communication, and emotional support is crucial to mitigate the dehumanizing effects of advancing technology in health-care delivery. Other challenges include legal, ethical, data security, and privacy issues, warranting careful consideration in telemedicine implementations.

Legal and Ethical Issues with AI Use

Use of AI within telemedicine does not come without legal and ethical issues that must be considered. Laws and

regulations are needed to ensure AI systems are transparent and their decision-making can be explained. AI technologies must prove to be fair, accurate, and nondiscriminatory. Regulations must also be in place to guide liability and clarify who is responsible for the decisions made by AI. Additional legal considerations include defining boundaries for AI use and developing international governance to maintain consistency across borders.

The most prevalent ethical concerns linked to the utilization of AI involve obtaining informed consent for data usage, ensuring algorithmic fairness, removing bias, and understanding the role of human judgment in AI-driven decisions. (Gerke et al., 2020). Although data is essential for effective machine learning, the critical issue is whether each patient must consent for their health information to be included in the data collection. Before permitting AI to use stored data from medical records to create algorithms, providers should have satisfactory answers to the following questions: Who owns an individual's health-care records? With whom will health information be shared? Is the patient's consent necessary to share their data? According to the Health Insurance Portability and Accountability Act (HIPAA), the patient owns their health-care records and must give consent for them to be shared.

Effective use of AI must also acknowledge the potential for bias. AI bias occurs because humans select the data used to develop the AI algorithms and are responsible for the decision-making process through which the algorithms are applied. AI systems are trained with data that reflect bias and often are not representative of diverse populations. Biased data leads to biases in the patterns identified and the recommendations provided. Addressing bias in AI-powered telemedicine requires a multidimensional approach. Diverse teams, accurate data, and extensive testing are needed to ensure accurate AI algorithms are developed without bias.

The role of human judgment in AI-driven decisions is crucial and multifaceted. While artificial intelligence systems are capable of data processing, pattern recognition, and decision-making, they lack the capacity to demonstrate the understanding, empathy, and wisdom that humans possess. Human validation is necessary to interpret and determine the accuracy of AI recommendations. Human judgment is also necessary to adapt AI-driven decisions to specific situations and consider factors that AI cannot capture. AI-powered glucose monitoring systems, for instance, may provide insights for diabetes management; however, endocrinologists must use their clinical judgment to interpret these trends, consider lifestyle factors, and make recommendations for insulin adjustments or other interventions. AI algorithms may also analyze data to predict patient deterioration; however, nurses and providers must draw on their judgment, interpret these predictions, assess the broader clinical picture, and make decisions regarding treatment adjustments or interventions. Ultimately, humans are responsible for the provisions of health care and will be held liable for actions and decisions taken, regardless of whether they are based on AI recommendations.

Data Security and Privacy

Data security protects personal information from unauthorized access. By adequately securing data, providers ensure it is accurate, reliable, and available to authorized users when they need it. While the delivery of all health care requires participants to follow HIPAA laws, telemedicine adds a layer of complexity to data security and privacy. Because cybercriminal attacks are a major concern when sensitive personal health information is shared, telemedicine requires a secure platform that meets HIPAA compliance (DHHS, n.d.). Additional technological factors that impact data security include the potential hacking of virtual visits and the use of cellular data or public Wi-Fi that is not secure (Houser et al., 2023).

Due to the data security risks involved, federal regulations are in place to guide organizations in implementing strategies to keep patient data secure. Strong network security features, controlled access rights, and encryption are strategies used to deliver HIPAA-compliant telemedicine. Other strategies include using secured websites that feature the "lock" icon in the address bar, requiring passwords for virtual visits, keeping antivirus software up-to-date, and avoiding public Wi-Fi and shared devices. Nurses must be knowledgeable of the data security policies established by their health-care agency and implement measures to ensure compliance with these policies.

Privacy is a human right; therefore, all individuals have the right to keep their personal information private. Data privacy involves properly handling, processing, storing, and using personal information. Furthermore, additional environmental factors outside the provider's control may affect a virtual care session. For example, the lack of privacy—whether real or perceived—may decrease the likelihood that patients will share sensitive health information with the provider. It may also expose details of the patient's living conditions. Though unauthorized exposure violates a patient's privacy, it is often beneficial for the provider to gain a better understanding of the environmental

factors affecting the patient's health. With the patient's consent, the provider may conduct a home safety assessment.

To safeguard patient privacy during telemedicine visits, patients should be educated to seek out a private setting, wear headphones, and be mindful of their surroundings before initiating the virtual visit. Privacy standards should be incorporated into the agency's policies, procedures, and workflows. Staff and providers should receive patient privacy training that is directed toward the specific use of telemedicine.

AI, Technology, and Nursing Education

AI and related technological advancements have drastically changed how education is delivered. In particular, they have played instrumental roles in the use of simulations utilizing augmented and virtual reality. Using AI algorithms, education can provide personalized training experiences that are customized to the learner's needs. AI also allows educators to collect and analyze data to identify areas of opportunity within the curriculum, such as an increased focus on remote learning.

Simulation

Simulation plays a crucial role in nursing education because it helps nurses to practice skills in safe, controlled replications of clinical scenarios. AI has enhanced the capabilities of simulation, including the ability to present a variety of patient profiles that allow the learner to practice providing comprehensive care to a more diverse population (Figure 37.5). For example, it allows the inclusion of psychosocial dynamics, introducing patient variability that better prepares learners for real-life situations and clinical encounters. Additionally, the automation of scenarios enables them to progress independently, relieving instructors of system management responsibilities. This autonomy allows instructors to focus their attention on observing and assessing students' interactions during the simulation.

FIGURE 37.5 AI-driven virtual simulations provide realistic clinical scenarios, such as this demonstration of CPReality, allowing nursing students to practice assessing, diagnosing, and providing care in a safe and controlled environment. These simulations can adapt to student actions, providing varied scenarios and challenges. (credit: "CPReality Demo" by Penn Libraries-TRL/Flickr, CC BY 2.0)

Augmented Reality/Virtual Reality

The technology of **augmented reality (AR)** superimposes a computer-generated environment onto the real world to create an interactive experience for the user. In contrast, **virtual reality (VR)** integrates hardware (a headset) and software (the VR platform) to create an immersive, simulated environment; typically, the user is represented by an interactive **avatar**, a digital representation of an individual created within a virtual environment. AI algorithms play a pivotal role in enabling avatars to respond and clinical variations to unfold as virtual scenarios progress. These algorithms also facilitate voice recognition within the virtual environment, allowing avatars to recognize user commands and respond appropriately. AI also allows three-dimensional (3D) scenes to be created by a single photo, provides motion tracking data, and collects, stores, and analyzes user-specific data as individuals navigate

the scenario.

Benefits of incorporating AI into AR and VR include an improved user interaction and user experience, as well as the possibility of augmenting human intelligence and reducing educational costs. AI algorithms in AR/VR systems can analyze individual learning patterns and preferences. By tailoring content and experiences to the specific needs of each learner, personalized learning enhances comprehension and knowledge retention, optimizing the educational process. If a learner demonstrates mastery in a particular area, the system can advance to more challenging material, promoting efficient learning. AI-driven assessments in AR/VR environments provide immediate and detailed feedback to learners, allow individuals to identify and rectify mistakes promptly, and enable remote learning opportunities to make education more accessible. Students can engage in immersive learning experiences without the need for extensive physical infrastructure, lowering expenses related to building and maintaining educational facilities.

The Nurse's Role

Technology has instrumentally changed health care and the way in which care is provided. Nurses are responsible for learning, integrating, and supporting the evolution of technology within health care. This responsibility brings both benefits and challenges.

Emerging technologies have the potential to make the nurse's workload more manageable. Electronic health records and digital records improve accessibility, accuracy, and clarity of documentation. Technology may also reduce the nurse's risk of error and liability by automating tasks with precision and speed. The integration of additional technology leads to improved communication capabilities, facilitating real-time interactions that have the potential to enhance care coordination and minimize delays in providing health-care services. As technologies improve patient care and allow it to be provided in rural and remote areas, the health of the patient may improve, thereby reducing the number of patient visits and overall workload of the nurse.

As new and innovative technologies emerge, nurses must engage in continuous learning to stay updated on the latest techniques for providing care. Each new technology requires training, the establishment of new workflows, and patient education. The constant state of change can be overwhelming and take a toll on nurses, possibly leading to resistance toward adopting new technologies and eventually to burnout. While the role of the nurse may shift with the advancement of technology, the nurse will continue to be essential to the processes of coordinating patient care, developing trusting relationships with patients, and adapting to new technologies that allow us to provide the best care for our patients. The nurse's role will retain its essential qualities of wisdom, clinical judgment, and compassion—qualities that cannot be replaced by technology.

37.2 Health Informatics

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the impact of health informatics
- Identify the legal boundaries on health informatics, communications, and technology
- Differentiate between electronic health records and electronic medical records

Health-care informatics is focused on the applications of the massive quantities of data generated by the health-care industry. These data are used to develop strategies to positively influence and improve the delivery of health care. Legislation and governing institutions provide legal boundaries around health informatics by developing guidelines, regulations, and initiatives to support national adoption and acceptance of health informatics. Many of these initiatives have supported the elimination of electronic medical records and the widespread adoption of electronic health records (EHRs).

Health Informatics

Informatics is the science of information. When we talk about informatics, we are talking about the use of technology and computer systems to process data and information. Informatics is a broad term that can be applied to many disciplines. Within health care, the concept can be further broken down by specialty area, such as biomedical, clinical, medical, nursing, population health, and public health informatics. These specialized fields collectively form the broader domain of health informatics.

The field that integrates information science with health care is called **health informatics** (Saba & McCormick, 2015). In other words, it is a specialized field within health care that combines information, technology, and health-care knowledge to improve patient care. Through health informatics, care may be streamlined and coordinated so that quality care can be delivered in the most efficient and cost-effective manner.

Health informatics helps to identify, define, manage, and communicate data, information, knowledge, and wisdom within health care. It creates information structures, processes, and technologies that can be used to support nurses, providers, consumers, patients, and the interdisciplinary teams that guide decision-making. Additionally, informatics enhances collaboration, communication, safety, satisfaction, efficiency, and effectiveness within the delivery of health care.

Information and Communications Technology

All communication technologies that enable users to access, retrieve, store, transmit, and manipulate digital information make up **information and communications technology (ICT)** (Figure 37.6). A broader term for information technology (IT), ICT includes technologies such as the internet, wireless networks, computers, cell phones, software, and other media applications such as videoconferencing and social networking. ICT allows for remote care, interdisciplinary clinical support, and knowledge support. The use of ICT has the potential to promote patient-centered care at a lower cost, improve quality of care and information sharing, educate patients and health professionals, encourage relationships between patients and their health providers, and reduce travel time.

FIGURE 37.6 Information and communications technology (ICT) consists of many components, including hardware, software, data, and access to the internet. (attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

Predictive Medicine and Precision Health

The use of laboratory and genetic tests to determine an individual's probability of developing a disease is called **predictive medicine**. The goal of predictive medicine is to use biomarkers to predict an individual's risk for developing a clinical disorder, predict the most effective treatment, and then intervene before the patient develops the condition. While genetics-based predictive medicine has been used for quite some time, the scope of this field is expanding to include conditions beyond those solely reliant on genetic predictions.

Considering the massive amounts of health-care data that are collected, stored, and processed, and the new analytical techniques available, predictive medicine is one of the most promising applications of informatics. Using its power, providers may soon be able to individualize the risk for a variety of health outcomes and determine individualized treatment options for patients. For predictive medicine to be successful, however, significant efforts will be needed to purchase, develop, and refine the necessary information technology infrastructure. Furthermore, predictive medicine has its limitations: in particular, its reliance on stored data for predictive modeling means its accuracy is limited to the quality of the data available; 100 percent precision cannot be guaranteed. Therefore, it

becomes vital for nurses and all health-care providers to prioritize accurate and appropriate data collection, maintain proper assessment techniques, and comprehend the potential impact of the data they enter on a patient's chart—not only on the patient's immediate needs but on future applications throughout health care.

In comparison, **precision health** refers to an innovative approach to health care that considers individual differences in genetics, environment, and lifestyle. The goal of precision health is to tailor medical care and treatment plans to the unique characteristics of each patient, with the aim of achieving the best possible outcomes. At the core of precision health is the integration of genomic information, where an individual's genetic makeup is analyzed to unveil insights into disease susceptibility, response to medications, and inherent genetic factors influencing health. Precision health allows health-care professionals to develop personalized treatment plans that consider not only genetic factors but also environmental and lifestyle influences. This approach is particularly promising in areas such as cancer treatment, where targeted therapies based on genetic profiles can lead to more effective and less toxic interventions.

By tailoring interventions to the specific needs of each patient, precision health aims to optimize treatment effectiveness, minimize adverse effects, and improve overall health outcomes. However, precision health also presents challenges, including the need for robust and secure data management systems, ethical considerations related to privacy and consent, and the integration of this approach into routine clinical practice. Additionally, disparities in access to genetic testing and other precision health tools must be addressed to ensure equitable health-care outcomes for diverse populations. Despite these challenges, precision health holds great promise in revolutionizing health care, moving away from the traditional, one-size-fits-all model toward a more individualized and targeted approach to medical care.

Epidemic Tracking

The field that applies science and technology to meet the needs of public health is called **public health informatics**. This specialized field encompasses population health, policy development, and the accessibility of public health services; however, its main focus is to promote health and prevent diseases within populations and communities.

The public health domain of informatics is responsible for several functions, including the surveillance and prevention of epidemics and the spread of diseases. Collecting, analyzing, and disseminating data related to diseases, health outcomes, and injuries is called **surveillance**; through careful surveillance, public health officials can reduce the spread of disease and other poor health outcomes and injuries. Incidence and prevalence are two key epidemiological concepts used within surveillance measures to quantify and describe the occurrence of diseases or health-related events within a population. The number of new cases of a specific disease or health-related event that occur within a defined population during a specified time period is called **incidence**; it measures the risk of developing a condition. In comparison, **prevalence** represents the total number of cases (both new and existing) of a particular disease or condition in a population at a specific point in time or over a specific period; it indicates how widespread the condition is within the population (Arnold et al., 2020).

A recent example of surveillance is the contact tracing conducted by state and local health departments, the Centers for Disease Control and Prevention (CDC), and other public health agencies during the COVID-19 pandemic. Incidence and prevalence measures were constantly evaluated to determine the risk of developing COVID-19 and the extent of the virus's spread by region. By tracking reports of positive COVID-19 cases and conducting follow-ups, officials documented the movements, interactions, and duration of contact of positive cases. This enabled the mapping of cases and facilitated the implementation of quarantine measures to slow the spread of the virus (Ibrahim, 2020).

Legislation and Governing Institutions

Legislation and governing institutions play a significant role in the development of health informatics, communications, and technology. They create organization, structure, and policy, while also offering support for ongoing advancements and improvements. It is crucial for nurses to comprehend the legal framework that underpins health informatics so they can advocate for changes that promote safer, more effective, and more efficient information technologies in health care.

Legislation

There are several important pieces of legislation that impact health-care informatics. Perhaps the best known is the

Health Insurance Portability and Accountability Act (HIPAA), passed in 1996 to curtail health-care fraud and abuse, enforce standards for health information, guarantee the security and privacy of health information, and ensure health insurance portability for employed persons (Office of the National Coordinator for Health Information Technology [ONC], n.d.-b). The law also identifies consequences for any health-care providers who violates its provisions. Nurses should be familiar with the following main components of HIPAA:

- The Privacy Rule describes what information is protected and how the protected information can be used or disclosed.
- The Security Rule describes who is protected and what safeguards must be in place to protect electronic protected information.
- The Enforcement Act describes what compliance consists of, when and how investigations must occur, how to report noncompliance, and how consequences for privacy and security breaches should be enforced (ONC, n.d.-b).

Another piece of legislation that has shaped nursing informatics is the **American Recovery and Reinvestment Act (ARRA)**, which was passed in 2009 to stimulate the economy following the Great Recession of 2007–2009. Lawmakers identified the economic value of health information technology and the related need to improve health-care delivery. As such, concepts of health-care informatics are embedded throughout the act. The act is divided into two parts:

- Part A addresses health information technology policies and standards, as well as privacy and security.
- Part B addresses Medicare and Medicaid health information technology, as well as incentives to providers and organizations that adopt EHRs and meaningful use (which will be defined later in this section) (Federal Communications Commission, n.d.).

