LILLEY'S
Pharmacology
for Canadian Health Care Practice

TABLE OF CONTENTS

About the Authors, v
Reviewers, vii
Preface, ix
Acknowledgements, xiii

PART 1 Pharmacology Basics

- 1 Nursing Practice in Canada and Drug Therapy, 1
- 2 Pharmacological Principles, 14
- 3 Legal and Ethical Considerations, 36
- 4 Patient-Focused Considerations, 47
- 5 Gene Therapy and Pharmacogenomics, 67
- 6 Medication Errors: Preventing and Responding, 75
- 7 Patient Education and Drug Therapy, 88
- 8 Over-the-Counter Drugs and Natural Health Products, 98
- 9 Vitamins and Minerals, 111
- 10 Principles of Drug Administration, 133

PART 2 Drugs Affecting the Central Nervous System

- 11 Analgesic Drugs, 164
- 12 General and Local Anaesthetics, 195
- 13 Central Nervous System Depressants and Muscle Relaxants, 214
- 14 Central Nervous System Stimulants and Related Drugs, 228
- 15 Antiepileptic Drugs, 244
- 16 Antiparkinsonian Drugs, 262
- 17 Psychotherapeutic Drugs, 278
- 18 Substance Misuse, 308

PART 3 Drugs Affecting the Autonomic Nervous System

- 19 Adrenergic Drugs, 325
- 20 Adrenergic-Blocking Drugs, 338
- 21 Cholinergic Drugs, 350
- 22 Cholinergic-Blocking Drugs, 361

PART 4 Drugs Affecting the Cardiovascular and Renal Systems

- 23 Antihypertensive Drugs, 371
- 24 Antianginal Drugs, 394
- 25 Heart Failure Drugs, 408
- 26 Antidysrhythmic Drugs, 423
- 27 Coagulation Modifier Drugs, 444
- 28 Antilipemic Drugs, 469
- 29 Diuretic Drugs, 485
- 30 Fluids and Electrolytes, 500

PART 5 Drugs Affecting the Endocrine System

- 31 Pituitary Drugs, 519
- 32 Thyroid and Antithyroid Drugs, 528
- 33 Antidiabetic Drugs, 537
- 34 Adrenal Drugs, 563

- 35 Women's Health Drugs, 574
- 36 Men's Health Drugs, 596

PART 6 Drugs Affecting the Respiratory System

- 37 Antihistamines, Decongestants, Antitussives, and Expectorants, 606
- 38 Respiratory Drugs, 621

PART 7 Drugs Affecting the Gastrointestinal System and Nutrition

- 39 Acid-Controlling Drugs, 640
- 40 Antidiarrheal Drugs and Laxatives, 654
- 41 Antiemetic and Antinausea Drugs, 667
- 42 Nutritional Supplements, 679

PART 8 Anti-infective and Anti-inflammatory Drugs

- 43 Antibiotics Part 1: Sulfonamides, Penicillins, Cephalosporins, Macrolides, and Tetracyclines, 691
- 44 Antibiotics Part 2: Aminoglycosides, Fluoroquinolones, and Other Drugs, 715
- 45 Antiviral Drugs, 731
- 46 Antitubercular Drugs, 753
- 47 Antifungal Drugs, 764
- 48 Antimalarial, Antiprotozoal, and Anthelmintic Drugs, 774
- 49 Anti-inflammatory and Antigout Drugs, 789

PART 9 Immune and Biological Modifiers and Chemotherapeutic Drugs

- 50 Immunosuppressant Drugs, 804
- 51 Immunizing Drugs and Pandemic Preparedness, 815
- 52 Antineoplastic Drugs Part 1: Cancer Overview and Cell Cycle-Specific Drugs, 832
- 53 Antineoplastic Drugs Part 2: Cell Cycle-Nonspecific and Miscellaneous Drugs, 859
- 54 Biological Response-Modifying Drugs and Antirheumatic Drugs, 872

PART 10 Miscellaneous Therapeutics: Hematological, Dermatological, Ophthalmic, and Otic Drugs

- 55 Anemia Drugs, 892
- 56 Dermatological Drugs, 903
- 57 Ophthalmic Drugs, 918
- 58 Otic Drugs, 939

Appendix: Pharmaceutical Abbreviations, 945
Answers to Review Questions, 946
Bibliography, 949
Index of Glossary Terms, 966
Drug Index, 973
General Index, 981

ABOUT THE AUTHORS

KARA SEALOCK

Dr. Kara Sealock completed a Bachelor of Nursing in 2000, a Masters of Education in 2012, and a Doctorate of Education, specializing in adult learning, in 2019. Kara has been a nursing educator since 2008 and has worked in various roles such as a preceptor, clinical instructor, and theory instructor with a focus in medical/surgical care, critical care, and gerontology. Kara teaches pathophysiology, assessment, and pharmacology at the University of Calgary. She has considerable years of clinical experience in medical/surgical environments, research experience working with cardiology and endocrinology clients; however, the majority of her career has been positioned in critical care with an adult focus in intensive care and coronary care environments. Kara has substantive experience in preparing undergraduate nursing students for NCLEX-RN as she has facilitated preparation workshops and mock examination opportunities, and assumes an active role in preparing students for success. She currently sits on the Nursing Education Program Approval Committee at the College and Association of Registered Nurses (CARNA). Kara's knowledge in adult learning, combined with her clinical and theoretical experience contributes to an enhanced foundation of learning bridging theory and practice for undergraduate nursing education. Kara is currently a senior instructor with a specific focus in teaching for the Faculty of Nursing at the University of Calgary.

CYDNEE SENEVIRATNE

Dr. Cydnee Seneviratne received a diploma in Nursing in 1991 and has dedicated her career to advancing neuroscience nursing, chronic stroke care, and gerontology. She received a BScN from the University of Victoria in 1995 and a Master of Nursing in 1997 from the University of Calgary. Cydnee received a FUTURE Program for Cardiovascular Nurse Scientists Fellowship (a CIHR Strategic Training Program in Health Research) while completing her PhD in 2007 at the University of Calgary and completed a post-doctoral fellowship in 2010 funded by the Heart and Stroke Foundation of Canada. Cydnee has been a nursing instructor in clinical, laboratory, and classroom settings (specifically pharmacology and pathophysiology) at the University of Calgary for 19 years and has remained closely linked to the clinical setting during her time as the Associate Dean of Undergraduate Practice Education. In the Associate Dean role, she was chair of the Nursing Education Program Approval Committee at the College and Association of Registered Nurses (CARNA) where she was instrumental in crafting undergraduate and nurse practitioner program approval processes. Cydnee is currently a senior instructor and is a leader in Interprofessional Simulation Education for the Faculty of Nursing.

LINDA LANE LILLEY

Dr. Linda Lilley received her diploma from Norfolk General School of Nursing, BSN from the University of Virginia, Master of Science (Nursing) from Old Dominion University, and PhD in Nursing from George Mason University. As an Associate Professor Emeritus and University Professor at Old Dominion University, her teaching experience in nursing education spans over 25 years, including almost 20 years at Old Dominion. Linda's teaching expertise includes drug therapy and the nursing process, adult nursing, physical assessment, fundamentals in nursing, oncology nursing, nursing theory, and trends in health care. The awarding of the university's most prestigious title of University Professor reflects her teaching excellence as a tenured faculty member. She has also been a two-time university nominee for the State Council of Higher Education in Virginia award for excellence in teaching, service, and scholarship. Linda received the 2012 Distinguished Nursing Alumni Award from Old Dominion University School of Nursing for her "continued work on the successful pharmacology textbook published by Elsevier" and to recognize her "extraordinary work and the impact [the book] has had on baccalaureate education." While at Old Dominion University, Linda mentored and taught undergraduate and graduate students as well as registered nurses returning for their BSN. Linda authored the MED ERRORS column for the American Journal of Nursing between 1994 and 1999, as well as numerous other peer-reviewed, published articles in professional nursing journals. Since retiring in 2005, Linda continues to be active in nursing, serving as a member on dissertation committees with the College of Health Sciences and maintaining membership and involvement in numerous professional and academic organizations. Since January of 2014, Dr. Lilley continues to serve on the volunteer review panel for the monthly newsletter publication Nurse Advise-ERR (ISMP affiliated; the ISMP [Institute for Safe Medication Practices] is a nonprofit organization educating the healthcare community and consumers about safe medication practices). Linda has served as a consultant with school nurses in the city of Virginia Beach and as a member on the City of Virginia Beach's Health Advisory Board. Linda also served as an appointed member on the national advisory panel on medication error prevention with the U.S. Pharmacopeia in Rockville, Maryland. She continues to educate nursing students and professional nurses about drug therapy and the nursing process and speaks on the topics of drug therapy, safe medication use, humor and healing, and grief and loss.

SHELLY RAINFORTH COLLINS

Shelly Rainforth Collins received her Doctor of Pharmacy degree from the University of Nebraska, College of Pharmacy in 1985, with High Distinction. She then completed a clinical pharmacy residency at Memorial Medical Center of Long Beach in Long Beach, California. She worked as a pediatric

clinical pharmacist (neonatal specialist) at Memorial Medical Center before moving to Mobile, Alabama, where she was the Assistant Director of Clinical Pharmacy Services at Mobile Infirmary Medical Center. After moving to Chesapeake, Virginia, she served as the Clinical Pharmacy Specialist/Coordinator of Clinical Pharmacy Services at Chesapeake Regional Medical Center in Chesapeake, Virginia for 19 years. Her practice focused on developing and implementing clinical pharmacy services as well as medication safety and Joint Commission medication management standards and national patient safety goals. She is president of Drug Information Consultants, a business offering consultation and expert witness review for attorneys on medical malpractice cases. She holds certifications in Medication Therapy Management, Anticoagulation Management, and Immunizations. Shelly was awarded the Clinical Pharmacist of the Year Award in 2007 from the Virginia Society of Healthsystem Pharmacists. She led a multidisciplinary team that won the Clinical Achievement of the Year Award from George Mason University School of Public Health in 2007 for promoting safety with narcotics in patients with sleep apnea; this program has also received national recognition. She was awarded the Service Excellence Award from Chesapeake Regional Medical Center. Shelly's professional affiliations include the American Society of Healthsystem Pharmacists, the Virginia Society of Healthsystem Pharmacists, and the American Pharmacists Association.

JULIE S. SNYDER

Julie Snyder received her diploma from Norfolk General Hospital School of Nursing and her BSN and MSN from Old Dominion University. After working in medical-surgical nursing, she worked in nursing staff development and community education. Later, she transferred to the academic setting and taught fundamentals of nursing, pharmacology, physical assessment, and adult medical-surgical nursing at a university school of nursing. Julie has recently worked as a Quality Initiative Coordinator and a Clinical Nurse Educator in a local hospital. She is now a Lecturer at the School of Nursing of Regent University in Virginia Beach, Virginia. She has been certified by the ANCC in Nursing Continuing Education and Staff Development and currently holds ANCC certification in Medical-Surgical Nursing. She is a member of Sigma Theta Tau International and was inducted into Phi Kappa Phi as Outstanding Alumni for Old Dominion University. She has worked for Elsevier as a reviewer, ancillary writer, and author since 1997. Julie's professional service has included serving on the Virginia Nurses' Association Continuing Education Committee, serving as Educational Development Committee chair for the Epsilon Chi chapter of Sigma Theta Tau, serving as an item writer for the ANCC, working with a regional hospital educators' group, and serving as a consultant on various projects for local hospital education departments. In addition, she has conducted pharmacology review classes for recent nursing graduates.

Professor, Practical Nursing Program

Coordinator, Critical Care Nursing Program
Durham College
Oshawa, Ontario

INTRODUCTION

The fourth edition of *Lilley's Pharmacology for Canadian Health Care Practice* incorporates both the nursing process and evidence in practice as it is relevant to Canadian nursing. This text provides the most current and clinically relevant information in an appealing, understandable, and practical format. The clear writing style and full-colour design of *Lilley's Pharmacology for Canadian Health Care Practice* are ideal for today's busy nursing student. The book presents drug information that both RN and PN nursing students need to know for whatever exam they are preparing to take. It also provides information on what the professional nurse may encounter during drug administration in a variety of health care settings, including accounts of real-life medication errors and tips for avoiding those errors. Features that help set the book apart include:

- A focus on the role of prioritization in nursing care
- A strong focus on drug classes to help students acquire a better knowledge of how various drug classes work in the body, allowing them to apply this knowledge to individual drugs
- Canadian content relevant to Canadian students and educators that will strengthen their knowledge of the field
- Clinical practice guidelines produced or endorsed in Canada by national, provincial, or territorial medical or health organizations, or by professional societies, government agencies, or expert panels
- Ethnocultural examples that reflect the varied and complex ethnodemographic diversity of Canada
- Ease of readability to make this difficult content more understandable

For this edition, the author team has not only focused on providing the most “need-to-know” information but also the most up to date research related to pharmaceuticals while emphasizing the nursing process and prioritization. In addition, a brief discussion of pharmacology related to transgender men and women who may or may not be transitioning is included in this edition. In future editions a more fulsome discussion will be included in chapters 35 and 36. Many of the updates for this edition are in response to student and instructor feedback.

MARKET RESEARCH

To aid in the preparation of this text, nursing instructors from across Canada participated in extensive, detailed reviews of the Third Canadian Edition. These reviewers assessed changes that had occurred in the field of pharmacology since publication of the third edition and determined what was needed to better teach this subject to nursing students and how their evolving learning needs could be met.

This Canadian edition maintains the philosophy of making the challenging subject of pharmacology approachable and easy to understand. Additional concerns raised and enhancements suggested by educators and nursing students who served as

reviewers or consultants throughout the manuscript's development, as well by the authors of this text, also have been addressed.

ORGANIZATION

This book includes 58 chapters presented in 10 parts, organized by body system. The 10 “concepts” chapters in Part 1 lay a solid foundation for the subsequent drug units and address the following topics:

- The nursing process and drug therapy
- Pharmacological principles
- Legal and ethical considerations
- Ethnocultural and lifespan considerations related to pharmacology
- Gene therapy and pharmacogenomics
- Preventing and responding to medication errors
- Patient education and drug therapy
- Over-the-counter drugs and natural health products
- Vitamins and minerals
- Drug administration techniques, including 100 drawings and photographs

Parts 2 through 10 present pharmacology and nursing management in a time-tested body systems and drug function framework. This approach facilitates learning by grouping functionally related drugs and drug groups. It provides an effective means of integrating the content into medical-surgical/adult health nursing courses or for teaching pharmacology in a separate course.

The 48 drug chapters in these 9 Parts constitute the main portion of the book. Drugs are presented in a consistent format with an emphasis on drug classes and key similarities and differences among the drugs in each class. Each chapter is subdivided into two discussions, beginning with (1) a brief overview of relevant anatomy, physiology, and pathophysiology and a complete discussion of pharmacology, followed by (2) a comprehensive yet succinct application of the nursing process.

Pharmacology is presented for each drug group in a consistent format:

- Mechanism of Action and Drug Effects
- Indications
- Contraindications
- Adverse Effects (often including Toxicity and Management of Overdose)
- Interactions
- Dosages

Drug class discussions conclude with specially highlighted Drug Profiles—brief narrative “capsules” of individual drugs in the class or group, including pharmacokinetics tables for each drug. Key drugs (prototypical drugs within a class) are identified throughout with a  symbol for easy identification.

The pharmacology section is followed by a Nursing Process discussion that relates to the entire drug group. This nursing

content is covered in the following, familiar nursing process format:

- Assessment
- Nursing Diagnoses
- Planning (including Goals and Expected Patient Outcomes)
- Implementation
- Evaluation

At the end of each Nursing Process section is a Patient Teaching Tips box that summarizes key points for nursing students and practising nurses to include in the education of patients about their medications. These boxes focus on teaching how the drugs work, possible interactions, adverse effects, and other information related to the safe and effective use of the drug(s). The role of the nurse as patient educator and advocate continues to grow in importance in professional practice, so there is emphasis on this key content in each chapter in this edition.

Lilley's Pharmacology for Canadian Health Care Practice also reflects the latest drug information and research through the following special boxes:

- Evidence in Practice
- Ethnocultural Implications
- Lab Values Related to Drug Therapy
- Legal and Ethical Principles
- Natural Health Products
- Preventing Medication Errors
- Special Populations: Adolescents
- Special Populations: Children
- Special Populations: The Older Adult
- Legal and Ethical Principles
- Pharmacokinetic Bridge to Nursing Process

NEW TO THIS EDITION

The hallmark readability and user-friendliness of *Lilley's Pharmacology for Canadian Health Care Practice* helps students navigate easily through the textbook and thus the difficult subject of pharmacology and the nursing process.

This textbook continues to feature “need-to-know” content as well as up to date research related to pharmaceutical interventions and Canadian legislation. Information on drug adverse effects reflects only the most common and most serious adverse effects rather than listing all reported adverse effects. These adverse effects are listed in order of those most commonly seen. Another area continued from the previous addition is that of drug dosages; only those dosages that are seen in most common indications are included in the text and tables. (For other dosages, the student should refer to an up-to-date drug handbook or drug reference such as, *Mosby's Canadian Nursing Drug Reference*.) This need-to-know approach to drug indications and adverse effects is crucial in helping the adult learner focus on the most essential content needed for safe drug administration.

Drugs included in the text are as up-to-date as possible and include related research to ensure students receive accurate information. The availability of drugs changes frequently because manufacturers discontinue production or as a result of shortages.

The use of abbreviations has been limited to the most common abbreviations. While the use of abbreviations is not encouraged overall, abbreviations are still approved and used by

agencies, and may also be part of the documentation method. The Institute of Safe Medication Practices (ISMP) Canada's “Do Not Use List” of abbreviations, symbols, and dose designations has been adhered to within this text.

It is important to remember that although this textbook provides all of the need-to-know *pharmacology* content that students will need for an entry level of practice, it is first and foremost a *nursing* textbook rather than a pharmacology textbook, with a strong emphasis on the nursing process and professional nursing practice. The section on implementation also offers all of the most essential information, followed by a section on the evaluation of therapeutic and adverse effects. These changes highlight the significance of the nursing process as a foundation in drug therapy while helping the student to make strong cognitive connections among nursing diagnoses, goals, and expected patient outcomes.

The pharmacology and nursing content in each of the 58 chapters has been thoroughly revised and critically reviewed by nursing instructors, practising nurses, and PharmDs to reflect the latest drug information and nursing content. Key updates include:

- Updated population and incidence statistics in each chapter
- Summary of Canadian cannabis/marihuana regulations and the Cannabis Act in Chapter 3
- Revision of Chapters 4 and 7 include Indigenous health and healing practices, an explanation of the Indigenous medicine wheel, and alternative medicinal interventions in response to the Truth and Reconciliation Commission of Canada's *Calls to Action*
- Revision of Chapter 11 includes an explanation of current practices when/if an opioid overdose occurs in the community, including a stepwise explanation of how to administer Naloxone
- Additional Examination Review Questions at the end of each chapter

ADDITIONAL TEACHING AND LEARNING FEATURES

The book also includes a variety of innovative teaching and learning features that prepare the student for important content to be covered in each chapter and encourage review and reinforcement of that content. Chapter-opener features include the following:

- Learning objectives
- Summary of Drug Profiles in the chapter, with page number references
- List of High-Alert Drugs in the chapter, with page number references
- Key terms with definitions and page number references (key terms being in **bold** type throughout the narrative to emphasize this essential terminology)

The following features appear at the end of each chapter:

- Patient Teaching Tips related to drug therapy
- Key Points boxes summarizing important chapter content
- Examination Review Questions, with answers provided at the end of the book for quick and easy review
- Critical Thinking activities
- List of Evolve Resources available to students
- References for works cited in the chapter

In addition to the special boxes listed previously, other special features that appear throughout the text include:

- Case Studies in every chapter, with answer guidelines provided on the Evolve website
- Dosages tables listing generic and trade names, pharmacological class, usual dosage ranges, and indications for the drugs

For a more comprehensive listing of the special features, please see the inside back cover of the book.

COLOUR

The use of colour continues to complement the text by making the book engaging for nursing students. Colour is used throughout to:

- Highlight important content
- Illustrate how drugs work in the body in numerous anatomical and drug process colour illustrations
- Improve the visual appearance of the content to make it more engaging and appealing to today's more visually sophisticated reader

The use of colour and other visual engagement devices in these ways significantly improves students' involvement and understanding of pharmacology.

SUPPLEMENTAL RESOURCES

A comprehensive ancillary package is available to students and instructors using *Lilley's Pharmacology for Canadian Health Care Practice*. The following supplemental resources have been thoroughly revised for this edition and can significantly assist in the teaching and learning of pharmacology.

Study Guide

The student study guide—carefully aligned with the content and focus of the book—includes the following:

- Student Study Tips that reinforce the Study Skills available on the Evolve site and provide a “how to” guide to applying test-taking strategies
- Worksheets for each chapter, with Examination Review questions (with application-based, alternate-item, and dosage calculation questions), critical thinking and application questions, and other activities
- Case Studies followed by related critical thinking questions
- An updated Overview of Dosage Calculations with helpful tips for calculating doses, sample drug labels, practice problems, and a quiz
- Answers to all questions (provided in the back of the book) to facilitate self-study

Evolve Web Site

Located at <http://evolve.elsevier.com/Canada/Lilley/pharmacology>, the Evolve Web site for this book includes the following elements:

For Students

- More than 550 Review Questions for Exam Preparation
- Answers to Critical Thinking Activities from the book
- Printable Chapter Summaries for each chapter

- Answers to Case Studies from the book
- Audio Glossary
- Unfolding Case Studies
- Integrated Study Skills Tips present valuable study skills topics related to each Part within the text, including time management, note-taking, studying, test-taking and others. These tips help students learn the particularly demanding subject of pharmacology while also equipping them with tools that they can use in other courses and as lifelong learners who are building an evidence-based practice.
- Book-specific Next Generation NCLEX Case Studies (both single-episode and unfolding)

For Instructors

- *TEACH for Nurses* Lesson Plans that focus on the most important content from each chapter and provide innovative strategies for student engagement and learning. These new Lesson Plans include strategies for integrating nursing curriculum standards, links to all relevant student and instructor resources, and an original instructor-only Case Study in each chapter.
- ExamView® Test Bank that features more than 800 examination-format test questions (including alternate-item questions) with text page references, rationales, and answers coded for NCLEX® Client Needs category, nursing process step, and cognitive level (Bloom's taxonomy). The robust ExamView® testing application, provided at no cost to faculty, allows instructors to create new tests; edit, add, and delete test questions; sort questions by NCLEX® Client Needs category, cognitive level, and nursing process step; and administer and grade tests online, with automated scoring and gradebook functionality.
- PowerPoint® Lecture Slides consisting of more than 2100 customizable text slides for instructors to use in lectures. The presentations include Unfolding Case Studies and applicable illustrations from the book's Image Collection. Audience Response System Questions (three or more discussion-oriented questions per chapter for use with i>Clicker and other systems) are folded into these presentations.
- Generic Next Generation NCLEX Case Studies for Pharmacology (both single-episode and unfolding)
- An Image Collection with over 250 full-colour images from the book for instructors to use in lectures
- Access to all student resources listed above

Elsevier eBooks

More than just words on a screen, Elsevier eBooks on VitalSource come pre-loaded with interactive learning features that empower students to engage with course content in entirely new ways.

Ideal for use both inside the classroom and out, Elsevier eBooks on VitalSource gives students the ability to access textbook content any time, any place via desktop computer, laptop, tablet, or smartphone.

It includes study aids such as highlighting, e-note taking, and the ability to share notes with other students or with instructors. Even more importantly, it allows students and instructors to do a comprehensive search within the specific text or across a number of titles. Please check with your Elsevier sales representative for more information.

ICONS AT A GLANCE

NEXT GENERATION NCLEX

The National Council for the State Boards of Nursing (NCSBN) is a not-for-profit organization whose members include nursing regulatory bodies. In empowering and supporting nursing regulators in their mandate to protect the public, the NCSBN is involved in the development of nursing licensure examinations, such as the NCLEX-RN®. In Canada, the NCLEX-RN® was introduced in 2015 and is, as of the writing of this text, the recognized licensure exam required for practising RNs in Canada.

The NCLEX-RN® will, as of 2023, be changing in order to ensure that its item types adequately measure clinical judgement, critical thinking, and problem-solving skills on a consistent basis. The NCSBN will also be incorporating into the examination what they call the Clinical Judgement Measurement Model (CJMM), which is a framework that the NCSBN has created to measure a novice nurse's ability to apply clinical judgement in practice.

These changes to the examination come as a result of research findings which indicated that novice nurses have a much higher-than-desirable error rate with patients (i.e., errors that cause patient harm) and, upon NCSBN's investigation, the discovery that the overwhelming majority of these errors were caused by failures of clinical judgement.

Clinical judgement has been a foundation underlying nursing education for decades, based on the work of a number of nursing theorists. The theory of clinical judgement that most closely aligns to what NCSBN is basing their CJMM is the work by Christine A. Tanner.

The new version of the NCLEX-RN® is loosely being identified as the "Next-Generation NCLEX" or "NGN", and will feature the following:

- 6 key skills in the CJMM: recognizing cues, analyzing cues, prioritizing hypotheses, generating solutions, taking actions, and evaluating outcomes.
- Approved item types as of June 2020: multiple response, extended drag and drop, cloze (drop-down), enhanced hot-spot (highlighting), and matrix/grid. More question types may be added.
- All new item types are accompanied by mini-case studies with comprehensive patient information—some of it relevant to the question, and some of it not.
- Case information may present a single, unchanging moment in time (a "single episode" case study) or multiple moments in time as a patient's condition changes (an "unfolding" case study).
- Single-episode case studies may be accompanied by 1-6 questions; unfolding case studies are accompanied by 6 questions.

For more information (and detail) regarding the NCLEX-RN® and changes coming to the exam, visit the NCSBN's website: <https://www.ncsbn.org/11447.htm> and https://ncsbn.org/Building_a_Method_for_Writing_Clinical_Judgment_It.pdf.

For further NCLEX-RN® examination preparation resources, see *Silvestri's Canadian Comprehensive Review for the NCLEX-RN Examination*, Second Edition, ISBN 9780323709385.

Prior to preparing for any nursing licensure examination, please refer to your provincial or territorial nursing regulatory body to determine which licensure examination is required in order for you to practice in your chosen jurisdiction.

WE WELCOME YOUR FEEDBACK

We always welcome comments from instructors and students who use this book so that we may continue to make improvements and be responsive to your needs in future editions. Please send any comments you may have for us to NHPIInstructorPremier@reedelsevier.com.

ACKNOWLEDGEMENTS

Our part in this book would not have been possible without the original efforts of the American authors who conceptualized and wrote *Pharmacology and the Nursing Process*, which has shaped the content of *Lilley's Pharmacology for Canadian Health Care Practice*. Linda Lane Lilley, RN, PhD; Shelly Rainforth Collins, PharmD; and Julie S. Snyder, MSN, RN, BC, are to be commended for their thorough and expert handling of a vast and complex subject matter and for creating an excellent foundation over which the Canadian content could be easily laid. We would like to express our gratitude to Beth Swart, the author of the inaugural Canadian editions of *Pharmacology for Canadian Health Care Practice*, 1ce–3ce. Over the years, she has written and revised an exemplar textbook used in nursing curricula across Canada. We thank her for her dedication and commitment to nursing education.

We dedicate *Lilley's Pharmacology for Canadian Health Care Practice* to our students, both past and present, who inspire us with their curiosity for learning, passion for the nursing profession, and dedication to caring for the Canadian population. We could not have met the challenges of authoring this pharmacology textbook without the support and understanding from our families and colleagues.

We could not have accomplished this project without the assistance of Theresa Fitzgerald, who encouraged, altered deadlines to fit our busy schedules, reminded us of deadlines, and supported us throughout the huge task of co-editing this book. Roberta A. Spinosa-Millman, Content Strategist at Elsevier Canada, who provided this opportunity for both of us. Many individuals at Elsevier are responsible for this Canadian edition. Our thanks go to Laurie Gower, Content Director; Sherry Hinman, Copy Editor; Jerri Hurlbutt, Copy Editor; and Richard T. Barber, Senior Project Manager for handling all the details involved in the final production of the book.

Thanks are due to the Canadian reviewers who reviewed content of this book and gave their invaluable comments, expertise, and editing suggestions on the draft manuscript. As existing diseases and disorders and their treatments evolve, bringing with them new challenges and information in pharmacology, we will no doubt be looking forward to future editions of this textbook.

Dr. Kara Sealock, RN, EdD, MEd, BN, CNCC (C), CCNE

Dr. Cydnee Seneviratne, RN, PhD, MN, BSc

PART 1 Pharmacology Basics

- 1 Nursing Practice in Canada and Drug Therapy, 1**
 Overview, 1
 Assessment, 2
 Analysis of Data, 4
 Nursing Diagnoses, 4
 Planning, 6
 Implementation, 6
 Evaluation, 10
 Evidence-Informed Practice, 11
- 2 Pharmacological Principles, 14**
 Overview, 16
 Pharmaceutics, 17
 Pharmacokinetics, 19
 Pharmacodynamics, 28
 Pharmacotherapeutics, 29
 Pharmacogenosy, 33
 Pharmacoeconomics, 33
 Toxicology, 33
 Summary, 34
- 3 Legal and Ethical Considerations, 36**
 Legal Considerations, 37
 New Drug Development, 39
 Health Canada Drug Approval Process, 40
 Legal Nursing Considerations and Drug Therapy, 42
 Ethical Considerations, 43
- 4 Patient-Focused Considerations, 47**
 Overview, 47
 Assessment, 60
 Nursing Diagnoses: Age-Related, 61
 Planning, 61
 Implementation, 62
 Evaluation, 63
 Nursing Diagnoses: Ethnocultural, 63
- 5 Gene Therapy and Pharmacogenomics, 67**
 Overview, 68
 Basic Principles of Genetic Inheritance, 68
 Discovery, Structure, and Function of DNA, 69
 Gene Therapy, 70
 Pharmacogenetics and Pharmacogenomics, 71
 Application of Genetic Principles as a Result of Drug Therapy and the Nursing Process, 72
- 6 Medication Errors: Preventing and Responding, 75**
 General Impact of Errors on Patients, 75
 Medication Errors, 76
 Issues Contributing to Errors, 78

Preventing, Responding to, Reporting, and Documenting Medication Errors: A Nursing Perspective, 80
 Other Ethical Issues, 83
 Summary, 84

- 7 Patient Education and Drug Therapy, 88**
 Overview, 88
 Assessment of Learning Needs Regarding Drug Therapy, 89
 Nursing Diagnoses Regarding Learning Needs and Drug Therapy, 91
 Planning Regarding Learning Needs and Drug Therapy, 91
 Implementation Regarding Drug Therapy, 91
 Evaluation of Patient Learning Regarding Drug Therapy, 94
- 8 Over-the-Counter Drugs and Natural Health Products, 98**
 Over-the-Counter Drugs, 98
 Natural Health Products, 101
 Assessment, 105
 Nursing Diagnoses, 106
 Planning, 106
 Implementation, 107
 Evaluation, 107
- 9 Vitamins and Minerals, 111**
 Overview, 112
 Assessment, 127
 Nursing Diagnoses, 128
 Planning, 128
 Implementation, 128
 Evaluation, 129
- 10 Principles of Drug Administration, 133**
 Preparing For Drug Administration, 133
 Enteral Drugs, 135
 Parenteral Drugs, 141
 Topical Drugs, 157

PART 2 Drugs Affecting the Central Nervous System

- 11 Analgesic Drugs, 164**
 Overview, 166
 Treatment of Pain in Special Situations, 170
 Opioid Drugs, 172
 Nonopioid and Miscellaneous Analgesics, 180
 Assessment, 184
 Patient Teaching Tips, 193
- 12 General and Local Anaesthetics, 195**
 Overview, 196
 General Anaesthetics, 196
 Drugs for Procedural Sedation, 200
 Local Anaesthetics, 200
 Neuromuscular Blocking Drugs, 203
 Interactions, 205
 Dosages, 205

- Pharmacokinetic Bridge to Nursing Practice, 207
 - Assessment, 207
 - Nursing Diagnoses, 209
 - Planning, 209
 - Implementation, 209
 - Evaluation, 211

Nursing Practice in Canada and Drug Therapy

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. List the five phases of the nursing process.
2. Identify the components of the assessment process for patients receiving medications, including the collection and analysis of subjective and objective data.
3. Discuss the process of formulating nursing diagnoses for patients receiving medications.
4. Identify goals and outcome criteria for patients receiving medications.
5. Discuss the evaluation process involved in the administration of medications and reflected in the goals and outcome criteria.
6. Develop a collaborative plan of care using the nursing process and the principles of medication administration.
7. List and briefly discuss the Ten Rights associated with safe medication administration.
8. Discuss the professional responsibility and standards of practice for the professional nurse as a result of the medication administration process.