Within the American Recovery and Reinvestment Act is the **Health Information Technology for Economic and Clinical Health (HITECH) Act**. The act's purpose is to improve health-care quality by preventing errors and assisting with patient-centered decisions at the point of health-care delivery. The act also seeks to lower costs by reducing inefficiencies and service duplication, promote health through prevention and early detection, and improve the management of chronic diseases (Peterson & Holman, 2018). Moreover, it facilitates clinical research, works toward reducing health disparities, ensures the security of patient information, and strives to bolster public health by enabling early detection and response to infectious diseases and bioterrorism.

Overall, the HITECH Act has increased the adoption rate of EHRs and has contributed to a national health information infrastructure in which an individual EHR can be accessed by any provider (ONC, n.d.-c; Peterson & Holman, 2018). While the adoption of EHRs across the United States has increased significantly in recent years, not all Americans have access to these digital health records. The associated costs and complexities of implementing EHR systems pose barriers, particularly for smaller health-care providers in underserved areas that may face financial constraints. Additionally, the infrastructure and readiness for adopting EHRs vary across regions, with rural areas often encountering difficulties due to limited access to high-speed internet and advanced technology. Resistance to change, concerns about data privacy and security, and disparities in resources further contribute to uneven EHR adoption rates. Regulatory hurdles, including variations in state-level regulations and a lack of standardization in EHR systems, also impede the seamless exchange of health information. Achieving universal EHR coverage will require continued concerted efforts to address these multifaceted challenges and promote a more integrated and accessible digital health infrastructure.

The **Medicare Access and CHIP Reauthorization Act (MACRA)**, enacted in 2015, fundamentally transformed the way Medicare pays health-care providers. MACRA repealed the Sustainable Growth Rate formula and introduced the Quality Payment Program (QPP). This program established two tracks for provider reimbursement: the Merit-based Incentive Payment System (MIPS) and Advanced Alternative Payment Models (APMs). MIPS consolidates existing quality reporting programs into a unified framework, tying reimbursement to performance on measures related to quality, cost, improvement activities, and the promotion of interoperability. APMs provide financial incentives for practices to participate in innovative payment models designed to improve care quality and reduce costs. MACRA aims to shift the health-care system toward value-based care, emphasizing quality and outcomes while incentivizing providers to embrace new payment models that prioritize patient-centered, efficient, and coordinated care (ONC, n.d.-a).

The **Food and Drug Administration Safety and Innovation Act (FDASIA)** of 2012 developed "a report that contained strategies and recommendations for a risk-based regulatory framework for health IT, including medical mobile applications, which promoted innovation, protected patient safety, and avoided regulatory duplication" (FDA, 2020). The recommendations were a collaborative effort from the Food and Drug Administration (FDA), the Office of the National Coordinator for Health Information Technology (ONC), and the Federal Communications Commission (FCC).

The **21st Century Cures Act (Cures Act)** was signed into law in 2016. It was developed to promote and fund the acceleration of research to prevent and cure serious illness, accelerate drug and medical device development, address the opioid crisis, and improve the delivery of mental health services. The Cures Act Final Rule, a set of regulations issued by the ONC in the United States as a part of the 21st Century Cures Act, supports seamless and secure access, exchange, and use of electronic health information and is designed to give patients and their health-care providers secure access to health information (ONC, n.d.-b).

Finally, the **Coronavirus Aid, Relief, and Economic Security (CARES) Act**, passed in 2020 at the start of the COVID-19 pandemic, has significant implications for health care. The CARES Act highlighted the need to modernize public health data surveillance and infrastructure. The onset of the pandemic quickly demonstrated the deficiencies of the United States' current health-care system, which proved to be outdated and unable to keep up with patient needs. Modernizing the surveillance infrastructure would enable users to automatically obtain real-time data that is coordinated across the health-care system's various subsystems. The CARES Act also expanded access to telehealth and other connected health technology capabilities and supported the application of Smart health IT technologies and systems. Additionally, the act provided federal grants to evaluate and address the risks associated with cyber threats in remote customer service or telework practices (U.S. Department of the Treasury Office of Recovery Programs, 2023).

The Office of the National Coordinator for Health Information Technology (ONC) provides information about health IT laws, regulations, and policies (https://openstax.org/r/77ITlaws) on its website.

Governing Institutions

Governing institutions are critical for maximizing the potential of health informatics at both the national and global levels. They can assist by promoting the adoption of electronic health records, encouraging interoperability, providing incentives to improve quality and efficiency, and fostering technical advancements. Financial support is essential to aid the adoption of health information systems, facilitate information exchange, support research and development, and ensure robust information security measures.

The most notable U.S. agency at the forefront of informatics is the Office of the National Coordinator for Health Information Technology (ONC), which is a division of the Office of the Secretary for the U.S. Department of Health and Human Services (HHS). HHS is responsible for national health-care regulation. The ONC is responsible for delivering provisions of the Cures Act, including regulating health information technology, advancing interoperability, prohibiting information blocking, and enhancing the usability, accessibility, privacy, and security of health information technology. Its employees coordinate national efforts related to the access, exchange, and use of data, with the goal of advancing the development and use of health information technology capabilities and establishing expectations for data sharing (ONC, n.d.-a) (Figure 37.7).

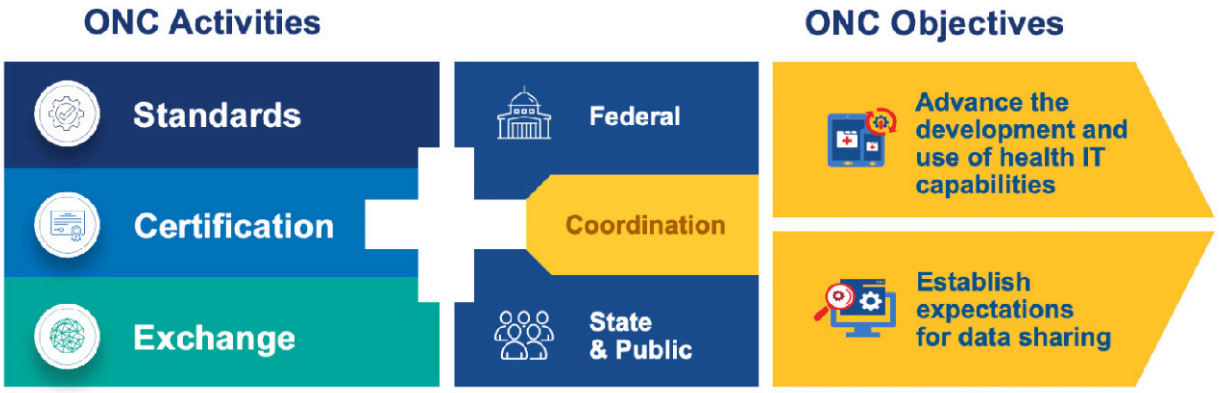

FIGURE 37.7 The ONC engages in activities related to standards, certification, and exchange of information to assist with the coordination of nationwide initiatives aimed at advancing the development and use of health IT capabilities and establishing expectations for data sharing. (credit: "ONC Act ivies ONC Objectives" by HealthIT.gov, Public Domain)

The Health Informatics and Interoperability Group (HIIG) within the Office of Burden Reduction & Health Informatics (OBRHI) oversees interoperability efforts by the Centers for Medicare and Medicaid Services (CMS), another division of HHS. The HIIG promotes the secure exchange, access, and use of electronic health information. This group plays a significant role in publishing policies and establishing a governance framework for interoperability (CMS, 2023b).

Another key institution is the Office of Health Informatics within the U.S. Food and Drug Administration (FDA). This agency provides health informatics tools, solutions, and expertise to enhance the ability of the FDA to promote public health. Some of its functions include developing and implementing health initiatives, promoting effective use of informatics, creating open-source informatics platforms, implementing standardized vocabularies, standardizing data collection and analysis, and researching informatics solutions (FDA, 2019).

The International Organization for Standardization (ISO) is a global federation that works to establish consensus standards globally. The American Health Information Management Association (AHIMA) has been leading the development of health information management standards at the ISO. Together, the ISO and AHIMA have been working to develop shared rules, content, and infrastructure. They are focused on developing standards for rules, guidelines, practice, data, information exchange, safety, privacy, and security (Orlova et al., 2017).

Electronic Health Records

An electronic health record (EHR) is a digital version of a patient's comprehensive medical history. EHRs are transportable, moving with the patient, and accessible by everyone involved in the patient's care—including the patient. They allow health-care information to be shared across practice settings, connecting providers both within a particular organization and between organizations, and have built-in tools that assist with decision-making. EHRs provide enhanced communication and coordination of care that can result in increased efficiency, cost savings, and a seamless delivery of care.

Providing patients with access to their health information empowers them to have more control over their health-care decisions. According to the HIPAA Privacy Rule, patients have a right to access and obtain their own medical records. This right is a legal and enforceable right, encompassing both paper and electronic formats (DHHS, 2022).

While the adoption of EHRs is intended to create a seamless delivery of care, they do not always support **interoperability**, the ability of different systems to "talk" to each other. According to the Healthcare Information and Management Systems Society, interoperability is "the ability of different information systems, devices and applications (systems) to access, exchange, integrate and cooperatively use data in a coordinated manner, within and across organizational, regional and national boundaries, to provide timely and seamless portability of information and optimize the health of individuals and populations globally" (HIMSS, n.d., para. 1).

Recognizing the importance of an electronic health record that moves with the patient, Congress created the **Meaningful Use Electronic Health Record (HER) Incentive Program** as an attempt to modernize the managing and sharing of health-care information. This program, which stemmed from the HITECH Act, was established in 2011

with the intent to increase the adoption of electronic health record usage within the United States. Under the meaningful use program, health-care providers must demonstrate the meaningful use of certified EHR technology to qualify for financial incentives provided by Medicare and Medicaid. The program is part of broader efforts to promote the adoption of EHRs, enhance health-care quality, and improve patient outcomes through the effective use of health information technology (Anumula & Sanelli, 2012).

Using the EHR in a "meaningful" way—that is, to its full extent—facilitating the electronic exchange of information so that quality of care may be improved is considered **meaningful use**. Examples of meaningful use include structuring data entry to ensure all pieces of critical information are captured, ensuring computerized provider order entry is occurring in practice, e-prescribing, capturing vital signs within the EHR, and ensuring medications are being reconciled at every visit (or, in an acute care setting, upon admission and discharge). Meaningfully implementing EHRs has the potential to improve quality, safety, and efficiency; reduce health disparities; engage patients and families; coordinate care; enhance privacy and security; and improve population and public health—all of which are priorities for health-care providers in the United States.

The Meaningful Use EHR Incentive Program was designed so that meaningful use would be achieved within three stages(Table 37.1) (Anumula & Sanelli, 2012; ONC, 2013).

Stage	Date Implemented	Purpose	Outcomes
1	2011	To facilitate data gathering and sharing	Providers tasked with transferring data to EHRs and sharing health information: e.g., by printing after-visit summaries to send home with the patient
2	2014	To advance clinical processes	Built on Stage 1 by adding new standards, such as online access for patients to their health information, electronic health information exchange between providers, and emphasis on utilizing the clinical decision support tools within EHRs
3	2017	To improve outcomes and demonstrate improvements in quality of care	Built on Stage 2 by using health information technology for population health management, clinical quality measurement, and public health reporting; ensures data is stored according to data regulations; improves care through implementation of electronic prescribing, clinical decision support systems, computerized provider order entry, and patient access to electronic records; emphasizes coordination of care through patient engagement with patient portals; supports health information exchange by implementing electronic summaries of care

TABLE 37.1 Stages of the Meaningful Use EHR Program

Once Stage 3 was introduced, the term "meaningful use" was officially replaced with "advancing care information," although the concept is often still referred to as meaningful use.

While the EHR Incentive Program made great strides in achieving meaningful use of EHRs, the U.S. health-care system continued to struggle with interoperability. Therefore, in 2018, the program was renamed the Promoting Interoperability Program. The Promoting Interoperability Program was intended to look beyond the original intent of the EHR Incentive Program by creating new measurements of EHR implementation and increasing the focus on interoperability and improving access to health information (CMS, 2023a).

Nevertheless, interoperability continues to lag within the U.S. health-care system due to the high volume of health information and the variety of EHR systems that use different techniques for programming and formatting. Because of the global nature of EHR systems—working together, talking together, and transcribing information to and from each other—standardization will be key to achieving interoperability. An important goal is to standardize terminology

so that concepts are presented in an unambiguous manner between a sender and receiver of information; it is also important to standardize the format of how the information is transported, the privacy and security measures in place, and the identifiers used to identify individual patients and providers. With all these features in place, any record could be read by anyone with the assurance that the same message is being sent and received.

Another strategy is to investigate how AI and machine learning can be used to transcribe data that have been programmed using different formats. AI and machine learning are already used to process large amounts of data, which can then be used to identify common trends, but they might also be used to pull information from various systems into a unified format. Strategies for achieving interoperability are managed by the Office of Interoperability and Standards (OIS), which is a division of the ONC (ONC, n.d.-a).

REAL RN STORIES

Nurse: Emile, BSN
Years in Practice: One
Clinical Setting: Orthopedic unit
Geographic Location: Rural town in Georgia

When I first graduated nursing school, I remember thinking I would never need to know about health IT legislation. However, I now realize it impacts my nursing practice on a daily basis. For example, I begin my shift by accessing the EHR system, which is designed to comply with the American Recovery and Reinvestment Act (ARRA), Health Information Technology for Economic and Clinical Health (HITECH) Act, and 21st Century CURES Act. Had it not been for these pieces of legislation, I would not have access to comprehensive and secure patient records to explore the patient's medical history or chart the care I provide. When discussing patient information with colleagues and documenting patient care activities, I follow strict protocols to protect patient confidentiality, ensuring compliance with the Health Insurance Portability and Accountability Act (HIPAA).

As I interact with diverse patient populations, I apply the guidelines outlined in the Patient Data Access and Security Implementation Act (PDASIA) to provide culturally sensitive care and tailor my communication and approach to meet the unique needs of each individual. I also actively participate in quality reporting initiatives to address quality measures as mandated by the Medicare Access and CHIP Reauthorization Act (MACRA), contributing to the hospital's efforts to improve patient outcomes. In response to the COVID-19 pandemic, I incorporated provisions from the Coronavirus Aid, Relief, and Economic Security (CARES) Act into my practice, such as embracing telehealth services to minimize in-person contact and using technology for remote patient monitoring to ensure continuity of care while adhering to safety protocols.

As you can see, health IT legislation significantly impacts how nurses practice and deliver care to our patients. My commitment to stay informed about evolving health-care regulations not only enhances patient care but also contributes to the hospital's compliance with the ever-changing landscape of health-care policies. Staying informed about health IT legislation empowers nurses to navigate the digital health-care landscape responsibly, contributing to improved patient outcomes and compliance with regulatory standards.

Electronic Medical Records

When talking about electronic patient records, you will likely encounter two important terms: electronic health record (EHR) and electronic medical record (EMR). While sometimes used interchangeably, these are very different terms with quite different implications for health care as we move into the digital future of health-care delivery.

Recall that EHRs are digital versions of a patient's complete medical history; they are intended to move with the patient from provider to provider. In contrast, an **electronic medical record (EMR)** is a digital form of a paper chart for use by one medical practice. The distinguishing factor to remember is that the digital chart is stored for use only by the respective practice. For the patient or another provider to access the chart, one must physically print it or save it to a digital storage device. This lack of portability decreases communication between providers and across health systems; it also makes it more difficult for patients to make informed decisions about their care. Other key differences between EMRs and EHRs are summarized in (Table 37.2). Due to government regulations and technological innovations, EMRs have largely been phased out and replaced with EHRs, allowing for a more

seamless delivery of care.