KEY TERMS

Adherence Active, voluntary, and collaborative involvement of the patient in the mutually acceptable, prescribed course of treatment or therapeutic plan. (p. 3)

Critical thinking The ability to reason and think rationally in order to understand, solve problems, and make decisions; a major component of the nursing process, often considered the foundation on which to provide the best possible patient care, supported by current best evidence. (p. 2)

Evidence-informed practice (EIP) Continuous, interactive process involving the explicit, conscious, and judicious consideration of the best research evidence available to make collaborative decisions between the health care team and the patient and family when providing patient care. (p. 11)

Goals Statements that are time-specific and describe generally what must be accomplished to address a specific nursing diagnosis. (p. 2)

Medication error Any preventable adverse drug event involving inappropriate medication use by a patient or health care provider. (p. 10)

Nonadherence An informed decision by a patient not to adhere to or follow a therapeutic plan or suggestion. (p. 4)

Nursing process An organizational framework for the practice of nursing that encompasses all steps taken by the nurse in caring for a patient: assessment, nursing diagnoses, planning (with goals and outcome criteria), implementation of the plan (with patient teaching), and evaluation. (p. 2)

Outcome criteria Descriptions of specific patient behaviours or responses that demonstrate the meeting or achievement of goals related to each nursing diagnosis. (p. 6)

Prescriber Any health care provider licensed by the appropriate regulatory body to prescribe medications. (p. 4)

OVERVIEW

The nursing practice environment in Canada is increasingly demanding, due in part to the increased acuity and complexity of patient care and the aging population. Nurses are expected to keep up to date with the rising use of intricate pharmacological therapies, including natural health products and over-the-counter drugs. In addition to rising costs, other factors such as

professional shortages, advances in treatment modalities, and new technologies continue to challenge the health care system. In such an environment, knowledge of drugs, their adverse effects, and their interactions is crucial for nurses to provide safe, ethical, competent care. Nurses are expected to be more accountable, with increased attention focused on safe medication practices. Evaluating and promoting therapeutic effects,

as well as reducing the harm associated with adverse effects, adverse interactions, and drug toxicity, and making decisions about prn (*pro re nata* or “as needed”) medications require excellent critical thinking and decision-making skills.

The **nursing process** is a well-established, research-supported framework for professional nursing practice. It is a flexible, adaptable, and adjustable five-step process consisting of assessment, nursing diagnoses, planning (including establishment of **goals** and outcome criteria), implementation (including patient education), and evaluation. As such, the nursing process ensures the delivery of thorough, individualized, and quality nursing care to patients. Through use of the nursing process combined with knowledge and skills, the professional nurse can develop effective solutions to meet patients’ needs. The use of the nursing process is one way to organize nursing care and may be viewed as controversial in some educational and health care institutions that use other decision-making frameworks. Some view the nursing process as a repetitive tool developed prior to the technology era that may assist in developing an initial plan of care but is limited in assisting to make the detailed judgements and decision making required today. Others view it as the foundation of problem solving and believe it fits well with evidence-informed practice. However, it is still considered the major systematic framework for professional nursing practice.

Usually, the nursing process is discussed within nursing courses and in textbooks on the fundamentals of nursing practice, nursing theory, physical assessment, adult and pediatric nursing, and other nursing specialty areas. Because the nursing process is so important in the care of patients, the process in all its five phases, along with evidence-informed practice examples, will be included in each chapter of this book as they relate to specific drug groups and classifications.

Critical thinking is one part of the nursing process and is often considered the foundation on which to provide the best possible patient care, supported by current best practice. *Clinical reasoning*, a more specific term, and *clinical judgement* are key components of critical thinking in nursing. Clinical reasoning refers to the way nurses analyze and understand patient care issues such as determining, preventing, and managing patient problems. A nurse who is proficient at clinical reasoning will be able to make timely and effective patient-centred decisions. Sound clinical reasoning is essential for preserving the standards of the nursing profession and promoting good patient outcomes. Clinical reasoning involves applying ideas to experience in order to arrive at a valid clinical judgement.

The elements of the nursing process address the physical, emotional, spiritual, sexual, financial, cultural, and cognitive aspects of a patient. Attention to these many aspects allows a more holistic approach to patient care. For example, a cardiologist may focus on cardiac functioning and pathology, a physiotherapist on movement, and a chaplain on the spiritual aspects of patient care. However, it is the professional nurse who thinks critically about processes, incorporates all of these aspects and points of information about the patient, and then uses this information to develop and coordinate patient care. Therefore, the nursing process remains a central process and framework

for nursing care. **Box 1.1** provides guidelines for nursing care planning related to drug therapy and the nursing process.

ASSESSMENT

During the initial assessment phase of the nursing process, data are collected, reviewed, and analyzed. Performing a comprehensive assessment allows the nurse to formulate a nursing diagnosis related to the patient’s needs—for the purposes of this textbook, specifically needs related to pharmacotherapy, of which one aspect is drug administration. Information about the patient may come from a variety of sources, including the patient; the patient’s family, caregiver, or significant other; and the patient’s chart. Methods of data collection include interviewing, direct and indirect questioning, observation, medical records review, head-to-toe physical examination, and nursing assessment. Data are categorized into objective and subjective data.

Subjective data include information obtained through a nursing history and shared through the spoken word by any reliable source, such as the patient, the spouse, another family member, a significant other, or a caregiver.

Objective data may be defined as any information gathered through the senses or that which is seen, heard, felt, or smelled. Objective data may also be obtained from a nursing physical assessment; past and present medical history; results of laboratory tests, diagnostic studies, or procedures; measurement of vital signs, weight, and height; and medication profile. Medication profiles include, but are not limited to, the following information: any and all drug use; use of home or folk remedies and natural health products or homeopathic treatments; intake of alcohol, tobacco, and caffeine; current or past history of illicit drug use; use of over-the-counter (OTC) medications (e.g., aspirin, acetaminophen, vitamins, laxatives, cold preparations, sinus medications, antacids, acid reducers, antidiarrheals, minerals, chemical elements); use of hormonal drugs (e.g., testosterone, estrogens, progestins, oral contraceptives); past and present health history and associated drug regimen(s); family history and racial, ethnic, or cultural attributes with attention to specific or different responses to medications as well as any unusual individual responses; and growth and developmental stage (e.g., Erikson’s developmental tasks) and issues related to the patient’s age and medication regimen. A holistic nursing assessment includes gathering of data about the whole individual, including physical and emotional realms, religious preference, health beliefs, sociocultural characteristics, race, ethnicity, lifestyle, stressors, socioeconomic status, education level, motor skills, cognitive ability, support systems, lifestyle, and use of any complementary and alternative therapies.

Assessment related to specific drugs is also important and involves the collection of specific information about prescribed, OTC, and natural health products or complementary and alternative therapeutic drug use, with attention to the drug’s actions; signs and symptoms of allergic reaction; adverse effects; dosages and routes of administration; contraindications; drug incompatibilities; drug–drug, drug–food, and drug–laboratory test interactions; and toxicities and available antidotes.

BOX 1.1 Guidelines for Nursing Care Planning

The sample in this study presents useful information for developing a nursing process–focused care plan for patients receiving medications. Brief listings and discussions of what must be contained in each phase of the nursing process are included. This sample may be used as a template for formatting nursing care plans in a variety of patient care situations or settings.

Assessment**Subjective Data**

Subjective data include all spoken information shared by the patient as part of taking a nursing history, such as concerns, problems, or stated needs (e.g., patient reports “dizziness, headache, vomiting, and feeling hot for 10 days”).

Objective Data

Objective data include information available through the senses, that is, what is seen, felt, heard, and smelled. Among the sources of data are the chart, laboratory test results, reports of diagnostic procedures, physical assessment results, and examination findings. Examples of specific data are age, height, weight, allergies, medication profile, and health history.

Nursing Diagnoses

Once the assessment phase has been completed, the nurse analyzes subjective and objective data about the patient and the drug and formulates nursing diagnoses. The following is an example of a nursing diagnosis statement: “Deficient knowledge related to lack of experience with medication regimen and Grade 2 reading level as an adult, as evidenced by inability to perform a return demonstration and inability to state adverse effects to report to the prescriber.” This statement of the nursing diagnosis can be broken down into three parts, as follows:

- Part 1: “Deficient knowledge.” This is the statement of the human response of the patient to illness, injury, medications, or significant change. This can be an actual response, an increased risk, or an opportunity to improve the patient’s health status. The nursing diagnosis related to knowledge may be identified as either inadequate or ready for enhanced (knowledge).
- Part 2: “Related to lack of experience with medication regimen and Grade 2 reading level as an adult.” This portion of the statement identifies factors related to the response; often it includes multiple factors with some degree of connection between them. The nursing diagnosis statement does not necessarily claim that there is a cause-and-effect link between these factors and the response, only that there is a connection.
- Part 3: “As evidenced by inability to perform a return demonstration and inability to state adverse effects to report to the prescriber.” This statement

lists clues, cues, evidence, or data that support the nurse’s claim that the nursing diagnosis is accurate.

Nursing diagnoses are prioritized in order of criticality, based on patient needs or problems. The ABCs of care (airway, breathing, and circulation) are often used as a basis for prioritization. Prioritizing always begins with the most important, significant, or critical need of the patient. Nursing diagnoses that involve actual responses are always ranked above nursing diagnoses that involve only risks.

Planning: Goals and Expected Patient Outcome Criteria

The planning phase includes the identification of short-term and long-term goals and outcome criteria, provides time frames, and is patient oriented. Goals are objective, realistic, and measurable patient-centred statements with time frames and are broad, whereas outcome criteria are more specific descriptions of patient goals.

Implementation

In the implementation phase, the nurse intervenes on behalf of the patient to address specific patient problems and needs. This is done through independent nursing actions; collaborative activities such as physiotherapy, occupational therapy, and music therapy; and implementation of medical orders. Family, significant others, and caregivers assist in carrying out this phase of the nursing care plan. Specific interventions that relate to particular drugs (e.g., giving a particular cardiac drug only after monitoring the patient’s pulse and blood pressure), nonpharmacological interventions that enhance the therapeutic effects of medications, and patient education are major components of the implementation phase. See the previous text discussion of the nursing process for more information on nursing interventions.

Evaluation

Evaluation is the part of the nursing process that includes monitoring whether patient goals and outcome criteria related to the nursing diagnoses are met. Monitoring includes observing for therapeutic effects of drug treatment as well as for adverse effects and toxicity. Many indicators are used to monitor these aspects of drug therapy as well as the results of appropriately related nonpharmacological interventions. If the goals and outcome criteria are met, the nursing care plan may or may not be revised to include new nursing diagnoses; such changes are made only if appropriate. If goals and outcome criteria are not met, revisions are made to the entire nursing care plan with further evaluation.

Nursing pharmacology textbooks provide a more nursing-specific knowledge base regarding drug therapy as a result of the nursing process. Use of current references or those dated within the last 3 years is highly recommended. Examples of authoritative resources include the *Compendium of Pharmaceuticals and Specialties* (CPS; a subscription-based e-CPS is also available online), the drug manufacturer’s insert, drug handbooks, and a licensed pharmacist. Some reliable online resources include Health Canada’s Drug Product Database (<http://www.hc-sc.gc.ca/dhp-mps/prodpharma/databasdon/index-eng.php>) and the Objective Comparisons for Optimal Drug Therapy (<http://www.rxfiles.ca/>). Other online resources are cited throughout this textbook.

Gather additional data about the patient and a given drug by asking yourself these simple questions: What is the patient’s oral intake? Tolerance of fluids? Swallowing ability for pills, tablets, capsules, and liquids? If there is difficulty swallowing,

what is the degree of difficulty and are there solutions to the problem, such as the use of thickening agents with fluids or the use of other dosage forms? What are the results of laboratory and other diagnostic tests related to organ functioning and drug therapy? What do kidney function studies (e.g., urea nitrogen, creatinine) show? What are the results of liver function tests (e.g., total protein, bilirubin, alkaline phosphatase, creatinine phosphokinase, other liver enzymes)? What are the patient’s white blood cell and red blood cell counts? Hemoglobin and hematocrit levels? Current as well as past health status and presence of illness? What are the patient’s experiences with use of any drug regimen? What has been the patient’s relationship with health care providers or experiences with previous therapeutic regimens? What are current and past values for blood pressure, pulse rate, temperature, and respiratory rate? What medications is the patient currently taking, and how is the patient taking and tolerating them? Are there issues with **adherence** (implying

collaboration and an active role between patients and their health care providers)? Has there been any use of traditional or folk medicines or remedies? What is the patient's understanding of the medication? Are there any age-related concerns? If patients are not reliable historians, family members, significant others, or caregivers may provide answers to these questions.

Once assessment of the patient and the drug has been completed, the specific prescription or medication order (from any **prescriber**) must be checked for the following six elements: (1) patient's name, (2) date the drug order was written, (3) name of drug(s), (4) drug dosage amount and frequency, (5) route of administration, and (6) prescriber's signature.

It is also important during the assessment to consider the traditional, nontraditional, expanded, and collaborative roles of the nurse. Physicians and dentists are no longer the only practitioners legally able to prescribe and write medication orders. Registered nurses do not order medications; they follow standard orders established by physicians. In some cases, depending on agency and provincial or territorial regulatory body, registered nurses can administer medications without a physician's order (e.g., registered nurses with an additional "certified practice"), according to agency-specific protocols, such as pyrexia protocols or bowel protocols, or certain classifications of drugs.

In some provinces (e.g., Ontario, British Columbia, Alberta), the scope of practice for registered nurses was expanded to allow nurses the authority to dispense certain medications under certain circumstances. Dispensing involves preparing and transferring a medication for a patient or the patient's representative to be administered at a later date—for example, if a patient has a day pass and requires medication while absent or if a client is discharged from the emergency department and requires medication to be started. Dispensing entails ensuring that the medication is pharmaceutically and therapeutically appropriate for the intended use and that it will be used properly. It may also include accepting payment for a medication on behalf of a nurse's employer.

Nurse practitioners and physician assistants have the professional privilege of legally prescribing medications. As of 2016, in Canada, there are 400 physician assistants (PAs), who support physicians in a variety of health care settings. The role for PAs began in Canada within the Canadian Forces Health Services 50 years ago, and physician assistants now practise in Manitoba, New Brunswick, Ontario, and Alberta. Physician assistants are meant to extend the role of the physician; they work under the supervision of physicians and are not independent practitioners. In Manitoba and New Brunswick, PAs are regulated through their respective College of Physicians and Surgeons; in Ontario and Alberta, PAs practise by delegation under the *Medicine Act* and the *Medical Act*, respectively. PAs are autonomous decision makers and perform a range of diagnostic and therapeutic services, including writing prescriptions. PAs must complete a two-year educational program that is accredited by the [Canadian Medical Association \(2019\)](#). Nurse practitioners (NPs) are registered nurses with an advanced degree who practise in the Extended Class. They have extra education and experience and are legally competent to diagnose, order, and interpret diagnostic tests; prescribe medications; and perform procedures.

ANALYSIS OF DATA

Once data about the patient and drug have been collected and reviewed, critically analyze and synthesize the information. Verify all information and document appropriately. It is at this point that the sum of the information about the patient and drug is used in the development of nursing diagnoses.

CASE STUDY

The Nursing Process and Pharmacology

Katie, a 27-year-old teacher, is visiting the clinic today for a physical examination. She states that she and her husband want to "start a family," but she has not had a physical for several years. She was told when she was 22 years of age that she had "anemia" and was given iron tablets but states that she has not taken them for years. She said she "felt better" and did not think she needed them. She denies any use of tobacco or illegal drugs; she states that she may have a drink with dinner once or twice a month. She uses tea tree oil on her face twice a day to reduce acne breakouts. She denies using any other drugs.

1. During the physical assessment, what other questions does the nurse need to ask?
2. After laboratory work is performed, Katie is told she is slightly anemic. The prescriber recommends that she resume taking iron supplements as well as folic acid. She is willing to try again and says that she is "all about doing what's right to stay healthy and become a mother." What nursing diagnoses would be appropriate at this time?
3. Katie is given a prescription that reads as follows: "ferrous fumarate 300 mg, PO for anemia." When she goes to the pharmacy, the pharmacist tells her that the prescription is incomplete. What is missing? What should be done?
4. After 4 weeks, Katie's latest laboratory results indicate that she still has anemia. However, Katie states, "I feel so much better that I'm planning to stop taking the iron tablets. I hate to take medicine." How should the nurse handle this?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

NURSING DIAGNOSES

Nursing diagnoses are developed by professional nurses and are used as a means of communicating and sharing information about the patient and the patient experience. Nursing diagnoses are the result of critical thinking, creativity, and analysis of the data collected about the patient and the drug. They are clinical judgements about how a person responds to health conditions and life processes or vulnerability for that response. Nursing diagnoses related to drug therapy will most likely develop out of data associated with the following: inadequate knowledge; risk of injury; **nonadherence**; various disturbances, deficits, excesses, or impairments in bodily functions; and other problems or concerns as a result of drug therapy. The development and classification of nursing diagnoses has been carried out by NANDA International (NANDA-I) (formerly North American Nursing Diagnosis Association [NANDA]). NANDA-I is the formal organization

recognized by professional nursing groups (e.g., the Canadian Nurses Association [CNA] and the American Nurses Association) (NANDA International, 2014). NANDA-I is considered the major contributor to the development of nursing knowledge and the leading authority in the development and classification of nursing diagnoses. The purpose of NANDA-I is to increase the visibility of nursing's contribution to the care of patients and to further develop, refine, and classify the information and phenomena related to nurses and professional nursing practice. The use of a standardized language of nursing diagnoses documents the analysis, synthesis, and accuracy required in making a nursing diagnosis and establishes nursing's contribution to cost-effective, efficient, quality health care. See Box 1.2 for more information about the 2015–2017 NANDA-I–approved nursing diagnoses.

BOX 1.2 A Brief Look at NANDA and the Nursing Process

NANDA International (NANDA-I) (formerly known as the North American Nursing Diagnosis Association International) fulfills the following roles: (1) increases the visibility of nursing's contribution to patient care, (2) develops, refines, and classifies information and phenomena related to professional nursing practice, (3) provides a working organization for the development of evidence-informed nursing diagnoses, and (4) supports the improvement of quality nursing care through evidence-informed practice and access to a global network of professional nurses. In 1987, NANDA and the American Nurses Association endorsed a framework for establishing nursing diagnoses, and in 1990, *Nursing Diagnoses* became the official journal of NANDA. In 2001 and 2003, NANDA modified and updated the listing of nursing diagnoses, but nursing diagnoses continued to be submitted for consideration by the ad hoc research committee of NANDA. This period resulted in changes such as replacement of the phrase *risk for* with *potential for*. The terms *impaired*, *deficient*, *ineffective*, *decreased*, *increased*, and *imbalanced* replaced the outdated terms *altered* and *alteration*, although the outdated terms may still be in use.

In 2002, NANDA changed its name to NANDA-I ("I" for international) to reflect the organization's global reach. Every 2 years, revisions are made to the nursing diagnoses, adding new and revised nursing diagnoses as well as retiring outdated ones. Most current is the *Nursing Diagnoses 2015–2017: Definitions and Classifications*, which provides more "linguistically congruent diagnoses" (Herdman & Kamitsuru, 2014). The guide includes a total of 235 diagnoses supported by definitions, defining characteristics, related factors, and risk factors. There are 26 new diagnoses and 13 revised diagnoses, based on global evidence. Seven diagnoses were removed. Changes were made to some of the definitions of nursing diagnoses, which impacted the risk and health promotion diagnoses. The word *risk* was removed from "risk" diagnoses and replaced with *vulnerable*; the health promotion diagnoses were altered to ensure that they are suitable for use across the health–illness continuum. Defining characteristics also were altered.

There are 13 domains (spheres of knowledge) of diagnoses that are further divided into 47 classes (groupings that share common attributes). The new diagnoses include 14 vulnerable diagnoses, one health promotion diagnosis, and 11 problem-focused diagnoses, in the area of: (1) cardiovascular function; (2) elimination; (3) emancipated decision making; (4) frailty in the elderly; (5) mobility; (6) mood and emotional regulation; (7) nutrition; (8) pain; (9) skin/tissue/mucous membrane function; (10) surgical recovery; and (11) thermoregulation. These domains are further divided into classes.

Herdman, T. H., & Kamitsuru, S. (2014). In *NANDA international nursing diagnoses: Definitions & classification, 2015–2017*. Used by arrangement with Wiley Blackwell.

More recently, a long-term project of the International Council of Nurses (ICN) to provide a unified language system was initiated. The International Classification for Nursing Practice (ICNP) is a framework that can be cross-mapped with other health care classification systems such as NANDA to create multidisciplinary health vocabularies or lexicons within information systems (International Council of Nurses, 2014). The overall intent is that nursing diagnoses, nursing interventions, and nursing outcomes within the ICNP would be used in health care record documentation. The CNA has endorsed the ICNP as the standard for collecting nursing data. The objectives of the ICNP are as follows: (1) to establish a common language for describing nursing practice in order to improve communication among nurses and between nurses and others; (2) to describe the nursing care of people (individuals, families, and communities) in a variety of settings, both institutional and noninstitutional; (3) to enable comparison of nursing data across clinical populations, settings, geographic areas, and time; (4) to demonstrate or project trends in the provision of nursing treatments and care and the allocation of resources to patients according to their needs, based on nursing diagnoses; (5) to stimulate nursing research through links to data available in nursing information systems and health information systems; and (6) to provide data about nursing practice in order to influence health policy-making. "ICNP seeks to cover nursing diagnoses (which may also be used to represent nursing outcomes) and nursing interventions in entirety, accepting that this is a formative process and that nursing covers a broad range of health care and is not a clearly bounded discipline" (International Classification for Nursing Practice, 2017). There is a disparity in opinion across Canada about whether NANDA diagnoses, patient problems (actual or potential), nursing priorities, diagnostic reasoning, or clinical impression identification is the better approach.

Formulation of nursing diagnoses is usually a three-step process, with nursing diagnoses stated as follows: Part I of the statement is the human response of the patient to illness, injury, or significant change. This response can be an actual problem, an increased risk of developing a problem, or an opportunity or intent to increase the patient's health. Part II of the nursing diagnosis statement identifies the factor(s) related to the response, with often more than one factor named. The nursing diagnosis statement does not necessarily claim a cause-and-effect link between these factors and the response; it indicates only that there is a connection between them. Part III of the nursing diagnosis statement contains a listing of clues, cues, evidence, or other data that support the nurse's claim that this diagnosis is accurate. Tips for writing a nursing diagnosis include the following: begin with a statement of a human response; connect Part I of the statement or the human response with Part II—the cause—using the phrase *related to*; ensure that Parts I and II are not restatements of one another; include several factors in Part II of the statement, such as associated factors, if appropriate; select a cause for Part II of the statement that can be changed by nursing interventions; avoid negative wording or language; and, finally, list clues or cues that led to the nursing diagnosis in Part III of the statement, which may also include more defining characteristics (e.g., "as evidenced by").

The diagnoses most relevant to drug therapy will be used in this textbook. These nursing diagnoses, as well as all other phases of the nursing process, will be presented in the chapters to follow because of the framework of practice that the nursing process provides to all professional nurses; they are also used to organize the nursing sections of this textbook.

PLANNING

After data are collected and nursing diagnoses formulated, the planning phase begins; this phase includes identification of goals and outcome criteria. The major purposes of the planning phase are to prioritize the nursing diagnoses and specify goals and outcome criteria, including the time frame for their achievement. The planning phase provides time to obtain special equipment for interventions, review the possible procedures or techniques to be used, and gather information either for oneself (the nurse) or for the patient. This step leads to the provision of safe care if professional judgement is combined with the acquisition of knowledge about the patient and the medications to be given.

Goals and Expected Patient Outcome Criteria

Goals are objective, measurable, and realistic, with an established time period for achievement of the outcomes, which are specifically stated in the outcome criteria. Patient goals reflect expected and measurable changes in behaviour through nursing care and are developed in collaboration with the patient. Patient goals developed in the planning phase of the nursing process are behaviour based and may be categorized into physiological, psychological, spiritual, sexual, cognitive, motor, or other domains.

Outcome criteria are concrete descriptions of patient goals. They are patient focused, succinct, and well thought out. Outcome criteria also include expectations of behaviour indicating something that can be changed and with a specific time frame or deadline. The ultimate aim of these criteria is the safe and effective administration of medications. Outcome criteria also reflect each nursing diagnosis and serve as a guide to the implementation phase of the nursing process. Formulation of outcome criteria begins with the analysis of the judgements made about patient data and subsequent nursing diagnoses and ends with the development of a nursing care plan. Outcome criteria provide a standard for measuring movement toward goals. In regard to medication administration, these outcomes may address special storage and handling techniques, administration procedures, equipment needed, drug interactions, adverse effects, and contraindications. In this textbook, specific time frames generally are not provided in each chapter's nursing process section because every patient care situation is individualized.

IMPLEMENTATION

Implementation is guided by the preceding phases of the nursing process (i.e., assessment, nursing diagnoses, and planning). Implementation requires constant communication and collaboration with the patient and members of the health care team involved in the patient's care, as well as any family members, significant other, or other caregivers. Implementation consists

of initiation and completion of specific nursing actions by the nurse, as defined by nursing diagnoses, goals, and outcome criteria. Nursing interventions or actions may be independent, collaborative, or dependent upon a prescriber's order. Statements of interventions include frequency, specific instructions, and any other pertinent information. With medication administration, the nurse needs to know and understand all the information about the patient and about each medication prescribed (see assessment questions on p. 2). Implementation is based on the nurse's clinical judgement and knowledge. It also is important for the nurse to recognize that patients differ significantly in their attitude toward taking medications. The principles of informed consent and choice should underpin medication administration. It is critical for the nurse to explain the benefits and risks of a treatment in a way that the patient can grasp. Once patients understand the potential benefits and risks of therapy, they can make meaningful decisions.

Nurses are also advocates for all marginalized patients who face a diversity of issues related to equitable treatment and allocation of resources surrounding medications. Vulnerable and marginalized patients face lack of drug coverage, the inability to pay for prescriptions, and a multitude of other barriers that require health care providers to provide facilitation and timely responses.

Nurses must also adhere to safe administration practices to prevent errors. Traditionally, in years past, nurses adhered to the Five Rights of medication administration: right drug, right dose, right time, right route, and right patient. However, these rights have been expanded to Ten Rights (summarized in [Box 1.3](#)). The Ten Rights are discussed in detail in the next sections of this chapter. The "rights" of medication administration have been identified as basic standards of care as a result of drug therapy. Nurses are required to practise under their provincial or territorial regulatory body's standards and agency policy, and these may vary. However, even the implementation of the Ten Rights does not reflect the complexity of the role of the professional nurse because they focus more on the individual patient than on the system as a whole or the entire medication administration process, beginning with the prescriber's order. Viewed from an individual patient focus, additional rights (or entitlements) must be considered when administering medications. These rights include the following:

- Patient safety, ensured by use of the correct procedures, equipment, and techniques of medication administration and documentation
- Individualized, holistic, accurate, and complete patient education
- Double-checking and constant analysis of the system (i.e., the process of drug administration, including all personnel involved, such as the prescriber, the nurse, the nursing unit, and the pharmacy department, as well as patient education)
- Proper drug storage
- Accurate calculation and preparation of the dose of medication and proper use of all types of medication delivery systems
- Careful checking of the transcription of medication orders
- Accurate use of the various routes of administration and awareness of the specific implications of their use

BOX 1.3 Ten Rights of Medication Administration

1. *Right Drug (or Right Medication)*: Ensuring that the drug to be administered is the right medication that was ordered.
2. *Right Dose*: Ensuring that the dose ordered is correct for the patient's age and body parameters, and questioning doses that do not seem correct or are outside the patient's usual dose range.
3. *Right Time*: Ensuring that the drug is administered at the time ordered, at the right frequency, and according to institutional policy.
4. *Right Route*: Ensuring that the drug is administered by the route ordered as well as verifying that the route is safe and appropriate for the patient.
5. *Right Patient*: Ensuring that the drug is being administered to the patient it was intended for, by checking the drug order information against the patient's identification band.
6. *Right Reason*: Ensuring that the drug ordered is being given for the right reason, thus necessitating prior knowledge of the drug's actions and adverse effects.
7. *Right Documentation*: Ensuring that documentation of the medication administration is done after the drug has been administered, not before; moreover, ensuring that any unusual variances in time, dose, and drug reactions are properly recorded, as well as if the patient has refused the drug.
8. *Right Evaluation (or Right Assessment)*: Ensuring that any special assessment requirements have been made prior to the drug administration, such as specific pulse rate and blood pressure readings and laboratory results; moreover, ensuring that appropriate monitoring of the patient has been done following drug administration and that follow-up measures are taken if the drug has not achieved its desired effect.
9. *Right Patient Education*: Ensuring that the patient has been given proper explanation of the drug being given, the reason for its administration, and what to expect in terms of the drug's effects and possible adverse effects.
10. *Right to Refuse*: Ensuring that the patient understands his right to refuse the drug being administered and to be informed of the potential consequences of refusal.

- Close consideration of special situations (e.g., patient difficulty in swallowing, use of a nasogastric tube, unconsciousness of the patient, advanced patient age)
- Implementation of all appropriate measures to prevent and report medication errors

Right Drug

Administration of the right drug begins with the registered nurse's valid licence to practise. Unregulated care providers (UCPs) may also assist with medication administration. Nurses may teach UCPs medication administration and documentation, but the nurse remains ultimately accountable for the process of medication administration. The registered nurse is responsible for checking all medication orders or prescriptions. Prepouring a medication and not administering it at the time of pouring, or having another nurse or student administer it, increases the risk of errors and confuses the line of accountability for the preparation of the medication. It is the nurse's responsibility and best practice to prepare medications as close as possible to the time they are to be administered, watch the patient take the medication, and not allow another individual to administer a medication for the nurse and sign it off. (NOTE: there are rare exceptions to this best practice, such as preloading

syringes for a mass immunization program or an urgent need for drugs during a cardiac arrest.) To ensure that the correct drug is given, the nurse must check the specific medication order against the medication label or profile three times before giving the medication. Conduct the first check of the right drug, drug name, and drug expiration date while preparing the medication for administration. At this time, consider whether the drug is appropriate for the patient and, if you are in doubt or believe an error is possible, contact the prescriber or pharmacist immediately (see Evidence in Practice box on this page). Safety huddles are held on most acute care units, often with a pharmacist, to discuss new medications, changes to practice, or ways to manage errors. Usually a pharmacist is assigned to each unit to be available to answer questions. It is also appropriate at this time to note the drug's indication and be aware that a drug may have multiple indications, including off-label use and non-Health Canada-approved indications. In this textbook, each particular drug is discussed in the chapter that deals with its main indication, but drugs with multiple uses may also be cross-referenced in other chapters.

EVIDENCE IN PRACTICE

Patient Safety: Examining the Adequacy of the Five Rights of Medication Administration

Review

Patient safety is of utmost importance in health care today. For decades, the Five Rights (right drug, right patient, right dose, right route, right time) of medication administration have been the standard for safe medication practices; they are taught routinely in educational settings and implemented in practice. The Five Rights were found to be lacking because of the focus on individual performance and the failure to include individual factors and system deficiencies. Patients are no longer passive recipients of care and are choosing to play increasingly greater roles in the process of care.

Type of Evidence and Results of the Study

Martyn, Paliadelis, and Perry (2019) conducted an appreciative inquiry qualitative study to understand registered nurses' experiences of medication administration using the Five Rights. In total, 20 inpatient medical/surgical registered nurses participated in the study. The researchers found that although in most instances, participants displayed inconsistent use of the Five Rights, they did implement other strategies such as organization and patient-centred care to ensure improved patient safety when administering medication. Findings opened new conversations around the linear process encouraged by the Five Rights framework that do not consider the complex environment of contemporary health care settings.

Link of Evidence to Nursing Practice

The Five Rights are no longer sufficient for safe administration of medication. In most provinces, nursing associations recommend that seven or ten rights be used, which includes a medication history and assessment, interpretation of assessment data, anticipating risks, providing patient education, and planning for evaluation of medication effectiveness as well as observing for potential interactions with other medications, food, or natural health products. Each of these clinical judgement actions requires vigilance and clinical reasoning but it is important to refer to provincial nursing (RN/LPN) association and health care institution recommendations. Medication administration is a complex, interrelated process involving many players and steps. Collaboration among all players, including the patient, caregiver, and family, is essential to safe, ethical, and competent care.

All medication orders or prescriptions are required by law to be signed by the prescriber involved in the patient's care. If a verbal order is given, the prescriber must sign the order within 24 hours or as per facility protocol. Verbal, telephone, or texting orders are often used in emergencies and time-sensitive patient care situations. Preprinted orders based on current evidence may also be available under certain circumstances. To be sure that the right drug is given, information about the patient and drug (see previous discussion of the assessment phase) must be obtained to make certain that all variables and data have been considered. Approved, current, authoritative references (see earlier discussion) are the reliable sources of information about prescribed drugs. Avoid relying upon the knowledge of peers as this is unsafe nursing practice. Remain current in your knowledge of generic (nonproprietary) drug names as well as trade names (proprietary name that is registered by a specific drug manufacturer); however, in clinical practice, only the drug's generic name is used, to reduce the risk of medication errors. A single drug often has numerous trade names, and drugs in different classes may have similarly spelled names, increasing the possibility of medication errors (see Preventing Medication Errors box). Therefore, when it comes to the "right drug" phase of the medication administration process, use the drug's generic name to help avoid a medication error and enhance patient safety. (See [Chapter 2](#) for more information on the naming of drugs.)

If there are questions about a medication order at any time during the medication administration process, contact the prescriber for clarification. Never make any assumptions when it comes to drug administration, and, as previously emphasized in this chapter, confirm at least three times the right drug, right dose, right time, right route, right patient, and right reason—when removing the drug from the patient drawer or cabinet, when pouring the drug, and in many instances at the bedside, with the third check involving an identifier from the patient (this may not be required by all agencies), before giving the medication. You must adhere to the Ten Rights of medication administration according to the provincial or territorial regulatory body under which you are practising. With the increasing use of technology (e.g., texting, fax, email, cellphones) in health care to make communication between health care providers more "timely" and cost efficient, it is important to caution the nurse about the risks involved. Recommendations for use of wireless technology include protected security features (e.g., data encryption, password protection, device swiping). There may be specific agency policies for the transmission of patient information and documentation of the medical information or order transmitted, as well as procedures for the information becoming part of the permanent health record.

Right Dose

Whenever a medication is ordered, a dosage is identified from the prescriber's order. Always check the dose and confirm that it is appropriate to the patient's age and size. Check appropriate laboratory and diagnostic results such as potassium, creatinine, and ammonia levels. Also, check the prescribed dose against the available drug stocks and against the normal dosage range.

Recheck all mathematical calculations, and pay careful attention to decimal points, the misplacement of which could lead to a tenfold or even greater overdose. Leading zeros, or zeros placed before a decimal point, are allowed, but in numbers less than 1, trailing zeros, or zeros following the decimal point, are to be avoided. For example, 0.2 mg is allowed but 2.0 milligrams is not acceptable because it could easily be mistaken for 20 mg, especially with unclear penmanship. Patient variables (e.g., vital signs, age, sex, weight, height) require careful assessment because of the need for dosage adjustments in response to specific parameters. Children and older adult patients are more sensitive to medications than younger and middle-age adult patients; thus, use extra caution with drug dosage amounts for these patients.

PREVENTING MEDICATION ERRORS

Right Dose?

The nurse is reviewing the orders for a newly admitted patient. One order reads: "Acetaminophen, 2 tablets PO, every 4 hours as needed for pain or fever."

The pharmacist calls to clarify this order, saying, "The dose is not clear." What does the pharmacist mean by this? The order says "2 tablets." Isn't that the dose?

NO! If you look up acetaminophen in a drug resource book, you will see that acetaminophen tablets are available in strengths of both 325 mg and 500 mg. The order is missing the "right dose" and needs to be clarified. *Never* assume the dose of a medication order.

Right Time

Each health care agency or institution has a policy regarding routine medication administration times; therefore, always check this policy. However, when giving a medication at the prescribed time, the nurse may be confronted with a conflict between the timing suggested by the physician and specific pharmacokinetic and pharmacodynamic (see [Chapter 2](#)) drug properties, concurrent drug therapy, dietary influences, laboratory or diagnostic testing, and specific patient variables. For example, the prescribed right time for administration of anti-hypertensive drugs may be four times a day, but for an active, professional 42-year-old male patient working 13 to 14 hours a day, taking a medication four times a day may not be feasible, and this regimen may lead to nonadherence and subsequent complications. Appropriate actions include contacting the prescriber and inquiring about the possibility of prescribing another drug with a different dosing frequency (e.g., once or twice daily).

For routine medication orders, nurses have long adhered to medication administration according to the 30-minute rule: no more than 30 minutes before or after the actual time specified in the prescriber's orders (i.e., if a medication is ordered to be given at 0900 hours every morning, the medication may be given anytime between 0830 and 0930 hours). According to the Institute for Safe Medication Practices ([Institute for Safe Medication Practices Canada, 2011](#)), such rigid rules lead to nurses taking shortcuts and subsequently making errors. The ISMP points out that "a one-size-fits-all, inflexible requirement

BOX 1.4 Recommended Guidelines for Timely Administration of Medications

Type of Scheduled Medication	Goals for Timely Administration
Time-Critical Scheduled Medications	
Facility-defined time-critical medications*	Administer at the exact time indicated when necessary (e.g., rapid-acting insulin); otherwise within 30 minutes before or after the scheduled time.
Including but not limited to medications with a dosing schedule more frequent than every 4 hours	
Non-Time-Critical Scheduled Medications	
Daily, weekly, monthly medications	Administer within 2 hours before or after the scheduled time.
Medications prescribed more frequently than daily, but no more frequently than every 4 hours	Administer within 1 hour before or after the scheduled time.

*Limited number of drugs where delayed or early administration of more than the 30 minutes may cause harm or subtherapeutic effect. Adapted from Institute for Safe Medication Practices. (2011). *Guidelines for timely medication administration: Response to the CMS '30-minute rule.'* Retrieved from <http://www.ismp.org/newsletters/acute/articles/20110113.asp>. Used with permission from the Institute for Safe Medication Practices.

to administer all scheduled medications within 30 minutes of the scheduled time is a precarious mandate, given that relatively few medications truly require exact timing of doses.” The ISMP has recommended guidelines for the timely administration of drugs (see Box 1.4).

Medications designated to be given stat (immediately) must be administered within 30 minutes of the time the order is written. Assess and follow the hospital or facility policy and procedure for any other specific information concerning the 30-minutes-before-or-after rule. For medication orders with the annotation *prn*, the medication must be given at special times and under certain circumstances. For example, for an analgesic ordered every 4 hours *prn* for pain, after one dose of the medication, the patient reports pain. After assessment, intervention with another dose of analgesic would occur, but only 4 hours after the previous dose. In addition, because of the increasing incidence of medication errors related to the use of abbreviations, many prescribers are using the wording *as required* or *as needed* instead of the abbreviation *prn*. Military time is used when medication and other orders are written into a patient's chart (Fig. 1.1).

Nursing judgement may lead to some variations in timing, and the nurse must document any change and the rationale for the change. If medications are ordered to be given once every day, twice daily, three times daily, or even four times daily, the times of administration may be changed if doing so is not harmful to the patient and if the medication or patient's condition does not require adherence to an exact schedule, but only if the change is approved by the prescriber. Never underestimate the effect of a change in the dosing or timing of medication because one missed dose of certain medications can be life threatening. Other factors must be considered in determining the right time, such as multiple-drug therapy,

Fig. 1.1 The 24-hour clock. (From Sorrentino, S. A., & Remmert, L. N. (2012). *Mosby's textbook for nursing assistants* (8th ed.). p. 69, Fig. 6-6. St Louis, MO: Mosby.)

drug-drug or drug-food compatibility, scheduling of diagnostic tests, bioavailability of the drug (e.g., the need for consistent timing of doses around the clock to maintain blood levels), drug actions, and any biorhythm effects such as those that occur with steroids. It is also critical to patient safety to avoid using abbreviations for *any* component of a drug order (i.e., dose, time, and route).

Right Route

As previously stated, the nurse must know the particulars about each medication before administering it to ensure that the right drug, dose, and route are being used. A complete medication order includes the route for administration. If a medication order does not include the route, the nurse must ask the prescriber to clarify it. Never assume the route of administration.

Right Patient

Checking the patient's identity before giving each medication dose is critical to the patient's safety. Ask the patient to state his or her own name and then check the patient's identification band to confirm the patient's name, identification number, age, and allergies. With children, the parents or legal guardians are often the ones who identify the patient for the purposes of administration of prescribed medications. With newborns and labour and delivery situations, the mother and baby have identification bracelets with matching numbers, which must be checked before giving medications. With older adults or patients with altered sensorium or level of consciousness, asking them to state their names is neither realistic nor safe. Therefore, checking the identification band against the medication profile, medication order, or other treatment or service orders is crucial to avoid errors. Accreditation Canada (2019) has required organizational practices to improve the quality and safety of health services.

One practice is to use at least two identifiers before providing care, treatment, or services to patients. Accreditation Canada identifies that the information obtained must be specific to the patient. Examples include a person-specific identification number such as a registration number; patient identification cards such as the health card with name, address, and date of birth; patient barcodes; double witnessing; or a patient wristband. The two identifiers may be in the same location, such as on a wristband. The patient's room number is not an acceptable identifier.

Right Reason

The nurse must ensure that the drug is being given for the right reason and clarify any medication orders that do not seem to fit within a right reason. When uncertain, always check the CPS or contact the pharmacy or prescriber for clarification. If the nurse administers an unfamiliar drug and remains unknowledgeable about its action and intended effect, the drug may cause harm, although unintended, to the patient. Sometimes a medication may be administered for a reason that is not obvious, as the classification is not the reason for the administration. For example, lactulose, although classified as a laxative, is also used for the treatment of hepatic encephalopathy to bind with ammonia to reduce toxic levels.

Right Documentation

Documentation of information related to medication administration is crucial to patient safety. Recording patient observations and nursing actions has always been an important ethical responsibility, but it has become a major medical–legal consideration as well. Because of its significance in professional nursing practice, correct documentation is becoming known as the “sixth right” of medication administration. Always assess the patient's chart for the presence of the following information: date and time of medication administration, name of medication, dose, route, and site of administration. Documentation of drug action may also be performed in the regularly scheduled assessments for any changes in symptoms the patient is experiencing, adverse effects, toxicity, and any other drug-related, physical or psychological symptoms.

Documentation must also reflect any improvement in the patient's condition, symptoms, or disease process as well as whether there has been no change or a lack of improvement. Not only must you document these observations, but you must also report them to the prescriber promptly, in keeping with your critical thinking and judgement. Document any teaching, as well as an assessment of the degree of understanding exhibited by the patient. Other information that needs documentation includes the following:

1. If a drug is *not* administered, with the reason why and any actions taken
2. Refusal of a medication with information about the reason for refusal, if possible. If a medication is refused, respect the patient's right (to refuse), determine the reason by assessing the patient's knowledge level as it pertains to refusing the drug, and document. Take appropriate action, including notifying the prescriber, and revise the nursing care plan. Never return unwrapped medication to a container and discard

according to agency policy; if wrapper remains intact, return medication to the pharmacy and revise the nursing care plan as needed.

3. Actual time of drug administration
4. Data regarding clinical observations and treatment of the patient if a medication error has occurred

If there has been a medication error, complete an incident report with the entire event, surrounding circumstances, therapeutic response, adverse effects, and notification of the prescriber described in detail. However, do not record completion of an incident report in the medical chart. Always follow specific individual agency policies/protocols regarding medication errors and incident reporting.

Most provinces and territories are using or are moving to implement electronic health records. The electronic health record (EHR) is a collection of the personal health information of a patient that is stored electronically and kept under strict security. This information is accessible online from many separate, interoperable automated systems within an electronic network. It provides an online profile of a patient's drug prescription history. The system also informs of drug interactions.

Medication Errors

When the “rights” of drug administration are discussed, medication errors must be considered. Medication errors are a major problem for all in health care, regardless of the setting. The National Coordinating Council for Medication Error Reporting and Prevention (2019) defines a **medication error** as “any preventable event that may cause or lead to inappropriate medication use or patient harm while the medication is in the control of the health care professional, patient, or consumer. Such events may be related to professional practice, health care products, procedures, or systems, including prescribing, order communication, product labelling, packaging, and nomenclature, compounding, dispensing, distribution, administration, education, monitoring, and use” (<https://www.nccmerp.org/about-medication-errors>). Both patient-related and system-related factors must always be considered when the medication administration process and the prevention of medication errors are being examined. See [Chapter 6](#) for further discussion of medication errors and their prevention.

EVALUATION

Evaluation occurs after the collaborative plan of care has been implemented. It is a systematic, ongoing, and dynamic part of the nursing process as a result of drug therapy. It includes monitoring the fulfillment of goals and outcome criteria, as well as the patient's therapeutic response to the drug and its adverse effects and toxic effects. Documentation is also an important component of evaluation. The move to EHRs and computer workstations that are located in patient rooms or wherever care is provided enables nurses to document point-of-care and real-time charting. Documentation must be accurate and present a clear and comprehensive picture of the patient's outcome criteria (see Legal & Ethical Principles box).

LEGAL & ETHICAL PRINCIPLES

Nursing Documentation: Use of Technology

In many agencies, the transition to technology carries compelling implications for the nursing profession and the health care system. With the use of electronic health systems, handwriting is no longer needed, thus producing more legible and comprehensive patient records. Technology can take many forms, for example, computerized records, emails, faxes, texts, cellphones, tablets, and recordings. The use of technology carries a higher risk of breach of confidentiality. Nurses have an ethical responsibility to safeguard information obtained in the nurse–patient relationship. Therefore, certain precautions are required to protect privacy and maintain confidentiality:

- Do not disclose or allow access to any personal identification number or password. These are electronic signatures.
- Select a password that cannot be easily deciphered.
- Log off the system when you are not using it or when leaving the screen, to secure the computer and files.
- Protect patient data shown on screens with the use of a screen saver or “sleep,” with the location of the device, or with the use of privacy screens.
- Maintain confidentiality of all electronic data, including print copies of any data.
- Make sure that all discarded print data that contains patient information is shredded.
- Access patient information only if it is essential to provide nursing care for that patient; doing so for purposes other than providing nursing care is a breach of confidentiality.

Retrieved from <https://www.crnbc.ca/standards/lists/standardre-sources/151nursingdocumentation.pdf>.

Evaluation also includes monitoring the implementation of standards for nursing practice. Several standards are in place to help in the evaluation of outcomes of care, such as those established by nursing provincial and territorial governing bodies and the Canadian Council on Health Services Accreditation (CCHSA). Within the CCHSA, guidelines are established

for nursing services, policies, and procedures. The *Canadian Nurses Association Code of Ethics* (2017) and the *Canadian Council for Practical Nurse Regulators (CCPNR) Code of Ethics for Licensed Practical Nurses* (2013), as well as specific provincial/territory medication practice standards are also used in establishing and evaluating standards of care.

EVIDENCE-INFORMED PRACTICE

In this information era, nurses encounter a plethora of health conditions and possible treatments, which include pharmacotherapeutics. In order to stay informed and current, **evidence-informed practice (EIP)**, also referred to as *evidence-based practice*, has emerged in the past 10 years as the “gold standard” for using current, valid, and relevant information when making clinical decisions. When applying EIP, results include more accurate diagnoses, effective and efficient interventions, and improved patient outcomes. Evidence derived from systematic reviews of randomized clinical trials (RCTs) is often considered the strongest level of evidence; however, descriptive and qualitative studies as well as expert opinions may be considered when making decisions. The development of clinical practice guidelines based on scientific evidence helps to integrate the best research evidence into practice. Within this textbook, Evidence in Practice boxes will be used to identify current, clinically relevant research evidence about specific prescription drugs as well as natural health products.

In summary, the nursing process is an ongoing and constantly evolving process (see **Box 1.1**). As it relates to drug therapy, the nursing process is the way in which the nurse gathers, analyzes, organizes, provides, and acts upon data about the patient within the context of prudent nursing care and standards of care. The nurse’s ability to conduct astute assessments, formulate sound nursing diagnoses, establish goals and outcome criteria, correctly administer drugs, and continually evaluate patients’ responses to drugs increases with additional experience and knowledge.

KEY POINTS

- The nursing process is an ongoing, constantly changing, and evolving framework for professional nursing practice. It may be applied to all facets of nursing care, including medication administration.
- The phases of the nursing process include assessment; development of nursing diagnoses; planning, with establishment of goals and outcome criteria; implementation, including patient education; and evaluation.
- Nursing diagnoses are formulated based on objective and subjective data and help to drive the nursing care plan. Nursing diagnoses have been developed through a formal process, including NANDA-I and the International Classification for Nursing Practice, and are constantly updated and revised.

Safe, therapeutic, and effective medication administration is a major responsibility of professional nurses as they apply the nursing process to the care of their patients.

- Nurses are responsible for safe and prudent decision making in the nursing care of their patients, including the provision of drug therapy; in accomplishing this task, they attend to the Ten Rights and adhere to legal and ethical standards related to medication administration and documentation. There are additional rights related to drug administration. These rights deserve worthy consideration before initiation of the medication administration process. Observance of all these rights enhances patient safety and helps avoid medication errors.

EXAMINATION REVIEW QUESTIONS

1. An 86-year-old patient is being discharged to home on digoxin and has little information regarding the medication. Which statement best reflects a realistic outcome of patient teaching activities?
 - a. The patient and patient's daughter will state the proper way to take the drug.
 - b. The nurse will provide teaching about the drug's adverse effects.
 - c. The patient will state all the symptoms of digoxin toxicity.
 - d. The patient will call the prescriber if adverse effects occur.
2. A patient has a new prescription for a blood pressure medication that may cause him to feel dizzy during the first few days of therapy. Which is the best nursing diagnosis for this situation?
 - a. Activity intolerance
 - b. Potential for injury
 - c. Disturbed body image
 - d. Self-care deficit
3. A patient's chart includes an order that reads as follows: digoxin 0.025 mcg once daily at 0900 hours. Which action by the nurse is correct?
 - a. The nurse gives the drug via the transdermal route.
 - b. The nurse gives the drug orally.
 - c. The nurse gives the drug intravenously.
 - d. The nurse contacts the prescriber to clarify the dosage route.
4. The nurse is compiling a drug history for a patient. Which question from the nurse will obtain the most information from the patient?
 - a. "Do you depend on sleeping pills to get to sleep?"
 - b. "Do you have a family history of heart disease?"
 - c. "When you have pain, what do you do to relieve it?"
 - d. "What childhood diseases did you have?"
5. A 77-year-old man who has been diagnosed with an upper respiratory infection tells the nurse that he is allergic to penicillin. What is the most appropriate response by the nurse?
 - a. "That is to be expected—lots of people are allergic to penicillin."
 - b. "This allergy is not of major concern because the drug is given so commonly."
 - c. "What type of reaction did you have when you took penicillin?"
 - d. "Drug allergies don't usually occur in older individuals because they have built up resistance."
6. The nurse is preparing a care plan for a patient who has been newly diagnosed with type 2 diabetes mellitus. Put into correct order the steps of the nursing process, with 1 being the first step and 5 being the last step.
 - a. Implementation
 - b. Planning
 - c. Assessment
 - d. Evaluation
 - e. Nursing diagnoses
7. The nurse is reviewing new medication orders that have been written for a newly admitted patient. Which orders will the nurse need to clarify? *Select all that apply.*
 - a. Metformin (Glucophage®) 1000 mg PO twice a day
 - b. Sitagliptin (Januvia®) 50 mg daily
 - c. Simvastatin (Zocor®) 20 mg PO every evening
 - d. Irbesartan (Avapro®) 300 mg PO once a day
 - e. Docusate (Colace®) as needed for constipation
8. The nurse is reviewing data collected from a medication history. Which of these data are considered objective data? (Select all that apply.)
 - a. White blood cell count 22,000 mm³
 - b. Blood pressure 150/94 mm Hg
 - c. Patient rates pain as an "8" on a 10-point scale
 - d. Patient's wife reports that the patient has been very sleepy during the day
 - e. Patient's weight is 150 lb

CRITICAL THINKING ACTIVITIES

1. What are the crucial responsibilities of the nurse when implementing drug therapy?
2. When medications were administered during the night shift, a patient refused to take his 0200 hours dose of an antibiotic, claiming that he had just taken it. What actions by the nurse would ensure sound decision making and maintain patient safety?
3. During a busy shift, the nurse notes that the chart of a newly admitted patient has a few orders for medications

and diagnostic tests that were taken by telephone by another nurse. The nurse is on the way to the patient's room to do an assessment when the unit secretary says that one of the orders reads as follows: "furosemide, 20 mg, stat." What is the priority action by the nurse? How does the nurse go about giving this drug? Explain the best action to take in this situation.

Pharmacological Principles

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Define common terms used in pharmacology (see Key Terms).
2. Discuss the application of pharmaceutics, pharmacokinetics, and pharmacodynamics in drug therapy.
3. Explain the properties of various drug dosage forms and identify the advantages and disadvantages of the dose forms and drug delivery systems used in drug therapy.
4. Discuss the relevance of the four facets of pharmacokinetics (absorption, distribution, metabolism, excretion) to professional nursing practice, as a result of drug therapy, for a variety of patients and health care settings.
5. Discuss the use of natural drug sources in the development of new drugs.
6. Describe evidence-informed nursing practice.
7. Discuss the role of evidence-informed practice as it relates to pharmacology and medication administration.
8. Develop a collaborative plan of care that considers general pharmacological principles in carrying out drug therapy.

KEY TERMS

Additive effects Drug interactions in which the effect of a combination of two or more drugs with similar actions, administered at the same time, is the action of one plus the action of the other, with the total effect of both drugs being given (compare with *synergistic effects*). (p. 31)

Adverse drug event (ADE) Any undesirable occurrence as a result of administering or failing to administer a prescribed medication. (p. 31)

Adverse drug reaction (ADR) Any unexpected, unintended, undesired, or excessive response to a medication given at therapeutic dosages (compare with *adverse drug event*). (p. 32)

Adverse effects A general term for any undesirable effects that are a direct response to one or more drugs. (p. 30)

Agonists Drugs that bind to and stimulate the activity of one or more receptors in the body. (p. 29)

Allergic reaction An immunological hypersensitivity reaction resulting from the unusual sensitivity of a patient to a medication; a type of adverse drug event. (p. 32)

Antagonists Drugs that bind to and inhibit the activity of one or more receptors in the body; also called *inhibitors*. (p. 29)

Antagonistic effects Drug interactions in which the effect of a combination of two or more drugs is less than the sum of the individual effects of the same drugs given alone; usually caused by an antagonizing (blocking or reducing) effect of one drug on another. (p. 31)

Bioavailability A measure of the fraction of drug administered dose that is delivered unchanged to the systemic circulation (from 0% to 100%). (p. 19)

Biotransformation One or more biochemical reactions involving a parent drug. (p. 24)

Blood-brain barrier The barrier system that restricts the passage of various chemicals and microscopic entities (e.g., bacteria, viruses) between the bloodstream and the central nervous system but allows for the passage of essential substances such as oxygen. (p. 24)

Chemical name The name that describes the chemical composition and molecular structure of a drug. (p. 16)

Contraindication Any condition, especially one that is a result of a disease state or patient characteristic, including current or recent drug therapy, that renders a form of treatment improper or undesirable. (p. 29)

Cytochrome P450 The general name for a large class of enzymes that play a significant role in drug metabolism and drug interactions. (p. 24)

Dependence A state in which there is a compulsive or chronic need, as for a drug. (p. 30)

Dissolution The process by which solid forms of drugs disintegrate in the gastrointestinal tract and become soluble before they are absorbed into the circulation. (p. 17)

Drug Any chemical that affects the physiological processes of a living organism. (p. 16)

Drug actions The processes involved in the interaction between a drug and body cells (e.g., the action of a drug on a receptor protein); also referred to as *mechanisms of action*. (p. 17)

Drug classification A method of grouping drugs; may be based on structure or therapeutic use. (p. 16)

Drug effects The physiological reactions of the body to a drug. They can be therapeutic or toxic and describe how

the body is affected by the drug. The terms *onset*, *peak*, and *duration* are used to describe drug effects (most often referring to therapeutic effects). (p. 27)

Drug-induced teratogenesis The development of congenital anomalies or defects in the developing fetus that are caused by the toxic effects of drugs. (p. 33)

Drug interaction Alteration of the pharmacological or pharmacokinetic activity of a given drug caused by the presence of one or more additional drugs; it is usually a result of effects on the enzymes required for metabolism of the involved drugs. (p. 31)

Duration of action The length of time the concentration of a drug in the blood or tissues is sufficient to elicit a therapeutic response. (p. 27)

Enzymes Protein molecules that catalyze one or more of a variety of biochemical reactions, including those that are a result of the body's physiological processes or drug metabolism. (p. 28)

First-pass effect The initial metabolism in the liver of a drug absorbed from the gastrointestinal tract before the drug reaches the systemic circulation through the bloodstream. (p. 19)

Generic name The name given to a drug approved by Health Canada; also called the *nonproprietary name* or the *official name*. The generic name is much shorter and simpler than the chemical name and is not protected by trademark. (p. 16)

Glucose-6-phosphate dehydrogenase (G6PD) deficiency A hereditary condition in which red blood cells break down when the body is exposed to certain drugs. (p. 32)

Half-life In pharmacokinetics, the time it takes for the blood level of a drug to be reduced by 50%; also called *elimination half-life*. (p. 26)

Idiosyncratic reaction An abnormal and unexpected response to a medication, other than an allergic reaction, that is peculiar to an individual patient. (p. 32)

Incompatibility The characteristic that causes two parenteral drugs or solutions to undergo a reaction when mixed or given together that results in the chemical deterioration of at least one of the drugs. (p. 31)

Intra-arterial Within an artery (e.g., intra-arterial injection). (p. 23)

Intra-articular Within a joint (e.g., intra-articular injection). (p. 23)

Intrathecal Within a sheath (e.g., the theca of the spinal cord), as in an intrathecal injection into the subarachnoid space. (p. 23)

Medication error (ME) Any preventable adverse drug event involving inappropriate medication use by a patient or health care provider; may or may not cause patient harm. (p. 32)

Medication use process The prescribing, dispensing, and administering of medications and the monitoring of their effects. (p. 32)

Metabolite A chemical form of a drug that is the product of one or more biochemical (metabolic) reactions involving the parent drug. Active metabolites are those

that have pharmacological activity of their own, even if the parent drug is inactive (see *prodrug*). Inactive metabolites lack pharmacological activity and are simply drug waste products awaiting excretion from the body (e.g., via the urinary, gastrointestinal, or respiratory tract). (p. 32)

Onset of action The time required for a drug to elicit a therapeutic response after dosing. (p. 27)

Parent drug The chemical form of a drug that is administered before it is metabolized by the body's biochemical reactions into its active or inactive metabolites. A parent drug that is not pharmacologically active is called a *prodrug*. A prodrug is then metabolized to pharmacologically active metabolites. (p. 19)

Peak effect The time required for a drug to reach its maximum therapeutic response in the body. (p. 27)

Peak level The maximum concentration of a drug in the body after administration, usually measured in a blood sample for therapeutic drug monitoring. (p. 28)

Pharmaceutics The science of preparing and dispensing drugs, including dosage form design (e.g., tablets, capsules, injections, patches, etc.). (p. 16)

Pharmacodynamics The study of the biochemical and physiological interactions of drugs at their sites of activity; it examines the properties of drugs and their pharmacological interactions with body protein receptors. (p. 16)

Pharmacoeconomics The study of economic factors impacting the cost of drug therapy. (p. 17)

Pharmacogenetics The study of the influence of genetic factors on drug response, including the nature of genetic aberrations that result in the absence, overabundance, or insufficiency of drug-metabolizing enzymes (also called *pharmacogenomics*; see Chapter 5). (p. 32)

Pharmacognosy The study of drugs that are obtained from natural plant and animal sources. (p. 17)

Pharmacokinetics The study of drug absorption, distribution, metabolism, and excretion (ADME) of drugs. (p. 17)

Pharmacology The broadest term for the study or science of drugs. (p. 16)

Pharmacotherapeutics The treatment of pathological conditions through the use of drugs; also called *therapeutics*. (p. 17)

Prodrug An inactive drug dosage form that is converted to an active metabolite by various biochemical reactions once it is inside the body. (p. 24)

Receptor A molecular structure within or on the outer surface of a cell. Receptors bind specific substances (e.g., drug molecules), and one or more corresponding cellular effects (drug actions) occur as a result of this drug-receptor interaction. (p. 28)

Steady state The physiological state in which the amount of drug removed via elimination is equal to the amount of drug absorbed with each dose. (p. 27)

Substrates Substances (e.g., drugs or natural biochemicals in the body) on which enzymes act. (p. 25)

Synergistic effects Drug interactions in which the effect of a combination of two or more drugs with similar actions is

greater than the sum of the individual effects of the same drugs given alone (compare with *additive effects*). (p. 31)

Therapeutic drug monitoring The process of measuring drug levels to identify a patient's drug exposure and to allow adjustment of dosages with the goals of maximizing therapeutic effects and minimizing toxicity. (p. 28)

Therapeutic effect The desired or intended effect of a particular medication. (p. 28)

Therapeutic index The ratio between the toxic and therapeutic concentrations of a drug. (p. 30)

Thin-film drug delivery Drug products that dissolve in the mouth and are absorbed through the oral mucosa. (p. 18)

Time-release technology A technique used in tablets and capsules such that drug molecules are released in the patient's gastrointestinal tract over an extended period. (p. 18)

Tolerance Reduced response to a drug after prolonged use. (p. 30)

Toxic The quality of being poisonous (i.e., injurious to health or dangerous to life). (p. 17)

Toxicity The condition of producing adverse bodily effects due to poisonous qualities. (p. 28)

Toxicology The study of poisons, including toxic drug effects, and applicable treatments. (p. 17)

Trade name The commercial name given to a drug product by its manufacturer; also called the *proprietary name*. (p. 16)

Trough level The lowest concentration of a drug reached in the body after it falls from its peak level, usually measured in a blood sample for therapeutic drug monitoring. (p. 28)

OVERVIEW

Any chemical that affects the physiological processes of a living organism can broadly be defined as a **drug**. The study or science of drugs is known as **pharmacology**. Pharmacology encompasses a variety of topics, including the following:

- Absorption
- Biochemical effects
- Biotransformation (metabolism)
- Distribution
- Drug history
- Drug origin
- Drug receptor mechanisms
- Excretion
- Mechanisms of action
- Physical and chemical properties
- Physical effects
- Therapeutic (beneficial) effects
- Toxic (harmful) effects

Pharmacology includes the following several subspecialty areas: pharmacetics, pharmacokinetics, pharmacodynamics, pharmacogenetics (pharmacogenomics), pharmacoeconomics, pharmacotherapeutics, pharmacognosy, and toxicology. Knowledge of these areas of pharmacology enables the nurse to better understand how drugs affect humans. Without understanding basic pharmacological principles, the nurse cannot fully appreciate the therapeutic benefits and potential toxicity of drugs.

Throughout the process of its development, a drug will acquire at least three different names. The **chemical name** describes the drug's chemical composition and molecular structure. The **generic name**, or nonproprietary name, is often much shorter and simpler than the chemical name. The generic name is used in most official drug compendiums to list drugs. The **trade name**, or proprietary name, is the drug's registered trademark and indicates that its commercial use is restricted to the owner of the patent for the drug (Fig. 2.1). The patent owner is

usually the manufacturer of the drug. Trade names are generally created by the manufacturer with marketability in mind. For this reason, they are usually shorter and easier to pronounce and remember than generic names. The patent life of a newly discovered drug molecule in Canada is 20 years. This is the length of time from patent approval until patent expiration. Because the research processes for new drug development normally require about 10 years, a drug manufacturer generally has the remaining 10 years for sales profits before patent expiration. A significant amount of these profits serves to offset the multi-million-dollar costs for research and development of the drug.

After the patent for a given drug expires, other manufacturers may legally begin to manufacture *generic* drugs with the same active ingredient. At this point, the drug price usually decreases substantially. Due to the high cost of drugs, many institutions have implemented programs in which one drug in a class of several drugs is chosen as the preferred agent, even though the drugs do not have the same active ingredients. This is called *therapeutic equivalence*. Before one drug can be therapeutically substituted for another, the drugs must have been proven to have the same therapeutic effect on the body.

Drugs are grouped together based on their similar properties. This is known as a **drug classification**. Drugs can be classified by their structure (e.g., β -adrenergic blockers) or by their therapeutic use (e.g., antibiotics, antihypertensives, antidepressants). Within the broad classification, each class may have subclasses—for example, penicillins are a subclass within the group of antibiotics, and β -adrenergic blockers are a subclass within the group of antihypertensives.

Three basic phases of pharmacology—*pharmaceutics*, *pharmacokinetics*, and *pharmacodynamics*—describe the relationship between the dose of a drug given to a patient and the activity of that drug in treating the patient's disorder. **Pharmaceutics** is the study of how various dosage forms influence the way in which the drug affects the body. **Pharmacokinetics**, on the other hand, is the study of what the drug does to the body.

Fig. 2.1 Chemical structure of the common analgesic ibuprofen and the chemical, generic, and trade names for the drug.

Pharmacokinetics is the study of what the body does to the drug, involving the processes of absorption, distribution, metabolism, and excretion of drugs. Pharmacodynamics involves drug–receptor relationships. Figure 2.2 illustrates the three phases of drug activity, starting with the pharmaceutical phase, proceeding to the pharmacokinetic phase, and finishing with the pharmacodynamic phase.

Pharmacotherapeutics (also called *therapeutics*) focuses on the clinical use of drugs to prevent and treat diseases. It defines the principles of **drug actions**—the cellular processes that change in response to the presence of drug molecules. Some drug mechanisms of action are more clearly understood than others. Drugs are categorized into pharmacological classes according to their physiological functions (e.g., β -adrenergic blockers) and primary disease states treated (e.g., anticonvulsants, anti-infectives). Under the mandate of the *Food and Drugs Act and Regulations*, including the *Controlled Drugs and Substances Act* ([Government of Canada, 2019 https://laws-lois.justice.gc.ca/eng/acts/C-38.8/](https://laws-lois.justice.gc.ca/eng/acts/C-38.8/)), Health Canada regulates the approval and clinical use of all drugs, including the requirement of an expiration date on all drugs. This textbook focuses almost exclusively on current Health Canada–approved indications for the drugs discussed in each chapter and on drugs that are currently available in Canada at the time of this writing. Only Health Canada–approved indications are permitted to be described in the manufacturer’s written information, or labelling, for a given drug product. At times, prescribers may elect to use drugs for non–Health Canada–approved indications. This use is known as *off-label prescribing* and often requires seasoned clinical judgement on the part of the prescriber. Evolving over time in clinical practice, previously off-label indications often become Health Canada–approved indications for a given drug.

The study of the adverse effects of drugs and other chemicals on living systems is known as **toxicology**. Toxic effects are often an extension of a drug’s therapeutic action. Therefore, toxicology often involves overlapping principles of both pharmacotherapy and toxicology.