Electronic Medical Record (EMR)	Electronic Health Record (EHR)
A digital version of a paper chart from one provider only	A digital version of a patient's overall health history from various health-care providers
Cannot be shared with another health-care provider	Designed to easily share health information across various health-care settings
Not intended to allow patient information to move outside one health-care setting	Designed to allow medical information to move with the patient to various health-care settings
Used for diagnosis and treatment only	Includes various built-in tools for supporting medical decision-making

TABLE 37.2 EMRs vs. EHRs

Patient Portals

A **patient portal** is a secure online platform that provides patients with twenty-four-hour access to their personal health information. By connecting to the internet and logging in with their secure username and password, patients may access information such as recent health-care visits, discharge summaries, medications, immunizations, allergies, procedure results, and lab results. Some portals even allow the patient to securely message their provider, request prescription refills, schedule appointments, check insurance benefits and coverage, update contact information, make payments, download and complete medical forms, and view educational materials. Not only do patient portals save time, enhance communication between patients and providers, and provide support to patients, they also allow patients to become more engaged and in control of their own health and care.

37.3 Influences on Delivery of Health Care

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss the impact of information technology on health care
- Identify ways that information technology transforms direct and indirect patient care
- Discuss the nurse's role in fostering the use and advancement of technology in health care

In recent years, information technology has been at the forefront of revolutionizing numerous industries, and health care is no exception. The integration of technology into health-care systems has led to significant advancements, positively impacting patient care and outcomes. As the health-care landscape continues to evolve, nurses find themselves at the forefront of this digital transformation, playing a vital role in leveraging technology to improve health-care services.

Impact of Information Technology on Health Care

Information technology has revolutionized health care and will continue to do so in the future. Key areas of influence include:

- Communication: EHRs, telemedicine, and secure messaging systems have significantly improved communication between health-care providers and patients, enabling more timely and efficient exchange of information.
- Patient outcomes: Information technology has facilitated the use of advanced diagnostic tools, personalized treatment plans, and evidence-based practices, all of which contribute to improved patient outcomes. Real-time data monitoring and predictive analytics also help in early detection and prevention of medical conditions.
- Data utilization: The integration of big data analytics in health care allows for the collection, analysis, and interpretation of vast amounts of patient data, enhancing overall clinical decision-making, supporting research and development, and enabling health-care providers to deliver more accurate and effective care.

- Operational efficiency: Automation of administrative tasks, such as appointment scheduling, billing, and inventory management, has streamlined operations, reduced errors, and increased efficiency in health-care facilities.
- Patient engagement: Health information technologies, such as patient portals and mobile health applications, empower patients to take an active role in managing their health. These tools provide access to medical records, facilitate appointment bookings, and offer educational resources to support informed decision-making.
- Security and privacy: Advanced IT solutions have improved the security and privacy of patient information through the implementation of robust encryption protocols, access controls, and compliance with regulatory standards.

Communication

Information technologies have led to enhanced communication among the patient, provider, and care team. Through use of technologies such as EHRs, messaging systems, and patient portals, coordination of care has been enhanced. All parties can access the most up-to-date information, ask and answer questions, and review the plan of care to ensure understanding. Enhancing communication has resulted in benefits such as informed decision-making, stronger relationships, and decreased delays in care.

For example, patient portals allow patients to access their personal health information and provide two-way communication with their provider. Telemedicine has provided the opportunity for patients to receive care via real-time, two-way communication with a provider or via asynchronous transmission of patient information. Messaging systems allow nurses to quickly send medical updates and questions to the provider without causing interruptions to their workflow.

Other technologies have impacted communication during transitions of care. “Hand-off” communication tools have structured the reporting of patient-specific information from one caregiver to another. Discharge summaries provide a snapshot of the patient’s condition, care that was provided, necessary education, and home care instructions. Not only have discharge summaries enhanced communication for patients upon discharge, but they also serve to ensure continuity of care upon transfer to other levels of care, thereby protecting patient safety.

Patient Outcomes

Information technologies are a valuable tool for improving health-care quality and safety. Technology has improved the accuracy, speed, and accessibility of diagnostics and has the potential to decrease the severity of chronic illnesses due to earlier detection and intervention. Telehealth platforms, for example, leverage technology to remotely monitor and manage chronic conditions. Patients can use wearable devices to track vital signs, and health-care providers can access real-time data to make timely adjustments to treatment plans; these practices enhance accessibility to care, reduce the need for frequent in-person visits, and help manage chronic illnesses more effectively. It has also led to enhanced patient safety by reducing medication errors, reducing adverse drug reactions, improving compliance to practice guidelines, and enhancing care coordination.

For example, **computerized provider order entry (CPOE)** has allowed providers to enter medical orders directly into the patient’s electronic medical record. Not only has this practice reduced the human error in transcribing orders, but it has also been instrumental in catching possible medication order errors, such as prescribing a medication that the patient may be allergic to or a medication that is contraindicated. Clinical decision supports—such as notifications, alerts, reminders, clinical guidelines, condition-specific order sets, clinical summaries, documentation templates, and diagnostic supports—have supplied providers with the necessary information to make informed decisions to support patient care.

Other examples of how technology has impacted patient care can be identified within the medication administration process. Bar code administration has helped to ensure the right medication for the right patient. Smart pumps are programmed to reduce errors with intravenous (IV) administration. Automated dispensing cabinets are electronic drug cabinets that store and dispense medications at the point of care. Medications may be placed within the patient’s profile by the pharmacy, thereby reducing the risk of the nurse removing the wrong medication. Additional features—such as dual-sign off on “high risk” and controlled medications (e.g. insulin, heparin), use of red or tall lettering to identify look-a-like drugs, and providing access to only the intended medication—have been implemented to enhance medication administration safety.

CLINICAL SAFETY AND PROCEDURES (QSEN)

Leveraging Technology for Enhanced Health-Care Quality and Safety

Information technologies stand at the forefront of advancing health-care quality and safety, offering a myriad of benefits that positively impact patient outcomes.

- Patient-centered care: Innovative tools such as AI-powered diagnostics and genomic medicine accelerate diagnostic processes, enabling a patient-centered approach by swiftly identifying conditions and potentially mitigating the severity of chronic illnesses.
- Evidence-based practice: Embracing EHRs ensures adherence to practice guidelines, promoting standardized and evidence-based care. This technological integration reduces medication errors and adverse drug reactions, contributing to enhanced patient safety.
- Quality improvement: The use of technology in chronic disease management, including remote monitoring devices and telehealth platforms, fosters continuous quality improvement. Real-time data exchange allows for timely interventions, ultimately reducing the severity of chronic conditions and improving overall health outcomes.
- Safety: Electronic communication platforms and health information exchange systems play a crucial role in enhancing care coordination. By enabling real-time collaboration among health-care teams, technology contributes to a safer health-care environment, reducing the likelihood of errors.

By integrating these technological advancements, nurses are better equipped to provide patient-centered, evidence-based care, foster continuous quality improvement, and enhance safety measures, aligning with the core competencies outlined by the Quality and Safety Education for Nurses (QSEN).

Role of Data in Patient Care

Information technologies provide insightful data that can be analyzed to improve the delivery of health care for individuals and populations—for example, by investigating methods of improving the provision of clinical care, enhancing disease prevention, and measuring the effectiveness of various treatment options. Technologies that enable the collecting and storing of data in real time have led to improved decision-making, advancements in treatment analysis, production of research, and root-cause analyses when a breakdown in care is identified. By identifying warning signs in data, providers can implement interventions before a disease or condition worsens. Data collected during the COVID-19 pandemic, for example, allowed for contact tracing of the virus and tracking of "hot spots" that experienced a high incidence rate of the virus. In collecting and analyzing this data, public health officials could identify trends and put measures in place to decrease the spread of the virus.

LINK TO LEARNING

Read this article for more information about the benefits of data analytics in health care (https://openstax.org/r/77DataAnalytics) from Maryville University.

The role of data in health care cannot be underestimated. Data is needed for continuous improvement in what we do and how we do it. For data to be meaningful, however, it must be accurate, complete, reliable, relevant, and timely. Data must also be standardized to allow for a mutual understanding of the data and interoperability between systems. Four types of standards must be addressed (Table 37.3): terminology standards, content standards, data exchange or transport standards, and privacy and security standards.

Type of Standard	Purpose	Example
Terminology	Ensure clarity of meaning, help to provide a mutual understanding of what is meant, and ultimately help to reduce miscommunication	ICD-10 codes to codify medical diagnoses
Content	Ensure that medical data is properly organized and represented in forms that are clear and easy to understand	Rules for structuring medical records or encoding data elements
Data exchange/ transport	Facilitate the movement of information between different health systems	The exchange of direct personal health information from one provider to another
Privacy/ security	Establish rules to protect sensitive health data	HIPAA

TABLE 37.3 Standards for Data Analytics in Health Care

Transforming Patient Care

New, innovative information technologies are transforming both direct and indirect patient care. The comprehensive integration and adoption of digital technologies, processes, and strategies across an organization to fundamentally change how they operate and deliver value, or **digital transformation**, gives health-care organizations the opportunity to gain a competitive advantage by modifying their business processes, culture, and customer experiences. Organizations can leverage digital technologies to improve operational decision-making related to patient flow, staffing, scheduling, and supply chain management. For example, a decision-support algorithm can be used to remove bias from operational tasks or predict the level of care a patient may need or the number of expected admissions, discharges, and transfers during a specified time period. Algorithms can also be used to predict nurse absenteeism to determine staffing patterns and needs. Data related to the timing of procedures, time spent in the post-anesthesia care (PACU), and timing of discharge education can be used to create scheduling algorithms. In terms of supply chain management, radio-frequency identification (RFID) technologies can be used to track and locate supplies and devices, and electronic databases can be used to keep track of supplied inventory, in both cases decreasing operating costs for the organization.

Information technologies have also improved the workload of nurses and other care providers. For example, the process of centralizing patient records into EHRs has eliminated time spent searching through paper charts, helped to clarify and streamline the documentation of care, and enabled the setting of electronic reminders for tasks that need to be completed. Such time-saving measures create more time for nurses and providers to spend with patients.

Technologies intended to improve safety, efficiency, and quality are also transforming how we deliver care and the resulting patient outcomes. The way care was delivered ten years ago is quite different than today, and the care we deliver today will look very different in ten years. Rapid advances in care will be revolutionized through evidence-based practice (EBP), research, advances in technologies, and federal regulatory organizations such as The Joint Commission and the Centers for Medicare and Medicaid Services.

Smart Beds

A **smart medical bed** is a highly innovative hospital bed with additional technical features that support best practice for patient care. They are a Class 2 medical device (which are subject to specific regulatory controls to ensure their safety and efficacy) and have become a gold standard in patient care. High-tech beds reinforce patient safety and improve patient care outcomes.

Available features depend on the type of bed purchased; however, most smart beds include fall prevention features. Bed alarms signal staff when the patient is getting out of the bed. Some beds are even programmed with verbal

commands that will tell the patient not to get up until help arrives. As an added feature, the verbal prompts can sometimes be set in different languages to accommodate diverse patients. Additional safety features to prevent falls include motion-activated night-lights and reminders for the health-care staff, such as alerts if the wheels are not locked or the bed alarm is not set.

Data captured from smart beds can be used to improve patient care. For example, by conducting a debrief in the event a patient falls to determine which settings were activated, how long the bed alarm had been sounding, and how the patient had moved prior to the fall. The data may also be used to prevent falls: for example, by analyzing the patient's movements to determine which bed alarm setting would be most appropriate for the patient.

Smart beds can also be used to reduce the prevalence of pressure ulcers. The latest mattresses include pressure-redistribution functions that help to redistribute weight over bony prominences. Some mattress surfaces are made of "microclimate" technology that reduces body heat and absorbs excess moisture, thereby preventing the breakdown of skin. Additional features may also include supports to help the care team turn the patient.

By utilizing special sensors, smart beds can also capture data that may be used to support clinical diagnostics. Some beds can detect the patient's pulse, respirations, and temperature. If abnormalities are noted, the provider or health-care team is alerted to check on the patient. Smart beds can also capture patient weights—they can even be programmed to subtract the weight of the bed linens from the patient's weight to ensure accuracy.

Other features enhance convenience for the patient: for instance, a call bell may be built into the side rails for use when the handheld call bell cannot be reached. Some beds also include USB ports for the patient to charge their electronics and storage compartments for easy access to their belongings. Additional features to support patient comfort include adjustable head and foot positions, back and leg massagers, and Bluetooth speakers.

Wearable Devices

A **wearable device** is a health monitoring device worn on the body to monitor health data. Using biosensors, wearable devices can collect data such as heart rate, blood pressure, respirations, sleep patterns, activity, blood glucose, and more. These devices can be used to monitor fitness, wellness, and disease management; to store patient health information; and to provide patient reminders (Smuck et al., 2021).

There are many different types of wearable devices on the market, with new technologies constantly being developed. Smartwatches, for instance, can detect oxygen saturations and pulse and provide ECG readings. While smartwatches cannot provide accurate blood pressure readings, there are blood pressure cuffs that will automatically connect to a smartphone to store data that can be shared with the provider. Fitness trackers can be used to measure heart rate, steps, activity, and sleep patterns. A **continuous glucose monitor (CGM)**, a device to automatically estimate blood glucose levels, can be scanned to provide blood sugar readings (Figure 37.8). Sensors reduce the need for routine finger sticks (finger sticks are still needed for calibration and quality control) and allow blood sugar readings to be shared instantaneously with the provider. All these technologies enable patients to take a more proactive approach to their health and well-being, while also sharing important data with their providers.

(a) (b)

FIGURE 37.8 (a) A wearable glucose monitor utilizes a sensor to capture blood glucose readings. (b) By gently waving or tapping a mobile device over the sensor, the mobile application will present the blood glucose reading and store it for future reference. (credit a and b: reproduced with permission from Laurie Sparks)

Smart Pumps

A **smart pump** is an intravenous (IV) infusion device that combines computer technology and drug libraries to limit the potential for medication errors. Embedded software provides a drug library that stores usual concentrations, dosing, and dose limits for each medication. The nurse may search the drug library for the medication to be administered, automatically populating the pump settings. Safeguards can also be programmed to alert the nurse if the dose exceeds a predetermined limit. These features reduce the likelihood of the medication being programmed and delivered incorrectly.

Additional safety features of smart pumps include alerts of possible adverse drug reactions and the ability to input patient weight to determine the appropriate dose of medication. Smart pumps also provide a variety of alarms to alert the nurse of line occlusions, air bubbles, and completed infusions, as well as reminders to start the infusion and plug the IV pump into the power outlet.

Many smart pumps enhance interoperability by integrating the IV pump with the patient's EHR. Bar code medication administration allows the medication to be verified within the patient's orders. Once the medication is scanned, the EHR will then send the administration details (such as medication name, rate, dose) to the smart pump for the nurse to verify before initiating the administration. Following this process minimizes the risk of human error in programming the smart pump and promotes accurate documentation of medication administration in the EHR. Two-way communication between the smart pump and the EHR enables the pump to feed information (such as volume infused and rates of titratable drugs) back to the EHR, reducing the need for the nurse to manually input this information into the chart. Nevertheless, the nurse administering the medication is ultimately responsible for any errors that may occur, so they should always have a questioning and critical thinking mindset as they work.

Like other information technologies, smart pumps produce data that may be captured, stored, and analyzed. Drug libraries, for instance, detail the lower and upper bounds that govern each medication's safe infusion rate—information that can be used to support point-of-care decisions. If a hard stop is overridden, data can be collected to determine the date, time, nurse, and reason selected for the override. In the event of a medication error, data can be reviewed to determine if the drug library was used to program the pump, if the correct medication was

selected from the drug library, and if the pump was programmed correctly. Vital signs, such as continuous capnography of respirations and pulse-oximetry, can be collected when patient-controlled analgesia is used. These data can be automatically populated in the EHR, and the care team can be alerted of the potential for adverse reactions, such as narcotic-induced respiratory depression.

Role of the Nurse

Nurses play a vital role in fostering the use of technology and supporting the advancement of technology in health care. As nurses, we must embrace the reality that technology is here to stay and use it to our advantage to deliver the very best care possible. When we embrace technology, we open the door to possibilities that will transform the nursing profession and enhance the provision of quality outcomes in health care.