The study of natural (versus synthetic) drug sources (both plants and animals) is called **pharmacognosy**. **Pharmacoeconomics** focuses on the economic aspects of drug therapy.

In summary, pharmacology is a dynamic science that incorporates several different disciplines. Traditionally,

Fig. 2.2 Phases of drug activity. (From McKenry, L. M., Tessier, E., & Hogan, M. (2006). *Mosby’s pharmacology in nursing* (22nd ed.). St. Louis: Mosby.)

chemistry has been seen as the primary basis of pharmacology, but pharmacology also relies heavily on physiology and biology.

PHARMACEUTICS

Different drug dosage forms have different pharmaceutical properties. Dosage form determines the rate at which drug **dis-solution** (dissolving of solid dosage forms and their absorption [e.g., from gastrointestinal tract fluids]) occurs. A drug to be ingested orally may be in either a solid form (tablet, capsule, or powder) or a liquid form (solution or suspension). Table 2.1 lists various oral drug preparations and the relative rate at which they are absorbed. Oral drugs that are liquids (e.g.,

TABLE 2.1 Drug Absorption of Various Oral Preparations

Liquids (e.g., elixirs, syrups)	Fastest ↓ Slowest
Suspension solutions	
Powders	
Capsules	
Tablets	
Coated tablets	
Enteric-coated tablets	

elixirs, syrups) are already dissolved and are usually absorbed more quickly than solid dosage forms. Enteric-coated tablets, by contrast, have a coating that prevents them from being broken down in the acidic pH environment of the stomach and therefore are not absorbed until they reach the more alkaline pH of the intestines. This pharmaceutical property results in slower dissolution and slower absorption.

Particle size within a tablet or capsule can make different dosage forms of the same drug dissolve at different rates, become absorbed at different rates, and thus have different times to onset of action. An example is the difference between micronized fenofibrate and nonmicronized fenofibrate. Micronized fenofibrate, for example, reaches a maximum concentration peak faster than does the nonmicronized formulation. Dosage form design for injectable drugs tends to be more straightforward than that for oral dosage forms. However, some injections are carefully formulated to reduce drug toxicity (e.g., liposomal amphotericin B).

Combination dosage forms contain multiple drugs in one dose. Examples of these combination forms include the cholesterol and antihypertensive medications atorvastatin calcium/amlodipine besylate tablets called Caduet and bacitracin zinc/neomycin sulphate/polymyxin B sulphate/hydrocortisone ointment (generic). There are numerous combination dosage forms; key examples are cited in the various chapters of this book.

A variety of dosage forms exist to provide both accurate and convenient drug delivery systems (Table 2.2). These delivery systems are designed to achieve a desired therapeutic response with minimal adverse effects. Many dosage forms have been developed to encourage patient adherence with the medication regime. **Time-release technology** is a technique used in tablets and capsules such that drug molecules are released in the patient’s gastrointestinal tract over an extended period of time. Use of this technology allows drugs to be released continuously and more slowly into the bloodstream. This results in prolonged drug absorption as well as duration of action. This is the opposite of immediate-release dosage forms, which release all of the active ingredients immediately upon dissolution in the gastrointestinal tract. Extended-release dosage forms are normally easily identified by various capital letter abbreviations attached to their names. Examples of this nomenclature are SR (slow release or sustained release), SA (sustained action), CR

TABLE 2.2 Dosage Forms

Route	Forms
Enteral	Tablets, capsules, oral soluble wafers, pills, time-release capsules, time-release tablets, enteric-coated tablets, elixirs, suspensions, solutions, lozenges or troches, caplets, rectal* suppositories, sublingual or buccal tablets
Parenteral	Injectable forms, solutions, suspensions, emulsions, powders for reconstitution
Topical	Aerosols, ointments, creams, pastes, powders, solutions, foams, gels, transdermal patches, inhalers, rectal* and vaginal suppositories

*Note: Rectal enteral form is inserted into the rectum, while the topical rectal form is applied to the skin around the rectum.

(controlled release), XL (extended length), and XT (extended time). Continuous release is another example. Convenience of administration correlates strongly with patient adherence, because these forms often require fewer daily doses. Extended-release oral dosage forms must not be crushed, as this could cause accelerated release of drug from the dosage form and possible toxicity. Enteric-coated tablets also are not recommended for crushing. This would cause disruption of the tablet coating designed to protect the stomach lining from the local effects of the drug and prevent the drug from being prematurely disrupted by stomach acid. The ability to crush a tablet or open a capsule can facilitate drug administration when patients are unable or unwilling to swallow a tablet or capsule and when medications need to be given through an enteral feeding tube. Capsules, powder, or liquid contents can often be added to soft foods such as applesauce or pudding or dissolved in a beverage. Granules contained in capsules are usually for extended drug release and normally should not be crushed or chewed by the patient. However, they can often be swallowed when sprinkled on a soft food. Consultation with a pharmacist, reading the product literature, or use of another suitable source is necessary if there is any question about whether a drug can be crushed or mixed with specific food or beverages.

An increasingly popular dosage form, **thin-film drug delivery**, refers to drug products that dissolve in the mouth and are absorbed through the oral mucosa. These include orally disintegrating tablets as well as thin wafers that also dissolve in the mouth when contact with liquid occurs. Depending on the specific drug product, the dosage form may dissolve on the tongue, under the tongue, or in the buccal (cheek) pocket.

The specific characteristics of various dosage forms have a large impact on how and to what extent the drug is absorbed. For a drug to work at a specific site in the body it must either be applied directly at that site in an active form or have a way of getting to that site. Oral dosage forms rely on gastric and intestinal enzymes and pH environments to break down the medication into particles that are small enough to be absorbed into the circulation. Once absorbed through the mucosa of the stomach

Fig. 2.3 First-pass effect of a drug by the liver before its systemic availability. (From McKenry, L. M., & Salerno, E. (1995). *Mosby's pharmacology in nursing* (19th ed.). St. Louis: Mosby.)

or intestines, the drug is then transported to the site of action by blood or lymph.

Many topically applied dosage forms work directly on the surface of the skin. Once the drug is applied, it is already in a form that allows it to act immediately. However, with other topical dosage forms, the skin acts as a barrier through which the drug must pass to get to the circulation; once there, the drug is then carried to the site of action (e.g., fentanyl transdermal patches for pain).

Dosage forms that are administered via injection are called *parenteral* forms. They must have certain characteristics to be safe and effective. The arteries and veins that carry drugs throughout the body can easily be damaged if the drug is too concentrated or corrosive. To be administered safely, the pH of injections must be similar to that of the blood. Parenteral dosage forms that are injected intravenously are immediately placed into solution in the bloodstream and do not have to be dissolved in the body. Therefore, 100% absorption is assumed to occur immediately upon intravenous or intra-arterial injection.

PHARMACOKINETICS

A drug's time to onset of action, time to peak effect, and duration of action are all characteristics defined by pharmacokinetics.

Pharmacokinetics is the study of what happens to a drug from the time it is put into the body until the **parent drug** and all metabolites have left the body. Thus, the study of drug absorption, distribution, metabolism, and excretion represents the combined focus of pharmacokinetics.

Absorption

Absorption is the movement of a drug from its site of administration into the bloodstream for distribution to the tissues. **Bioavailability** describes the extent of drug absorption. For example, a drug that is absorbed from the intestine must first pass through the liver before it reaches the systemic circulation (Fig. 2.3). If a large proportion of a drug is chemically changed into inactive metabolites in the liver, then a much smaller amount of drug will pass into the circulation (i.e., will be bioavailable). Such a drug is said to have a high **first-pass effect** (e.g., oral nitrates). First-pass effect reduces the bioavailability of drugs to less than 100%. Drugs administered by the intravenous route are 100% bioavailable because 100% of the drug reaches the systemic circulation. Drugs administered by mouth have reduced bioavailability (less than 100%) because a fraction of the drug reaches the systemic circulation. If two medications have the same bioavailability and same concentration of active ingredient, they are said to be bioequivalent (e.g., a trade-name drug and the same generic drug).

Various factors affect the rate of drug absorption. How a drug is administered, or its route of administration, affects the rate and extent of absorption of that drug. Although a number of dosage formulations are available for delivering medications, they can all be categorized into three basic routes of administration: enteral (gastrointestinal tract), parenteral, and topical.

CASE STUDY

Nitroglycerin Therapy

Four patients with angina are receiving a form of nitroglycerin, as follows:

Charlotte, age 88, takes 10 mg four times a day to prevent angina.

Dale, age 63, takes a form that delivers 0.2 mg/hr, also to prevent angina.

Raissa, age 58, takes 0.4 mg only if needed for chest pain.

Kenneth, age 62, is in the hospital with severe, unstable angina and is receiving 100 mcg/hr.

You may refer to the section on nitroglycerin in [Chapter 24](#) or to a nursing drug handbook to answer these questions.

1. State the route or form of nitroglycerin that each patient is receiving. In addition, specify the generic name(s) and trade name(s) for each form.
2. For each patient, state the rationale for the route or form of drug that was chosen. Which forms have immediate action? Why would this be important?
3. Which form or forms are most affected by the first-pass effect? Explain your answer.

For answers see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Route

Enteral Route. In enteral drug administration, the drug is absorbed into the systemic circulation through the mucosa of the stomach or small or large intestine. The rate of absorption can be altered by many factors. Orally administered drugs are absorbed from the intestinal lumen into the mesenteric blood system and transported by the portal vein to the liver. Once the drug is in the liver, hepatic enzyme systems metabolize it, and the remaining active ingredients are passed into the general circulation. Enteric coating is designed to protect the stomach by having drug dissolution and absorption occur in the intestines. Taking an enteric-coated medication with a large amount of food may cause it to be dissolved by acidic stomach contents and thus reduce intestinal drug absorption and negate the coating's stomach-protective properties. If a large proportion of a drug is chemically processed into inactive metabolites in the liver, then a much less active drug will make it into circulation. Such a drug would have a high first-pass effect. Consequently, the oral dose has to be calculated to compensate for the lower bioavailability. For example, nitroglycerin administered orally undergoes rapid liver metabolism and as a result, has almost no pharmacological effect. If administered sublingually, the drug is absorbed into the system circulation via the rich supply of blood vessels under the tongue and is carried to its site of action prior to circulating through the liver.

The same drug given intravenously will bypass the liver altogether. This prevents the first-pass effect from taking place and therefore allows all of the drug to reach the circulation. For this reason, parenteral doses of drugs with a high first-pass effect are much smaller than enterally (orally) administered doses, yet they produce the same pharmacological response. See [Table 2.3](#) for further discussion of the advantages, disadvantages, and nursing considerations as a result of the different routes of administration.

Many factors can alter the absorption of drugs, including acid changes within the stomach, absorption changes in the intestines, and the presence or absence of food and fluid. Various factors that affect the acidity of the stomach include the time of day; the age of the patient; and the presence and types of medications (e.g., H_2 blockers or proton pump inhibitors [see [Chapter 39](#)]), foods, or beverages.

Anticholinergic drugs slow gastrointestinal transit time (or the time it takes for substances in the stomach to be dissolved for eventual transport to and absorption from the intestines). This may reduce the amount of drug absorption and therapeutic effect for acid-susceptible drugs that become broken down by stomach acids. The presence of food may enhance the absorption of some fat-soluble drugs or of drugs that are more easily broken down in an acidic environment.

Drug absorption may also be altered in patients who have had portions of the small intestine removed because of disease. This condition is known as *short bowel syndrome*. Similarly, bariatric weight loss surgery reduces the size of the stomach. As a result, medication absorption can be altered because stomach contents are delivered to the intestines more rapidly than usual after such surgery. This phenomenon is called *gastric dumping*. Examples of drugs to be taken on an empty stomach and those to be taken with food are provided in [Box 2.1](#). The stomach and small intestine are highly vascularized. When blood flow to the area is decreased, absorption may also be decreased. Sepsis and exercise are examples of circumstances under which blood flow to the gastrointestinal tract is often reduced. In both cases, blood tends to be routed to the heart and other vital organs. In exercise, blood is also routed to the skeletal muscles.

Sublingual and Buccal Routes. Drugs administered by the sublingual route are absorbed rapidly into the highly vascularized tissue under the tongue—the oral mucosa. Sublingual nitroglycerin is an example. Sublingually administered drugs are absorbed rapidly because the area under the tongue has a large blood supply. These drugs bypass the liver and yet are systemically bioavailable. The same applies for drugs administered by the buccal route (the oral mucosa between the cheek and the gum). Through these routes, drugs such as nitroglycerin are absorbed rapidly into the bloodstream and delivered rapidly to their site of action (e.g., coronary arteries).

Parenteral Route. The parenteral route is the fastest route by which a drug can be absorbed, followed by the enteral and the topical routes. *Parenteral* is a general term meaning any route of administration other than the gastrointestinal tract. It most commonly refers to injection. Intravenous injection delivers the drug directly into the circulation, where it is distributed with the blood throughout the body. Drugs given by intramuscular

TABLE 2.3 Routes of Administration and Related Nursing Considerations

Route	Advantages	Disadvantages	Nursing Considerations
Intravenous (IV)	Provides rapid onset (drug delivered immediately to bloodstream); allows more direct control of drug level in blood; gives option of larger fluid volume, therefore diluting irritating drugs; avoids first-pass metabolism.	Higher cost; inconvenience (e.g., not self-administered); irreversibility of drug action in most cases and inability to retrieve medication; risk of fluid overload; greater likelihood of infection; possibility of embolism.	Continuous intravenous infusions require frequent monitoring to be sure that the correct volume and amount are administered and that the drug reaches safe, therapeutic blood levels. Intravenous drugs and solutions must be checked for compatibilities. Intravenous sites are to be monitored for redness, swelling, heat, and drainage—all indicative of complications, such as thrombophlebitis. If intermittent intravenous infusions are used, clearing or flushing of the line with normal saline before and after is generally indicated to keep the intravenous site patent and minimize incompatibilities.
Intramuscular (IM)	Intramuscular injections are good for poorly soluble drugs, which are often given in “depot” preparation form and are then absorbed over a prolonged period; onsets of action differ depending on route. IM route also provides a more immediate onset of action than PO for certain drugs prior to establishment of IV access (e.g., in the emergency department) or if the patient does not require IV access but is vomiting.	Discomfort of injection; inconvenience; bruising; slower onset of action compared to intravenous, although quicker than oral in most situations.	Using landmarks to identify correct intramuscular site is always required and recommended as a nursing standard of care. For adults, the intramuscular site of choice is the ventral gluteal muscle with use of a 38-mm (sometimes 25-mm in extremely thin or emaciated patients) and 20- to 25-gauge needle for aqueous solutions and 18- to 25-gauge needle for viscous or oil-based solutions. However, the deltoid muscle in the upper arm is the site of choice for vaccine administration in adults. Selection of the correct size of syringe and needle is key to safe administration by these routes and is based on thorough assessment of the patient as well as the characteristics of the drug.
Subcutaneous	Drugs given via the subcutaneous route are those that require slow, sustained absorption of a medication, such as insulin and low-molecular-weight heparin solutions. It is also often used in surgery and palliative care for slower absorption of pain medication and prolonged pain relief. The medication is injected under the epidermis into the fat and connective tissue beneath the dermis, where there is less blood flow and consequently a slower, steadier absorption rate compared with that of the intramuscular route.	Discomfort of injection; inconvenience; bruising; slower onset of action compared to intravenous/intramuscular, although quicker than oral in most situations. A wide variety of insulin pens and preloaded heparin syringes with tiny needles are available, enabling the 90-degree angle for injection. Subcutaneous injection into the abdomen should be to the right or left of and 5 cm away from the umbilicus to avoid the umbilical veins and the risk of bleeding.	Using landmarks to identify the correct subcutaneous site is always required and recommended as a nursing standard of care. Common sites for injection include the lateral and posterior aspects of the upper arm and under the greater trochanter of the femur in the thigh and abdominal area. Subcutaneous injections are recommended to be given at a 90-degree angle with a proper-size syringe and needle (4 to 8 mm); in emaciated or extremely thin patients, the subcutaneous angle is 45 degrees. Subcutaneous injections require a 26- to 30-gauge, 8-mm needle. Selection of correct size of syringe and needle is key to safe administration by the subcutaneous route and is based on thorough assessment of the patient as well as the characteristics of the drug.

TABLE 2.3 Routes of Administration and Related Nursing Considerations—cont'd

Route	Advantages	Disadvantages	Nursing Considerations
Oral	Usually easier, more convenient, and less expensive; safer than injection as dosing more likely to be reversible in cases of accidental ingestion (e.g., through induction of emesis, administration of activated charcoal).	Variable absorption; inactivation of some drugs by stomach acid or pH; problems with first-pass effect or presystemic metabolism; greater dependence of drug action on patient variables.	Enteral routes include oral administration and involve a variety of dosage forms (e.g., liquids, solutions, tablets, and enteric-coated pills or tablets). Some medications are recommended to be taken with food, while others are recommended not to be taken with food; it is also suggested that oral dosage forms of drugs be taken with a sufficient amount of fluid, such as 180 to 240 mL of water. Other factors to consider include other medicines being taken at the same time and concurrent use of dairy products or antacids. If oral forms are given via nasogastric tube or gastrostomy tube, tube placement in stomach must be assessed prior to giving the medication and the patient's head is to remain elevated; flushing the nasogastric tube with at least 30 to 60 mL of water before and after giving the drug is recommended to help maintain tube patency and prevent clogging; enteric-coated drugs cannot be crushed and administered via nasogastric tube, while capsules may be opened but granules are not to be crushed for administration.
Sublingual, buccal (subtypes of oral, but more parenteral than enteral)	Absorbed more rapidly from oral mucosa than oral route and leads to more rapid onset of action; avoids breakdown of drug by stomach acid; avoids first-pass metabolism because gastric absorption is bypassed.	Patient may swallow pill instead of keeping under tongue until dissolved; pills often smaller, increasing difficulty to handle. Salivary secretions are necessary for the absorption of sublingual medications.	Drugs given via the sublingual route are to be placed under the tongue; once dissolved, the drug may be swallowed. When using the buccal route, medication is placed between the cheek and gum. Both of these dosage forms are relatively nonirritating; the drug usually is without flavour and is water-soluble.
Rectal	Provides relatively rapid absorption; good alternative when oral route not feasible; useful for local or systemic drug delivery; usually leads to mixed first-pass and non-first-pass metabolism.	Possible discomfort and embarrassment to patient; often higher cost than oral route.	Absorption via this route is erratic and unpredictable, but it provides a safe alternative when nausea or vomiting prevents oral dosing of drugs. The patient must be placed on his left side so that the normal anatomy of the colon allows safe and effective insertion of the rectal dosage form. Suppositories are inserted using a gloved hand or gloved index finger and water-soluble lubricant. Drug must be administered exactly as ordered.
Topical	Delivers medication directly to affected area; decreases likelihood of systemic drug effects.	Sometimes awkward to self-administer (e.g., eye drops); can be messy; usually higher cost than oral route.	Most dermatological drugs are given via topical route in form of a solution, ointment, spray, or drops. Maximal absorption of topical drugs is enhanced with skin that is clean and free of debris; if measurement of ointment is necessary—such as with topical nitroglycerin—application must be done carefully and per instructions (e.g., apply 2.5 cm of ointment). Gloves help minimize cross-contamination and prevent absorption of drug into the nurse's own skin. If the patient's skin is not intact, sterile technique is needed.
Transdermal (subtype of topical)	Provides relatively constant rate of drug absorption; one patch can last 1 to 7 days, depending on drug; avoids first-pass metabolism.	Rate of absorption can be affected by excessive perspiration and body temperature; patch may peel off; cost is higher; used patches must be disposed of safely; may cause skin irritation.	Transdermal drugs should be placed on alternating sites and on a clean, nonhairy, nonirritated area, and only after the previously applied patch has been removed and that area cleansed and dried. Transdermal drugs generally come in a single-dose, adhesive-backed drug application system.
Inhalational	Provides rapid absorption; drug delivered directly to lung tissues, where most of these drugs exert their actions.	Rate of absorption can be too rapid, increasing the risk of exaggerated drug effects; requires more patient education for self-administration; some patients may have difficulty with administration technique.	Inhaled medications are to be used exactly as prescribed and with clean equipment. Instructions need to be given to the patient/family/caregiver regarding medications to be used, as well as the proper use, storage, and safekeeping of inhalers, spacers, and nebulizers. Chapter 10 describes and shows how medications are inhaled.

BOX 2.1 Drugs to Be Taken on an Empty Stomach and With Food

Many medications are taken on an empty stomach with an adequate intake of fluid (180 to 240 mL of water). The nurse must give patients specific instructions regarding those medications *not* to be taken with food but on an empty stomach. Examples include alendronate sodium and risedronate sodium.

Medications that are generally taken with food include carbamazepine, iron and iron-containing products, hydralazine, lithium, propranolol, spironolactone, nonsteroidal anti-inflammatory drugs, and theophylline.

Often, macrolides and oral opioids are taken with food (even though they are specified to be taken with a full glass of water and on an empty stomach) to minimize the gastrointestinal irritation associated with these drugs. If you are in doubt, consult with a licensed pharmacist or a current authoritative drug resource.

injection and subcutaneous injection are absorbed more slowly than those given intravenously. These drug formulations are usually absorbed over a period of several hours; however, some are specially formulated to be released over days, weeks, or months.

Drugs can be injected intradermally, subcutaneously, intravenously, intramuscularly, intrathecally, intra-articularly, or intra-arterially. Physicians and advanced practice nurses usually give **intra-arterial**, **intrathecal**, or **intra-articular** injections. Medications given by the parenteral route have the advantage of bypassing the first-pass effect of the liver. Parenteral administration offers an alternative route of delivery for those medications that cannot be given orally and poses fewer obstacles to absorption. However, drugs that are administered by the parenteral route must still be absorbed into cells and tissues before they can exert their pharmacological effect (see [Table 2.3](#)).

PREVENTING MEDICATION ERRORS

Does IV = PO?

The prescriber writes an order for “furosemide 80 mg IV STAT $\times$ 1 dose” for a patient who is short of breath because of pulmonary edema. When the nurse goes to give the drug, only the PO form is immediately available. Someone must go to the pharmacy to pick up the IV dose. Another nurse says, “Go ahead and give the pill. He needs it fast. It’s all the same!” But is it?

Remember, the oral forms of medications must be processed through the gastrointestinal tract, be absorbed through the small intestine, and undergo the first-pass effect in the liver before the drug can reach the intended site of action. In contrast, IV forms are injected directly into the circulation and can act almost immediately because the first-pass effect is bypassed. The time until onset of action for the PO form is 30 to 60 minutes; for the IV form, this time is 5 minutes. This patient is in respiratory distress, and the immediate effect of the diuretic is desired. In addition, because of the first-pass effect, the available amount of orally administered drug that reaches the site of action would be less than the available amount of intravenously administered drug. Therefore, IV does NOT equal PO! Never change the route of administration of a medication; if questions come up, always check with the prescriber.

Subcutaneous, Intradermal, and Intramuscular Routes.

Injections into the fatty subcutaneous tissues under the dermal layer of the skin are referred to as *subcutaneous* injections. Injections under the more superficial skin layers immediately

underneath the epidermal layer of skin and into the dermal layer are known as *intradermal* injections. Injections given into the muscle beneath the subcutaneous fatty tissue are referred to as *intramuscular* injections. Muscles have a greater blood supply than the skin does; therefore, drugs injected intramuscularly are typically absorbed faster than drugs injected subcutaneously. Absorption from either of these sites may be increased by applying heat to the injection site or by massaging the site. Both methods increase blood flow to the area, thereby enhancing absorption. In contrast, the presence of cold, hypotension, or poor peripheral blood flow compromises the circulation, reducing drug activity by reducing drug delivery to the tissues. Most intramuscularly injected drugs are absorbed over several hours. However, specially formulated long-acting intramuscular dosage forms called *depot drugs* have been designed for slow absorption over a period of several days to a few months or longer. The intramuscular corticosteroid methylprednisolone acetate can provide anti-inflammatory effects for several weeks. The intramuscular contraceptive medroxyprogesterone acetate normally prevents pregnancy for 3 months per dose.

Topical Route. The topical route of drug administration involves application of medications to various body surfaces. Several topical drug delivery systems exist. Topically administered drugs can be applied to the skin, eyes, ears, nose, lungs, rectum, or vagina. Topical application delivers a uniform amount of drug over a longer period, but the effects of the drug are usually slower in their onset and more prolonged in their duration of action as compared with oral or parenteral administration. This can be a problem if the patient begins to experience adverse effects from the drug and a considerable amount of drug has already been absorbed. All topical routes of drug administration avoid first-pass effects of the liver, except for rectal drug administration. Because the rectum is part of the gastrointestinal tract, some drug will be absorbed into the capillaries that feed the portal vein to the liver. However, some drugs will also be absorbed locally into the perirectal tissues. Therefore, rectally administered drugs are said to have a mixed first-pass and non-first-pass absorption and metabolism. [Box 2.2](#) lists the drug routes and indicates whether they are associated with first-pass effects in the liver.

Ointments, gels, and creams are common types of topically administered drugs. Examples include sunscreens, antibiotics, and nitroglycerin ointment. The drawback to their use is that their systemic absorption is often erratic and unreliable. Generally, these medications are commonly used for local effects rather than for systemic effects. Topically applied drugs can also be used in the treatment of illnesses of the eyes, ears, and sinuses. Eye, ear, and nose drops are administered primarily for local effects, whereas nasal sprays may be used for both systemic (e.g., sumatriptan for migraine headaches) and local (e.g., oxymetazoline for nasal sinus congestion). Vaginal medications may also be given for systemic effects (e.g., progestational hormone therapy with progesterone vaginal suppositories) but are more commonly used for local effects (e.g., treatment of vaginal infection with miconazole vaginal cream).

Transdermal Route. Transdermal drug delivery through adhesive drug patches is an elaborate topical route of drug

BOX 2.2 Drug Routes and First-Pass Effects

First-Pass Routes

Hepatic arterial
Oral
Portal venous
Rectal*

Non-First-Pass Routes

Aural (instilled into the ear)
Buccal
Inhaled
Intra-arterial
Intramuscular
Intranasal
Intraocular
Intravaginal
Intravenous
Subcutaneous
Sublingual
Transdermal

*Leads to both first-pass and non-first-pass effects.

administration that is commonly used for systemic drug effects. Some examples of drugs administered by this route are fentanyl (for pain), nitroglycerin (for angina), nicotine (for smoking cessation), estrogen (for menopausal symptoms), and rivastigmine (for Alzheimer's disease). Transdermal patches are usually designed to deliver a constant amount of drug per unit of time for a specified time period. For example, a nitroglycerin patch may deliver 0.2, 0.4, or 0.6 mg/hr over 24 hours, whereas a fentanyl patch may deliver 25 to 100 mcg/hr over a 72-hour period.

This route is suitable for patients who cannot tolerate oral administration and provides a convenient method for drug delivery.

Inhalation Route. Inhalation is another type of topical drug administration. Inhaled drugs are delivered to the lungs as micrometre-sized drug particles. This small drug size is necessary for the drug to be transported to the small, thin-walled air sacs (alveoli) within the lungs. Once the small particles of drug are in the alveoli, drug absorption is rapid via capillary contact. Many pulmonary and other types of diseases can be treated with such topically inhaled drugs. Examples of inhaled drugs are zanamivir, used for the prevention of influenza; salbutamol sulphate, used to treat bronchial constriction in individuals with asthma; and fluticasone propionate, used for its anti-inflammatory properties in patients with asthma and allergies.

Distribution

Distribution refers to the transport of a drug by the bloodstream to its site of action (Fig. 2.4). Drugs are distributed first to those areas with extensive blood supply. Areas of rapid distribution include the heart, liver, kidneys, and brain. Areas of slower distribution include muscle, skin, and fat. Once a drug enters the circulating blood, it is distributed throughout the body. At this point, it is also starting to be eliminated by the organs that

metabolize and excrete drugs—primarily the liver and kidneys. Only drug molecules that are not bound to plasma proteins can freely distribute to extravascular tissue (outside the blood vessels) to reach their site of action. Albumin is the most common blood protein and carries the majority of protein-bound drug molecules (Fig. 2.5). If a given drug binds to albumin, only a limited amount of the drug is *not* bound. This unbound portion is pharmacologically active and is considered “free” drug, whereas “bound” drug is pharmacologically inactive. Certain conditions that cause low albumin levels, such as extensive burns and malnourished states, result in a larger fraction of free (unbound and active) drug. This situation can raise the risk of drug toxicity.

When an individual is taking two medications that are highly protein bound, these medications may compete for binding sites on the albumin protein. Because of this competition, there is more free, unbound drug. This can lead to an unpredictable drug response called a *drug–drug interaction*. A drug–drug interaction occurs when the presence of one drug decreases or increases the action of another drug administered concurrently (i.e., given at the same time).

A theoretical volume, called the *volume of distribution*, is sometimes used to describe the potential volume within various areas where drugs may be distributed. These areas, or *compartments*, may be the blood (*intravascular space*), total body water, body fat, or other body tissues and organs. Typically, a drug that is highly water soluble (hydrophilic) will have a small volume of distribution and high blood concentrations. In contrast, fat-soluble drugs (lipophilic) have a large volume of distribution and low blood concentrations.

There are some sites in the body into which it may be difficult to distribute a drug. These sites typically either have a poor blood supply (e.g., bone) or have physiological barriers that make it difficult for drugs to pass through (e.g., the brain due to the **blood–brain barrier**).

Metabolism

Metabolism, also referred to as **biotransformation**, is the next step after absorption and distribution. It involves the biochemical alteration of a drug into any of the following: an inactive metabolite, a more soluble compound, a more potent metabolite (as in the conversion of an inactive **prodrug** to its active form), or a less active metabolite. The organ most responsible for the biotransformation or metabolism of drugs is the liver. Other metabolic tissues include the skeletal muscles, kidneys, lungs, plasma, and intestinal mucosa.

Hepatic metabolism involves the activity of a large class of enzymes, the **cytochrome P450** enzymes (or simply P450 enzymes), also known as *microsomal enzymes*. These enzymes control a variety of reactions that aid in the metabolism of medications. They are largely targeted against lipid-soluble (*nonpolar* [no charge]) drugs (also known as *lipophilic* [“fat loving”]), which are typically difficult to eliminate. These include most medications. Those medications with water-soluble (*polar* or *hydrophilic* [“water loving”]) molecules may be more easily metabolized by simpler chemical reactions such as hydrolysis. Some of the chemical reactions by which the liver can

Fig. 2.4 Drug transport in the body.

Fig. 2.5 Protein binding of drugs. Albumin is the most prevalent protein in plasma and the most important of the proteins to which drugs bind. Only unbound (free) drug molecules can leave the vascular system. Bound molecules are too large to fit through the pores in the capillary wall.

metabolize drugs are listed in Table 2.4. Drug molecules that are the metabolic targets of specific enzymes are said to be **substrates** for those enzymes. Specific P450 enzymes are identified by standardized number and letter designations. Some of the most common P450 enzymes and their corresponding common drug substrates are listed in Table 2.5.

The biotransformation capabilities of the liver can vary considerably from patient to patient. Age can alter biotransformation (young or older adult patient) as can an unhealthy liver. The various factors that can alter biotransformation include genetics, diseases, and the concurrent use of other medications (Table 2.6). Nurses must be alert to the various factors that can alter transformation with the accumulation of active metabolites and the potential for subsequent toxicity.

Many drugs can inhibit drug-metabolizing enzymes; these drugs are called *enzyme inhibitors*. Decreases or delays in drug metabolism result in the accumulation of the drug and prolongation of the effects of the drug, which can lead to drug toxicity. In contrast, some drugs can stimulate drug metabolism and are called *enzyme inducers*. The presence of these drugs can cause decreased pharmacological effects. This often occurs with the repeated administration of certain drugs that stimulate the formation of new microsomal enzymes.

Excretion

Excretion is the elimination of drugs from the body. Whether they are parent compounds or active or inactive metabolites, all

TABLE 2.4 Mechanisms of Biotransformation

Type of Biotransformation	Mechanism	Result
Oxidation Reduction Hydrolysis	Chemical reactions	Increase polarity of chemical, making it more water soluble and more easily excretable. This often results in a loss of pharmacological activity. Form a less toxic product with less activity.
Combination with another substance (e.g., glucuronide, glycine, sulphate, methyl groups, alkyl groups)	Conjugation (e.g., glucuronidation, glycination, sulfation methylation, alkylation)	

TABLE 2.5 Common Liver Cytochrome P450 Enzymes and Corresponding Drug Substrates

Enzyme	Common Drug Substrates
1A2	amitriptyline, caffeine, theophylline, verapamil, warfarin
2C9	diclofenac, glyburide, ibuprofen, losartan, rosiglitazone, tamoxifen
2C19	amitriptyline, diazepam, phenytoin, proton pump inhibitors, propranolol
2D6	amitriptyline, carvedilol, codeine, fentanyl, fluoxetine, haloperidol, hydrocodone, oxycodone, paroxetine, tricyclic antidepressants, risperidone, timolol
2E1	acetaminophen, ethanol
3A4	azole antifungals, amiodarone, atorvastatin, many chemotherapeutic drugs, diltiazem, ethinyl estradiol, indinavir, lidocaine, lovastatin, macrolides, progesterone, ritonavir, simvastatin, testosterone, verapamil

TABLE 2.6 Examples of Conditions and Drugs That Affect Drug Metabolism

Category	Example	DRUG METABOLISM	
		Increased	Decreased
Diseases	Cardiovascular dysfunction		X
	Kidney insufficiency		X
Condition	Starvation		X
	Obstructive jaundice		X

	phenytoin (P450 inducer)	X	
	rifampin (P450 inducer)	X	

*Whether a person is a poor or high metabolizer depends on the individual genetic makeup.

drugs must eventually be removed from the body. The primary organ responsible for this elimination is the kidney. Two other organs that play an important role in the excretion of drugs are the liver and the bowel. Most drugs are metabolized in the liver by various mechanisms. Therefore, by the time most drugs reach the kidneys, they have undergone extensive biotransformation, where the drug is converted to a less active form, and only a relatively small fraction of the original drug is excreted as the original compound. Other drugs may bypass hepatic metabolism and reach the kidneys in their original form. Drugs that have been metabolized by the liver become more polar and water-soluble. This change makes their elimination by the kidney much easier because the urinary tract is water-based. The kidneys are also capable of metabolizing various drugs, although usually to a lesser extent than the liver.

The actual act of kidney excretion is accomplished through glomerular filtration, active tubular reabsorption, and active tubular secretion. Free (unbound) water-soluble drugs and metabolites go through passive glomerular filtration. Many substances present in the nephrons go through active reabsorption and are taken back up into the circulation and transported away from the kidney. This process is an attempt by the body to retain needed substances. Some substances may also be secreted into the nephron from the vasculature surrounding it. The processes of filtration, reabsorption, and secretion in urinary elimination are shown in Fig. 2.6. Chronic kidney disease affects renal drug elimination. Certain drugs may require dosage adjustments (e.g., dose reductions or less frequent dosing) based on creatinine clearance or glomerular filtration rate.

The excretion of drugs by the intestines is another common route of elimination. This process is referred to as *biliary excretion*. Drugs eliminated by this route are taken up by the liver, released into the bile, and eliminated in the feces. Once certain drugs, such as fat-soluble drugs, are in the bile, they may be reabsorbed into the bloodstream, returned to the liver, and again secreted into the bile. This process is called *enterohepatic recirculation*. Enterohepatically recirculated drugs persist in the body for much longer periods. Less common routes of elimination are the lungs and the sweat, salivary, and mammary glands.

Half-Life

Another pharmacokinetic variable is the **half-life** of a drug. The half-life is the time required for serum drug levels to be reduced by one-half (50%) during the elimination phase. It is a measure

Fig. 2.6 Renal drug excretion. The primary processes involved in drug excretion and the approximate location where these processes take place in the kidney are illustrated. *GFR*, glomerular filtration rate.

TABLE 2.7 Example of a Drug Half-Life Viewed From Different Perspectives						
Perspectives	Changing Values					
Hours after peak concentration	0	8	16	24	32	40
Drug concentration (mg/L)	100 (peak)	50	25	12.5	6.25	3.125 (trough)
Number of half-lives	0	1	2	3	4	5
Percentage of drug removed	0	50	75	88	94	97

of the rate at which the drug is eliminated from the body. For instance, if the peak level of a particular drug is 100 mg/L and the measured drug level in 8 hours is 50 mg/L, then the estimated half-life for that drug is 8 hours. The concept of drug half-life viewed from several different perspectives is shown in Table 2.7.

After about five half-lives, most drugs are effectively removed from the body. At that time approximately 97% of the drug has been eliminated, and what little amount remains is too small to have either therapeutic or toxic effects.

The concept of half-life is clinically useful for determining when a steady state will be reached in a patient taking a drug. **Steady state** refers to the physiological state in which the amount of drug removed via elimination (e.g., kidney clearance) is equal to the amount of drug absorbed with each dose. This physiological plateau phenomenon typically occurs after four to five half-lives of administration of a drug. Therefore, if a drug has an extremely long half-life, it will take much longer for the drug to reach steady-state blood levels. Once steady-state blood levels

have been reached, there are consistent levels of drug in the body that correlate with maximum therapeutic benefits.

Onset, Peak, and Duration

The pharmacokinetic terms *absorption*, *distribution*, *metabolism*, and *excretion* are all used to describe the movement of drugs through the body. The term *drug actions* refers to the processes involved in the interaction between a drug and a cell (e.g., a drug’s action on a receptor). The terms *onset*, *peak*, *duration*, and *trough* are used to describe **drug effects**. *Peak* and *trough* are also used to describe drug concentrations, which are usually measured from blood samples.

A drug’s **onset of action** is the time required for the drug to elicit a therapeutic response. A drug’s **peak effect** is the time required for it to reach its maximal therapeutic response. Physiologically, this point corresponds to increasing drug concentrations at the site of action. The **duration of action** of a drug is the length of time that its concentration is sufficient (without more doses) to elicit a therapeutic response. These concepts are illustrated in Fig. 2.7.

Fig. 2.7 Characteristics of drug effects and relationship to the therapeutic window. *MEC*, minimal effective concentration.

The length of time until the onset, peak of action, and duration of action play an important part in determining the **peak level** (highest blood level) and **trough level** (lowest blood level) of a drug. If the peak blood level is too high, then drug **toxicity** may occur. The toxicity may be mild, such as intensification of the effects of the given drug (e.g., excessive sedation resulting from overdose of a drug with sedative properties). However, it can also be severe (e.g., damage to vital organs due to excessive drug exposure). If the trough blood level is too low, then the drug may not be at therapeutic levels to produce a response. (A common example is antibiotic drug therapy with aminoglycoside antibiotics; see [Chapter 44](#)). In **therapeutic drug monitoring**, peak (highest) and trough (lowest) values are measured to verify adequate drug exposure, maximize therapeutic effects, and minimize drug toxicity. This monitoring is often carried out by a clinical pharmacist working with other members of the health care team.

PHARMACODYNAMICS

Pharmacodynamics is the relationship between drug concentrations and the pharmacological response (actions of the drug). Drug-induced changes in normal physiological functions are explained by the principles of pharmacodynamics. A positive change in a faulty physiological system is called a **therapeutic effect** of a drug. Such an effect is the goal of drug therapy. Understanding the pharmacodynamic characteristics of a drug can aid in assessing the drug's therapeutic effect.

Mechanism of Action

Drugs can produce actions (therapeutic effects) in several ways. The effects of a particular drug depend on the cells or tissue targeted by the drug. Once the drug is at the site of action, it can modify (increase or decrease) the rate at which that cell or

tissue functions, or it can modify the strength of function of that cell or tissue. A drug cannot, however, cause a cell or tissue to perform a function that is not part of its natural physiology.

Drugs can exert their actions in three basic ways: through receptors, enzymes, and nonselective interactions. It should also be noted that not all mechanisms of action have been identified for all drugs. Thus, a drug may be said to have an unknown or unclear mechanism of action, even though it has observable therapeutic effects in the body.

Receptor Interactions

A **receptor** can be defined as a reactive site on the surface or inside of a cell. If the mechanism of action of a drug involves a receptor interaction, then the molecular structure of the drug is critical. Drug–receptor interaction is the joining of the drug molecule with a reactive site on the surface of a cell or tissue. Most commonly, this site is a protein structure within the cell membrane. Once a drug binds to and interacts with the receptor, a pharmacological response is produced ([Fig. 2.8](#)). The degree to which a drug attaches and binds with a receptor is called its **affinity**. The drug with the best “fit” and strongest affinity for the receptor will elicit the greatest response from the cell or tissue. A drug becomes bound to the receptor through the formation of chemical bonds between the receptor on the cell and the active site on the drug molecule. Drugs interact with receptors in different ways, by either eliciting or blocking a physiological response. [Table 2.8](#) describes the different types of drug–receptor interaction.

Enzyme Interactions

Enzymes are substances that catalyze nearly every biochemical reaction in a cell. Drugs can produce effects by interacting with these enzyme systems. For a drug to alter a physiological response in this way, it may either inhibit (more common) or

Fig. 2.8 Drugs act by forming a chemical bond with specific receptor sites, similar to a key and lock—the better the “fit,” the better the response. Drugs with complete attachment and response are called **agonists**. Drugs that attach but do not elicit a response are called **antagonists**. Drugs that attach, elicit some response, and also block other responses are called **partial agonists** or **agonist-antagonists**.

TABLE 2.8 Drug-Receptor Interactions

Drug Type	Action
Agonist	Drug binds to the receptor; there is a response.
Partial agonist (agonist-antagonist)	Drug binds to the receptor; the response is diminished compared with the response elicited by an agonist.
Antagonist	Drug binds to the receptor; there is no response. Drug prevents binding of agonists.
Competitive antagonist	Drug competes with the agonist for binding to the receptor. If it binds, there is no response.
Noncompetitive antagonist	Drug combines with different parts of the receptor and inactivates it; agonist then has no effect.

enhance (less common) the action of a specific enzyme. This process is called *selective interaction*. Drug-enzyme interaction occurs when the drug chemically binds to an enzyme molecule in such a way that it alters (inhibits or enhances) the enzyme's interaction with its normal target molecules in the body.

Nonselective Interactions

Drugs with nonspecific mechanisms of action do not interact with receptors or enzymes. Instead, their main targets are cell membranes and various cellular processes such as metabolic activities. These drugs can either physically interfere with or chemically alter cellular structures or processes. Some cancer drugs and antibiotics have this mechanism of action. By incorporating themselves into the normal metabolic process, they cause a defect in the final product or state. This defect may be an improperly formed cell wall that results in cell death through cell lysis, or it may be the lack of a necessary energy substrate, which leads to cell starvation and death.

PHARMACOTHERAPEUTICS

Before drug therapy is initiated, an end point or expected outcome of therapy should be established. This desired therapeutic

outcome is patient specific, established in collaboration with the patient, and if appropriate, determined with other members of the health care team. Outcomes need to be clearly defined and must be either measurable or observable by patient monitoring. Outcome goals must be realistic and prioritized so that drug therapy begins with interventions that are essential to the patient's well-being. Examples include curing a disease, eliminating or reducing a pre-existing symptom, arresting or slowing a disease process, preventing a disease or other unwanted condition, or otherwise improving quality of life.

Patient therapy assessment is the process by which a health care provider integrates knowledge of medical and drug-related facts with information about a specific patient's medical and social history. Items to be considered in the assessment are drugs currently used (prescription drugs, over-the-counter drugs, natural health products, and illicit drugs), pregnancy and breastfeeding status, and concurrent illnesses that could contraindicate initiation of a given medication. A **contraindication** for a medication is any patient condition, especially a disease state, that makes the use of the medication dangerous for the patient. Careful attention to this assessment process helps to ensure an optimal therapeutic plan. The implementation of a treatment plan can involve several types and combinations of therapies. The type of therapy can be categorized as acute, maintenance, supplemental (or replacement), palliative, supportive, prophylactic, or empirical.

Types of Therapy

Acute Therapy

Acute therapy often involves more intensive drug therapy and is implemented in patients who are acutely ill (those with a rapid onset of illness) or even critically ill. It is often needed to sustain life or treat disease. Examples are the administration of vasopressors to maintain blood pressure and cardiac output after open heart surgery, the use of volume expanders for a patient who is in shock, and intensive chemotherapy for a patient with newly diagnosed cancer.

Maintenance Therapy

Maintenance therapy typically does not eradicate problems the patient may already have but does prevent progression of a disease or condition. It is used for the treatment of chronic illnesses such as hypertension. In the latter case, maintenance therapy maintains the patient's blood pressure within target limits, which prevents certain end-organ damage. Another example of maintenance therapy is the use of oral contraceptives for birth control.

Supplemental Therapy

Supplemental (or replacement) therapy supplies the body with a substance needed to maintain normal function. This substance may be needed because it cannot be made by the body or because it is produced in insufficient quantity. Examples are the administration of insulin to patients with diabetes and of iron to patients with iron-deficiency anemia.

Palliative Therapy

The goal of palliative therapy is to make the patient as comfortable as possible. Palliative therapy focuses on providing patients with

relief from the symptoms, pain, and stress of a serious illness. The goal is to improve quality of life for both the patient and the family. It is typically used in the end stages of an illness, when all attempts at curative therapy have failed; however, it can be provided along with curative treatment. Examples are the use of high-dose opioid analgesics to relieve pain in the final stages of cancer.

Supportive Therapy

Supportive therapy maintains the integrity of body functions while the patient is recovering from illness or trauma. Examples are provision of fluids and electrolytes to prevent dehydration in a patient with influenza who is vomiting and has diarrhea, and administration of fluids, volume expanders, or blood products to a patient who has lost blood during surgery.

Prophylactic Therapy and Empirical Therapy

Prophylactic therapy is drug therapy provided to prevent illness or other undesirable outcome during planned events. An example is the administration of disease-specific vaccines to individuals travelling to geographic areas where a given disease is known to be endemic.

Empirical therapy is based on clinical probabilities. It involves administration of a drug when a certain pathological condition has an uncertain but high likelihood of occurrence based on the patient's initial presenting symptoms. A common example is use of antibiotics active against the organism most commonly associated with a specific infection before the results of the culture and sensitivity reports are available.

Monitoring

Once the appropriate therapy has been implemented, the effectiveness of that therapy—that is, the clinical response of the patient to the therapy—must be evaluated. Evaluating the clinical response requires familiarity with both the drug's intended therapeutic action (beneficial effects) and its unintended possible **adverse effects** (predictable adverse drug reactions). Examples of monitoring include observing for the therapeutic effect of reduced blood pressure following administration of antihypertensive drugs and observing for the toxic effect of leukopenia after administering antineoplastic (cancer chemotherapy) drugs. Another example is performing a pain assessment after giving pain medication. It should be noted that this text generally highlights only the most common adverse effects of a given drug, but it may have many other, less commonly reported adverse effects. Always keep in mind that patients may sometimes experience less common and less readily identifiable adverse drug effects. Consult comprehensive references, a pharmacist, or poison control centre staff whenever there is uncertainty regarding adverse effects that a patient may be experiencing.

All drugs are potentially toxic and can have cumulative effects. Recognizing these toxic effects and knowing their manifestations are integral components of the monitoring process. A drug can accumulate when it is absorbed more quickly than it is eliminated or when it is administered before the previous dose has been metabolized or cleared from the body. Knowledge of the organs responsible for metabolizing and eliminating a drug,

combined with knowledge of how a particular drug is metabolized and excreted, enables the nurse to anticipate problems and treat them appropriately if they occur.

Therapeutic Index

The ratio of a drug's toxic level to the level that provides therapeutic benefits is referred to as the drug's **therapeutic index**. The safety of a drug therapy is determined by this index. A low therapeutic index means that the difference between a therapeutically active dose and a toxic dose is small. This type of drug has a greater likelihood than other drugs of causing an adverse reaction, and therefore its use requires closer monitoring. Examples of such drugs are warfarin and digoxin. In contrast, a drug with a high therapeutic index, such as amoxicillin, is rarely associated with overdose events.

Drug Concentration

All drugs reach a certain concentration in the blood. Drug concentrations can be an important tool for evaluating the clinical response to drug therapy. Certain drug levels are associated with therapeutic responses, whereas other drug levels are associated with toxic effects. Toxic drug levels are typically seen when the body's normal mechanisms for metabolizing and excreting drugs are compromised. This commonly occurs when liver and kidney functions are reduced or when the liver or kidneys are immature (as in neonates). Dosage adjustments should be made in these patients to appropriately accommodate their reduced metabolism and excretion.

Patient's Condition

Another patient-specific factor to be considered is the patient's weight (e.g., obese or weakness or wasting of the body), presence of a critical illness, and the patient's concurrent diseases or other medical conditions. A patient's response to a drug may vary greatly depending on physiological and psychological demands. Disease of any kind, infection, cardiovascular function, and gastrointestinal function are just a few of the physiological elements that can alter a patient's therapeutic response. Stress, depression, and anxiety can also be important psychological factors affecting response.

Tolerance and Dependence

To provide optimal drug therapy, it is important to understand and differentiate between tolerance and dependence. **Tolerance** is a decreasing response to repeated drug doses. **Dependence** is a physiological or psychological need for a drug. Physical dependence is the physiological need for a drug to avoid physical withdrawal symptoms (e.g., tachycardia in a patient dependent on opioids). Psychological dependence, also known as *addiction*, is the obsessive desire for the effects of a drug. Addiction often involves the recreational use of drugs such as benzodiazepines, narcotics, and amphetamines but can also occur as a result of chronic persistent pain. See [Chapter 18](#) for further discussion of dependence and addiction.

Interactions

Drugs may interact with other drugs, with foods, or with agents administered as part of laboratory tests. Knowledge

TABLE 2.9 Examples of Drug Interactions and Their Effects on Pharmacokinetics

Pharmacokinetic Phase	Drug	Mechanism	Result
Absorption	Antacid with levofloxacin hemihydrate	Antacids bind to the levofloxacin hemihydrate, preventing adequate absorption	Decreased effectiveness of levofloxacin hemihydrate, resulting from decreased blood levels (harmful)
Distribution	warfarin with amiodarone	Both drugs compete for protein-binding sites	Higher levels of free (unbound) warfarin and amiodarone, which increases actions of both drugs (harmful)
Metabolism	erythromycin with cyclosporine	Both drugs compete for the same liver enzymes	Decreased metabolism of cyclosporine, possibly resulting in toxic levels of cyclosporine (harmful)
Excretion	amoxicillin with probenecid	Inhibits the secretion of amoxicillin into the kidneys	Elevates and prolongs the plasma levels of amoxicillin (can be beneficial)

of drug interactions is vital for the appropriate monitoring of drug therapy. The more drugs a patient receives, the more likely that a drug interaction will occur. This is especially true in older adults, who typically have an increased sensitivity to drug effects and are receiving several medications. In addition, over-the-counter medications and natural health products can interact significantly with prescribed medications. Food also can interact significantly with certain drugs. See [Table 2.9](#) for the most common food and drug interactions.

Alteration of the action of one drug by another is referred to as **drug interaction**. A drug interaction can either increase or decrease the actions of one or both involved drugs. Drug interactions can be either beneficial or harmful. Numerous drug interactions can occur and have been reported. Please note that only those drug interactions that are considered to be significant—with at least a high probability of occurring—or those that require dosage or therapy adjustment are discussed in this textbook. An authoritative resource may be used as a means of exploring all possible drug interactions.

Concurrently administered drugs may interact with each other and alter the pharmacokinetics of one another during any of the four phases of pharmacokinetics: absorption, distribution, metabolism, or excretion. [Table 2.9](#) provides examples of drug interactions during each of these phases. Most commonly, drug interactions occur when there is competition between two drugs for metabolizing enzymes, such as the cytochrome P450 enzymes listed in [Table 2.5](#). As a result, the speed of metabolism of one or both drugs may be enhanced or reduced. This change in metabolism of one or both drugs can lead to subtherapeutic or toxic drug actions.

Many terms are used to categorize drug interactions. When two drugs with similar actions are given together, they can have **additive effects**. This means that the combined effects of the drugs combine such that if two drugs of similar action are administered at the same time, the action of one plus the action of the other results in the total effect of both drugs being given. This can be represented by $1 + 1 = 2$ (summation of effects). Examples are the many combinations of analgesic products, such as acetylsalicylic acid and opioid combinations (acetylsalicylic acid and codeine) and acetaminophen and opioid combinations (acetaminophen and oxycodone). The total analgesic effect of both drugs results. Often drugs are used together for

their additive effects so that smaller doses of each drug can be given.

Synergistic effects occur when the action of one drug enhances the action of another. The two drugs administered together interact in such a way that their combined effects are greater than the sum of the effects for each drug given alone ($1 + 1 = \text{greater than } 2$). The combination of hydrochlorothiazide with lisinopril for the treatment of hypertension is one example. It is important to remember that synergistic effects can also result in dangerous effects—for example, the combination of alcohol and acetaminophen may result in liver damage.

Antagonistic effects are said to occur when the combination of two drugs results in drug effects that are less than the sum of the effects for each drug given separately ($1 + 1 = \text{less than } 2$). An example of this type of interaction occurs when the antibiotic ciprofloxacin is given simultaneously with antacids, vitamins, iron, or dairy products. These drugs reduce the absorption of ciprofloxacin and lead to decreased effectiveness of the antibiotic.

Incompatibility is a term most commonly used to describe parenteral drugs. Drug incompatibility occurs when two parenteral drugs or solutions are mixed together, and the result is a chemical deterioration of one or both of the drugs. The combination of two such drugs usually produces a precipitate, haziness, or colour change in the solution. Before administering any intravenous medication, the nurse must always inspect the bag for precipitate. If the solution appears cloudy or if visible flecks are seen, the bag must not be given to the patient and must be discarded. An example of incompatible drugs is the combination of parenteral furosemide and heparin sodium.

Adverse Drug Events

The recognition of the potential hazards and actual detrimental effects of medication use is a topic that continues to receive much attention in the literature. This focus has contributed to an increasing body of knowledge regarding this topic as well as the development of new terminology. Health care institutions are also under increasing pressure to develop effective strategies for preventing adverse effects of drugs.

Adverse drug event (ADE) is a broad term for any undesirable occurrence involving medications. A similarly broad term seen in the literature is *drug misadventure*. Patient

outcomes associated with ADEs vary from no effects or mild discomfort to life-threatening complications, permanent disability, disfigurement, or death. ADEs can be preventable (see discussion of medication errors [MEs] later in [Chapter 6](#)) or nonpreventable. Fortunately, many ADEs result in no measurable patient harm. ADEs can be both external and internal. The most common causes of ADEs external to the patient are errors by caregivers (both professional and nonprofessional) and malfunctioning of equipment (e.g., intravenous infusion pumps). An ADE can be internal, or patient induced, such as when a patient fails to take medication as prescribed or drinks alcoholic beverages that he was advised not to consume while taking a given medication. An impending ADE that is noticed before it actually occurs is considered a potential ADE (and appropriate steps should be taken to avoid such a “near miss” in the future). A less common situation, but one still worth mentioning, is an adverse drug withdrawal event. This is an adverse outcome associated with discontinuation of drug therapy, such as hypertension caused by abruptly discontinuing blood pressure medication or return of infection caused by stopping antibiotic therapy too soon.

The two most common broad categories of ADEs are medication errors and adverse drug reactions. A **medication error (ME)** is a preventable situation in which there is a compromise in the Ten Rights of medication use: right patient, right drug, right time, right route, right dose, right documentation, right reason, right patient education, right to refuse, and right assessment or evaluation. (See Preventing Medication Errors box on page 23.) MEs are more common than adverse drug reactions. MEs occur during the prescribing, dispensing, administering, or monitoring of drug therapy. These four phases are collectively known as the **medication use process**. See [Chapter 6](#) for further discussion of MEs.

An **adverse drug reaction (ADR)** (see [Chapter 6](#)) is any reaction to a drug that is unexpected and undesirable and occurs at therapeutic drug dosages. ADRs may or may not be caused by MEs. ADRs may result in hospital admission, prolongation of hospital stay, change in drug therapy, initiation of supportive treatment, or complication of a patient's disease state. ADRs are caused by processes inside the patient's body. They may or may not be preventable, depending on the situation. Mild ADRs (e.g., drug adverse effects—see later in this chapter) usually do not require a change in the patient's drug therapy or other interventions. More severe ADRs, however, are likely to require changes to a patient's drug regimen. Severe ADRs can be permanently or significantly disabling, life threatening, or fatal. They may require or prolong hospitalization, lead to organ damage (e.g., to the liver, kidneys, bone marrow, skin), cause congenital anomalies, or require specific interventions to prevent permanent impairment or tissue damage.

ADRs that are specific to drug groups are discussed in the corresponding drug chapters in this book. Four general categories are discussed here: pharmacological reaction, hypersensitivity (allergic) reaction, idiosyncratic reaction, and drug interaction.

A pharmacological reaction is an extension of the drug's normal effects in the body. For example, a drug that is used to lower blood pressure in a patient causes a pharmacological ADR when it lowers the blood pressure to the point at which the patient becomes unconscious.

Pharmacological reactions that result in adverse effects are predictable, well-known ADRs resulting in minor or no changes in patient management. They have predictable frequency and intensity, and their occurrence is a result of the dose. They also usually resolve with a change in dose or discontinuation of drug therapy.

An **allergic reaction** (also known as a *hypersensitivity reaction*) involves the patient's immune system. Immune system proteins known as *immunoglobulins* recognize the drug molecule, its **metabolite(s)**, or another ingredient in a drug formulation as a dangerous foreign substance. At this point, an immune response may occur in which immunoglobulin proteins bind to the drug substance to neutralize the drug. Various chemical mediators, such as histamine, as well as cytokines and other inflammatory substances (e.g., prostaglandins [[Chapter 38](#)]), usually are released during this process. This response can range from mild reactions such as skin erythema or mild rash to severe or even life-threatening reactions such as constriction of bronchial airways and tachycardia.

It can be assumed throughout this textbook that use of any drug is contraindicated if the patient has a known allergy to that specific drug product. Allergy information may be reported by patients as part of their history or may be observed by health care providers during a patient encounter. In either case, every effort must be made to document as fully as possible the name of the drug product and the degree and details of the adverse reaction that occurred—for example, “Penicillin; skin rash, pruritus” or “Penicillin; urticaria and anaphylactic shock requiring emergency intervention.”

In more extreme cases of disease or injury (e.g., cancer, snakebite), it may be deemed reasonable to administer a given drug despite a reported allergic or other adverse reaction. In such cases, the patient will likely be premedicated with additional medications (e.g., acetaminophen [Tylenol®], diphenhydramine [Benadryl®], prednisone) in an attempt to control any adverse reactions that may occur.

An **idiosyncratic reaction** is not the result of a known pharmacological property of a drug or patient allergy but instead occurs unexpectedly in a particular patient. Such a reaction is a genetically determined abnormal response to ordinary doses of a drug. The study of such traits, which are solely revealed by drug administration, is called **pharmacogenetics** (see [Chapter 5](#)). Idiosyncratic drug reactions are usually caused by a deficiency or excess of drug-metabolizing enzymes. Many pharmacogenomic disorders exist, for example, **glucose-6-phosphate dehydrogenase (G6PD) deficiency**.

People who lack proper levels of G6PD have idiosyncratic reactions to a wide range of drugs (see Ethnocultural Implications box). There are more than 80 variations of the disease, and all produce some degree of drug-induced hemolysis.

ETHNOCULTURAL IMPLICATIONS

Glucose-6-Phosphate Dehydrogenase Deficiency

Globally, glucose-6-phosphate dehydrogenase (G6PD) deficiency is the most common enzyme defect. It is found predominantly in African, Middle Eastern, and South Asian populations. G6PD is an enzyme found in abundant amounts in the tissues of most individuals. It reduces the risk of hemolysis of red blood cells when they are exposed to oxidizing drugs such as acetylsalicylic acid. G6PD deficiency is inherited as an X-linked, recessive condition; consequently, the condition usually occurs in boys. Drugs to avoid in patients with G6PD deficiency are nitrofurantoin, primaquine, probenecid, and sulfonamides.

The final type of ADR is due to drug interaction. As described earlier, drug interaction occurs when the simultaneous presence of two (or more) drugs in the body produces an unwanted effect. This unwanted effect can result when one drug either accentuates or reduces the effects of another drug. Some drug interactions are intentional and beneficial (see Table 2.9). However, most clinically significant drug interactions are harmful. Drug interactions specific to drugs are discussed in detail in the chapters dealing with those drugs.

Other Drug Effects

Other drug-related effects that must be considered during therapy are teratogenic, mutagenic, and carcinogenic effects. These can result in devastating patient outcomes and in many instances can be prevented by appropriate monitoring.

Teratogenic effects of drugs or other chemicals result in structural defects in the fetus. Compounds that produce such effects are called *teratogens*. Prenatal development involves a delicate program of interrelated embryological events. Any significant disruption in this process of embryogenesis can have a teratogenic effect. Drugs that are capable of crossing the placenta can cause **drug-induced teratogenesis**. Drugs administered during pregnancy can produce different types of congenital anomalies. The period during which the fetus is most vulnerable to teratogenic effects begins with the third week of development and usually ends after the third month. Chapter 4 describes the Health Canada safety classification for drugs used by pregnant women.

Mutagenic effects are permanent changes in the genetic composition of living organisms and consist of alterations in the chromosome structure, the number of chromosomes, or the genetic code of the deoxyribonucleic acid (DNA) molecule. Drugs that are capable of inducing mutations are called *mutagens*. Radiation, viruses, chemicals (e.g., industrial chemicals such as benzene), and drugs can all act as mutagenic agents in human beings. Drugs that affect genetic processes are active primarily during cell reproduction (mitosis).

Carcinogenic effects are the cancer-causing effects of drugs, other chemicals, radiation, and viruses. Agents that produce such effects are called *carcinogens*. Some exogenous causes of cancer are listed in Box 2.3.

PHARMACOGNOSY

Plants are an important and long-established resource of preparations used in medicine. *Pharmacognosy* involves the process

BOX 2.3 Exogenous Carcinogens

- Food-production procedures
- Oncogenic viruses
- Smoking

of identifying medicinal plants and their ingredients, pharmacological effects, and therapeutic efficacy. Although many drugs in current use are synthetically derived, most were first isolated in nature. For example, almost all major groups of wild plants in Canada have edible members that are reported to have been used by indigenous people. Algae (e.g., seaweed), fungi (e.g., mushrooms), and roots are commonly used for their medicinal purposes. The four main sources for drugs are plants, animals, minerals, and laboratory synthesis. Plants provide many weak acids and weak bases (alkaloids) that are useful and potent drugs. Alkaloids are more common, including atropine (belladonna plant), caffeine (coffee bean), and nicotine (tobacco leaf). Animals are the source of many hormone drugs. Conjugated estrogens are derived from the urine of pregnant mares, hence the drug trade name Premarin. *Equine* is the term used for any horse-derived drug. Insulin comes from two sources: pigs (porcine) and humans. Human insulin is now far more commonly used than animal insulins thanks to the use of recombinant DNA techniques. Heparin sodium is another commonly used drug that is derived from pigs (porcine heparin). Some common mineral sources of currently used drugs are salicylic acid, aluminum hydroxide, and sodium chloride.

PHARMACOECONOMICS

Pharmacoeconomics is the study of the economic factors influencing the cost of drug therapy. One example is performing a cost-benefit analysis of one antibiotic versus another when competing drugs are considered for inclusion in a hospital formulary. Such studies typically examine treatment outcomes data (e.g., how many patients recovered and how soon) in relation to the comparative total costs of treatment with the drugs in question.

TOXICOLOGY

The study of poisons and unwanted responses to both drugs and other chemicals is known as *toxicology*. Toxicology is the science of the adverse effects of chemicals on living organisms. Clinical toxicology deals specifically with the care of patients who have been poisoned. Poisoning can result from a variety of causes, ranging from drug overdose to ingestion of household cleaning agents to snakebite. Poison control centres are health care institutions equipped with sufficient personnel and

information resources to recommend appropriate treatment for poisoning. They are usually staffed with specially trained pharmacists, nurses, and physicians who triage incoming calls and refer complex cases to clinical toxicologists.

Effective treatment for poisoning is based on a system of priorities, the first of which is to preserve the patient's vital functions by maintaining airway, breathing, and circulation. The second priority is to prevent absorption of the toxic agent or speed its elimination from the body using one or more clinical methods available. Several common poisons and their specific antidotes are listed in [Table 2.10](#).

SUMMARY

A thorough understanding of pharmacological principles of pharmacokinetics, pharmacodynamics, pharmacotherapeutics, and toxicology is essential in drug therapy and for safe, quality nursing practice. Medications may be helpful in treating disease, but unless the nurse has an adequate, up-to-date knowledge base and clinical skills and engages in critical thinking and good decision making, any treatment may become harmful. Application of pharmacological principles enables the nurse to provide safe and effective drug therapy

TABLE 2.10 Common Causes of Poisoning and Their Antidotes

Substance	Antidote
Acetaminophen	Acetylcysteine
Organophosphates (e.g., insecticides)	Atropine
Tricyclic antidepressants, quinidine	Sodium bicarbonate
Iron salts	Deferoxamine
Digoxin and other cardiac glycosides	Digoxin antibodies
Ethylene glycol (e.g., automotive antifreeze solution), methanol	Ethanol (same as alcohol used for drinking), administered intravenously
Benzodiazepines	Flumazenil
β -blockers	Glucagon
Opiates, opioid drugs	Naloxone
Carbon monoxide (by inhalation)	Oxygen (at high concentrations), known as bariatric therapy

while always acting on behalf of the patient and respecting the patient's rights. Nursing considerations associated with various routes of drug administration are summarized in [Table 2.3](#).

KEY POINTS

- The following drug therapy definitions are important to remember: *pharmacology*—the study or science of drugs; *pharmacokinetics*—the study of drug distribution among various body compartments after a drug has entered the body, including the phases of absorption, distribution, metabolism, and excretion; and *pharmaceutics*—the science of dosage form design.
- The nurse's role in drug therapy and the nursing process is more than just memorizing the names of drugs, their uses, and associated interventions. It involves a thorough comprehension of all aspects of pharmaceutics, pharmacokinetics, and pharmacodynamics and the sound application of this

drug knowledge to a variety of clinical situations. Refer to [Chapter 1](#) for more detailed discussion of drug therapy as it relates to the nursing process.