How nurses perceive technology will influence the perceptions of others and ultimately impact the usage and acceptance of technology within the health-care arena. It is important that nurses take the lead in the transformation of services and involve themselves in all aspects of designing, developing, and implementing technologies. The feedback from nurses regarding the performance of technology is invaluable in shaping the adoption and improvement of new tools in health-care settings. Nurse managers recognize the significance of frontline health-care professionals' experiences and insights in assessing the practicality and effectiveness of technology. Nurses' opinions serve as a crucial gauge of usability, functionality, and overall impact on patient care. This user-centric approach allows nurse managers to make informed decisions about technology adoption, ensuring that the tools align with the workflow, enhance efficiency, and contribute positively to patient outcomes. Regular feedback loops also empower nurses to play an active role in the iterative improvement of technology, fostering a collaborative and adaptive approach to health-care innovation.

Education

One of the primary roles of nursing is education. We educate our patients on all aspects of care, including technology. As nurses, it is our responsibility to educate our patients about the role of technology in health care, its benefits, and the ways in which it facilitates the delivery of care.

We should encourage patients to embrace technology and empower them to use technology to take an active role in their care. One way to do this is to educate patients on how to set up and use a patient portal. Engaging in discussion and offering to assist with setting up their account before leaving the visit will increase the likelihood of successfully creating their portal account. Once logged in, nurses can help patients to navigate the portal and locate important features they may frequently use. Similarly, we can help patients to set up telemedicine accounts and demonstrate how to request and access a visit. Patients should also be educated on what to expect during a telemedicine visit, as well as tips to enhance their experience, such as minimizing background noise and distractions and setting up audio and video in advance.

As patients take a more active role in their care, nurses may need to teach them how to locate credible sources of health information that are current, relevant, accurate, serve the right purpose, and are sourced by experts with authority in the topic. Even with the increased use of technology and the internet in today's world, we need to be cognizant that not all patients have access to such digital advantages. The gap between those who have and those who lack access to the internet and such technologies is referred to as the **digital divide**. As health-care providers, we need to be aware that the digital divide exists and ask our patients if they have access to the internet before providing them with electronic and web-based information sources and options of care.

Nurses also play a role in educating fellow nurses and providers. A nurse who takes the lead in implementing new technologies can become a **super user**: a clinical end user who receives specific training that enables them to provide support and education to others. Not only do super users provide technical support, but they also serve to create excitement, engagement, and ownership in the implementation of the technology.

Informatics

From their position at a patient's bedside, nurses are key informants about current trends, needs, ideal workflows, challenges, and gaps in care. By involving nurses from the beginning of the technology design process, technologies can be developed with the end user in mind to address actual health-care issues, which may sometimes be different than what developers originally planned to address.

Involving nurses in the development of technologies will enhance the user's experience when interacting with an

object, a product, or a service. The concept of user experience focuses on who the user is, what they need, what their abilities and limitations are, and if they value the product, system, or service. The goal of creating a good user experience is to maximize usefulness and pleasure in using the product, service, system, or interface. Nurses may also improve **usability**, the ease with which people can use a product to achieve a certain goal.

REAL RN STORIES

Nurse: Lisa, BSN
Years in Practice: Two
Clinical Setting: Medical-surgical unit
Geographic Location: Small rural city in North Carolina

Our organization had been using an electronic medical record; however, we decided to switch to a more nationally known electronic health record. I was selected to be a super user to help educate staff on how to use the system. Super users attended an eight-hour training session to learn the system and how to use it. Having this training before the system was implemented made me feel much more at ease on "go-live" day. I knew what to expect, where to find the information I needed, and how to navigate the chart. I served as a resource for my peers for the first week after implementation, helping them to navigate the system, boost their confidence, and create excitement about the change.

While all staff received training on the system ahead of time, the super user training was provided by nursing informaticists and was geared toward how nurses would interact within the system. Staff training was provided by information technology (IT) support from the EHR company; however, the trainers were not nurses. While IT super users were available to support staff during the transition, it was the nurse super users who had the biggest impact in supporting the user experience. Nurse super users were able to provide insight into the clinical workflows and share tips with staff for charting and finding the information they need, when they need it, in the most convenient way. One nurse even mentioned she had "learned more from me in ten minutes than she did during her training course." While the IT team has the technical knowledge of information technologies, nurses are essential to bridging the gap between the health-care team and the IT team by providing the nursing and health perspectives to ensure successful implementation of health informatic technologies.

Strategies for Staying Current

As nurses, we must continuously strive to stay abreast of the most current and up-to-date methods for delivering care. This includes staying well-informed on current uses of informatics and information technology, implications for practice, and data usage, as well as future trends of care. As such, nurses should participate in continuing education opportunities as informatics and information technologies continue to be developed.

Several well-regarded organizations provide educational opportunities, advocacy, and continuing development within the realm of health-care informatics. The Healthcare Information and Management Systems Society (HIMSS) is the oldest nursing informatics organization. Created in 1961, this organization is the global leader in health innovation, public policy, and workforce development. Other professional organizations can be found in Table 37.4; they exist alongside many others that continue to develop as the specialty of health informatics accelerates. It is important for nurses to take an active role in these professional organizations to stay up-to-date on the continual evolution of health-care technologies and to bring the nursing perspective to conversations about the future of care.

Professional Organization	Mission	Strategic Goals	Website
American Medical Informatics Association (AMIA)	"AMIA aims to lead the way in transforming health care through trusted science, education, and the practice of informatics. AMIA connects a broad community of professionals and students interested in informatics. AMIA is the bridge for knowledge and collaboration across a continuum, from basic and applied research to the consumer and public health arenas." (AMIA, n.d., para 1)	1. Advance science of informatics 2. Promote informatics education 3. Ensure effective use of health information technology 4. Advance informatics profession 5. Member services and development	https://amia.org/
American Nursing Informatics Association (ANIA)	"The purpose of ANIA is to advance nursing informatics through education, research, and practice in all roles and settings." (ANIA, n.d., para 1)	1. Provide informatics nursing education 2. Support informatics nursing research and EBP 3. Advance informatics nursing practice	https://www.ania.org/

TABLE 37.4 Informatics Professional Organizations

Professional Organization	Mission	Strategic Goals	Website
Alliance for Nursing Informatics (ANI)	"To advance nursing informatics practice, education, policy, research and leadership through a unified voice of nursing informatics organizations." (ANI, n.d., para 1)	1. Membership outreach 2. Nursing informatics competencies, education, and training 3. Provide national leadership for health information technologies 4. Promote professional practice of nursing informatics 5. Support nursing informatics research	https://www.allianceni.org
American Health Information Management Association (AHIMA)	"AHIMA is the leading voice and authority in health information, wherever it is found. Our people work at the intersection of healthcare, technology, and business." (AHIMA, n.d., para 1)	1. Help families make informed decisions 2. Guide EBP 3. Educate health information professionals	https://www.ahima.org/
International Medical Informatics Association (IMIA)	". . . to bring people together from around the world to advance biomedical and health informatics science, education, and practice through mutual learning and exchange of knowledge, skills and ideas." (IMIA, n.d., para 2)	1. Advocacy 2. Collaboration 3. Membership engagement 4. Promote academic and professional excellence	https://imia-medinfo.org/wp/

TABLE 37.4 Informatics Professional Organizations

Another way nurses can stay well-informed about the evolving field of informatics is by reading current literature. Several journals that are geared toward health informatics include the *Journal of Healthcare Information Management*, *Online Journal of Nursing Informatics*, *JAMIA* (the *Journal of the American Medical Informatics Association*), and *CIN: Computers, Informatics, Nursing, and International Journal of Medical Informatics*. As the nursing informatics specialty continues to grow, new journals may be created to disseminate the important work

and knowledge that result.

Nurses interested in a career in informatics may obtain an advanced degree or certification in the field. While some entry-level informatics positions do not require an advanced degree, earning a master of science in nursing (MSN) or a doctor of nursing practice (DNP) provides nurses with considerable professional opportunities. Most graduate nursing programs that provide a specialization in informatics focus on health information systems, data management, or health law/ethics. Upon completion of a graduate program, one may earn their certification in informatics nursing by sitting for a national certification exam such as the Informatics Nursing Certification Exam, established by the American Nurses Credentialing Center (ANCC). HIMSS has also established two exams: the Certified Associate in Healthcare Information and Management Systems (CAHIMS), for relatively new informaticists, and the Certified Professional in Healthcare Information Management Systems (CPHIMS), for more advanced informaticists.

Beyond Bedside

While all nurses are users of nursing informatics, it is important to note that nursing informatics is considered a nursing specialty. A nurse who works within this specialty is called an **informatics nurse specialist (INS)**. This specialty of nursing is unique because it brings clinical knowledge to the world of technology to create useful and usable solutions to make nurses' lives easier and patient care safer and more effective. Informatics nurse specialists have contributed to health care through the purchase, design, and implementation of information systems, as well as by developing, critiquing, and promoting standard terminology to be used in health-care informatics. According to the U.S. Bureau of Labor Statistics, employment for health informatics specialists is projected to grow 9 percent between 2020 and 2030 (U.S. Bureau of Labor Statistics, 2022).

With the advent of nursing informatics as a specialty, the American Nurses Association (ANA) developed scope and standards of practice for nursing informatics. There are a wide variety of roles in which nurse informaticists can apply the ANA scope and standards of practice. They can take charge of planning and managing informatics projects through a project manager role. They can become consultants and share their advice, opinions, and recommendations with others. They can be educators, developing and implementing trainings and educational materials for organizational systems or upgrades. They can create new informatics or clinical knowledge as researchers. They can design, produce, or market new informatics solutions or products as product designers or developers. As decision support or outcomes managers, they can work to ensure that data integrity and reliability are maintained. They can advocate for patients and support the development of health-care policy. As clinical analysts, they can function as liaisons between the worlds of clinical practice and information technology. Informatics nurse specialists may also become entrepreneurs, creating marketable business ideas, solutions, or products for the health-care market.

Not only do nurse informaticists have the potential to impact the delivery of health care, but they are also involved in what can be a very financially rewarding career. According to a 2020 survey conducted by the Healthcare Information and Management Systems Society (HIMSS), 49 percent of nursing informaticist salaries reached $100,000 per year and 10 percent of salaries reached $151,000 or higher (HIMSS, 2020). Obtaining a doctorate degree or certification in informatics contributed to the highest salaries, as did experience in the field.

LINK TO LEARNING

To learn more about nursing career opportunities in the field of informatics, read this interview with nurse informaticists (https://openstax.org/r/77Informatics) from the Healthcare Information and Management Systems Society (HIMSS).

Summary

37.1 Telemedicine and Artificial Intelligence

- Telemedicine enables remote health-care delivery using technology for diagnosis and treatment.
- Artificial intelligence (AI) enables machines to solve problems and perform tasks that typically require human intelligence by leveraging the power of computer science and robust data sets (IBM, n.d.-a).
- AI enhances telemedicine by providing telemonitoring, diagnosis, treatment plans, patient engagement, and chronic disease management. The integration of AI and telemedicine can lead to improved quality of care, reduced costs, improved outcomes, optimized resources, and increased access to care. Challenges of utilizing telemedicine include the need to learn how to use new technologies, potential health disparities, limitations in remote treatment for certain conditions, and the potential to dehumanize patient care. Establishing laws and regulations is crucial for determining liability, defining boundaries, enhancing transparency, providing informed consent of data use, and ensuring data security and privacy.
- Reliable data are essential for accurate AI algorithms, while human expertise is needed to validate AI-produced diagnoses and recommendations.
- Technological advancements, including AI, have transformed nursing education through enhanced simulation, augmented reality, and virtual reality. Nurses have a responsibility for learning, integrating, and supporting the evolution of health-care technologies. It is important to identify how technology has improved the role of the nurse and minimize challenges, such as resistance to change and burnout.

37.2 Health Informatics

- Health informatics is a specialized field that combines information, technology, and health-care knowledge to improve patient care.
- Informatics enhances collaboration, communication, safety, satisfaction, efficiency, and effectiveness within the delivery of health care. Examples of advances in health informatics that have been used to improve care include information and communication technologies, predictive medicine, and epidemic tracking.
- Pieces of legislation related to health informatics include the Health Insurance Portability and Accountability (HIPAA) Act, American Recovery and Reinvestment Act (ARRA), Health Information Technology for Economic and Clinical Health (HITECH) Act, Medicare Access and CHIP Reauthorization Act (MACRA), 21st Century Cures Act (Cures Act), Food and Drug Administration Safety and Innovation Act (FDASIA), and Coronavirus Aid, Relief, and Economic Security (CARES) Act.
- Health IT is governed by agencies such as the Office of the National Coordinator for Health Information Technology (ONC), the Health Informatics and Interoperability Group (HIIG), the Centers for Medicare and Medicaid Services (CMS), the U.S. Department of Health and Human Services (HHS), the Office of Health Informatics within the Food and Drug Administration (FDA), the International Organization for Standardization (ISO), and the American Health Information Management Association (AHIMA).
- Interoperability in health care refers to the seamless exchange and use of electronic health information across different systems, enabling coordinated and patient-centered care.
- Meaningful use incentivizes health-care providers to adopt and effectively use electronic health records to enhance patient care, improve outcomes, and promote health IT interoperability.
- An electronic medical record (EMR) is a digital form of a paper chart for use by one medical practice, whereas electronic health records (EHRs) are comprehensive medical records that are portable and move with the patient. EHRs provide enhanced communication and coordination of care, resulting in increased efficiency, cost savings, and seamless delivery of health care.

37.3 Influences on Delivery of Health Care

- Information technology has revolutionized health care by significantly impacting aspects of communication, patient outcomes, and data used for patient care.
- Health-care technology has transformed patient care by improving safety, efficiency, quality, and patient outcomes. Examples of technologies that have transformed patient care include smart beds, wearable devices, and smart pumps.
- Nurses play a critical role in the adoption of health technologies. Educating patients and staff on the advantages of technology and tips for utilizing it will empower them to accept and engage in the technology.

Thus, it is important for nurses to actively engage in designing, developing, and implementing new technologies.
- Continuing education related to informatics is available through professional organizations and journals. Advanced degrees and certifications are also available as pathways to informatics roles beyond the bedside.