- Drug actions are a result of the pharmacological, pharmaceutical, pharmacokinetic, and pharmacodynamic properties of a given medication, and each of these has a specific influence on the overall effects produced by the drug in a patient.
- Selection of the route of administration is based on patient variables and the specific characteristics of the drug.
- Nursing considerations vary depending on the drug as well as the route of administration.

EXAMINATION REVIEW QUESTIONS

1. An older adult woman took a prescription medicine to help her to sleep; however, she felt restless all night and did not sleep at all. The nurse recognizes that this woman has experienced which type of reaction or effect?
 - a. Allergic reaction
 - b. Idiosyncratic reaction
 - c. Mutagenic effect
 - d. Synergistic effect
2. While caring for a patient with cirrhosis or hepatitis, the nurse knows that abnormalities in which phase of pharmacokinetics may occur?
 - a. Absorption
 - b. Distribution
 - c. Metabolism
 - d. Excretion
3. A patient who has advanced cancer is receiving opioid medications around the clock to “keep him comfortable” as he nears the end of his life. Which term best describes this type of therapy?
 - a. Palliative therapy
 - b. Maintenance therapy
 - c. Supportive therapy
 - d. Supplemental therapy
4. The nurse is giving medications to a patient in heart failure. The intravenous route is chosen instead of the intramuscular route. Which patient factor most influences the decision about which route to use?
 - a. Altered biliary function
 - b. Increased glomerular filtration
 - c. Reduced liver metabolism
 - d. Diminished circulation

5. A patient has just received a prescription for an enteric-coated stool softener. When teaching the patient, the nurse should include which statement?
 - a. “Take the tablet with 60 to 90 mL of orange juice.”
 - b. “Avoid taking all other medications with any enteric-coated tablet.”
 - c. “Crush the tablet before swallowing if you have problems with swallowing.”
 - d. “Be sure to swallow the tablet whole without chewing it.”
6. Each statement describes a phase of pharmacokinetics. Put the statements in order, with 1 indicating the phase that occurs first and 4 indicating the phase that occurs last.
 - a. Enzymes in the liver transform the drug into an inactive metabolite.
 - b. Drug metabolites are secreted through passive glomerular filtration into the renal tubules.
 - c. A drug binds to the plasma protein albumin and circulates through the body.
 - d. A drug moves from the intestinal lumen into the mesenteric blood system.
7. A drug that delivers 500 mg has a half-life of 4 hours. How many milligrams of drug will remain in the body after 1 half-life?
8. The nurse is reviewing the various forms of topical medications. Which of these are considered topical medications? (Select all that apply.)
 - a. Rectal ointment for hemorrhoids
 - b. Eye drops for inflammation
 - c. Sublingual tablet for chest pain
 - d. Inhaled medication for asthma
 - e. Intradermal injection for tuberculosis testing

CRITICAL THINKING ACTIVITIES

1. A patient tells the nurse during the assessment that he experiences some “strange” problem with drug metabolism that he was born with, so he is not to take certain medications. What type of disorder is this patient referring to, and what are the problems it can cause in the patient when specific medications are taken? What is the nurse’s priority action when a patient shares this information?
 2. Charles is admitted to the trauma unit with multisystem injuries from an automobile accident. He arrived at the unit with multiple abnormal findings, including shock from blood loss, decreased cardiac output, and urinary output of less than 30 mL/hr. Which route of administration would you expect to be the best choice for this patient? Explain your answer.
 3. You are administering medications to a patient who had an enteral tube inserted 2 days earlier for continuous feedings. As you review the medication list, you note that one drug is an enteric-coated tablet ordered to be given twice a day. What is the best action regarding giving this drug to this patient?
- For answers see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Legal and Ethical Considerations

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Briefly discuss the important components of drug legislation at the provincial and federal levels.
2. Provide examples of how drug legislation impacts drug therapy, professional nursing practice, and the nursing process.
3. Discuss the various categories of controlled substances, and provide specific drug examples in each category.
4. Identify the process involved in the development of new drugs, including the investigational new drug application, the phases of investigational drug studies, and the process for obtaining informed consent.
5. Discuss the ethical principles of drug administration and how they apply to pharmacology and the nursing process.
6. Identify the principles involved in making an ethical decision.
7. Develop a collaborative care plan that addresses the legal and ethical care of patients, with a specific focus on drug therapy and the nursing process.

KEY TERMS

Bias Any systematic error in a measurement process. One common effort to avoid bias in research studies involves the use of blinded study designs. (p. 41)

Benzodiazepines and Other Targeted Substances

Regulations Implemented in 2000, these regulations specify the requirements for producing, assembling, importing, exporting, selling, providing, transporting, delivering, or destroying benzodiazepines and other targeted substances. (p. 39)

Blinded investigational drug study A research design in which subjects in the study are purposely made unaware of whether the substance they are administered is the drug under study or a placebo. This method serves to minimize bias on the part of research subjects in reporting their body's responses to investigational drugs. (p. 41)

Canada Health Act Canada's federal legislation for publicly funded health care insurance. (p. 42)

Controlled Drugs and Substances Act (CDSA) A Health Canada act that makes it a criminal offence to possess, traffic, produce, import, or export controlled substances. (p. 39)

Controlled substances Any drugs listed on one of the "schedules" of the *Controlled Drugs and Substances Act* (also called a *scheduled drug* if it is an item under the Food and Drug Regulations Part G). (p. 39)

Double-blind, investigated drug study A research design in which both the study investigator(s) and the subjects are purposely made unaware of whether the substance administered to a given subject is the drug under study or a placebo. This method minimizes bias on the part of both the investigator and the subject. (p. 41)

Drug Identification Number (DIN) A computer-generated number assigned by Health Canada, placed on the label of

prescription and over-the-counter drug products that have been evaluated by the Therapeutic Products Directorate (TPD) and approved for sale in Canada. (p. 40)

Ethics A set of principles, rights and responsibilities, and duties governing the moral values, beliefs, actions, and behaviours of human conduct and the rules and principles that ought to govern them. (p. 44)

Food and Drugs Act The main piece of drug legislation in Canada that protects consumers from contaminated, adulterated, and unsafe drugs and labelling practices; also addresses appropriate advertising and selling of drugs, foods, cosmetics, and therapeutic devices. (p. 38)

Food and Drug Regulations An adjunct to the *Food and Drugs Act*, these regulations clarify terms used in the Act and state the processes that companies must carry out to comply with the Act in terms of importing, preparing, treating, processing, labelling, advertising, and selling foods, drugs, cosmetics, natural health products including herbal products, and medical devices. (p. 38)

Informed consent Written permission obtained from a patient consenting to a specific procedure (e.g., receiving an investigational drug), after the patient has been given information regarding the procedure deemed necessary for the patient to make a sound or "informed" decision. (p. 40)

Investigational new drug (IND) A drug not yet approved for marketing by the Therapeutic Products Directorate of Health Canada but available for use in experiments to determine its safety and efficacy. (p. 40)

Investigational new drug application An application that must be submitted to the Therapeutic Products Directorate of Health Canada before a drug can be studied in humans. (p. 40)

Malpractice A special type of negligence or the failure of a professional or individual with specialized education and training to act in a reasonable and prudent way. (p. 43)

Negligence The failure to act in a reasonable and prudent manner or failure of the nurse to give the care that a reasonably prudent (cautious) nurse would render or use under similar circumstances. (p. 43)

New drug submission The type of application that a drug manufacturer submits to the Therapeutic Products Directorate of Health Canada following successful completion of required human research studies. (p. 41)

Notice of Compliance A notification issued when Health Canada decides that a drug and its manufacturing process are safe and effective, allowing the pharmaceutical company to sell the product by prescription to the Canadian population. (p. 40)

Placebo An inactive (inert) substance (e.g., saline, distilled water, starch, sugar) that is not a drug but is formulated to resemble a drug for research purposes. (p. 41)

Precursor Control Regulations A scheme intended to allow Canada to fulfill its international obligations and meet its domestic needs with respect to the monitoring and control of precursor chemicals such as methamphetamine, gamma-hydroxybutyric acid (GHB), and other drugs listed in Schedules I, II, and III of the *Controlled Drugs and Substances Act*, across Canadian borders and within Canada. (p. 39)

Priority Review of Drug Submissions A Health Canada policy that allows for earlier review of drug products for serious, life-threatening, or severely debilitating diseases or conditions for which there is no effective drug on the Canadian market. (p. 40)

Special Access Programme A program that allows health care providers to apply for access to drugs currently unavailable for sale in Canada. (p. 41)

LEGAL CONSIDERATIONS

Prescription drug use is vital to treating and preventing illness. However, due to safety reasons, its use is regulated and enforced by several different agencies, including Health Canada, the Royal Canadian Mounted Police (RCMP), and individual provincial or territorial laws. Traditionally, only medical doctors and doctors of osteopathy had the privilege of prescribing medications. Dentists and podiatrists are also allowed to prescribe medications so long as it is within the scope of their practice. In some provinces or territories, other health care providers may also prescribe, including licensed physician's assistants, pharmacists, and nurse practitioners. In 2015, the Canadian Nurses Association (CNA, 2015) created a framework for RN prescribing in Canada. Based on this beginning framework, both the College and Association of Registered Nurses of Alberta (CARNA) and the College of Nurses of Ontario (CNO) have created standards for educating nurses to prescribe medications and order diagnostic tests in specialty clinical areas. As of May 1, 2019, registered nurses in Alberta who work in specialty areas have had the ability to prescribe certain medications and order diagnostic tests.

As the number and complexity of prescriptions continue to increase and technology continually changes, so do the laws regarding their use. With the ever-changing role of the professional nurse and other members of the health care team, and with the increasing pace of technologic advances, each role becomes more complex. Professional nurses have gained even more autonomy over their nursing practice. With this increasing autonomy comes greater liability and legal accountability; therefore, professional nurses must be aware and duly consider this responsibility as they practise. Specific laws and regulations are discussed later.

Canadian Drug and Related Legislation

Concerns over the sale and use of foods, drugs, cosmetics, and medical devices began in Canada long before such concerns

arose in the United States. Canadian drug legislation began in 1875, when the Parliament of Canada passed an act to prevent the sale of adulterated foods, drinks, and drugs. Since that time, food and drugs have been controlled on a national basis. The Health Products and Food Branch Inspectorate (HPFB) of Health Canada is the federal regulator responsible for the administration and enforcement of the *Food and Drugs Act* and Food and Drug Regulations, as well as the *Controlled Drugs and Substances Act*, the two Acts that form the underlying foundation for the drug laws in Canada. The Therapeutic Products Directorate (TPD) is the Canadian federal authority that regulates these Acts. These Acts are designed to protect the Canadian consumer from potential health hazards and fraud or deception in the sale and use of foods, drugs, cosmetics, and medical devices.

The *Personal Information Protection and Electronic Documents Act* (PIPEDA) is federal law governing the collection, use, and disclosure of personal information. Several provinces and territories have legislation that deals specifically with the collection, use, and disclosure of personal health information by health care providers and health care organizations. For example, Ontario has the *Personal Health Information Protection Act* (PHIPA) of 2004, while British Columbia has the *Personal Health Information Access and Protection of Privacy Act* of 2008. Such acts require all health care providers, health insurance and life insurance companies, public health authorities, employers, and schools to maintain patient privacy regarding protected health information. Protected health information includes any individually identifying information such as patients' health conditions, account numbers, prescription numbers, medications, and payment information. Such information can be oral or recorded in any paper or electronic form. In 2013, a proposal was introduced to revise PHIPA to the *Electronic Personal Health Information Protection Act* (EPHIPA), intended to address the

TABLE 3.1 Additions to the Food and Drugs Act

Schedule	Description
Schedules C and D	Drugs in these schedules must list where the drug was manufactured and the process and conditions of manufacturing.
Prescription Drug List	Replaces Schedule F. This is a list of medicinal ingredients in a drug that requires a prescription. Excluded are drugs listed in the <i>Controlled Drugs and Substances Act</i> schedules that require a prescription.
Part G	These drugs, also known as <i>controlled drugs</i> , affect the central nervous system (CNS); labels on these drugs are marked <i>C</i> . Controlled drugs are categorized into three parts: Part I: designated controlled drugs with misuse potential that may be used for designated medical conditions outlined in Food and Drug Regulations. <i>Examples</i> : amphetamines, methylphenidate, pentobarbital, preparations containing one controlled drug and one or more active noncontrolled drug Part II: controlled drugs with misuse potential prescribed for medical conditions. <i>Examples</i> : sedatives such as barbiturates and derivatives (e.g., secobarbital), thiobarbiturates (e.g., pentothal sodium) Part III: controlled drugs with misuse potential. <i>Examples</i> : anabolic steroids (e.g., androstanolone), weight reduction drugs (anorexiant)
Narcotic Drugs and Preparations	Drugs with high-misuse potential. <i>Examples</i> : morphine, codeine more than 8 mg, amides (e.g., methadone), coca and derivatives (e.g., cocaine), benzazocines (analgesics such as pentazocine), fentanyl
Part J	These are restricted drugs with high-misuse potential, dangerous physiological and psychological adverse effects, and no recognized medical use. <i>Examples</i> : lysergic acid diethylamide (LSD), mescaline (peyote), harmaline, psilocin and psilocybin (magic mushrooms)
Benzodiazepines and Other Targeted Substances Regulations	A “targeted substance” is either a controlled substance that is included in Schedule I or a product or compound that contains a controlled substance that is included in Schedule I. These are drugs with misuse potential. <i>Examples</i> : benzodiazepine tranquilizers such as diazepam, lorazepam, flunitrazepam, zolpidem

technological realities of electronic health records. The primary purpose of federal legislation is to ensure the safety and efficacy of new drugs and, in the case of privacy laws, to protect patient confidentiality.

Canadian Food and Drugs Act

The Canadian **Food and Drugs Act** is the primary piece of legislation governing foods, drugs, cosmetics, and medical devices in Canada. The Act has been amended several times since its inception in 1953. **Table 3.1** summarizes these amendments. Schedule A of the Act lists the diseases for which treatments may not be promoted to the public. Sections 3(1) and 3(2) of the *Food and Drugs Act* prohibit any label claim or advertisement that is both directed to the general public and contains treatment, preventative, or cure claims for Schedule A diseases. Revisions to Schedule A came into force on June 1, 2008. The updated Schedule A generally includes life-threatening diseases such as cancer and acute forms of specific diseases. For example, “liver disease,” which covers all liver diseases, disorders, and abnormalities, is now listed as “hepatitis,” which is a more specific disease. The legend *Canadian Standard Drug*, or CSD, must appear on the inner and outer labels of the drug packaging to show that a drug meets the standards for which it is prescribed.

According to the Act, and to protect the consumer, drugs must comply with official prescribed standards stated in recognized pharmacopoeias and formularies listed in Schedule B of the Act. Recognized pharmacopoeias and formularies include the following:

- Pharmacopée française
- Pharmacopoeia Internationalis
- The British Pharmacopoeia

- The Canadian Formulary
- The National Formulary
- The Pharmaceutical Codex: Principles and Practices of Pharmaceuticals
- The United States Pharmacopoeia

Drugs listed in Schedule C are radiopharmaceuticals, and drugs listed in Schedule D include allergenic substances, immunizing agents (vaccines), insulin, anterior pituitary extracts, drugs obtained by recombinant DNA technology, and blood derivatives. The distribution of *drug samples*, defined as trial packages of medication, is also regulated, with the exception of the distribution under prescribed conditions to physicians, dentists, or pharmacists. All drugs that require a prescription are listed in Schedule F, with the exception of narcotics and controlled drugs. Schedule F to the Food and Drug Regulations was replaced by a list of prescription drugs called the Prescription Drug List. The prescription status helps to ensure that consumers receive adequate risk and benefit information from a health care provider before taking the drug. The *Pr* symbol in the upper left quarter of the label—a black box with the letters *Pr* in white, inside—identifies the product as a prescription drug. The *Food and Drugs Act* also regulates the information manufacturers may put on a drug label, including directions for use. A prescription may be refilled as often as indicated by the prescriber. Prescriptions are written (including facsimiles) or transmitted orally (via telephone to the pharmacist) by a qualified health care provider.

The **Food and Drug Regulations** are the current, consolidated regulations of the *Food and Drugs Act*. Parts G and J regulate controlled drugs and restricted drugs, respectively. Controlled drugs are dispensed only by prescription. A controlled drug must be marked with the symbol *C* in a clear

manner and in a conspicuous colour and size, in the upper left quarter of the label. The proper name of the drug must also appear on the label and either precede or follow the brand name of the drug.

Controlled Drugs and Substances Act

The **Controlled Drugs and Substances Act (CDSA)** was passed in 1997, replacing the *Narcotic Control Act* and Parts III and IV of the *Food and Drugs Act*. The CDSA provides the requirements for the control and sale of narcotics, controlled drugs, and substances of misuse (see Controlled Drugs and Substances Act, <https://laws-lois.justice.gc.ca/eng/acts/C-38.8/>). **Controlled substances** and substances for medical treatment may be legally obtained only with a prescription from a licensed medical practitioner. The letter N and the symbol are printed on the label of all controlled drugs. The CDSA is based on eight schedules that list controlled drugs and substances based on potential for misuse or harm or how easy they are to manufacture into illicit substances. A summary of Schedule I contains the most dangerous drugs, including opiates (opium, heroin, morphine, cocaine), fentanyl, and methamphetamine. Schedule II contains synthetic cannabinoid receptor type 1 agonists. All other cannabis-related drugs are now regulated under the Cannabis Regulations and the *Cannabis Act*. Schedule III contains the more dangerous drugs such as amphetamines and lysergic acid diethylamide (LSD). Schedule IV contains drugs such as barbiturates and anabolic steroids, which are dangerous but have therapeutic uses; a prescription is required for possession of drugs listed in Schedule IV. Schedules V and VI contain precursors required to produce controlled substances. Schedules VII and VIII contain amounts of cannabis and cannabis resin required for charge and sentencing purposes. The factors that determine the schedule under which a controlled substance should be placed are international requirements, the dependence potential and likelihood of abuse of the substance, the extent of its abuse in Canada, the danger it represents to the safety of the public, and the usefulness of the substance as a therapeutic agent. The RCMP is responsible for enforcing the CDSA and related sections of the Criminal Code and exempts members of police forces from sections of the CDSA for the purpose of performing their duties.

The **Benzodiazepines and Other Targeted Substances Regulations** specify similar restrictions in regard to benzodiazepines, their salts and derivatives, and other targeted substances mentioned in Schedules I and II. The **Precursor Control Regulations**, introduced in 2003, address the need for the control of essential and precursor chemicals routinely used in clandestine labs for the production of methamphetamine, ecstasy, and other Schedule III drugs. The Marihuana Medical Access Program ended in March 2014; it was replaced with the Marihuana for Medical Purposes Regulations, in 2015, and was ultimately repealed by the Canadian government when cannabis was legalized on October 17, 2018. The *Cannabis Act* and Cannabis Regulations (the latter of which falls under the *Controlled Drugs and Substances Act*, *Food and Drugs Act*, and the *Cannabis Act*) address cannabis for medical purposes and replaced the Access to Cannabis for Medical Purposed

Regulations (ACMPR). Individuals who use marihuana for medical reasons and are authorized by their health care provider can access cannabis and other related cannabis products (seeds, oils, and plants) in three ways: by buying direct from a seller licensed by the federal government, by registering with Health Canada to produce a prescribed amount of cannabis, or by assigning a designate to produce the product on their behalf (Government of Canada, 2018).

NEW DRUG DEVELOPMENT

The research into and development of new drugs is an ongoing process. The pharmaceutical industry is a multi-billion-dollar industry. Pharmaceutical companies must continuously develop new and better drugs to maintain a competitive edge. The research required for the development of these new drugs may take several years. Hundreds of substances are isolated but never make it to market. Once a potentially beneficial drug has been identified, the pharmaceutical company must follow a systematic process before the drug can be sold on the open market. This highly sophisticated process is regulated and carefully monitored by Health Canada. The primary purpose of Health Canada's TPD is to protect patients and ensure drug effectiveness.

This system of drug research and development is one of the most stringent in the world. It was developed out of concern for patient safety and drug efficacy. Much time, funding, and documentation are required to ensure that these two important objectives are met. Many drugs are marketed and used in foreign countries long before they get approval for use in Canada. Drug-related calamities are more likely to be avoided by this more stringent drug approval system. The thalidomide tragedy resulted from the use of a drug that was first marketed in Europe and then made available for distribution in Canada. In March 1962, thalidomide, used for nausea and morning sickness in pregnant women, was removed from the Canadian drug market due to resulting extreme physical malformations in newborns.

A balance must be achieved between making new, life-saving therapies available and protecting consumers from potential drug-induced adverse effects. In 2003, Canada introduced the Natural Health Products Regulations. These regulations cover natural health products such as vitamins and minerals, herbal remedies, homeopathic medicines, traditional medicines (e.g., traditional Chinese medicines), probiotics, and other products such as amino acids and essential fatty acids (e.g., omega-3). The manufacturer's primary obligation regarding such products is to not make "false or misleading" claims about their efficacy. For example, a product label may read "For depression," but cannot read "Known to cure depression." The availability of reliable, objective information about these kinds of products is limited but is growing as more formal research studies are conducted. In 2008, Bill C-51 was drafted to complement and support the current policies for foods and health products, including natural health products. Consumer demand for alternative medicine products continues to drive this process. Patients must exercise caution in using such products and communicate regularly with their health care providers regarding their use.

HEALTH CANADA DRUG APPROVAL PROCESS

The TPD of Health Canada is responsible for approving drugs for clinical safety and efficacy before they are brought to the market. There are stringent steps, each of which may take years, that must be completed before the drug can be approved. The TPD has made certain life-saving investigational drug therapies available sooner than usual by offering a **priority review of drug submissions** process, also known as “fast-track” approval. Eligible submissions undergo a shorter review target of 180 days, compared to 300 days for non-priority submissions. Acquired immune deficiency syndrome (AIDS) was the first major public health crisis for which the TPD began granting expedited drug approval. This process enabled pharmaceutical manufacturers to shorten the approval process and allowed prescribers to give medications that showed promise during early Phase I and Phase II clinical trials, to qualified patients with AIDS. In such cases, when a trial continues to show favourable results, the overall process of drug approval is hastened. The concept of expedited drug approval became controversial after the manufacturer recall of the anti-inflammatory drug rofecoxib (Vioxx), in 2004. This recall followed multiple case reports of severe cardiovascular events, including fatalities, associated with the use of this drug and concerns that the manufacturer withheld information about the drug’s risks. This unfortunate example has reduced the number of drugs approved via the expedited approval process.

The drug approval process is quite complex and prolonged. It normally begins with preclinical testing phases, which include in vitro studies (using tissue samples and cell cultures) and animal studies. Clinical (human) studies follow the preclinical phase. There are four clinical phases (see below). The drug is put on the market after Phase III is completed if an **investigational new drug application** submitted by the manufacturer is approved by the TPD. Phase IV consists of postmarketing studies. The collective goal of these phases is to provide information on the safety, toxicity, efficacy, potency, bioavailability, and purity of the new drug. A **Notice of Compliance** is issued when Health Canada decides that the drug and the manufacturing process are safe and effective, allowing the pharmaceutical company to sell the product by prescription to the Canadian population. Once a drug is approved for sale, it is assigned a computer-generated **Drug Identification Number (DIN)** by Health Canada. The DIN is placed on the label of prescription and over-the-counter (OTC) drug products.

Preclinical Investigational Drug Studies

Current medical ethics still require that all new drugs undergo laboratory testing using both in vitro (cell or tissue) and animal studies before any testing in human subjects can be done. In vitro studies include testing of the response of various types of mammalian (including human) cells and tissues to different concentrations of the investigational drug. Various types of cells and tissues used for this purpose are collected from living or dead animal or human subjects (e.g., surgical or autopsy specimens). In vitro studies help researchers determine early on if

a substance might be too toxic for human patients. Many prospective new drugs are ruled out for human use during this pre-clinical phase of drug testing. However, a small percentage of the many drugs tested in this manner are referred for further clinical testing in human subjects.

Four Clinical Phases of Investigational Drug Studies

Before any testing on humans begins, the subjects must provide informed consent, and the consent must be documented. **Informed consent** involves the careful explanation to the human test patient or research subject of the purpose of the study, the procedures to be used, the possible benefits, and the risks involved. This explanation is followed by written documentation on a consent form. The informed consent document, or consent form, must be written in language that is understood by the patient and must be dated and signed by the patient and at least one witness. Informed consent is always voluntary. By law, informed consent must be obtained more than a given number of days or hours before certain procedures are performed and must always be obtained when the patient is fully mentally competent. The informed consent process may be carried out by a nurse or other health care provider, depending on how a given study is designed.

Medical ethics dictate that participants in experimental drug studies be informed volunteers and not be coerced to participate in any way. Therefore, informed consent must be obtained from all patients (or their legal guardians) before they can be enrolled in an **investigational new drug (IND)** study. Some patients may have unrealistic expectations of the IND’s usefulness. Often they have the misconception that because an investigational drug is new it must automatically be better than existing forms of therapy. Other volunteers may be reluctant to enter the study because they think they will be treated as “guinea pigs.” Whatever the circumstances of the study, the research subjects must be informed of all potential hazards as well as the possible benefits of the new therapy. It must be stressed to all patients that involvement in IND studies is voluntary and that any individual can either decline to participate or quit the study at any time without affecting the delivery of any previously agreed-upon health care services.

Phase I

Phase I studies usually involve small numbers of healthy subjects (normally fewer than 100) rather than those who have the disease or ailment that the new drug is intended to treat. An exception might be a study involving a toxic drug used to treat a life-threatening illness. In this case, the only study subjects might be those who already have the illness and for whom other viable treatment options may not be available. The purpose of Phase I studies is to determine the potential adverse effects, the optimal dosage range, and the pharmacokinetics of the drug (i.e., absorption, distribution, metabolism, and excretion) and to determine if further testing is needed. Blood tests, urinalyses, assessments of vital signs, and specific monitoring tests are also performed. These trials usually last from a few days to a few weeks.

Phase II

Phase II studies involve larger numbers of volunteers (usually around 100 to 300) who have the disease or ailment that the drug is designed to diagnose or treat. Study participants are closely monitored for the drug's effectiveness and to identify any adverse effects. Therapeutic dosage ranges are refined during this phase. If no serious adverse effects occur, the study can progress to Phase III.

Phase III

Phase III studies involve larger numbers of patients (normally 1000 to 3 000), who are followed by medical research centres and other types of health care facilities. The patients may be treated at the centre or may be spread over a wider geographic area. The purpose of this larger sample size is to provide information about infrequent or rare adverse effects that may not have been observed during previous, smaller studies. To enhance objectivity, many studies are designed to incorporate a placebo. A **placebo** is an inert substance that is not a drug (e.g., normal saline), given to a portion of the research subjects to separate out the real benefits of the investigational drug from the apparent benefits arising out of researcher or subject **bias** regarding expected or desired results of the drug therapy. A study incorporating a placebo is called a *placebo-controlled study*. If the study subject does not know whether the drug being administered is a placebo or the investigational drug but the investigator does know, the study is referred to as a **blinded investigational drug study**. In most studies, neither the research staff nor the subjects being tested know which subjects are being given the real drug and which are receiving the placebo. This method further enhances the objectivity of the study results and is known as a **double-blind, investigational drug study** because both the researchers and the subjects are "blinded" to the actual identity of the substance administered to a given subject. Both the drug and placebo dosage forms given to patients often look identical, except for a secret code that appears on the medication itself or its container. At the completion of the study, this code is revealed or broken to determine which study patients received the drug and which were given the placebo. The code can also be broken before study completion by the principal investigator in the event of a clinical emergency that requires a determination of what individual patients received.

The three objectives of Phase III studies are to establish the drug's clinical effectiveness, safety, and dosage range. After Phase III is completed, Health Canada's TPD and Biologics and Genetic Therapies Directorate (BGTD) receive a report from the manufacturer, at which time the drug company submits a **new drug submission**. The approval of the application paves the way for the pharmaceutical company to market the new drug exclusively until the patent for the drug molecule expires. As mandated by the Canadian *Patent Act*, this is normally 20 years after discovery of the molecule and includes the 10- to 12-year period generally required to complete drug research. Therefore, a new drug manufacturer typically has 8 to 10 years after drug marketing to recoup research costs, which are usually in the hundreds of millions of dollars for a single drug.

Phase IV

Phase IV studies are postmarketing studies voluntarily conducted by pharmaceutical companies to obtain further proof of the therapeutic and adverse effects of the new drug. However, these studies may be mandated by Health Canada. Data from such studies are usually gathered for at least 2 years after the drug's release. Often these studies compare the safety and efficacy of the new drug with that of another drug in the same therapeutic category. An example would be a comparison of a new nonsteroidal anti-inflammatory drug with ibuprofen in the treatment of osteoarthritis. Some medications make it through all phases of clinical trials without causing any problems among study patients. However, when they are used in the larger general population, severe adverse effects may appear for the first time. If a pattern of severe reactions to a newly marketed drug begins to emerge, Health Canada may request that the manufacturer of the drug issue a voluntary recall. The drug can still be prescribed; however, the prescriber must be made aware of the potential risk. If the drug manufacturer refuses to recall the medication, and if the number or severity of reactions reaches a certain level, then the Health Products and Food Branch Inspectorate of Health Canada may seek court action to condemn the product and allow it to be seized by legal authorities. Such an action, in effect, becomes an involuntary recall on behalf of the manufacturer. There are three designated classes of drug recall, based on Health Canada's response to postmarketing data for a given drug:

- Class I: The most serious type of recall—use of the drug product carries a reasonable probability of serious adverse health effects or death.
- Class II: Less severe—use of the drug product may result in temporary or medically reversible health effects, but the probability of lasting major adverse health effects is low.
- Class III: Least severe—use of the drug product is not likely to result in any significant health problems.

Notification by Health Canada of a drug recall or drug warnings may be in the form of press releases, website announcements, or letters to health care providers. Health Canada's MedEffect website provides a voluntary program called MedEffect Canada, in which professionals and consumers are encouraged to report any adverse events seen with newly approved drugs. The Government of Canada's Recalls and Safety Alerts Database is a current comprehensive list of advisories, warnings, and recalls: <http://www.hc-sc.gc.ca/dhp-mpps/medeff/advisories-avis/index-eng.php>. Drug information of this kind is continually evolving as new events are observed and reported by clinicians and patients. Recommended actions change with time, so use the most current information available along with sound clinical judgement.

Special Access Programme

The Health Canada **Special Access Programme** allows health care providers compassionate access to drugs unavailable for sale in Canada. The Special Access Programme is limited to those with serious or life-threatening conditions (e.g., intractable depression, epilepsy, transplant rejection, hemophilia and other blood disorders, terminal cancer, and AIDS) who may

require experimental drugs for compassionate reasons or on an emergency basis when other conventional therapies have failed. New regulations were introduced in October 2013 that prevent special access to certain unauthorized controlled substances (e.g., products containing heroin, unauthorized forms of cocaine, or other restricted drugs such as LSD, ecstasy, “magic mushrooms,” and “bath salts.”)

Patient Access to and Costs of Prescription Drugs

The twenty-first century in Canada has seen rapid growth in prescription drug use and costs. High drug expenses in Canada are a significant barrier for people to access prescription drugs outside of hospital. Law, Cheng, Dhalla, Heard, & Morgan (2012) found evidence that suggests that out-of-pocket expenses for drugs, occurring in one in ten Canadians, influence the decision to not adhere to prescription medications. Canadians affected are those with low incomes, those without drug benefits, and those in poor health.

Prescription drugs are not covered under the [Canada Health Act](#). Patients must pay for a drug unless the drug is covered by a private drug plan or a federal, provincial, or territorial (F/P/T) drug plan. Most provincial plans provide for some costs of drugs to those who are poor, older adults, those with catastrophic drug costs, and people with certain conditions (e.g., cancer, HIV/AIDS). The federal government provides coverage for indigenous peoples (see Non-insured Health Benefits First Nation and Inuit Health Branch: Drug Benefit list—January 2019). Each Canadian province and territory has a formulary committee that decides which drugs are listed on its formulary and reimbursed by the drug benefit health plan, which have restricted access, and which are not covered. There is a wide variety of access to prescription drugs across the country—provincial and territorial drug plans vary in eligibility criteria, drugs covered, and financing. For example, most drugs are paid for, for patients age 65 and over; however they are required to pay dispensing fees (such fees vary among pharmacies, based on the patient’s drug coverage plan) and not all drugs are covered. For example, there may not be coverage if a trade name drug is prescribed rather than a generic drug. The decision for provinces and territories to list a drug is based on a variety of factors, such as effectiveness analyses, cost, government priorities, and patient advocacy. Some drugs may be restricted if they require special monitoring or if the cost is high.

Drug Advertising

Drug advertising in Canada is regulated by Health Canada. Direct-to-consumer advertising (such as ads in consumer magazines and on subways) is restricted to simply giving the names of prescription drugs, but these ads do not make claims for product effectiveness. (This is not the case in the United States.) Advertisements in professional health care journals contain claims and prescribing information. Advertising Standards Canada (ASC) and the Pharmaceutical Advertising Advisory Board (PAAB) review and clear advertisements according to standards set by the *Food and Drugs Act*. Although the clearance procedure is voluntary, most companies comply with the regulations.

BOX 3.1 Nurse Practice Acts

Nurse practice acts (NPAs) are regulatory laws that are instrumental in defining the scope of nursing practice and that protect public health, safety, and welfare. Nursing practice in Canada is regulated by separate acts in each of the 10 provinces and 3 territories. These acts grant self-governance to the nursing profession, direct entry into nursing practice, define the scopes of practice, and identify disciplinary actions. NPAs are the most significant part of legislation in regard to professional nursing practice. Together, it is NPAs and common law that define nursing practice. Each province and territory has a website on which the NPAs are defined and outlined. For example, for nurses practising in New Brunswick or British Columbia, the websites are, respectively: <http://www.nanb.nb.ca/> and <https://www.bccnp.ca/Pages/Default.aspx>.

LEGAL NURSING CONSIDERATIONS AND DRUG THERAPY

Provincial and territorial legislation dictates the boundaries for professional nursing practice. Nursing practice standards of care and nurse practice acts identify the definition of the scope and role of the professional nurse ([Box 3.1](#)). Nurse practice acts further define/identify: (1) the scope of nursing practice, (2) expanded nursing roles, (3) educational requirements for nurses, (4) standards of care, (5) minimally safe nursing practice, and (6) differences between nursing and medical practice. In addition, provincial/territorial regulatory bodies of nursing define specific nursing practices such as guidelines concerning the administration of intravenous therapy. Additionally, guidelines from professional nursing groups (e.g., CNA), nursing specialty groups, institutional policies and procedures, and provincial/territorial hospital licensing laws all help to identify the legal boundaries of nursing practice. There is also case law or common law, consisting of prior court rulings that affect professional nursing practice.

The CNA advances the practice and profession of nursing to improve health outcomes and strengthen Canada’s health care system. The CNA is the national voice for nurses and has developed standards for nursing practice, policy statements, and similar resolutions. The standards describe the scope, function, and role of the nurse and establish clinical practice standards. Accreditation Canada requires that accredited hospitals fulfill certain standards in regard to nursing practice. One such requirement is that these institutions must have written policies and procedures. These policies and procedures are usually quite specific and are contained in policy and procedures manuals found on most nursing units, although many organizations now post their policies not only internally, on the intranet, but also externally, via the internet. The nurse must know the policies and procedures of the employing institution because if the nurse is involved in a lawsuit, these policies and procedures are one of the standards by which the nurse will be measured. Nursing specialty organizations also define standards of care for nurses who are certified in specialty areas, such as oncology, surgical care, or critical care. Standards of care help to determine whether a nurse is acting appropriately when performing professional duties. It is critical to safe nursing practice to

BOX 3.2 Areas of Potential Liability for Nurses

Area	Examples Regarding Drug Therapy and the Nursing Process
Failure to ensure safety	Lack of adequate monitoring; failure to identify patient allergies and other risk factors regarding medication therapy; inappropriate drug administration technique; failure to implement appropriate nursing actions based on a lack of proper assessment of patient's condition
Medication errors	Failure to clarify unclear medication order; failure to identify and react to adverse drug reactions; failure to be familiar with medication prior to its administration; failure to maintain level of professional nursing skills for current practice; failure to identify patient's identity prior to drug administration; failure to document drug administration in medication profile
Failure to assess/evaluate	Failure to see significant changes in patient's condition after taking a medication; failure to report the changes in condition after medication; failure to take a complete medication history and nursing assessment/history; failure to monitor patient after medication administration

remain up to date on the ever-changing obligations and standards of practice and care. If standards of care are not met, the nurse becomes liable for **negligence** and **malpractice** (Box 3.2). Current nursing literature remains an authoritative resource for information on new standards of care. Provincial/territorial nursing associations have websites that include links to specific nurse practice acts and standards of care.

The legal–ethical dimensions of professional nursing care are also addressed in the legislation passed to amplify the guidelines contained in the Government of Canada *Privacy Act* (1985). The *Privacy Act* regulates how federal government institutions collect, use, and disclose personal information. Under these federal regulations (see page 37), the privacy of patient information is protected, and standards are included for the handling of electronic data about patients (PIPEDA). PIPEDA also defines the rights and privileges of patients in order to protect privacy without diminishing access to quality health care. The assurance of privacy—even prior to establishment of the PIPEDA guidelines—was based on the principle of respect of an individual's right to determine when, to what extent, and under what circumstances private information can be shared or withheld from others, including family members. In addition, confidentiality must be preserved; that is, the individual identities of patients or research study participants are not to be linked to information they provide and cannot be publicly divulged. PIPEDA addresses the issues of confidentiality and privacy by prohibiting prescribers, nurses, and other health care providers from sharing with others any patient health

care information, including laboratory results, diagnoses, and prognoses, without the patient's consent. Conflicting obligations arise when a patient wants to keep information away from insurance companies, and matters remain complicated and challenging in the era of improving technology and computerization of medical records. Health care facilities continue to work diligently, however, to adhere to PIPEDA guidelines and use special access codes to limit who can access information in computerized documents and charts.

In summary, federal and provincial or territorial legislation, standards of care, and nurse practice acts provide the legal framework for safe nursing practice, including drug therapy and medication administration. Further, as discussed in Chapter 1, the standard “Rights” of medication administration are yet another measure for ensuring safety and adherence to laws necessary for protecting the patient. Chapter 1 also discusses other patient rights that are part of the standards of practice of every licensed registered nurse and every student studying the art and science of nursing.

ETHICAL CONSIDERATIONS

Decisions in health care are seldom made independently of other people and are made with consideration of the patient, family, nurses, and other members of the health care team. All members of the health care team must make a concentrated effort to recognize and understand their own values and be considerate, nonjudgemental, and respectful of the values of others. The use of drug therapy has evolved from just administering whatever was prescribed to providing responsible drug therapy for the purpose of achieving defined outcomes that improve a patient's quality of life based on the nursing process.

Ethical principles are useful strategies for members of the health care team and include standards or truths on which ethical actions are made. Some of the most useful ethical principles in nursing and health care, specifically drug therapy, include autonomy, beneficence, nonmaleficence, justice, fidelity, and veracity (see Legal & Ethical Principles box: Ethical Principles in Nursing and Health Care). However, day-to-day practice in nursing and health care poses many potential ethical conflicts. Each situation is different and requires compassionate and humane solutions. When answers to ethical dilemmas remain unclear and ethical conflict occurs, then the appropriate action must be based on ethical principles.

Ethical Nursing Considerations and Drug Therapy

Ethical nursing practice is based on basic ethical principles such as beneficence, autonomy, justice, fidelity, veracity, and confidentiality. The CNA *Code of Ethics for Registered Nurses* (2017), the Canadian Council for Practical Nurse Regulators (CCPNR) Code of Ethics (2013), and the International Council of Nurses (ICN) Code of Ethics for Nurses (2012) serve as frameworks of practice for nurses and as ethical guidelines for nursing care (see the Legal & Ethical Principles box: International Council of Nurses *Code of Ethics for Nurses*).

LEGAL & ETHICAL PRINCIPLES

Ethical Principles in Nursing and Health Care (example Code of Ethics)

Element	Example
Providing safe, compassionate, competent, and ethical care	Nurses have an ethical responsibility to provide compassionate, safe, and competent care. Nurses must always question unsafe, incompetent practice or conditions that interfere with their ability to provide safe, compassionate, competent, and ethical care. By building trustworthy relationships, nurses engage in compassionate care that addresses the needs of individuals, families, and communities.
Promoting health and well-being	Nurses work with and provide care to persons to achieve their highest level of health and well-being.
Promoting and respecting informed decision making	Nurses must always acknowledge, respect, promote, and advocate for a person's ability to be informed of all information in order to make decisions about their health care.
Honouring dignity	Nurses support persons receiving care by maintaining their dignity and integrity through recognizing and respecting the intrinsic worth of each person.
Maintaining privacy and confidentiality	Nurses acknowledge the importance of privacy and confidentiality and safeguard personal, family, and community information obtained in the context of a professional relationship.
Promoting justice	Nurses uphold principles of justice by safeguarding human rights, equity, and fairness and by promoting the public good.
Being accountable	Nurses are accountable for their actions and answerable for their practice. Nurses must maintain their fitness to practice.

Based on Canadian Nurses Association. (2017). *Code of ethics for registered nurses*. Ottawa, ON: Retrieved from <https://www.cna-aic.ca/-/media/cna/page-content/pdf-en/code-of-ethics-2017-edition-secure-interactive.pdf>.

LEGAL & ETHICAL PRINCIPLES

International Council of Nurses Code of Ethics for Nurses

The International Council of Nurses (ICN) first adopted *The ICN Code of Ethics for Nurses* in 1953; the Code has been revised several times since then, most recently in 2012. The 2012 revision is available in English, French, Spanish, and German. This Code is a globally accepted guide for ethical practice in nursing, based on social values and needs. The preamble identifies the four fundamental responsibilities of nurses—promoting health, preventing illness, restoring health, and alleviating suffering—and points out that the need for nursing is universal. The Code makes it clear that inherent in professional nursing practice is respect for human rights, including the right to life, dignity, and the right to be treated with respect. Nursing care is respectful of and unrestricted by considerations of age, colour, creed, culture, disability or illness, sexual orientation, nationality, politics, race, or social status. Nurses render services to the individual, family, and community. The Code describes four principal elements that provide a framework for the standards of ethical conduct it defines: nurses and people, nurses and practice, nurses and the profession, and nurses and co-workers. The 2012 updated code reflects the current professional emphases on positive work environments and the use of evidence-informed practice. *The ICN Code of Ethics for Nurses* serves as a guide for action based on social values and needs and should be understood, internalized, and applied by nurses in all aspects of their work. Nurses can obtain assistance in translating these standards into conduct by discussing the Code with co-workers and collaborating with their national nurses' associations in the application of ethical standards in nursing practice, education, management, and research.

Adherence to these ethical principles and codes of ethics ensures that the nurse is acting on behalf of the patient and with the patient's best interests. The professional nurse has the responsibility to provide safe nursing care to patients regardless of the setting, person, group, community, or family involved. Although it is not within the nurse's realm of ethical and professional responsibility to impose her values or standards on the patient, it is within the nurse's realm to provide information and to assist the patient in facing decisions regarding health care.

The nurse also has the right to refuse to participate in any treatment or aspect of a patient's care that violates the nurse's personal ethical principles. However, this must be done without abandoning the patient, and in some facilities the nurse may be transferred to another patient care assignment only if the transfer is approved by the nurse manager or nurse supervisor. The nurse must always

remember, however, that the CNA *Code of Ethics for Registered Nurses* and professional responsibility and accountability require the nurse to provide non-judgemental nursing care from the start of the patient's treatment until the time of the patient's discharge. If transferring to a different assignment is not an option because of institutional policy and because of the increase in the acuteness of patients' conditions and the high patient-to-nurse workload, then the nurse must always act in the best interests of the patient while remaining an objective patient advocate.

It is always the nurse's responsibility to provide the highest quality nursing care and practise within the professional standards of care. The CNA *Code of Ethics for Registered Nurses*; *The ICN Code of Ethics for Nurses*; standards of nursing practice; federal, provincial, or territorial codes; ethical principles; and the previously mentioned legal principles and legislation are readily accessible and provide nurses with a sound, rational framework for professional nursing practice.

Another area of ethical consideration regarding drug therapy and the nursing process is the use of placebos. A placebo is a drug dosage form (e.g., tablet or capsule) without any pharmacological activity due to a lack of active ingredients. However, there may be reported therapeutic responses, and placebos have been found to be beneficial in certain patients, such as those being treated for anxiety. Indeed, in an online survey of 606 physicians, including psychiatrists and nonpsychiatrists, 20% prescribed placebos regularly as part of routine clinical practice (Raz et al., 2011). Placebos are also administered frequently in experimental studies of new drugs to evaluate and measure the pharmacological effects of a new medicine compared with those of an inert placebo. Except in new drug studies, however, placebo use is considered to be unethical, creating mistrust among the nurse, the prescriber, and the patient. Many health care agencies limit the use of placebos to research only, to avoid the possible mistrust. In Canada, there are no specific formal guidelines on the use of placebos. If administration of a placebo is part of a research study or clinical trial, the informed consent process must be thorough and patients must be informed of their right to (1) leave the study at any time without any pressure or coercion to stay, (2) leave the study without consequences to medical care, (3) receive full and complete information about the study, and (4) be aware of all alternative options and receive information on all treatments, including placebo therapy, being administered in the study.

CASE STUDY

Clinical Drug Trial

A patient on the cardiac telemetry unit, Claude, has had a serious heart condition for years and has been through every known protocol for treatment. The cardiologist has admitted him to a telemetry unit for observation during a trial of a new investigational drug. Claude exclaims, “I have high hopes for this drug. I’ve read about it on the internet and the reports are wonderful. I can’t wait to get better!”

1. What is the best way for the nurse to respond to this statement?

The physician meets with Claude and the nurse to explain the medication and how the double-blind experimental drug study will work. The purpose of the medication and potential hazards of the therapy are

described, as well as the laboratory tests that will be performed to measure the drug’s effectiveness. The physician then asks the nurse to have Claude sign the consent form. When the nurse goes to get Claude’s signature, he says, “I’ll sign it, but I really didn’t understand what that doctor told me about the placebo.”

2. Should the nurse continue with getting the consent form signed? Explain your answer.

3. Claude tells the nurse, “How can I make sure I have the real drug and not the fake drug? I really want to see if it will help my situation.” What is the nurse’s best response?

4. After a week, Claude tells the nurse, “I don’t see that this drug is helping me. In fact, I feel worse. But I’m afraid to tell the doctor that I want to stop the medicine. What do I do?” What is the nurse’s best response?

KEY POINTS

- Various pieces of federal legislation, as well as provincial or territorial law, provincial or territorial practice acts, and institutional policies, have been established to help ensure the safety and efficacy of drug therapy and the nursing process.
- Privacy guidelines have increased awareness concerning patient confidentiality and privacy. It is important to understand the federal, provincial, or territorial legislation as it relates to drug therapy and the nursing process.
- The *Food and Drugs Act* and the *Controlled Drugs and Substances Act* provide nurses and other health care providers with information on drugs that cause little to no dependence versus those associated with a high level of abuse and dependency.
- Always obtain informed consent as needed with complete understanding of your role and responsibilities as a patient advocate in obtaining such consent.
- In the IND research process, adhere to the study protocol while also acting as a patient advocate and honouring the patient’s right to safe, quality nursing care.
- Adhere to legal guidelines, ethical principles, and the CNA *Code of Ethics for Registered Nurses* so your actions are based on a solid foundation.
- Placebo use remains controversial and if a placebo is ordered, question the prescriber about the specific rationale for its use.

EXAMINATION REVIEW QUESTIONS

- Ahmed is undergoing major surgery and asks the nurse about a living will. He states, “I don’t want anybody making decisions for me. And I don’t want to prolong my life.” Ahmed is demonstrating
 - Autonomy
 - Beneficence
 - Justice
 - Veracity
- Jennifer is being counselled for possible participation in a clinical trial for a new medication. After she meets with the physician, the nurse is asked to obtain her signature on the consent forms. The nurse knows that this “informed consent” indicates which of the following?
 - Once therapy has begun, the patient cannot withdraw from the clinical trial.
 - The patient has been informed of all potential hazards and benefits of the therapy.
 - The patient has received only the information that will help to make the clinical trial a success.
 - No matter what happens, the patient will not be able to sue the researchers for damages.
- A new drug has been approved for use, and the drug manufacturer has made it available for sale. During the first 6 months, Health Canada receives reports of severe adverse effects that were not discovered during the testing and considers whether to withdraw the drug. This illustrates which phase of investigational drug studies?
 - Phase I
 - Phase II
 - Phase III
 - Phase IV
- When discussing the laws on legal marihuana use in Canada with a patient, which facts does the nurse consider? (Select all that apply.)
 - Marihuana is considered a legal substance.
 - Medical marihuana is produced via Health Canada-regulated producers.
 - The Marihuana Medical Access Program governs the use of medical marihuana.
 - Licensed regulators are required to provide quarterly reports upon request to provincial and territorial licensing bodies.

- e. Medical marihuana can legally be consumed in other forms.
5. The nurse is reviewing the four clinical phases of investigational drug studies. Place the four phases in the correct order of occurrence.
 - a. Studies that are voluntarily conducted by pharmaceutical companies to obtain more information about the therapeutic and adverse effects of a drug
 - b. Studies that involve small numbers of volunteers who have the disease or ailment that the drug is designed to diagnose or treat
 - c. Studies that involve small numbers of healthy subjects who do not have the disease or ailment that the drug is intended to treat
 - d. Studies that involve large numbers of patients who have the disease that the drug is intended to treat; these studies establish the drug's clinical effectiveness, safety, and dosage range

Critical Thinking Activities

1. During a busy shift, the nurse is called to the telephone to speak to a family member of Sheila, who was admitted with pneumonia. The caller states, "I'm her grandson, and I want to know if the pneumonia she has is that contagious bug that's going around hospitals. Is she going to die?" Which guidelines will the nurse use to answer the family member?
2. The nurse is assessing a newly admitted 55-year-old woman. During the assessment, the nurse finds that the patient uses cannabis for anxiety. What questions are appropriate regarding the patient's use of cannabis?
3. Using the suggestions given in this chapter of your textbook, interview someone who is not in your ethnocultural group about cultural practices and drug therapy. Compare the person's practices with those of your family.

Patient-Focused Considerations

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Discuss the influences of a patient's age on the effects of drugs and drug responses.
2. Summarize the impact of age-related physiological changes on pharmacokinetic aspects of drug therapy.
3. Explain how these age-related changes in pharmacokinetics influence various drug effects and drug responses across the lifespan.
4. Provide several examples of how age affects the absorption, distribution, metabolism, and excretion of drugs.
5. Identify drug-related concerns during pregnancy and lactation and provide an explanation of the physiological basis for these concerns.
6. Calculate a drug dose for a pediatric patient using the various formulas available.
7. Identify the importance of a body surface area nomogram for drug calculations in pediatric patients.
8. Discuss the various ethnocultural factors that may influence an individual's response to medications.
9. Identify various ethnocultural phenomena affecting health care and use of medications.
10. List the drugs more commonly associated with variations in response that are more commonly due to ethnocultural factors.
11. Develop a collaborative plan of care for drug therapy and the nursing process that considers lifespan and ethnocultural considerations.

KEY TERMS

Active transport The active (energy-requiring) movement of a substance between different tissues via pumping mechanisms contained within cell membranes. (p. 48)

Culture The customary beliefs, social forms, and material traits of a racial, religious, or social group. (p. 55)

Diffusion The passive movement of a substance (e.g., a drug) between different tissues, from areas of higher concentration to areas of lower concentration. (Compare with *active transport*.) (p. 48)

Neonate A person younger than 1 month of age; newborn infant. (p. 49)

Nomogram A graphical tool for estimating drug dosages using various body measurements. (p. 50)

Older adult A person who is 65 years of age or older. (Note: Some sources consider older adults to be 50 to 55 years of age or older.) (p. 50)

Pediatric Pertaining to a person who is 18 years of age or younger. (Note: Some sources consider pediatric to be 12 years of age or younger.) (p. 49)

Polypharmacy The use of many different drugs concurrently in treating a patient, often one who has several health problems. (p. 52)

Race Descendants of a common ancestor; a tribe, family, or people believed to belong to the same lineage. (p. 55)

OVERVIEW

From the beginning to the end of life, the human body changes in many ways. These changes have a dramatic effect on the four phases of pharmacokinetics—drug absorption, distribution, metabolism, and excretion. Newborns, children, and older adults all have special needs. Drug therapy at the two ends of the spectrum of life is more likely to result in adverse effects and toxicity. This is especially true if certain basic principles are not understood and followed. Fortunately, response to drug therapy changes in a predictable manner in younger and older patients. Knowing the effect that age has on the pharmacokinetic characteristics of drugs helps predict these changes.

Most experience with drugs and pharmacology has been gained from the adult population. Most drug studies have focused on the population between 13 and 65 years of age. It has been estimated that approximately 75% of currently approved drugs lack Health Canada approval for pediatric use and therefore lack specific dosage guidelines for neonates and children (Rieder, 2011). Fortunately, many excellent pediatric drug dosage books are available. Most drugs are effective in younger and older patients, but often drugs behave differently in patients at the opposite ends of the age spectrum. It is vitally important from the standpoint of safe and effective drug administration to understand what these differences are and how to adjust for them.

Drug Therapy During Pregnancy

A fetus is exposed to many of the same substances as the mother, including any drugs that she takes—prescription, nonprescription, or illicit drugs. The first trimester of pregnancy is generally the period of greatest danger of drug-induced developmental defects.

Transfer of both drugs and nutrients to the fetus occurs primarily by **diffusion** across the placenta, although not all drugs cross the placenta. Recall from chemistry that diffusion is a passive process based on differences in concentration between different tissues. **Active transport** requires the expenditure of energy and often involves some sort of cell-surface protein pump. The factors that contribute to the safety or potential harm of drug therapy during pregnancy can be broadly broken down into three areas: drug properties, fetal gestational age, and maternal factors.

Drug properties that impact drug transfer to the fetus include the drug's chemistry, its dosage, and concurrently administered drugs. Examples of relevant chemical properties include molecular weight, protein binding, lipid solubility, and chemical structure. Important drug dosage variables include dose and duration of therapy.

Fetal gestational age is an important factor in determining the potential for harmful drug effects to the fetus. The fetus is at the greatest potential for drug-induced developmental defects during the first trimester of pregnancy. During this period, the fetus undergoes rapid cell proliferation. Skeleton, muscles, limbs, and visceral organs are developing at their most rapid rate. Self-treatment of any minor illness is strongly discouraged any time during pregnancy, but particularly during the first trimester. Gestational age is also important in determining when a drug can most easily cross the placenta to the fetus. During the last trimester, the greatest percentage of maternally absorbed drug gets to the fetus.

Maternal factors also play a role in determining drug effects on the fetus. Any change in the mother's physiology can affect the amount of drug to which the fetus may be exposed. Maternal kidney and liver functions affect drug metabolism and excretion. Impairment in either kidney or liver function may result in higher drug levels or prolonged drug exposure and thus increased fetal transfer. Maternal genotype may also affect how certain drugs are metabolized (pharmacogenetics). The lack of certain enzyme systems may result in adverse drug effects to the fetus when the mother is exposed to a drug that is normally metabolized by that enzyme.

Although exposure of the fetus to drugs is most detrimental during the first trimester, drug transfer to the fetus is more likely during the last trimester. This is the result of enhanced blood flow to the fetus, increased fetal surface area, and increased amount of free drug in the mother's circulation. There may be some specific situations when a drug may be used in one trimester but not in another.

It is important to use drugs judiciously during pregnancy; however, there are certain situations that require their use. Without drug therapy, maternal conditions such as hypertension, epilepsy, diabetes, and infection could seriously endanger both the mother and the fetus, and the potential for harm far outweighs the risks of appropriate drug therapy.

TABLE 4.1 Pregnancy Safety Categories

Subsection	Description
Pregnancy	Provides information about the use of the drug in women who are pregnant (e.g., dose and potential risk to the developing fetus). Information about the existence of a pregnancy registry that collects and maintains data on how pregnant women are affected when they use the prescribed drug or biological product is also required.
Lactation	Provides information about the use of the drug while breastfeeding (e.g., amount of drug in breast milk and potential effects on the child being breastfed).
Females and Males of Reproductive Potential	Provides information about how a drug may affect pregnancy testing, contraception, and infertility as it relates to the drug. This information has been included in labelling, but there was no consistent placement for it until now.

Note: Within the pregnancy and lactation subsections will be three subheadings: risk summary, clinical considerations, and data. These subheadings will provide more detailed information (e.g., human and animal data on the use of the drug, specific adverse reactions of concern for pregnant or breastfeeding women).

Source: U.S. Food & Drug Administration. (2016). Pregnancy and lactation labeling (drugs) final rule. Retrieved from <http://www.fda.gov/Drugs/DevelopmentApprovalProcess/DevelopmentResources/Labeling/ucm093307.htm>.

In 1979, in response to the thalidomide tragedy, the U.S. Food & Drug Administration (FDA) implemented labelling requirements with the intent of providing evidence-informed information about the use of medication in pregnancy. In 2014, the FDA introduced a labelling rule that replaces the former product letter risk categories—A, B, C, D, and X—with three detailed realistic subsections that describe the risks and benefits of prescription drugs and biologic medicines used by women who are pregnant and lactating. The three main categories include: pregnancy, lactation, and females and males of reproductive potential; the rule came into effect in June of 2015. **Health Canada (2018a)** recommends labelling risks for medication for both prescription and nonprescription medication. Canadian drug labels and monographs must include information regarding risk during pregnancy and for breastfeeding women.

(See **Health Canada [2015]** Guidance Document: Labelling of Pharmaceutical Drugs for Human Use: <https://www.canada.ca/en/health-canada/services/drugs-health-products/drug-products/applications-submissions/guidance-documents/labelling-pharmaceutical-drugs-human-use-2014-guidance-document.html#a521>; and **Health Canada [2018b]** Notice: Guidance Document: Labelling Requirements for Nonprescription Drugs: <https://www.canada.ca/en/health-canada/services/drugs-health-products/natural-non-prescription/legislation-guidelines/guidance-documents/labelling-requirements-non-prescription-drugs/notice-aug-2018.html>). The categories are described in Table 4.1.

Drug Therapy During Breastfeeding

Breastfed infants are at potential for exposure to drugs consumed by the mother. A wide variety of drugs easily cross

TABLE 4.2 Classification of Young Patients

Age Range	Classification
Younger than 38 wks gestation	Premature or preterm infant
Younger than 1 mo	Neonate or newborn infant
1 mo to younger than 1 yr	Infant
1 yr to 12 yr	Child
13 yr to 19 yr	Adolescent

Note: The meaning of the term *pediatric* may vary with the individual drug and clinical situation. Often the maximum age for a pediatric patient may be identified as 16 years of age. Consult manufacturer's guidelines for specific dosing information.

from the mother's circulation into the breast milk and subsequently to the breastfeeding infant. Drug properties like those discussed in the previous section influence the exposure of infants to drugs via breastfeeding. The primary drug characteristics that increase the likelihood of drug transfer via breastfeeding include fat solubility, low molecular weight, nonionization, and high concentration. Some drugs that are considered weak basics may accumulate in breast milk.

Fortunately, breast milk is not the primary route for maternal drug excretion. Drug levels in breast milk are usually lower than those in the maternal circulation. The actual amount of exposure depends largely on the volume of milk consumed. The ultimate decision as to whether a breastfeeding mother should take a drug depends on the risk–benefit ratio. The risks of drug transfer to the infant in relation to the benefits of continuing breastfeeding and the therapeutic benefits to the mother must be considered on a case-by-case basis.

Considerations for Children: Neonatal and Pediatric Patients

Pediatric patients are defined based on age. The term **neonate** is used for the period between birth and 1 month of age. An infant is between 1 and 12 months of age, a child is between 1 and 12 years of age, and an adolescent is between 13 and 19 years of age. The age ranges that correspond to the various terms applied to pediatric patients are shown in Table 4.2.

Physiology and Pharmacokinetics

Pediatric pharmacotherapy focuses on the unique therapeutic needs of neonates, infants, children, and adolescents. Patients in these age groups offer challenges distinct from those of adult patients. Drugs behave differently in this population; for example, medications may not be absorbed, distributed, metabolized, or eliminated in the same manner as in adults, causing increased or decreased efficacy or safety. As well, pediatric patients handle drugs much differently from adult patients, based primarily on the immaturity of vital organs. In both neonates and older pediatric patients, anatomical structures and physiological systems and functions are still in the process of developing. The [Special Populations: Children](#) box on this page lists those physiological

SPECIAL POPULATIONS: CHILDREN

Pharmacokinetic Changes in Children

Absorption

- Gastric pH is less acidic because acid-producing cells in the stomach are immature until approximately 1 to 2 years of age.
- Gastric emptying is slowed because of slow or irregular peristalsis, which can result in a greater time difference between drug administration and plasma concentration. Drug absorption may potentially be increased.
- First-pass elimination by the liver is reduced because of the immaturity of the liver and reduced levels of microsomal enzymes.
- Reduced bile salt formation decreases bioavailability of lipophilic drugs.
- Intramuscular absorption is faster and irregular.

Distribution

- Total body water is 70 to 80% in full-term infants, 85% in premature newborns, and 64% in children 1 to 12 years of age, resulting in increased distribution and dilution of water-soluble drugs in these groups.
- Fat content is lower in young patients because of greater total body water.
- Protein binding is decreased because of decreased production of protein by the immature liver; lower protein binding can result in higher concentrations of free drugs in the body.
- More drugs enter the brain because of an immature blood–brain barrier. Consequently, some drugs will have an enhanced effect.

Metabolism

- Levels of microsomal enzymes are decreased because the immature liver has not yet started producing enough.
- Once liver enzymes are produced, older children may have increased metabolism and require higher doses or more frequent administration of medications (particularly pain medications).
- Many variables affect metabolism in premature infants, infants, and children, including the status of liver enzyme production, genetic differences, and substances to which the mother was exposed during pregnancy. For example, the neonatal liver is not yet developed sufficiently to be able to metabolize a large proportion of drug substrates.

Excretion

- Glomerular filtration rate and tubular secretion and resorption are all decreased in young patients because of kidney immaturity; drug excretion is decreased.
- Perfusion to the kidneys may be decreased, which results in reduced kidney function, concentrating ability, and excretion of drugs.

factors that alter the pharmacokinetic properties of drugs in young patients.

Pharmacodynamics

Drug actions (or pharmacodynamics) are altered in young patients, and the maturity of various organs determines how drugs act in the body. Certain drugs may be more toxic, whereas others may be less toxic. The sensitivity of receptor sites may also vary with age; thus, higher or lower dosages may be required, depending on the drug. In addition, rapidly developing tissues may be more sensitive to certain drugs, and therefore smaller doses may be required. Because of this receptor sensitivity, certain drugs are generally contraindicated during the growth years. For instance, tetracycline may permanently discolour a young person's teeth; corticosteroids

may suppress growth when given systemically (but not when delivered via asthma inhalers, for example); and quinolone antibiotics may damage cartilage.

Dosage Calculations for Pediatric Patients

Most drugs have not been sufficiently investigated to ensure their safety and effectiveness in children. Despite this lack of research, there are numerous excellent pediatric dosage references. Because pediatric patients (especially premature infants and neonates) have small bodies and immature organs, they are particularly susceptible to drug interactions, toxicity, and unusual drug responses. Pediatric patients require different dosage calculations than adults do. Characteristics of pediatric patients that have a significant effect on dosage calculation include the following:

- The skin is thinner and more permeable.
- The stomach lacks acid to kill bacteria.
- The lungs have weaker mucous barriers.
- Body temperature is less well regulated and dehydration occurs easily.
- The liver and kidneys are immature and so drug metabolism and excretion are reduced.

Many formulas for pediatric dosage calculation have been used throughout the years. Formulas involving age, weight, and body surface area (BSA) are most commonly employed as the basis for calculations.

BSA-based formulas are the most accurate of the dosage formulas and are used primarily for calculating doses of chemotherapy and for high-risk infants such as preterm infants. The ratio of BSA varies with the length of the infant. For the BSA method, the nurse needs the following information:

- Drug order with drug name, dose, route, time, and frequency
- Information regarding available dosage forms
- Pediatric patient's height in centimetres (cm) and weight in kilograms (kg)
- BSA nomogram for children (e.g., West nomogram [shown in Fig. 4.1]; there are other modified formulations for determining BSA available)
- Recommended adult drug dosage

The West **nomogram** (see Fig. 4.1) uses a child's height and weight to determine the child's BSA. This information is then inserted into the BSA formula to obtain a drug dosage for a specific pediatric patient. Online calculators that determine BSA using the West nomogram and other applications are widely available online.

Consider the following examples:

$$\frac{\text{BSA of Child}}{\text{BSA of Adult}} \times \text{Adult dose} = \text{Estimated child's dose}$$

$$\text{BSA of Child (m}^2\text{)} \times \frac{\text{Manufacturer's Recommended dose}}{\text{m}^2} = \text{Estimated child's dose}$$

The most commonly used method to calculate drug dosages is the body weight method. Most drug references recommend dosages based on milligrams per kilogram of body weight. Weight-based dosage calculators are available online. The following information is needed to calculate the pediatric dosage:

- Drug order (as discussed previously)
- Pediatric patient's weight in kilograms (1 kg = 2.2 pounds)
- Pediatric dosage as per manufacturer or drug formulary guidelines
- Information regarding available dosage forms

When using either of the previous methods, the nurse must do the following to ensure the correct pediatric dose:

- Determine the pediatric patient's weight in kilograms
- Use a current drug reference to determine the usual dosage range per 24 hours in milligrams (mg) per kilogram (kg)
- Determine the dose parameters by multiplying the weight by the minimum and maximum daily doses of the drug (the safe range)
- Determine the total amount of the drug to administer per dose and per day
- Compare the drug dosage prescribed with the calculated safe range
- If the drug dosage raises any concerns or varies from the safe range, contact the health care provider or prescriber immediately and do not give the drug

A common source of medication error and potential toxicity is confusing pounds with kilograms. Unless otherwise noted, the child's weight is to be given in kilograms, not pounds. Take great care to ensure that the correct weight is reported to the prescriber. In calculating pediatric dosages, the factor of organ maturity must always be considered, along with BSA, age, and weight. When all of these physical developmental factors are considered, the likelihood of safe and effective drug administration is increased. Emotional developmental considerations must also be a part of the decision-making process in drug therapy with pediatric patients.