Key Terms

21st Century Cures Act (Cures Act) legislation passed in 2016 to promote and fund the acceleration of research to prevent and cure serious illness, accelerate drug and medical device development, address abuse crisis, and improve the delivery of mental health services

American Recovery and Reinvestment Act (ARRA) legislation passed in 2009 to stimulate the economy following a recession

artificial intelligence (AI) ability of machines, by applying computing power to large amounts of data, to solve complex problems and perform tasks that typically require human intelligence

augmented reality (AR) superimposition of a computer-generated environment onto the real world to create an interactive experience for the user

avatar digital representation of an individual created within a virtual environment

computerized provider order entry (CPOE) medical order that a provider enters directly into the patient's electronic medical record

consumer health informatics field of study and application that focuses on the use of information and communication technologies to empower individuals in managing their health and health care

continuous glucose monitor (CGM) device to automatically estimate blood glucose levels

Coronavirus Aid, Relief, and Economic Security Act (CARES Act) legislation passed in 2020 in response to the COVID-19 pandemic

digital divide gap between those who have access to the internet and related technologies and those who do not

digital transformation comprehensive integration and adoption of digital technologies, processes, and strategies across an organization to fundamentally change how they operate and deliver value

electronic medical record (EMR) digital form of a paper chart for use by one medical practice

Food and Drug Administration Safety and Innovation Act (FDASIA) legislation passed in 2012 to develop strategies and recommendations for a health IT regulatory framework

health informatics field that integrates information science with health care

Health Information Technology for Economic and Clinical Health (HITECH) Act legislation passed in 2009 (as part of ARRA) to promote electronic health records and a national health information infrastructure to support interoperability

incidence number of new cases of a specific disease or health-related event that occur within a defined population during a specified time period; measures the risk of developing a condition

informatics science of information

informatics nurse specialist (INS) nurse who specializes in nursing informatics

information and communications technology (ICT) all communication technologies that enable users to access, retrieve, store, transmit, and manipulate digital information

interoperability ability of different systems to "talk" to each other

machine learning ability of AI to analyze data by using algorithms and models that recognize patterns in data

meaningful use use of electronic health records to their full extent, facilitating the electronic exchange of information so that quality of care may be improved

Meaningful Use Electronic Health Record (EHR) Incentive Program initiative established by the U.S. government under the HITECH Act to encourage health-care providers to adopt and demonstrate meaningful use of certified EHR technology

Medicare Access and CHIP Reauthorization Act (MACRA) legislation passed in 2015 to reward Medicare clinicians with payment increases for delivering high-quality care and reduce payments for clinicians who do not meet performance standards

patient portal secure, online platform that provides patients with twenty-four-hour access to their personal health information

precision health innovative approach to health care that takes into account individual differences in genetics, environment, and lifestyle

predictive medicine use of laboratory and genetic tests to determine an individual's probability of developing a disease
prevalence total number of cases (both new and existing) of a particular disease or condition in a population at a specific point in time or over a specific period
public health informatics field that applies science and technology to meet the needs of public health
smart medical bed highly innovative hospital bed with additional technical features that support best practices for patient care
smart pump intravenous (IV) infusion device that combines computer technology and drug libraries to limit the potential for medication errors
super user clinical end user who receives specific training for providing support and education to others
surveillance collecting, analyzing, and disseminating data related to diseases, health outcomes, and injuries
telemedicine remote diagnosis and treatment of patients by means of telecommunications technology
usability ease with which people can use a product to achieve their goals
virtual reality (VR) use of hardware (a headset) and software (the VR platform) to create an immersive, simulated environment
wearable device health monitoring device worn on the body to monitor health data

Assessments

Review Questions

1. The nurse is discussing machine learning with a nursing student during a clinical rotation. What is an example of a statement made by the nursing student that would warrant further education?
   a. "Machine learning algorithms analyze patient data, including electronic health records and lifestyle information, to predict the risk of diseases such as diabetes or cardiovascular conditions."
   b. "Machine learning is used to analyze medical images (MRI, CT scans, x-rays) for the early detection and diagnosis of conditions like cancer."
   c. "Machine learning uses rule-based clinical decision support systems with a set of predetermined rules based on clinical guidelines to assist health-care providers in making decisions."
   d. "Machine learning algorithms match eligible patients with appropriate clinical trials by analyzing patient records and trial criteria."

2. A newly graduated nurse educates a patient on the benefits of artificial intelligence in health care. What is an example of a statement made by the nurse that would warrant further education by the nurse preceptor?
   a. "AI enhances the speed and accuracy at which health care is delivered."
   b. "AI can use algorithms to predict diagnoses and treatment plans."
   c. "AI can be used to provide personalized treatment plans to improve health outcomes."
   d. "AI analyzes real-time data to definitively diagnose patient conditions."

3. While telemedicine is associated with many benefits, it may also create challenges. How can the nurse help to reduce potential challenges of integrating AI into telemedicine?
   a. assume informed consent of using patient data for machine learning
   b. inform patients to seek telemedicine visits for all care needs
   c. educate patients without internet access to access telemedicine using public Wi-Fi
   d. verify all AI recommendations using human judgment and knowledge

4. What piece of legislation was responsible for widespread adoption of electronic health records?
   a. 21st Century Cures Act (Cures Act)
   b. Health Information Technology for Economic and Clinical Health (HITECH) Act
   c. Health Insurance Portability and Accountability Act (HIPAA)
   d. Medicare Access and CHIP Reauthorization Act (MACRA)

5. What piece of legislation was responsible for ensuring electronic medical records could be used in a meaningful way?

a. Coronavirus Aid, Relief, and Economic Security Act (CARES Act)
b. Food and Drug Administration Safety and Innovation Act (FDASIA)
c. Health Insurance Portability and Accountability Act (HIPAA)
d. Medicare EHR Incentive Program

6. What is an example of a statement that demonstrates an accurate understanding of the impact of legislation on health-care informatics?
a. "The CARES Act was developed to promote the acceleration of research to prevent and cure serious illness."
b. "The American Recovery and Reinvestment Act (ARRA) was responsible for adoption of electronic health records in a meaningful way."
c. "The 21st Century Cures Act (Cures Act) was developed to modernize the infrastructure of public health surveillance."
d. "The HITECH Act was developed to create privacy standards and stimulate the economy."

7. What is an example of a statement that demonstrates an accurate understanding of the governing institutions of health-care informatics?
a. "The Office of the National Coordinator for Health Information Technology (ONC) oversees regulating health information technology."
b. "The Office of Health Informatics within the Food and Drug Administration (FDA) works to establish global informatics standards."
c. "The International Organization for Standardization (ISO) researches informatics tools, solutions, and expertise."
d. "The Health Informatics and Interoperability Group (HIIG) coordinates national health information technology efforts."

8. What is the significance of the HITECH Act's impact on nursing documentation practices?
a. It encourages nurses to prioritize handwritten documentation over electronic records.
b. It has no influence on nursing documentation practices.
c. It emphasizes the adoption of electronic health records to improve accuracy and accessibility of documentation.
d. It made documentation in nursing practice more difficult and time-consuming.

9. As a nurse working in a technologically advanced health-care facility, how would the nurse best apply health informatics principles to optimize patient care?
a. Prioritize traditional, paper-based documentation for a comprehensive patient record.
b. Implement electronic health records (EHRs) to seamlessly capture, store, and retrieve patient information.
c. Limit the use of technology to avoid potential privacy and security concerns.
d. Rely solely on manual calculations for medication administration to ensure precision.

10. A nurse is educating a patient on uses for wearable devices. What is an example of a statement made by the patient that would warrant further education?
a. "Smartwatches ensure an accurate blood pressure is captured."
b. "Fitness trackers can help me to better understand my sleep patterns."
c. "Sensors can be used to detect my blood glucose levels."
d. "ECG readings may be captured via wearable devices."

11. What is an example of a statement that demonstrates an accurate understanding of the role of the nurse in fostering the use of technology?
a. "Nurse informaticists will tell the bedside nurses everything they need to know about technology."
b. "The user experience and usability impact the adoption of technology."
c. "Super users provide key insight into the development of technological products."

d. "Technology should be avoided if the patient doesn't know how to use it."

12. The nurse is precepting a nursing student. What is an example of a statement made by the nursing student that indicates an accurate understanding of informatics?
   a. "Super users provide peer-to-peer training and support during implementation of a product."
   b. "The digital divide refers to electronic health records not interacting with one another."
   c. "Usability refers to the user's experience while interacting with a product."
   d. "User experience refers to the ability of the user to achieve their goal when using the product."

Check Your Understanding Questions

1. What is telemedicine?

2. What is artificial intelligence?

3. What is health informatics?

4. What is the difference between an electronic health record and an electronic medical record?

5. What is the impact of health informatics on patient care?

6. How have smart pumps transformed direct patient care?

Reflection Questions

1. Reflect on your experiences with simulation or augmented or virtual reality. How was AI used? What role did these technologies play in preparing you for practice?

2. Many health-care organizations have adopted electronic health records, yet the goal of health records being accessible by all providers has not been achieved. Why is this?

3. How has information technology impacted health care?

What Should the Nurse Do?

Mrs. Johnson, a forty-year-old female, contacts the telemedicine service with complaints of persistent headaches and visual disturbances. She reports a medical history of hypertension and diabetes, currently managed with medications. During the video consultation, Mrs. Johnson mentions feeling fatigued and having trouble managing her blood glucose levels. Her vital signs include a blood pressure of 150/90 mmHg, heart rate of 80 bpm, respiratory rate of 16 breaths per minute, and a temperature of 37.2°C (99°F). Through the telemedicine platform, an AI algorithm analyzes Mrs. Johnson's symptoms and medical history, providing real-time suggestions for adjusting her diabetes management plan and recommending lifestyle modifications.

1. How did the AI algorithm contribute to your analysis of Mrs. Johnson's symptoms, and what key insights did it provide regarding her diabetes management?
2. Considering Mrs. Johnson's medical history of hypertension and diabetes, how did you prioritize hypotheses related to the cause of her persistent headaches and visual disturbances?

Mr. Klein, a fifty-five-year-old male, arrives at the primary care clinic presenting with symptoms of chronic fatigue, unexplained weight loss, and generalized weakness. His medical history includes hypertension and type 2 diabetes; both conditions are managed with medications. During the initial assessment, his vital signs reveal a blood pressure of 140/90 mmHg, heart rate of 82 bpm, respiratory rate of 18 breaths per minute, and a temperature of 98.6°F (37.0°C). Mr. Klein has a comprehensive electronic health record (EHR) that integrates information from various health-care providers and includes details about his chronic conditions. The nurse, leveraging health informatics, accesses and reviews the EHR to identify potential correlations between Mr. Klein's current symptoms and his medical history.

3. How did Mr. Klein's symptoms and medical history serve as cues for recognizing the importance of utilizing health informatics, particularly the electronic health record (EHR), in your assessment?
4. What solutions or interventions did you consider based on the information obtained from the EHR, and how did you prioritize potential diagnostic tests for further investigation?

Ms. Long, a sixty-five-year-old female, visits the outpatient clinic reporting a recent onset of shortness of breath and chest pain. She has a history of hypertension and hyperlipidemia, currently managed with medications. During the assessment, her vital signs include a blood pressure of 150/90 mmHg, heart rate of 100 bpm, respiratory rate of 22 breaths per minute, and a temperature of 98.6°F (37.2°C).

To enhance the efficiency of care, the clinic utilizes an integrated health information system. The nurse, recognizing the potential urgency of Ms. Long's symptoms, swiftly accesses the integrated health information system to retrieve the patient's electronic health record (EHR). Within moments, the nurse obtains crucial data, including recent diagnostic tests and a comprehensive medication history. The EHR reveals that Ms. Long underwent lipid profile testing and a cardiac stress test two months ago, both of which were within normal ranges. Her prescribed medications, including antihypertensives and statins, are up to date.

5. How did the analysis of Ms. Long's vital signs and EHR data contribute to your understanding of her current health status, and what key information did you extract from the EHR?
6. How would you communicate with Ms. Long to initiate an electrocardiogram (ECG), and what steps would you take to ensure a swift and seamless process?

Competency-Based Assessments

1. Verbalize how to educate a patient about telemedicine and prepare for a telemedicine visit.
2. Create a bulleted list of benefits to the patient for using patient portals.
3. Develop a presentation as if you were a nursing educator preparing to discuss informatics and its optimization in health care.
4. During the sample presentation, how would you incorporate an understanding of the nurse's role in fostering the use and advancement of technology in health care?

CHAPTER 38

Unfolding Case Study and NCLEX Preparation

FIGURE 38.1 Nurses use clinical judgment in practice by assessing patient conditions, interpreting data, and making informed decisions to provide safe, effective, and individualized care. (credit: Army Spc. Logan Ludwig/Joint Base San Antonio, public domain)

CHAPTER OUTLINE

INTRODUCTION Picture this: You're a new graduate nurse, fresh out of orientation on a critical care unit. You're getting a report on your patient, who has been admitted for an acute exacerbation of heart failure. The nurse mentions that the patient has been receiving a large dose of diuretic medications and has been having some irregular heartbeats on the telemetry monitor. Reflecting on your nursing knowledge, you remember that abnormal potassium levels can affect the heart's rhythm, so you pull up the patient's chart to check the latest entry for their potassium levels. Sure enough, the patient's potassium levels are very low, likely from the high dose of diuretics being administered. You quickly contact the provider to make them aware of the situation and recommend potassium replacement to bring the patient's levels back to normal. Had you not made this connection, the patient could have experienced cardiac arrest or other life-threatening symptoms related to low potassium levels. You used your nursing knowledge to make a clinical judgment that probably saved your patient's life.

It is imperative that new nurses are able to think critically and employ clinical judgment in practice. The rest of this chapter provides an unfolding case study that highlights how nurses can systematically work through the clinical judgment measurement model and use clinical judgment to make practice decisions.

38.1 Unfolding Case Study Dissection

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Examine the clinical decisions based on patient needs in the case study
- Recognize steps in application of patient care in the case study
- Identify patient care outcomes in the case study

UNFOLDING CASE STUDY

Nursing Care of a Patient Who Fell

Part 1

Mrs. Jackson, a 68-year-old female patient, presents to the emergency department after experiencing a fall at home. Her daughter witnessed the fall and brought Mrs. Jackson to the hospital saying, "My mom has been acting really confused after falling. I'm scared she might have a concussion."

Past Medical History	Medical History: Hypertension, atrial fibrillation, type 2 diabetes. Family History: Married for 45 years, 3 grown children. Mother deceased from Alzheimer's. Father alive, with hypertension and prostate cancer, currently undergoing treatment. Social History: Former ½ pack/day smoker, quit 15 years ago. Allergies: No known drug allergies Current Medications: • amlodipine (Norvasc) 5 mg PO daily • losartan (Cozaar) 50 mg PO daily • metformin (Glucophage) 500 mg PO daily • warfarin (Coumadin) 2 mg PO daily • aspirin 81 mg PO daily
Assessment	Time: 1200 General Survey: Patient appears anxious and confused. She is repeatedly asking, "Where am I? Why am I here?" Neurological: Alert and oriented x1, slurred speech, decreased sensation on right side of body. HEENT: Slight right facial droop. Respiratory: Clear lung sounds, normal breathing pattern. Cardiovascular: Rapid, thready pulse, capillary refill <2 seconds, warm extremities. Abdominal: Bowel sounds normoactive in all 4 quadrants, no tenderness. Musculoskeletal: muscle strength of right upper and right lower extremities, 2/5; left upper and lower extremities, 5/5 Integumentary: Skin pale but dry and intact.
Nursing Notes	Time: 1210 During assessment, signs/symptoms of stroke were noted. Code stroke paged overhead at 1208. Per protocol, patient transported for STAT CT scan. History obtained from daughter, who reports the time the patient was last seen normal was 1045.

Flow Chart	Time: 1215 pm Blood pressure: 148/79 mmHg Heart rate: 112 beats/minute Respiratory rate: 29 breaths/minute Temperature: 99.6 °F (37.5°C) Oxygen saturation: 92% on room air Pain: 4/10 Weight/BSA: 144lbs
Provider's Orders	Time: 1230 STAT CT scan STAT labs including point-of-care glucose, CBC, BMP, INR, PTT, HA1C, 12-lead ECG NPO order (swallow screen prior to any PO) Admit to neuro floor for observation Q15 minute neuro checks x 4 hours, then Q 1 hour Continuous telemetry monitoring Fasting lipid panel at 0600 tomorrow MRI with contrast
Test Results	Time: 1240 Noncontrast CT scan confirms acute ischemic infarction involving the left middle cerebral artery, no evidence of hemorrhage. Glucose 125 mg/dL INR 2.3
Nursing Notes	Time: 1245 Patient is within the time-appropriate time window for tPA, but history of anticoagulant use and INR >2 is a contraindication, per stroke protocol. Q15 minute neuro checks being completed. 12-lead ECG shows atrial fibrillation, provider notified. Patient made NPO and family updated on plan of care.

Part 2

Mrs. Jackson has been on the neuro unit for two days and is now showing a slight improvement in symptoms. The family has requested to meet with the unit's social worker to discuss rehabilitation options.

Assessment	Time: 0800 General Survey: Patient is calm and pleasant. States, "I feel ready to go home." Neurological: Alert and oriented x4, some intermittent slurred speech. Sensation improved. HEENT: Slight right facial droop. Respiratory: Clear lung sounds, normal breathing pattern. Cardiovascular: Strong pulse, normal sinus rhythm on the monitor, capillary refill <2 seconds, warm extremities. Abdominal: Bowel sounds normoactive in all 4 quadrants, no tenderness. Musculoskeletal: 4/5 muscle strength of right arm and right leg, left arm and left leg 5/5 Integumentary: Skin pale but dry and intact.
Flow Chart	Time: 0830 am Blood pressure: 138/82 mmHg Heart rate: 98 beats/minute Respiratory rate: 22 breaths/minute Temperature: 99.6 °F (37.5°C) Oxygen saturation: 98% on room air Pain: 2/10
Provider's Orders	Time: 0900 Start clopidogrel, loading dose of 300 mg today, 75 mg daily starting tomorrow, to take for 90 days Physical therapy consult Occupational therapy consult Bedside swallow study before PO (including meds), advance diet as tolerated Social work to coordinate discharge to home vs. rehab facility per PT/OT recommendations
Nursing Notes	Time: 1400 Bedside swallow study completed; patient passed. Clopidogrel loading dose administered, patient and family educated regarding the need to adhere to medication as prescribed to prevent future strokes. Patient and family expressed understanding. Physical and occupational therapy to evaluate patient this afternoon. Discharge planning to home vs. rehab facility in process with social work. Family has been updated on plan of care and all questions and concerns have been addressed.

Clinical Decisions Based on Patient Needs

As soon as the patient arrived at the emergency room, the nurse began the process of critically thinking about what needed to be done. The nurse assessed the patient's situation and then recognized, analyzed, and prioritized the patient's needs. Once the needs were prioritized, the nurse made clinical decisions about the care to provide, then developed and refined the planned nursing interventions. Each of these actions by the nurse is discussed in more detail in the following sections.

Assessment of Patient Situation

The nurse began assessing the patient as soon as they arrived at the hospital. The nurse was informed that the patient fell at home and was brought to the emergency department by her daughter, who is concerned that the patient may have a concussion. The nurse immediately performed a general survey, looking for cues that would be indicative of a concussion or injury from the fall. During the general survey, the nurse noticed that the patient appeared anxious and confused. The nurse hypothesized that the confusion could be related to head injury from the fall, but that there may be more going on, and further assessment was indicated. The nurse performed a quick head-to-toe assessment and recognized the following relevant cues:

- Alert and oriented only to self

- Slurred speech
- Slight right facial droop
- Rapid, thready pulse
- Decreased muscle strength in right side extremities
- Decreased sensation to right side of body

The nurse recognized that the patient's symptoms were consistent with a cerebrovascular accident (stroke) from using the FAST assessment and immediately activated a code stroke, recognizing the importance of initiating interventions in a timely manner. Additionally, the nurse recognized other important cues from the patient's medical history that increased the probability of a stroke: hypertension, atrial fibrillation, and type 2 diabetes. The nurse also took note of the patient's current medications, because that information often provides more context for a patient's situation. In this case, the patient was actively taking two antihypertensive medications, an antidiabetic medication, an anticoagulant, and a daily aspirin.

Recognize, Analyze, and Prioritize Patient Needs

After recognizing symptoms of stroke and alerting the stroke team, the nurse also quickly initiated patient transport to the imaging department for a STAT head CT to determine if the patient was actually experiencing a stroke, and to identify, if necessary, the type of stroke (e.g., ischemic, hemorrhagic). The nurse also recognized the importance of asking the patient's daughter when the patient was "last seen normal," as the patient must be in the allotted time window from the onset of symptoms to receive tissue plasminogen factor (tPA), a clot-busting medication that is used to treat ischemic stroke. The nurse then performed important diagnostic tests per the provider's order, including a point-of-care glucose, CBC, BMP, INR, PTT, HA1C, and 12-lead ECG.

Develop and Refine Interventions

Based on the provider's orders, the nurse performed a 12-lead ECG and found the patient's cardiac rhythm to be atrial fibrillation on the monitor. The nurse recognized that this cardiac rhythm is often a risk factor for stroke and hypothesized that it may have been a contributing factor to the patient's presenting symptoms.

Other nursing interventions included performing frequent neurological checks, frequent vital sign checks, analyzing lab and test results, and initiating NPO orders. The nurse recognized the importance of performing frequent neurological checks, because these checks provide tangible measurements of the subtle changes that may indicate the patient's status is worsening. While analyzing lab and test results, the nurse recognized that the CT report showed findings that were consistent with an ischemic stroke on the left side of the brain. These findings are consistent with the patient's right-sided symptoms, as symptoms of a stroke are often exhibited on the opposite side of the body in relation to their location in the brain. The nurse also recognized that the patient's blood glucose was slightly elevated, consistent with the patient's diabetes, but was likely not the cause of the patient's symptoms. Typically, hypoglycemia can mimic symptoms of stroke, not hyperglycemia. Lastly, the nurse initiated an NPO order for the patient because strokes increase the risk of dysphagia. At this point, the nurse should anticipate that the patient will require a bedside swallow screen and possibly future consultation with a speech language pathologist to determine their ability to swallow food, liquids, and medications before the NPO status will be changed.

Application of Nursing Care

Application of nursing care in the case study included the interventions mentioned in the previous section, as well as educating the patient and family about the plan of care. Experiencing a stroke can be stressful for both the patient and family members, so the nurse can help ease some anxiety by keeping everyone informed about what is happening. In this case, it was important for the nurse to let the patient's family members know that the patient had experienced a stroke, but that typical treatment (tPA) was contraindicated because of the patient's elevated INR value. The nurse should explain this in simple terms, avoiding complex medical jargon to ensure understanding. For example, the nurse might say, "We would typically give a medication that would dissolve the clot that is causing the stroke, but that medication carries a large risk of bleeding. Because the patient is on a blood thinner medication, she is already at an increased risk of bleeding, so if we gave this medication, it could cause her to experience bleeding in the brain, which is life-threatening. Instead, we are going to watch her closely to make sure her symptoms don't get worse and do all we can to improve them."

Incorporated Factors Affecting Patient Care

Caring for a patient who is having a stroke involves a lot of physical nursing tasks and skills, but it is also important to recognize the need to provide emotional support to the patient and their family members. Experiencing a stroke can cause a lot of anxiety, especially in this case, as the patient was unable to receive standard pharmacological treatment because of contraindications. The nurse should remain available to the patient and the family to discuss concerns and answer questions about the plan of care. It is important for the nurse to ask what kind of support or resources would help them cope with the diagnosis and, if possible, provide them. After being in the hospital for a few days and experiencing an improvement in symptoms, the nurse in the case study connected the patient and family to a social worker to help them transition from the hospital to home or to a rehabilitation facility.

Revising the Plan of Care

Even though the patient was not actively receiving treatment for the stroke, the nurse was still closely monitoring and assessing for subtle changes in health status that would indicate the need for a revised plan of care. Specifically, the nurse monitored the patient's vital signs and neurological status, looking for improvement or worsening of symptoms. As the patient progressed through the hospital stay, the plan of care required revision to account for discharge and possible rehabilitation.

Evaluate Outcomes

After performing interventions, the nurse evaluated outcomes by reassessing the patient's vital signs and neurological status. The patient's vital signs remained stable, and the neurological status improved. Also, the nurse must evaluate the patient and family's understanding of provided education. The nurse can do this by using the "teach back" strategy, which asks the learner to repeat the information in their own words to verify the message was received.

Evaluate Nursing Actions

In this case study, the nurse initially evaluated the patient's neurological status every 15 minutes, looking for worsening or improving of symptoms. Because the patient was unable to receive tPA, the nurse did not administer a specific treatment for the stroke, but closely monitored the patient's neurological status. This is an action that can be evaluated. For example, if the nurse notices that the patient's neurological status is worsening, they might hypothesize that the stroke has expanded or the patient may be experiencing a hemorrhagic transformation and would relay this information to the provider to determine the next course of action, which may involve a surgical intervention. Thankfully, in the case study, the patient's symptoms showed improvement a few days after the onset of the stroke, and the nurse began facilitating physical, occupational, and speech therapies to help the patient restore function and work toward discharge home. Additionally, the nurse facilitated communication between the patient and family and the social worker to initiate the process of leaving the hospital, either to home or to an appropriate rehabilitation facility for the patient to continue her journey of healing.

Another important way that the nurse monitored outcomes was ensuring patient and family understanding of the education provided. Specifically, the nurse provided information about the importance of taking the clopidogrel as prescribed to decrease the risk of subsequent strokes. To evaluate the patient and family's understanding, the nurse should consider asking them to "teach back" the information. This process helps the nurse feel confident that they understand the significance of adhering to the medication.

Revised Plan of Care

The nursing interventions were successful, as indicated by the improvement in the patient's neurological symptoms. If the symptoms had not improved, the nurse would have revised the plan of care to treat the patient's condition more effectively. This may have included alerting the provider about the lack of improvement in the patient's condition and/or requesting alternative treatment options, as available. The nurse was continually assessing the patient's condition, monitoring for signs of worsening or improvement to use as a guide for revising the plan of care as necessary. This continuous assessment occurs until the patient is discharged.

38.2 NCLEX Preparation

LEARNING OBJECTIVES

By the end of this section, you will be able to:

- Discuss assessment of nursing knowledge by the NCLEX
- Explain characteristics of the new NCLEX, including question types

Nursing judgment is a learned skill. The ability to think critically develops more fully over time in nursing practice. Basic understanding of the process is evaluated pre-licensure during the nurse's academic preparation and on the licensure examination for nursing graduates.

Every two years, the National Council of State Boards of Nursing (NCSBN) investigates nursing education and aspects of the nursing workforce via survey in the United States. These surveys provide information on the type of practice required and the availability of working nurses. This information is utilized for curriculum development in schools of nursing and workforce planning in health-care settings, as well as in the development of questions for NCLEX. This section addresses the measurement of nursing judgment, specifically on the licensure examination, and in nursing practice.

Assessment of Nursing Knowledge by the NCLEX-RN

The NCLEX-RN changed in 2023 due to research evidence of the need for nursing graduates to show increased understanding of safe practice at the entry level. The focus and formatting of the questions on the licensure examination changed to meet this goal. The examination now presents the test-taker with items (questions) that pose problem-solving scenarios, in short form as specific questions, or in longer form as client need categories. Candidates can expect items to address categories as depicted in Figure 38.2.

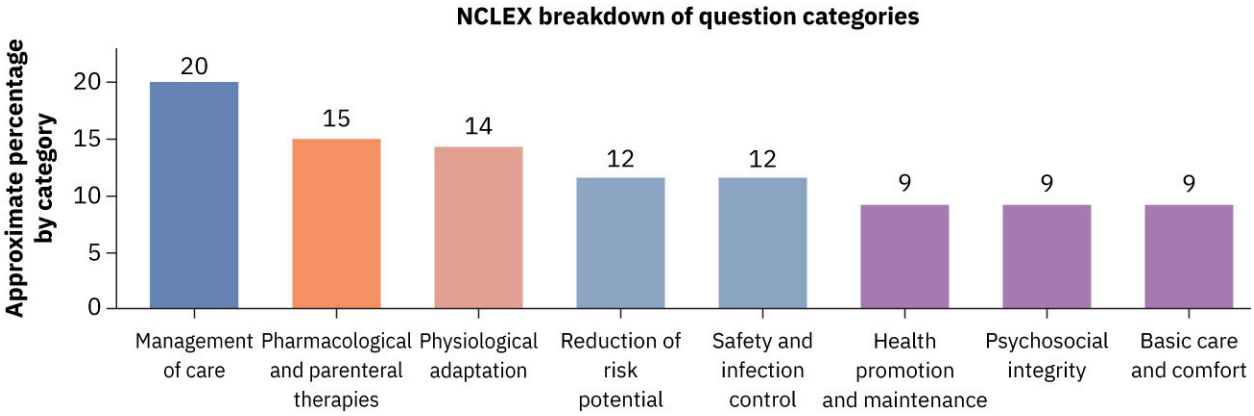

FIGURE 38.2 This graph shows the approximate breakdown in categories of questions on the NCLEX, but distributions may vary slightly based on individual examinations. (modification of work from *Psychiatric-Mental Health Nursing*. attribution: Copyright Rice University, OpenStax, under CC BY 4.0 license)

To guide the candidate's study, meaning of the categories depicted left-to-right on the graph are as follows:

- Management of care means the nurse observes scope of practice guidelines, incorporates all available support, delegates and directs others, and conserves resources.
- Pharmacological and parenteral therapies mean the nurse safely administers or supervises safe administration of prescribed medications, fluids, and blood products by all routes and teaches and monitors indication, intended effect, side effects, and adverse reactions.
- Physiologic adaptation means the nurse manages and promotes patients' adjustment to emergency, corrective, or supportive care, interventions, and treatments.
- Reduction of risk potential means the nurse monitors for complications of patients' diagnoses and educates and intervenes to mitigate potential harms and adverse outcomes to care and treatment.
- Safety and infection control means the nurse recognizes and mitigates harm and risks, observes practice standards, monitors patient acuity, and educates others.
- Health promotion and maintenance means the nurse brings preventative care and wellness care at all stages of human development, detects potential problems, and conducts health screening.
- Psychosocial integrity means the nurse promotes patients' adaptation and stress management, teaches

others, integrates nursing interventions, advocates for emotional, social, and spiritual wellness, and delivers psychiatric nursing care in therapeutic settings.
- Basic care and comfort mean the nurse provides and directs physical care for basic needs, such as nutrition, hydration, comfort, elimination, activity, and rest.

The essence of nursing practice is the identification of client needs, which are then addressed through the nursing process. By successful completion of the NCLEX-RN, nursing graduates show their competence at the entry level of practice.

Computerized Interactive Questions

The NCLEX-RN items measure clinical judgment by NGN (or Next Generation NCLEX) case study and stand-alone questions. Case studies present multiple questions about a realistic nursing care scenario. Stand-alone items ask for application of the six elements in Layer 3 of the CJMM, which are steps of the nursing process, and, as discussed in previous chapters, depict the actions the nurse can take. Answers may be entered by "click to specify" or "click to highlight" chosen responses. Test item formats include bow-tie, drag-and-drop, drop-down, extended multiple response, and matrix. Visualizing questions on a split screen is another new feature of the exam.

- Bow-tie: Move provided answers to provided categories.
- Drag-and-drop: Move provided answers to the correct target.
- Drop-down: Select an option from text, chart, or table.
- Extended multiple response: Select all applicable responses; partial credit is awarded for items with more than one key.
- Matrix: Select from a table of options in columns or rows.

Available Resources

Knowledge base and examination preparation together are essential for NCLEX success.

Schools of nursing provide preparation for the NCLEX throughout the nursing program, many utilizing a software package (e.g., Kaplan, ATI). Near graduation, programs offer more specific preparation in the forms of exit exams, capstone projects, clinical preceptorship/field placements, or wrap-up components of the school's software product. In addition, final semester students frequently present a project that is designed to bring together multiple concepts of nursing practice.

There are numerous NCLEX preparation offerings. Nursing graduates may personally decide how to customize the process. What is important to the test-taker? Graduates should consider their own learning style. Printed materials, online formats, mobile applications, videos on demand, practice questions, recorded mini-lectures, question libraries, and real-time study groups, coaches, and tutors are all available.

Graduates may want to consider whether the study resource contains access to customized study help and access to user reviews. Cost is another factor, whether purchase or subscription. The testing programs selected by the graduate's school of nursing can serve as a guide for NCLEX prep or prompt investigation into what other schools use. Important to consider is practice with simulated adaptive NCLEX-style test items. The graduate's selection of preparation packages should include those that provide a focus on Next Gen-type questions.

LINK TO LEARNING

The NCLEX Frequently Asked Questions page (https://openstax.org/r/77nclexfaq) provides a lot of useful information for nursing graduates preparing to take the exam.

Application of Clinical Judgment to Patient Care

Nursing graduates can think of the NCLEX-RN as a safety test. The test evaluates candidates' ability to decide how to proceed in patient care situations, as opposed to strict memorization of answers to standard questions. The candidate can expect scenarios posing complex decisions that require cultural competence and use of available resources. NCLEX-RN seeks to present situations that occur in real health-care settings. There is an increased focus

on client acuity and nursing management of change in condition. The goal is improvement in care that avoids medical errors by emphasizing clinical judgment and promoting optimal patient outcomes.

Summary

38.1 Unfolding Case Study Dissection

- Clinical judgment skills continue in licensed practice.
- Successfully stabilizing a client's anxiety, pain, or fear will enhance outcomes of care. In addition, nurses are likely to feel personally rewarded in their careers.

38.2 NCLEX Preparation

- Critical thinking and clinical judgment develop in nursing practice over time and through models like the CJMM. Schools of nursing evaluate these skills for successful completion of academic courses.
- The NCLEX evaluates these skills prior to licensure as a professional nurse. Nurses must act efficiently and safely, while identifying and seeking to meet client care goals.

Assessments

Review Questions

1. Based on the unfolding case study information, what assessment finding by the nurse is the most concerning?
    a. pale, dry skin
    b. blood pressure 148/79
    c. right-sided weakness
    d. history of type 2 diabetes

2. What is the best rationale for the NPO order and swallow study for Mrs. Jackson?
    a. to prevent aspiration due to possible dysphagia
    b. to prepare for potential surgical intervention
    c. to avoid interfering with blood glucose levels
    d. to reduce the risk of gastrointestinal bleeding

3. After two days on the neuro unit, Mrs. Jackson shows slight improvement in symptoms. What intervention is most appropriate for the nurse to take to address her current needs?
    a. discharge planning with no further follow-up
    b. starting clopidogrel and scheduling evaluation by physical therapy
    c. requesting a higher dose of warfarin to prevent further strokes
    d. maintaining strict bedrest to avoid further complications

4. What assessment category of the NCLEX would include how the nurse delegates to others?
    a. physiologic adaptation
    b. psychosocial integrity
    c. management of care
    d. reduction of risk potential

5. What question style on the new NCLEX involves selecting the correct option from the text, a chart, or a table?
    a. drop-down
    b. bowtie
    c. drag-and-drop
    d. matrix

Check Your Understanding Questions

1. What is the rationale behind not administering tPA to Mrs. Jackson upon finding an ischemic stroke on the CT scan?

2. What is the main reason the NCLEX was changed in 2023 to a new format?

Reflection Questions

1. How do you think having an interdisciplinary, interprofessional care team would affect Mrs. Johnson's quality of care and patient outcomes?
2. How do you think the new NCLEX will impact the clinical practice of new graduate nurses?

Competency-Based Assessments

1. Draw a flowchart illustrating steps that the nurse would take when caring for a patient admitted for a suspected stroke.

APPENDIX A

Diagnostic Studies and Interpretation

Diagnostic tests and procedures are used in clinical health-care settings to aid in the identification of a condition, disease, or prognosis with a high degree of accuracy. They are crucial to early detection and application of the proper treatment plan for each patient. Every provider is responsible for the analysis of each study and the individual action plan because of the interpretation. Every diagnostic has four phases. The first is to determine normal or acceptable ranges of the test. The second is to evaluate the accuracy of the test. The third is to determine clinical consequences of the results of the test. The fourth is to evaluate if more diagnostics are needed before determining an individual plan. Table A1 lists common laboratory tests and expected results. Table A2 displays commonly used diagnostic studies for providing competent and comprehensive patient care.

Serum, Plasma, and Whole Blood	
Red blood cell (RBC)	4.5–5.0 million cells/mm^3 (female) 4.7–6.2 million cells/mm^3 (male)
White blood cell (WBC)	4,500–11,000 cells/mm^3
Platelets	150,000–400,000/mm^3
Blood urea nitrogen (BUN)	6–24 mg/dL
Serum creatinine	0.6–1.2 mg/dL
Estimated glomerular filtration rate (eGFR)	> 60 mL/min/1.73m^2
Carbon dioxide	23–29 mmol/L
Glucose	65–110 mg/dL
Aldolase	22–59 mU/L
Chloride	95–105 mEq/L
Potassium	3.5–5.2 mEq/L
Sodium	135–145 mEq/L
Calcium	8.3–10.2 md/dL
Phosphorus	3.0–4.5 mg/dL
Magnesium	1.3–2.1 mEq/L
Serum osmolality	285–295 mOsm/kg H_2O

TABLE A1 Common Laboratory Tests

Albumin	3.5–5.5 g/dL
Total protein	5.5–8.3 g/dL
Bilirubin	0.1–1.2 mg/dL
Ammonia	11–32 mcmol/L
Aspartate aminotransferase (AST)	9–25 units/L (female) 10–40 units/L (male)
Alanine aminotransferase (ALT)	7 – 20 units/L (female) 10 – 55 units/L (male)
Copper	70–15 mcg/dL
Ferratin	18–160 ng/mL (females) 18–270 ng/mL (males)
Folic acid	3–13 ng/mL
Arterial Blood Gas (ABG)	
pH	7.35–7.45
Partial pressure of oxygen (PaO_2)	80–100%
Partial pressure of carbon dioxide ($PaCO_2$)	35–45 mmHg
Bicarbonate (HCO_3)	22–26 mEq/L
Hematology	
Fibrinogen	200–400 mg/dL
Erythrocyte count	3.6–5.0 × 1012/L (female) 4.2–5.4 × 1012/L (male)
ESR	0–20 mm/h (females less than 50 yrs) 0–30 mm/h (females greater than 50 yrs) 0–15 mm/h (males less than 50 yrs) 0–20 mm/h (males greater than 50 yrs)
Hematocrit	36–48% (female) 42–52% (male)
Hemoglobin	12–16 g/dL (female) 13–17 g/dL (male)
International normalized ratio (INR)	0.8–1.2 2–3 is normal for patients on warfarin

TABLE A1 Common Laboratory Tests

Prothrombin time (PT)	11–13 seconds 1.5–2× longer if on anticoagulants
Partial thromboplastin time (PTT)	60–70 seconds 1.5–2× longer if on anticoagulants
Activated partial thromboplastin time (aPTT)	25–35 seconds 1.5–2× longer if on anticoagulants
Cardiac Markers	
Total creatine kinase (CK)	500–2250 nkat/L (female) 917–2833 nkat/L (male)
Myoglobin	5–70 ng/mL
Troponin	<0.4 ng/mL
Atrial natriuretic peptide (ANP)	22–77 ng/L
Brain natriuretic peptide (BNP)	<100 ng/L
Lipid Panel	
High-density lipoprotein (HDL)	> 40 mmol/L
Low-density lipoprotein (LDL)	< 100 mmol/L
Triglycerides	< 120 mmol/L
Total cholesterol	< 170 mmol/L
Hemoglobin A1C	
Normal	< 5.7%
Prediabetes	5.7–6.4%
Diabetes	> 6.5%
Proteins	
Protein total	6–8 g/dL
Albumin	3.5–5.2 g/dL
Globulin	1.7–3.3 g/dL
Vitamins	
Vitamin A	30–120 mcg/dL

TABLE A1 Common Laboratory Tests

Vitamin B_1	1.6–4 mcg/dL
Vitamin B_6	5–30 ng/mL
Vitamin B_{12}	200–900 pg/mL
Vitamin E	0.5–1.8 mg/dL
Zinc	55–150 mcg/dL
Urine Chemistry	
Ketones	< 2.0 mg/dl
Amylase	1–17 units excreted per hour
Calcium	100–250 mg per 24/hour
pH	4.5–8
Osmolality	50–1200 mOsm/kg
Glucose	Negative
Note: These values could change slightly based on parameters set by specific health-care facilities	

TABLE A1 Common Laboratory Tests

Diagnostic	Description
Angioplasty	Widens the arteries and increases cardiac blood flow
Biopsy	Removes a sample of tissue or cells from the body for microscopic examination to diagnose cancer or other diseases
Bronchoscopy	Examines the larger airways: trachea and bronchi
Chest X-ray	Evaluates the lungs, heart, or chest wall to diagnose pneumonia, heart failure, emphysema, lung cancer, and other medical conditions
Colonoscopy	Examines the colon, or large intestine
Computed tomography scan (CT)	Evaluates all major parts of the body, including the abdomen, back, chest, and head
Electrocardiography (EKG or ECG)	Records the heart's electrical activity to detect abnormal rhythms, heart damage, or heart failure
Electroencephalogram (EEG)	Records the brain's electrical activity

TABLE A2 Common Diagnostic Procedures (Bolboacă, 2019)

Diagnostic	Description
Endoscopy	Examines the inside of certain tube-like structures in the body with a fluoroscope; for example, upper GI series examines the esophagus, stomach, and duodenum
Fecal occult blood test	Examines stool samples for traces of blood; also called a stool guaiac or hemoccult test
Lumbar puncture	Uses a needle to remove a sample of fluid from the space surrounding the spinal cord to diagnose infections, such as meningitis, and some neurological conditions.
Magnetic resonance imaging (MRI)	Uses a magnetic field to produce pictures of structures inside the body
Ultrasonography	Uses high frequency sound waves to generate snapshots or moving pictures of structures inside the body, especially vital organs; also called sonography
Ventilation-perfusion scan (V-Q scan)	Nuclear scan that examines both airflow (ventilation) and blood flow (perfusion) in the lungs
X-ray	Uses waves of electromagnetic radiation to create images of organs and other structures inside the body

TABLE A2 Common Diagnostic Procedures (Bolboacă, 2019)

APPENDIX B

Major Fluid and Electrolyte Imbalances

Any condition that can cause fluid electrolyte imbalances, such as cardiac, circulatory, endocrine, gastrointestinal or lung disorders, malnutrition, kidney dysfunction, or acid-base imbalance requires frequent monitoring of blood electrolytes (Ambati et al., 2023). Electrolyte evaluation is done through a blood specimen using lithium heparin tubes. Common laboratory ranges will vary slightly depending on location and facility protocols. Table B1 lists common laboratory ranges and clinical manifestations for each electrolyte.

Electrolyte	Normal Range	Mild to Moderate Range	Complications
Sodium	135–145 mmol/L	Hyponatremia: 125–135 mmol/L Hypernatremia: 145–160 mmol/L	May lead to neurological consequences such as seizures
Potassium	3.6–5.5 mmol/L	Mild hypokalemia: < 3.6 mmol/L Moderate hypokalemia: < 2.5 mmol/L Mild hyperkalemia: 5–5.5 mmol/L Moderate hyperkalemia: 5.5–6.5 mmol/L	May lead to cardiac arrhythmias, fatigue, lethargy, and muscle weakness
Calcium	8.8–10.7 mg/dL	Hypocalcemia: < 8.8 mg/dL Hypercalcemia: > 10.7–11.5 mg/dL	May lead to cardiac arrhythmias, fatigue, lethargy, and muscle weakness
Bicarbonate	23–30 mmol/L	Acidosis: < 23 mmol/L Alkalosis: > 30 mmol/L Increases or decreases depending on acid-base status either respiratory or metabolic	Acidosis: may inhibit O_2 transport at the cellular level Alkalosis: may cause tetany and paresthesia
Magnesium	1.46–2.68 mg/dL	Hypomagnesemia: < 1.46 mg/dL Hypermagnesemia: > 2.68 mg/dL	May lead to neurological consequences such as seizures, imbalances, fatigue, lethargy, and muscle weakness

TABLE B1 Electrolyte Imbalances (Hoppe et al., 2018)

Electrolyte	Normal Range	Mild to Moderate Range	Complications
Chloride	95–105 mEq/L	Hypochloremia: < 95 mEq/L Hyperchloremia: > 105 mEq/L	Hypochloremia may lead to fatigue and weakness Hyperchloremia may lead to high blood pressure, changes in fluid secretion, headache, metabolic acidosis, muscle cramps, arrythmias, and confusion
Phosphorus	3.4–4.5 mg/dL	Hypophosphatemia: < 2.5 mg/dL Hyperphosphatemia: > 4.5 mg/dL	May lead to bone and muscle disorders and increase risk of cardiovascular and neurological disorders

TABLE B1 Electrolyte Imbalances (Hoppe et al., 2018)

Significant variation can occur depending on the cause of each electrolyte imbalance. Many electrolytes are interdependent of one another, meaning that if one is abnormal, it can elicit a chain reaction causing others to become abnormal (Kraut & Madias, 2017). The delicate balance of fluid and electrolytes within the body to maintain homeostasis needs constant and comprehensive evaluation. Table B2 lists the most common causes.

Electrolyte	Cause
Sodium	Hyponatremia: adrenal insufficiency, cirrhosis, chronic hyperglycemia, heart failure, low dietary sodium intake, polydipsia, severe dyslipidemia, and syndrome of inappropriate antidiuretic hormone secretion (SIADH) Hypernatremia: hypertonic IV administration, osmotic diuresis, or unreplaced fluid loss via the skin or gastrointestinal tract
Potassium	Hypokalemia: aldosteronism or administration of loop diuretics Hyperkalemia: acute kidney injury, administration of beta blockers, insulin deficiency, metabolic acidosis
Calcium	Hypercalcemia: malignancy, hyperparathyroidism, malignancies, or tuberculosis Hypocalcemia: pancreatitis, parathyroid dysfunction, hypomagnesemia, or sepsis
Bicarbonate	Increase: metabolic alkalosis or respiratory acidosis Decrease: metabolic acidosis or respiratory alkalosis
Magnesium	Hypermagnesemia: ingestion of high amounts of oral magnesium, such as over-the-counter antacids, and renal failure Hypomagnesemia: alcohol use disorder, diuretic administration, or fluid loss such as from excessive vomiting and diarrhea

TABLE B2 Common Causes of Electrolyte Imbalances (Shrimanker & Bhattarai, 2023)

Electrolyte	Cause
Chloride	Hyperchloremia: administration of excessive IV NS, diarrhea, ingestion of saltwater, and excessive amounts of salt Hypochloremia: excessive vomiting, diarrhea, or other gastrointestinal fluid loss
Phosphorus	Hypophosphatemia: parathyroid disorders, and vitamin D deficiency Hyperphosphatemia: kidney injury and parathyroid disorders

TABLE B2 Common Causes of Electrolyte Imbalances (Shrimanker & Bhattarai, 2023)

ANSWER KEY

Chapter 6

Read the Electronic Health Record

1. Possible considerations: The elevated amylase and lipase levels are concerning and indicate potential blockage of the pancreatic duct. The patient's history of recent birth, elevated BMI, and symptoms surrounding ingestion of fatty food including increased abdominal pain are also worrying signs.
2. The most concerning information is the elevated liver enzymes combined with the findings from the CT scan indicating acute cholecystitis with potential pancreatitis. This suggests a significant inflammation and inability to eliminate bile that could lead to complications if not promptly managed.
3. An expected finding is the presence of inflamed bile duct due to blockage, because the patient has a known history of gallstones. The patient is the classic example of the 4 Fs (female, fat, forty, fertile). She has pain after ingestion of a fatty meal, accompanied with steatorrhea.
4. It is important to question if the patient has any history of allergic reactions to the previous anesthesia. Surgical removal of gallbladder is evident, and the nurse should identify the need to educate the patient on the procedure. Ask when the patient last ingested food or water. Additionally, considering the patient's recent delivery of twins, it is crucial to ask about blood loss or any abnormal experience with the delivery. Furthermore, questioning the adequacy of the current medication regimen and considering the need for IV fluids and pain medication or hospitalization should be discussed with the healthcare team.

Chapter 7

Read the Electronic Health Record

1. The numerical rating scale to assess pain should not be used for those who cannot quantify the severity of their pain (i.e., a patient who has difficulty communicating). Another scale that assesses pain in a nonverbal person should be used to quantify the patient's pain. The numbers assigned to the patient's pain may not be accurate because of his aphasia.
2. Pain medications were given at 14:45 and not reassessed within one hour; pain was not at target pain goal at 16:10, but no additional pain interventions were enacted; pain score and pain goal were left blank at 20:10; pain was not reassessed after 20:10 intervention.

Chapter 8

Read the Electronic Health Record

1. The elevated fasting glucose level of 254 mg/dL indicates severe hyperglycemia, characteristic of diabetic ketoacidosis (DKA). The high white blood cell count of 15,000 mL suggests an infection, which commonly accompanies DKA, due to compromised immune function. The normal red blood cell count indicates the patient is not currently experiencing anemia, and the elevated sodium level of 156 mg/dL reflects dehydration, a common consequence of DKA. The presence of urine ketones further confirms the body's breakdown of fats or proteins in the absence of insulin, contributing to the metabolic derangements seen in DKA.
2. The elevated white blood cell count of 15,000 mL suggests an inflammatory response and potential infection, which can exacerbate the patient's condition and complicate management. Poor response by leukocytes may indicate impaired immune function, placing the patient at increased risk of sepsis and other serious complications. Nurses should closely monitor the patient for signs of infection and collaborate with the health care team to initiate appropriate antimicrobial therapy and supportive care.
3. Priority nursing interventions include initiating insulin therapy to correct hyperglycemia and acidosis, administering intravenous fluids to address dehydration and electrolyte imbalances, and monitoring the patient closely for signs of infection. Additionally, providing supportive care, such as pain management and

emotional support, is crucial for optimizing patient outcomes. Continual assessment and reassessment of the patient's condition are essential to guide timely interventions and promote recovery from DKA.

Chapter 11

Unfolding Case Study

1. Option 1: Respiratory infection; Option 2: Increased SOB and fever
   Rationale: A respiratory infection would most likely be present in a patient with increased SOB and an elevated temperature. A panic attack or depression would most likely cause irritability, irrational thinking, lightheadedness, or dizziness. Asthma will most likely present with wheezing or tightness in the patient's chest, not usually with a fever. Depression may present with irritability, a hopeless outlook, and possible crying. Medication side effects may present with the indications the patient is taking them for. For example, fever or irritability would not be the cause of the absence of taking the medications of a beta blocker, ARB, or statin.
2.

Assessment Finding	Respiratory Infection	COPD	Pneumothorax
Pain in chest and intense chest pain that is worse with movement			X
Temperature: 101.2	X		
Tracheal deviation			X
Subcutaneous emphysema			X
Barrel-shaped chest		X	

   Rationale: The patient with pneumonia has a temperature of 101.2, which can indicate an infectious process and also has a positive blood culture result of *Streptococcus pneumoniae*. Lung fields will have crackles or decreased breath sounds, and the patient is not likely to experience wheezing. A fever is not likely to be present with COPD; increased SOB is most likely to be present. A patient with COPD can present with noted use of the accessory muscle, pursed lip breathing, and cyanosis. The anterior-posterior chest wall diameter can increase and become barrel shaped from the chronic air trapping as well as an increase in wheezing and cough. A pneumothorax occurs when a volume of air has entered the pleural space affects the degree of lung collapse. The patient will present with chest pain that increases with movement. Patients commonly report a rapid onset of dyspnea, cough, and intense chest pain that is worse with movement.

Read the Electronic Health Record

1. The patient's low oxygenation saturation accompanied with SOB and pleuritic chest pain alongside positive ultrasound findings indicate a pneumothorax.
2. The most concerning information is the decreased oxygenation. Air elimination, reduction of air leakage, and promoting re-expansion of the lung are the priorities.
3. An expected finding is the presence of a small pneumothorax based on patient description of a recent fall and current symptoms. The nurse expects the provider to apply supplemental oxygen and perform a small needle biopsy.

Chapter 12

Unfolding Case Study

1.

CUE	Acute MI	Possible sepsis	Bacterial pneumonia
Respiratory failure			X
Decreased cardiac contractility and dysfunction	X		
Lactic acid increased		X	

Rationale: Cardiac myocytes require adequate coronary perfusion for contractility. Decreased cardiac output due to left ventricular dysfunction as a result of the anteriolateral wall MI. Cardiogenic shock of the anterior wall MI is associated with higher hospital mortality when compared to solely an inferior MI. Systolic heart dysfunction has a higher rate of mortality. Hypovolemic shock and cardiogenic shock can lead to sepsis and septic shock. The patient is acidotic (increased lactic acid and respiratory acidosis), hypotensive, and hypovolemic. If the patient's cardiac decompensation is reversed, the progression of sepsis/septic shock may be adverted. The respiratory failure treatment has already been initiated with antibiotic therapy and mechanical ventilation.

2. Intervention: Administer vasopressors IV; Rationale: Hypotension, decreased cardiac contractility; Intervention: Hemodynamic monitoring; Rationale: Monitor the effectiveness of therapeutics for pulmonary and heart function
Rationale: Cardiac decompensation can begin to negatively affect the body's organs, and the administration of vasoconstrictors is necessary to increase tissue perfusion to the patient's organs. In addition to fluid resuscitation, IV vasopressor therapy is a fundamental treatment of possible septic shock-induced hypotension, as it aims at correcting the decreased vascular tone and improving organ perfusion pressure. Antiplatelets or anticoagulants are administered for patients who have had an MI to prevent the formation of blood clots. Positive end-expiratory pressure is not necessarily a treatment for bacterial pneumonia. PEEP maintains the expansion of the alveoli at the end of the patient's respiration. Diuretics are not administered if the patient is hypotensive or had a significant drop in BP from baseline.

Read the Electronic Health Record

1. The patient has a low potassium and a low magnesium.
2. Normal potassium levels should be between 3.5 and 5.0 and magnesium should be greater than 2.0.
3. The nurse should review the telemetry to see if there is any ectopy on the monitor. A set of vitals should be obtained. The nurse should get an order for electrolyte replacement.
4. Over the span of 15 hours, Mr. Smith's BNP is trending up, suggesting worsening HF.
5. The elevation in the liver function tests indicates liver damage, likely from right-sided heart failure, and the patient will likely have increased abdominal ascites and hepatosplenomegaly.

Chapter 13

Read the Electronic Health Record

1. The patient's history reveals very active young male with a risk-led lifestyle. Tibial fractures require the patient to remain non–weight-bearing for six weeks while in a long leg cast. This patient's chart indicates this may be problematic.
2. An expected finding is the presence of a tibial shaft fracture based on patient's description of accident and current symptoms. The nurse expects the provider to determine if surgery is indicated or not. If not, the patient will be placed in a long leg cast.
3. It is important to learn if the patient has any previous allergies to pain medications. Ensuring the patient has no allergies can prevent a reaction if the wrong medication is administered. The nurse should provide education regarding the need to maintain active knee and ankle range of motion during the recovery period. Deep vein thrombosis (DVT) prophylaxis should also be administered to non–weight-bearing, lower-extremity fractures.

Chapter 19

Read the Electronic Health Record

1. Possible considerations: the elevated WBC and CRP levels indicate an inflammatory or infectious process, which is concerning, given the patient's history of diverticular disease. The increased abdominal pain and fever are also worrying signs.
2. The most concerning information is the elevated WBC count and CRP levels, combined with the findings from the CT scan indicating acute diverticulitis with pericolonic fat stranding. This suggests a significant

inflammatory process that could lead to complications if not promptly managed.

3. An expected finding is the presence of inflamed diverticula in the sigmoid colon, because the patient has a known history of diverticular disease. The mild fever and elevated inflammatory markers (WBC and CRP) are also expected in the context of acute diverticulitis.
4. It is important to question if the patient has any history of allergic reactions to the prescribed antibiotics (ciprofloxacin and metronidazole). Additionally, considering the patient's decreased appetite and occasional nausea, it may be necessary to assess for any potential adverse reactions to the medications or need for adjustments in pain management. Furthermore, questioning the adequacy of the current antibiotic regimen and considering the need for IV antibiotics or hospitalization should be discussed with the health-care team.

Chapter 20

Read the Electronic Health Record

1. Sample answer: Exacerbation of CKD. Anticipate use of diuretics and possibly dialysis.

Chapter 23

Unfolding Case Study

1. a
   Rationale: IV resuscitation is an immediate need to increase tissue perfusion and reverse hypovolemia. Administration of vasopressors constrict the blood vessels and increase tissue perfusion. Obtaining a CXR is an early diagnostic test that can help diagnose a pulmonary infection consistent with sepsis. The hemodynamic measurements are obtained as clinically indicated. IV crystalloids are recommended to administer because they contain nonproteins, minerals, salts, and sugars, and are responsible for maintenance of adequate F&E balance. They are also usually the first choice for IV solution recommended.
2. a, c, e
   Rationale: Anuria, or absence of urine output, is an indication of organ failure in septic shock. MODS result when two or more organs are dysfunctional as the result of having progressive sepsis. An elevated lactic acid of > 4mm/L is indicative of septic shock. With the value rising, the lactic acid continues to demonstrate the progression of septic shock and MODS. Metabolic acidosis is a physiologic disturbance defined by a pH less than 7.35 and a low HCO_3 level. Metabolic acidosis can develop if sepsis progresses and there are too many acids in the blood, which decreases the bicarbonate. Respiratory acidosis can be reversed early in the sepsis progression.

Chapter 25

Unfolding Case Study

1. Option 1: Left knee injury, preop; Option 2: Pain
   Rationale: Patient has an old knee injury from playing sports in high school and college. The patient has been off of her medication, ibuprofen, and is likely in pain.
   A panic attack may cause irritability, irrational thinking, lightheadedness, or dizziness; however, it is not the primary reason the patient presented to the hospital, or cause of the patient's presenting problem.
   Depression may be present with a hopeless outlook and possible crying; however, it is not the primary reason she presented to the hospital. This certainly needs to be addressed by the nurse but is not the primary cause of the patient's priority problem. Medication side effects are unlikely as she only takes ibuprofen and has not taken in 1 week. The patient has a normal WBC and is afebrile, thus is not likely to have an infection, nor a cause of her knee injury. Although patient education is a priority, that is not the cause of a fever, possible infection, respiratory rate of 30, or irritability. Patient education is a high priority for the patient and begins preoperatively. The nurse will assess any knowledge gaps and provide these for the patient.

2.

Assessment Finding	Left knee injury repair	Depression	Anxiety
Pain in the left knee	X		
Lack of education for surgery			X
Grieving loss of prior activity and exercise tolerance		X	
Emotional support from her husband		X	
Withdrawn		X	

Rationale: The pain in the patient's left knee is a direct result of overuse and damage from her athletic career. The patient's anxiety can be a significant result of the unknown of the surgery scheduled for that day. Without explanation and expressed understanding by the patient, the anxiety will most likely manifest. The patient had admitted to depression from the loss of the active lifestyle and endurance in performing prior activities using her left knee. It is very likely this has been a contribution to her depression. Support from her husband most likely provides comfort and working towards acceptance. This may assist her depression from escalation and being more manageable. The patient admitted withdrawal and lack of pleasure from the regression of prior left knee injuries and damage. The mutual goals created with the nurse and the patient and husband need to be reasonable for the patient to assure the ability to comply. They may include the external support resources that have been provided to the patient and her husband along with the patient's agreement and confirmation of understanding of how to accomplish her goals. All of the nurse's assessment findings relate to the diagnoses listed; however, the correlations of the preceding assessments are the most likely reasons for the nurse's findings on patient presentation and obtained history.

Chapter 26

Unfolding Case Study

1. aspiration, bleeding

Rationale: The patient has a history of an adverse reaction of postoperative nausea and vomiting (PONV) immediately postoperatively. The patient also has many risk factors for nausea and vomiting from the anesthesia. The nurse must prioritize the management of the patient's potential complications such as airway protection because the patient is still sedated. The nurse must be prepared for nursing interventions, such as having antiemetics readily available, as well as the potential of hypotension as a result of the anesthetic medications along with hyperemesis and fluid and electrolyte imbalance. Given the patient was taking the maximum dose of ibuprofen pre-operatively and she stopped her ibuprofen 7 days pre-operatively, the nurse must be aware that there is a potential risk for bleeding. Seizures of all types are caused by abnormal electrical activity in the brain. Causes of seizures can include abnormal levels of sodium or glucose in the blood; brain infection, including meningitis and encephalitis; or a patient with a history of having seizures. Developing a fever intraoperatively is unlikely. Hypothermia is a core body temperature less than 36.0°C (96.8°F). It is a common incident in the immediate postoperative period. Often, the patient is hypothermic from the cold temperature in the surgical suite. Dysrhythmias may be more likely in a patient with a cardiovascular history as a result of cardiac muscle damage, electrical abnormalities, valve repairs, or history of a myocardial infarction.

2.

Options for 1	Options for 2
Hypovolemia	Provide appropriate IV fluid management per provider order.
Emesis, PONV	Administer an antiemetic per provider order.
Depression, pre-operative	Prepare the postoperative team. The patient will require support and empathy when learning of the total knee replacement due to admitted depression.

Rationale: Hypovolemia: Appropriate IV fluid management per provider order is administered to increase vascular permeability as probable result of the anesthesia, significant blood loss, fluid shift and third spacing loss, PONV, and lack of oral intake pre-operatively.
Emesis, PONV: Patient has a history of severe PONV post-anesthesia. The nurse needs to anticipate the same adverse effect may occur. Emesis or hyperemesis can also lead to hypotension requiring IV fluid replacement and fluid and electrolyte monitoring.
Depression, postoperative: Prepare the postoperative team that patient will need to learn postoperatively that she required a total knee replacement. Because of her admitted depression, this can include support and empathy from the staff, referral to social workers, counselors if present, or spiritual support if desired by patient. The husband may need support from the staff as well providing positive feedback and guidance for the recovery period.
Hypertension: The patient did not experience hypertension, but it is a possible complication.
Blood loss: The patient had minimal blood loss during the surgery and did not require blood transfusions.

Read the Electronic Health Record

1. The patient's history of hypertension (HTN) and diabetes (DM)
2. The patient does not have a recent blood glucose or labs entered into the chart yet; must verify safe for surgery before proceeding.
3. The nurse should expect blood glucose to be elevated and need for insulin prior to surgery. The nurse should expect the patient's blood pressure to be elevated and potential need for an IV antihypertensive medication to be ordered.
4. The nurse will question missing documentation objective data from the chart. The nurse will interview the patient and collect any missing data such as vital signs, and verify diagnostics were completed.

Chapter 27

Unfolding Case Study

1. a, c, e
Rationale: Normal Saline (0.9% sodium chloride) causes hyperchloremia and metabolic acidosis, which may move potassium from the intracellular space into the interstitial fluid and plasma. Normal saline is a cornerstone of intravenous solutions commonly used in the clinical setting. It is a crystalloid fluid that hydrates and improves electrolyte disturbances. The primary indications for the use of normal saline infusion that have been approved by the FDA:
    - extracellular fluid replacement (e.g., dehydration, hypovolemia, hemorrhage, sepsis)
    - mild sodium depletion

    Administration of antiemetic will limit the nausea and vomiting and further loss of fluids. Administration of pain medication needs observation for hypotension. If the patient has pain with a BP < 89/49, the provider needs to be notified for an alternate pain medication.
    There is no need to have a CXR, as there is no fluid buildup, lungs are clear, and there is no SOB. The need for ABG at this point is not necessary for treatment options. Ketorolac can be administered, separately, but close in time to the hydromorphone. There is no contraindication and the patient should not go long periods of time

without both the NSAID and analgesic.

2. a, d, e
   Rationale: The patient is eating regular food without N/V. The surgeon will send the patient home with oral ondansetron if needed. The patient's K+ level has returned to normal range and is asymptomatic of signs/symptoms of an elevated K+. The patient's pain has been moderately managed. The patient was educated to expect pain will not be a 0–1 level and will continue with increased activity and PT. Also to continue the same meds po for pain and inflammation as she was. The patient was also educated to not go more than 4–6 hours at the most without taking her pain and anti-inflammatory medication ordered by the provider. The pain will then become harder to manage and may not be as effective because of the length of time going without medication.
   The patient chemistries do not reflect a metabolic acidosis. The patient's oxygenations and kidney function are normal. The patient has feen afebrile with a normal WBC and no signs of infection. Multiple organ dysfunction syndrome involves dysfunction of two organs and extreme decreased tissue perfusion and oxygenation. Cardiac status and VS are within the patient's baseline.

Chapter 33

Read the Electronic Health Record

1. Sample answer: Low BP, skin cool to touch, tachycardic heart rate.
2. Sample answer: Perform a more thorough peripheral vascular assessment, look for capillary refill in the limb with the surgical intervention, check for edema, pulse quality.
3. Sample answer: The patient may go into early compartment syndrome from the trauma and surgical intervention; if there is a pulse deficit, this is a medical emergency and warrants a call to the provider. An ECG may be done as hyperkalemia can be driving the tachycardia, which is a sign of compartment syndrome/crush injury.
4. Answer may include rhabdomyolysis and the patient may need an emergent intervention.

Chapter 35

Read the Electronic Health Record

1. Answers will vary. Sample answer: Blood pressure is dropping, CVP is increasing, and indices are going down, indicating worsening heart failure and possible cardiogenic shock.
2. Answers will vary but may include listen to heart sounds and monitor for perfusion by looking at capillary refill, pulses, and so forth.
3. Answers will vary. Sample answer: Adjust the dose of dobutamine to improve BP. Initiate another medication if needed. Have provider assess patient to determine the need for other interventions.
4. Answers will vary but may include MODS and cardiogenic shock.