Considerations for Older Adult Patients

Due to the decline in organ function that occurs with advancing age, older adult patients handle drugs physiologically differently from adult patients. Drug therapy in older adults is more likely to result in adverse effects and toxicity.

An **older adult** is defined as one who is 65 years of age or older. The terms *elderly* and *older adult* have different meanings in different societies, so their definitions are somewhat arbitrary. In most developed countries, these terms refer to retirement age, which often occurs around the age of 65. However, for research purposes, subgroups of older adults, such as the "younger old" (ages 65 to 75), the "older old" (ages 75 to 85), and "oldest old" (ages 85+) may be identified. It is also important to note that chronological age is not a precise marker for changes that accompany aging. There are dramatic variations in health status, levels of participation, and independence among older adults of the same age.

This segment of the population is growing at a dramatic pace (See **Special Populations: Older Adults** box: Percentage

Fig. 4.1 West nomogram for infants and children. S.A., surface area. (Modified from data by Boyd, E., & West, C. D. (2011). In R. M. Kliegman, B. Stanton, J. St. Geme, et al. (Eds.) *Nelson textbook of pediatrics* (19th ed.). Philadelphia: Saunders.)

of Population Older than 65 Years of Age). At the beginning of the twentieth century, older adults constituted a mere 5% of the total population in Canada. At that time, more people died of infections than of degenerative, chronic illnesses such as heart disease, cancer, and diabetes. As medical and health care technology has advanced, so has the ability to prolong life. This shift has resulted in a growing population of older adults that is expected to continue for decades. [Statistics Canada \(2015\)](#) estimates that, by 2030, the older adult population will accelerate beyond previous 2013 estimations. When the youngest of the baby boomers turn

65 in 2030, the total Canadian population over the age of 65 will increase to 23.6%, and by 2063, this number could increase to up to 27.8% (see <https://www150.statcan.gc.ca/n1/pub/91-520-x/2014001/section02-eng.htm>). Older adults aged 85 years and over make up the fastest growing age group in Canada. Life expectancy is currently approximately 81 years. These trends are expected to continue as new disease prevention and treatment methods are developed. However, in contrast, compared to the overall Canadian population, First Nations, Inuit, and Métis populations are younger and growing at a faster rate.

SPECIAL POPULATIONS: OLDER ADULTS

Percentage of Population Older than 65 Years of Age

Year	Percentage Over Age 65
1900	5%
2001	12.6%
2021	18.5%
2031	22.8%
2061	25.5%

Source: Government of Canada. (2014). Government of Canada — Action for seniors report. Retrieved from <https://www.canada.ca/en/employment-social-development/programs/seniors-action-report.html>.

SPECIAL POPULATIONS: OLDER ADULTS

Alzheimer's Disease in Canada

- Alzheimer's disease is fatal, progressive, and degenerative, affecting approximately half a million Canadians, and the number of people affected is expected to increase to 937 000 by 2031 (Alzheimer Society Canada, 2018a).
- Advanced age is the most significant risk factor. Alzheimer's disease affects 16 000 of Canadians over the age of 65, and approximately 25 000 new cases of dementia are diagnosed each year (Alzheimer Society Canada, 2018b).
- Family history and genetics are significant risk factors. Risk increases by 10 to 40% if a first-degree relative has Alzheimer's disease. The ApoE4 gene is the most important genetic risk factor.
- Gender also is a significant risk factor; 65% of those with Alzheimer's disease diagnosed over the age of 65 are women (Alzheimer Society Canada, 2018c).
- Alzheimer's disease is characterized by the slow and initially insidious decline of memory and functional ability along with behavioural and personality changes. Hallmark abnormalities of Alzheimer's disease include deposits of the protein fragment beta-amyloid (plaques) and twisted strands of the protein tau (tangles) as well as evidence of nerve cell damage and death in the brain.
- Criteria and guidelines for diagnosing Alzheimer's disease recommend describing it in three stages. Studies are providing evidence that a pre-clinical stage, when brain degeneration occurs, may begin 10 years before the second stage, when clinical symptoms of mild cognitive impairment emerge. The third stage is dementia (The Lancet, 2013).
- Promising areas of research focused on early detection include biological markers such as low amyloid- β in cerebrospinal fluid and neuroimaging techniques. Such advances will facilitate the development of disease-modifying treatments, early diagnosis, and improve clinical care (Fraller, 2013).
- Currently, there is no pharmacological cure for Alzheimer's disease; however, there are several medications that may improve quality of life for those with Alzheimer's disease.

Issues in Clinical Drug Use in Older Adults

Older adults have considerable interindividual variability in health, disability, age-related changes, polymorbidity, and associated polypharmacy, making generalization of prescribing recommendations difficult. At any given time, the

average older adult takes up to 10 prescription drugs as well as over-the-counter (OTC) medications, which can increase the risk of drug interactions. According to the Canadian Institute for Health Information (2018), approximately 1.6 million seniors, or 1 in 4 Canadians over the age of 65, were prescribed 10 or more drug classes in 2016. The most commonly used drug in nearly half of all older adults in Canada is a statin for high cholesterol; also common are drugs prescribed for high blood pressure, acid reflux, and peptic ulcer disease (CIHI, 2018). Other commonly prescribed drugs for older adults include antihypertensives, beta blockers, diuretics, insulin, and potassium supplements. The most frequently used drugs are analgesics, laxatives, and nonsteroidal anti-inflammatory drugs (NSAIDs). Older adults, especially those of certain ethnicities, may use various folk remedies of unknown composition that are unfamiliar to their health care providers.

Not only do older adults consume a greater proportion of prescription and OTC medications, they commonly take multiple medications daily. One reason for the use of multiple medications is the occurrence of more chronic diseases, which now have even more drug options available for treatment. More than 80% of patients taking eight or more drugs have one or more chronic illnesses. More complicated medication regimens predispose older adults to self-medication errors, especially those with reduced visual acuity and manual dexterity. Such sensory and motor deficits can be particularly problematic when older adults split their own tablets. The practice of pill splitting occurs commonly for financial reasons because lower- and higher-strength tablets often have similar costs. Other factors that may contribute to medication errors in older adults include lack of adequate patient education and understanding of their drug regimens and use of multiple prescribers and multiple pharmacies. In this age of medical specialization, patients may see several prescribers for their many illnesses. It is therefore important for the patient to use only one pharmacy so that monitoring for drug interactions and duplicate therapy can occur.

Older adult patients are hospitalized frequently due to adverse drug reactions. Many people, including older adults, use natural health products, including herbal remedies and dietary supplements, which can interact with prescription drugs. The simultaneous use of multiple medications is called **polypharmacy**. The chance of a drug interaction is approximately 6% for a patient receiving 2 medications. The risk increases dramatically as the number of drugs the patient is taking increases. For a patient taking 5 medications, the chance of a drug interaction is 50%, and for those taking 10 or more medications, the chance is 100%.

Some drugs may be given specifically to counteract the adverse effects of other drugs (e.g., a potassium supplement to counteract the potassium loss caused by certain diuretic medications). This is one example of what is known as the *prescribing cascade*. Often it is difficult to distinguish adverse drug effects from disease symptoms. Although such prescribing is sometimes appropriate, it also increases the potential for

more adverse drug events (including drug interactions, hospitalization or prolonged hospital stays, hip fractures secondary to drug-induced falls, addiction risk, anorexia, confusion, urinary retention, and fatigue). Recognizing polypharmacy, and taking steps to reduce it whenever possible by decreasing the number or dosages of drugs taken, can significantly reduce the incidence of adverse outcomes. Various types of electronic health records, e-prescribing, computerized medical order entry, and electronic medication administration records (eMARs), as well as clinical decision support systems (used at the point of care to make evidence-informed decisions) have the potential to reduce inappropriate prescribing and polypharmacy in older adults. Appropriate drug doses for older adult patients may sometimes be one-half to two-thirds of the standard adult dose. As a rule, dosing for older adults should follow the advice, “Start low and go slow,” which means to start with the lowest possible dose (often less than an average adult dose) and increase the dose slowly, based on patient response.

Another important issue in this population is nonadherence with prescribed medication regimens. Drug nonadherence is reported to occur in roughly 40% of older adult patients and is associated with increased rates of hospitalization. Nonadherence is multifactorial and may include patient factors such as poor understanding of the disease, lack of involvement in the treatment decision-making process, reduced ability to purchase medication, and suboptimal medical literacy; the occurrence of adverse effects; physician factors such as prescribing complex drug regimens and not explaining the benefits and adverse effects of a medication effectively; and health system factors such as an overtaxed health care system with inadequate time engaged with patients for proper assessment and understanding of the patients’ needs (Brown & Bussell, 2011; Holt, Rung, Leon, et al., 2013).

Physiological Changes

Physiological changes associated with aging affect the actions of many drugs. As the body ages, the functioning of several organ systems slowly declines. The collective physiological changes associated with the aging process have a major effect on the disposition and action of drugs. Table 4.3 lists some of the body systems most affected by the aging process.

The sensitivity of older adults to many drugs requires careful monitoring and dosage adjustment. The criteria for drug dosages in older adults must include consideration of body weight and organ functioning, with emphasis on liver, kidney, cardiovascular, and central nervous system function (similar to the criteria for pediatric dosages). With aging, there is a general decrease in body weight.

Changes in drug molecule receptors in the body can make a patient more or less sensitive to certain medications. For example, older adults commonly have increased sensitivity to central nervous system depressant medications (e.g., anxiolytics, tricyclic antidepressants) because of reduced integrity of the blood–brain barrier.

TABLE 4.3 Physiological Changes in Older Adults

System	Physiological Change
Cardiovascular	↓ Cardiac output = ↓ absorption and distribution ↓ Blood flow = ↓ absorption and distribution
Gastrointestinal	↑ pH (alkaline gastric secretions) = altered absorption ↓ Peristalsis = delayed gastric emptying
Liver	↓ Enzyme production = ↓ metabolism ↓ Blood flow = ↓ metabolism
Kidney	↓ Blood flow = ↓ excretion ↓ Function = ↓ excretion ↓ Glomerular filtration rate = ↓ excretion

The most important organs from the standpoint of the breakdown and elimination of drugs are the liver and the kidneys. Measurement of kidney function is an essential element of care for older adults because it may evaluate effectiveness of drug therapies and allow for drug adjustments to prevent toxicity. Canadian guidelines to assess deteriorating kidney function and to stage kidney disease are based on the estimated glomerular filtration rate (eGFR) and the presence of albuminuria. *Albuminuria* is defined as a urine albumin-to-creatinine ratio greater than 2.0 mg/mmol for men and greater than 2.8 mg/mmol for women. Screening of the urine creatinine/albumin level should be incorporated into routine assessments for all older adults. The serum creatinine level in older adults may be lower because of the decline of muscle mass (creatinine is a by-product of muscle metabolism).

Liver function is assessed by testing the blood for liver enzymes such as aspartate aminotransferase (AST) and alanine aminotransferase (ALT). These laboratory values can help in assessing the ability to metabolize and eliminate medications and can aid in anticipating the risk of toxicity, drug accumulation, or both. Laboratory assessments need to be conducted at least annually, both for preventive health monitoring and for screening for possible toxic effects of drug therapy. Such assessments may be indicated more frequently (e.g., every 1, 3, or 6 months) in those patients requiring higher-risk drug regimens.

Pharmacokinetics

The pharmacokinetic phases of absorption, distribution, metabolism, and excretion (see Chapter 2) may be different in older adults from those in younger adults. Awareness of these differences helps the nurse ensure appropriate administration of drugs and monitoring of older adults. The **Special Populations: Older Adults** box: Pharmacokinetic Changes lists the four pharmacokinetic phases and summarizes how they are altered by the aging process.

Absorption. Absorption in older adults can be altered by many mechanisms. Advancing age results in reduced absorption of both dietary nutrients and drugs. Several physiological

SPECIAL POPULATIONS: OLDER ADULTS

Pharmacokinetic Changes

Absorption

- Gastric pH is less acidic because of a gradual reduction in the production of hydrochloric acid in the stomach.
- Gastric emptying is slowed because of a decline in smooth muscle tone and motor activity.
- Movement throughout the gastrointestinal tract is slower because of decreased muscle tone and motor activity.
- Blood flow to the gastrointestinal tract is reduced by 40 to 50% because of decreased cardiac output and decreased perfusion.
- The absorptive surface area is decreased because the aging process blunts and flattens villi.

Distribution

- In adults 40 to 60 years of age, total body water is 55% in males and 47% in females; in those over 60 years of age, total body water is 52% in males and 46% in females.
- Fat content is increased because of decreased lean body mass.
- Protein (albumin) binding sites are reduced because of decreased production of proteins by the aging liver and reduced protein intake.

Metabolism

- The levels of microsomal enzymes are decreased because the capacity of the aging liver to produce them is reduced.
- Liver blood flow is reduced by approximately 1.5% per year after 25 years of age, which decreases liver metabolism.

Excretion

- Glomerular filtration rate is decreased by 40 to 50%, primarily because of decreased blood flow.
- The number of intact nephrons is decreased.

changes account for this reduction in absorption. Older adult patients have a gradual reduction in the ability of the stomach to produce hydrochloric acid, which results in a decrease in gastric acidity and may alter the absorption of some drugs. In addition, the combination of decreased cardiac output and advancing atherosclerosis results in a general reduction in the flow of blood to major organs, including the stomach. By 65 years of age, there is an approximately 50% reduction in blood flow to the gastrointestinal tract. Absorption, whether of nutrient or drug, is dependent on good blood supply to the stomach and intestines. The absorptive surface area of an older adult person's gastrointestinal tract is often reduced, thus decreasing drug absorption.

Gastrointestinal motility is important for moving substances out of the stomach and through the gastrointestinal tract. Muscle tone and motor activity in the gastrointestinal tract are reduced in older adults. Often, this results in constipation, for which older adults frequently take laxatives. The use of laxatives may accelerate gastrointestinal motility enough to actually reduce the absorption of drugs.

Distribution. The distribution of medications throughout the body is also different in older adults. There seems to be a gradual reduction in the total body water content with aging. Therefore, the concentrations of highly water-soluble (hydrophilic) drugs may be higher in older adults because they have less body water in which the drugs can be diluted. The composition of the body

also changes with aging, with a decrease in lean muscle mass and an increase in body fat. In both men and women, there is an approximately 20% reduction in muscle mass between the ages of 25 and 65 years and a corresponding 20% increase in body fat. Fat-soluble (or lipophilic) drugs, such as hypnotics and sedatives, are distributed primarily to fatty tissues, which may result in prolonged drug actions or toxicity.

Older adult patients may have reduced protein concentrations, due in part to reduced liver function. Reduced dietary intake or poor gastrointestinal protein absorption can cause nutritional deficiencies and reduced blood protein levels. Regardless of the cause, the result is a reduced number of protein-binding sites for highly protein-bound drugs. This change results in higher levels of unbound (active) drug in the blood.

Remember that only drugs that are not bound to proteins are active. Therefore, the effects of highly protein-bound drugs may be enhanced if their dosages are not adjusted to accommodate any reduced serum albumin concentrations. Some highly protein-bound drugs are warfarin and phenytoin.

Metabolism. Metabolism declines with advancing age. The transformation of active drugs into inactive metabolites is performed primarily by the liver. The liver loses mass with age and slowly loses its ability to metabolize drugs effectively due to reduced production of microsomal (cytochrome P450) enzymes. There is also a reduction in blood flow to the liver because of reduced cardiac output and atherosclerosis. A reduction in the hepatic blood flow of approximately 1.5% per year occurs after 25 years of age. All of these factors contribute to prolonging the half-life of many drugs (e.g., warfarin), which can potentially result in drug accumulation if serum drug levels are not closely monitored.

Excretion. Kidney function declines in roughly two-thirds of older adults. A reduction in the glomerular filtration rate of 40 to 50%, combined with a reduction in cardiac output leading to reduced kidney perfusion, can result in delayed drug excretion and therefore drug accumulation. This is especially true for drugs with a low therapeutic index, such as digoxin. Kidney function needs to be monitored frequently. Appropriate dose and interval adjustments may be determined on the basis of results of kidney and liver function studies as well as the presence of therapeutic levels of the drug in the serum. If a decrease in kidney and liver function is known, the dosage is usually adjusted by the prescriber so that drug accumulation and toxicity may be minimized.

Problematic Medications for Older Adults

Certain classes of drugs are more likely to cause problems in older adult patients because of many of the physiological alterations and pharmacokinetic changes already discussed. [Table 4.4](#) lists some of the more common medications that are problematic. Some drugs to be avoided in older adults have been identified by various professional organizations such as the [Institute for Safe Medication Practices Canada \(2014\)](#), as well as by various other authoritative sources. Since the 1990s, an effective tool, the Beers Criteria, has been used to identify drugs that may be inappropriately prescribed, be inadequate, or cause adverse drug reactions in older adults (see the [Evidence in Practice](#) box on page 55). The Beers Criteria are useful and help determine risk-associated situations for older adults and specific drugs that may be problematic.

EVIDENCE IN PRACTICE

Update on Application of the Beers Criteria for Prevention of Adverse Drug Events in Older Adults

Review

In 1991, a panel of experts led by Mark H. Beers, MD, identified a list of “potentially inappropriate medications” (PIMs) for use in individuals 65 years of age and older. These criteria were intended for use with nursing home residents and then were expanded and revised to include all settings of geriatric care. The specific aim of the project was to predict adverse drug reactions (ADRs) in this age group. The Beers Criteria were updated in 1997 and 2002 and provided a listing of drugs and drug classes to be avoided in older adults. The criteria also identified disease states considered to be contraindications for some drugs. In 2005, research was conducted to confirm the relationship between PIM prescribing, as defined by Beers Criteria, and the occurrence of ADRs in older adult patients treated at outpatient clinics. In 2012, a list of medications was identified and classified into three categories: (1) potentially inappropriate medications and classes to avoid in older adults, (2) potentially inappropriate medications and classes to avoid in older adults with certain diseases and syndromes, and (3) medications to be used with caution in older adults. In 2015, the Beers Criteria expanded the 2012 list with several drugs removed from the list and with some additions.

Type of Evidence

The 2015 Beers Criteria uses a more comprehensive, systematic review and grading of evidence than the previous 2012 updates did. The quality of the criteria continued to include (1) application of an evidence-informed approach, (2) support of the American Geriatrics Society (AGS) in conjunction with an interdisciplinary panel of 13 experts in geriatric care and pharmacotherapy, (3) use of a time-tested method for developing care guidelines while using the Institute of Medicine’s standards for evidence/transparency as an important benchmark, and (4) an extensive review of more than 6 700 high-quality research studies and clinical trials about prescription medications for this age group.

Results of the Study

Consistent with the 2012 AGS Beers Criteria, the 2015 criteria support clinical judgement. They include 40 potentially problematic medications or classes of medications. In addition, the 2015 Beers Criteria include: (1) separate guidance on avoiding 13 drug–drug combinations known to cause harm; (2) a specific list of 20 problematic medications to avoid or doses that need to be adjusted in older adults based on the patient’s kidney function; and (3) three new medications and two new “classes” of medications added to the list (e.g., proton pump inhibitors). New in 2015 are companion guides to assist the health care provider in using the guidelines as well as potential alternative suggestions to the use of high-risk medications in the older adult.

Link of Evidence to Nursing Practice

These criteria update drugs to avoid and use with caution in older adults. In addition, they increase awareness of inappropriate medication use in this age group and may also be integrated into electronic health records. With the support of the AGS, the criteria will continue to develop over time and will continue to help improve the health of older adults. The criteria should be used as a starting point from which to develop a comprehensive process to improve medication appropriateness and safety.

Ethnocultural Considerations

Canada is a multiculturally diverse nation as evidenced by its constant and rapidly changing demographics, owing to persistent low fertility, strong immigration, and the number of descendants. Prior to the 1970s, 78.3% of immigration to Canada came from European countries (e.g., the United Kingdom, Italy, Germany, and the Netherlands). The influx of European-born immigrants has declined steadily.

At the time of the 2016 census, approximately 21.9% of the Canadian population had reported that they had been or were a landed immigrant or permanent resident. This is an important statistic because it is close to the 1921 census reported 22.3%, which was the highest since confederation ([Statistics Canada, 2017](#)). Recent immigrants to Canada, between 2011 and 2016, totaled 1 212 075, representing 3.5% of the Canadian population in 2016. It is estimated that one in five Canadians were born outside of Canada, with that proportion projected to increase up to 24.5%–30.0% by 2036. Asia and the Middle East (61.8%) remain the primary source of recent immigrants, followed by Africa (13.4%), with the remainder of immigrants being of European decent ([Statistics Canada, 2017](#)).

The Indigenous population is growing faster than the rest of the Canadian population, largely due to a younger population and high fertility. According to [Statistics Canada \(2018\)](#) there were 1 673 785 Indigenous people living in Canada in 2016, a 42.5% increase since 2006. Between 2006 and 2016 the First Nations population (including those registered or treaty members under the Indian act as well as those who are not) grew by 39.3% reaching 977 230 members, the Métis population grew by 51.2% to 587 545 members (the largest increase over ten years), and the Inuit population grew by 29.1% reaching 65 025 members. It is anticipated the Indigenous population will grow to over 2.5 million members within the next two decades.

The Indigenous population of Canada has endured many years of colonization that have deeply impacted this culture, robbing them of traditions including language, relationships with land and community, as well as traditional healing practices. In 2015, the final Truth and Reconciliation Commission (TRC) report was released ([TRC, 2015](#)). The TRC was formed in response to the largest class action lawsuit in Canada, launched on behalf of Indian Residential School survivors. The final TRC report contained over 6 200 statements from some of the 80 000 Indian Residential School survivors. Stories of separation from family and community, sexual abuse, death from illnesses including TB and influenza, inferior living conditions, starvation, physical punishment, forced labour, together with loss of language, family relationships, healing traditions, and cultural identity, were recorded.

Such ethnocultural demographic shifts and changes significantly impact Canada’s health care system and the delivery of care. The field of ethnopharmacology provides an expanding body of knowledge for understanding the specific impact of cultural factors on patient drug response. It is hampered, however, by the lack of clarity in terms such as **race**, **ethnicity**, and **culture**.

Race is based primarily upon genetically imparted physiological features, among which skin colour is a dominant,

TABLE 4.4 Medications and Conditions Requiring Special Considerations for Older Adults

Medication	Common Complications
Analgesics	
Opioids	Confusion, constipation, urinary retention, nausea, vomiting, respiratory depression, falls
Nonsteroidal anti-inflammatory drugs (NSAIDs)	Edema, nausea, gastric ulceration, bleeding, kidney toxicity
Anticholinergics and antihistamines	Blurred vision, dry mouth, constipation, confusion and sedation, urinary retention, tachycardia
Anticoagulants (heparin sodium, warfarin sodium)	Major and minor bleeding episodes, many drug interactions, dietary interactions
Antidepressants	Sedation and strong anticholinergic adverse effects (see above)
Antihypertensives	Nausea, orthostatic hypotension, diarrhea, bradycardia, heart failure, impotence
Cardiac glycosides (e.g., digoxin)	Visual disorders, nausea, diarrhea, dysrhythmias, hallucinations, decreased appetite, weight loss
CNS depressants (muscle relaxants, opioids)	Sedation, weakness, dry mouth, confusion, urinary retention, ataxia
Sedatives and hypnotics	Confusion, daytime sedation, ataxia, lethargy, increased risk of falls
Thiazide diuretics	Electrolyte imbalance, rashes, fatigue, leg cramps, dehydration
Condition	
Drugs Requiring Special Caution and Monitoring	
Bladder flow obstruction	Anticholinergics, antihistamines, decongestants, antidepressants
Clotting disorders	NSAIDs, aspirin, antiplatelet drugs
Chronic constipation	Calcium channel blockers, tricyclic antidepressants, anticholinergics
Chronic obstructive pulmonary disease	Long-acting sedatives and hypnotics, narcotics, beta blockers
Clotting disorders	NSAIDs, aspirin, antiplatelet drugs
Heart failure and hypertension	Sodium bicarbonate, decongestants, amphetamines, OTC cold products
Insomnia	Decongestants, bronchodilators, monoamine oxidase inhibitors
Parkinson's disease	Antipsychotics, phenothiazines
Syncope and falls	Sedatives, hypnotics, narcotics, central nervous system depressants, muscle relaxants, antidepressants, antihypertensives

but not the sole, attribute. Nevertheless, it is possible for a person to be of mixed races, some of which, such as the mestizo of Latin America, have become recognized as evolved races. Furthermore, terminology may be ambiguous. Scholars may prefer to use the term *Caucasian* rather than *White*, but the former may not be well understood by many respondents. Other terminology evolves over time, such as the evolution in the United States of *African-American* from *Black* and earlier from *negro*.

The term *First Nations* originated in the 1970s to replace the offensive terminology, *Indian*. In Canada, the term *Indigenous* includes Inuit, First Nations, and Métis. The terms *Indigenous* and *First Nations* are not interchangeable. The Inuit, meaning *people* in Inuktitut, the Inuit language, are a generally homogeneous Indigenous people who live in Nunavut, the Northwest Territories, Northern Quebec and Northern Labrador. The Inuit population forms about 5% of all Indigenous people in Canada. Métis are a distinct Indigenous group, with mixed ancestry as a result of intermarriage between Indigenous women and European men. Métis culture draws on a blend of diverse cultural origins and is unique because of this. Métis people make up approximately 30% of the total Indigenous population. About 68% live in urban areas, with less than 3% living on reserves. First Nations people, who make up approximately 65% of Indigenous people in Canada, belong to over 50 distinct cultural groups or band associations such as Cree, Mi'kmaq, or Dene. Forty-seven percent of First Nations people live on reserves (Raphael, 2009).

It is impossible to know a patient's genotype by either physical appearance or health care history. Ethnocultural assessment needs to be part of the assessment phase of the nursing process. Acknowledgment and acceptance of the influences of a patient's cultural beliefs, values, and customs is necessary to promote optimal health and wellness. Some practices are discussed in the **Ethnocultural Implications** box on page 57. It is important to emphasize that not every patient from the same country shares the same culture. Many countries encompass those of diverse ethnicities, languages, and religions. Even when a country is relatively homogeneous in terms of ethnicity, socioeconomic, political, urban/rural, or regional differences may result in significant diversity, affecting every aspect of health. For this reason, each patient must be individually assessed regarding traditional beliefs and practices. Such assessment requires development of skills in intercultural communication. "Recipe book" approaches to assessment of patients from certain countries or of certain religions are not appropriate and pose risks to quality and safety of care. Religion also has important implications for both health and health care provision. Many lifestyle choices (e.g., diet, use of alcohol and tobacco) are affected by religious belief. Beliefs regarding female modesty, death and dying, reproductive health, hygiene, use of blood products, and other issues have important implications for many areas of health care provision. The increasing religious diversity of Canada strengthens the imperative for health organizations to develop responsive

practice. It is important for health care providers to be aware of key areas affected by religious belief and practice in order to provide culturally responsive care. There is great diversity, not only within each of the world's religions, but also in individual faith and commitment to practice.

Ethnocultural Influences and Genetics on Drug Response

The concept of *polymorphism* is critical to an understanding of how the same drug may result in different responses in different individuals. For example, why might a patient

of Chinese origin require lower dosages of an antianxiety drug than a patient who is White? Why might a patient who is Black respond differently to antihypertensives from a patient who is White? Drug polymorphism refers to the effect of a patient's age, gender, size, body composition, and other characteristics on the pharmacokinetics of specific drugs. Factors contributing to drug polymorphism may be categorized into environmental factors (e.g., diet and nutritional status), cultural factors, and genetic (inherited) factors.

ETHNOCULTURAL CONSIDERATIONS

A Brief Review of Common Practices Among Canada's Major Cultural Groups

Cultural Group	Some Examples of Health Beliefs and Alternative Healers	Verbal and Nonverbal Communication; Touch/ Time	Family	Biological Variations
Asian	May believe in traditional medicine; hot and cold foods; herbs/teas/soups; use of acupuncturist, acupressurist, and herbalist	High respect of others, especially of individuals in positions of authority Not usually comfortable with custom of shaking hands with those of opposite sex Present-oriented	Have close extended family ties; family needs more important than individual needs	Many drug interactions, lactose intolerance, thalassemia
Black people of African descent	May practise folk medicine; employ "root doctors" as healers; spiritualist May use herbs, oils, and roots	Asking personal questions of someone met for the first time seen as intrusive and not proper Direct eye contact seen as rude Present-oriented	Have close extended family ties Women play important key role in making health care decisions	Keloid formation, sickle cell anemia, lactose intolerance
Indigenous	May believe in harmony with nature and ill spirits causing disease May use the medicine wheel and herbs such as: Tobacco: wild tobacco is usually not smoked except in pipe ceremonies and is used to give thanks after a successful harvest or gathering/hunt. Sweetgrass: used for smudging (cleansing) ceremonies. Not ingested as is poisonous. Cedar: is ceremonial and medicinal in both red and white form Sage: is a traditional medicine and is used as part of smudging ceremonies. May use traditional healers Smudge ceremonies, healing circles, and sweat lodge ceremonies as common healing rituals	Speak in low tone of voice Light touch of a person's hand is preferred versus a firm handshake as a greeting Present-oriented	Have close extended family ties; emphasis on family	Lactose intolerance, cleft uvula problems

Note: Each patient is unique and has his or her own cultural attitudes, beliefs, values, customs, and norms and specific health practices that may or may not reflect some of the above examples.

Medication response depends greatly on the level of the patient's adherence with the therapy regimen. Yet adherence may vary depending on the patient's cultural beliefs, experiences with medications, personal expectations, family expectations and influence, and level of education. Adherence is not the only factor, however. Prescribers must also be aware that some patients use alternative natural health remedies that can inhibit or accelerate drug metabolism and therefore alter a drug's response.

Environmental and economic factors (e.g., diet) can contribute to drug response. For example, a diet high in fat has been documented to increase the absorption of the drug griseofulvin (an antifungal drug). Malnutrition with deficiencies in protein, vitamins, and minerals may modify the functioning of metabolic enzymes, which may alter the body's ability to absorb or eliminate a medication.

Historically, most clinical drug trials were conducted using White men, often university students, as research subjects. However, there are data that demonstrate the impact of genetic factors on drug *pharmacokinetics* and drug *pharmacodynamics* or drug response (see Chapter 5). Some individuals of European and African descent are known to be *slow acetylators*. This means that their bodies attach acetyl groups to drug molecules at a relatively slow rate, which results in elevated drug concentrations. This situation may warrant lower drug dosages. A classic example of a drug whose metabolism is affected by this characteristic is the antituberculosis drug isoniazid. In contrast, some patients of Japanese and Inuit descent are more rapid acetylators and metabolize drugs more quickly, which predisposes them to subtherapeutic drug concentrations and may require higher drug dosages.

Levels of the cytochrome P450 enzymes (see Chapter 2) are also known to vary between ethnic groups. This variation has effects on the ability to metabolize many drugs. Most psychotropic drugs (see Chapter 17) are metabolized in the liver in a two-phase process. Cytochrome P450 enzymes often control Phase I of the hepatic metabolism of both antidepressants and antipsychotic drugs. This can affect plasma drug levels, and therefore the intensity of drug response, at different doses. Groups of Asian patients have been shown to be “poor metabolizers” of these drugs and often require lower dosages to achieve desired therapeutic effects. In contrast, White patients are more likely to be classified as “ultrarapid metabolizers” and may require higher drug dosages.

Variations are also reported between ethnic groups in the occurrence of adverse effects. For example, patients of African descent taking lithium may need to be monitored more closely than others for symptoms of drug toxicity, because serum drug levels may be higher than in White patients given the same dosage. Likewise, patients of Japanese and Taiwanese descent may require lower dosages of lithium. For the treatment of hypertension, thiazide diuretics appear to be more effective in Black people of African descent than in White people. Several additional examples of racial and ethnic differences in drug response are outlined in the [Ethnocultural Implications](#) box below.

 **ETHNOCULTURAL CONSIDERATIONS**

Examples of Varying Responses of Different Ethnocultural Groups to Major Drug Classes

Racial or Ethnic Group	Drug Classification	Response
Black of African Descent	Antihypertensive drugs	Black patients of African descent respond better to diuretics than to beta blockers and angiotensin-converting enzyme inhibitors; they respond less effectively to beta blockers and respond best to calcium channel blockers, especially diltiazem. They also respond less effectively to single-drug therapy.
Asian	Antipsychotic and antianxiety drugs	Asian patients require lower doses of certain drugs such as haloperidol and statins and also respond better to lower dosages of antidepressants. Chinese patients require lower dosages of antipsychotics. Japanese patients require lower dosages of antimania drugs.

Note: The comparison group for all responses is patients who are White.

Individuals throughout the world share common views and beliefs regarding health practices and medication use. However, there are also specific ethnocultural influences, beliefs, and practices. Awareness of ethnocultural differences is critical for the care of patients because of the constantly changing Canadian demographic. As a result of these changes, attending to each patient's cultural background helps to ensure safe and high-quality nursing care, including medication administration.

For example, some Black people of African descent have health beliefs and practices that include an emphasis on proper diet and rest; the use of herbal teas, laxatives, and protective bracelets; and the use of folk medicine, prayer, and the “laying on of hands.” Reliance on various home remedies can also be an important component of their health practices. Some patients of Asian descent, especially Chinese patients, believe in the concepts of *yin* and *yang*. Yin and yang are opposing forces that lead to illness or health, depending on which force is dominant in the individual and whether the forces are balanced. Balance produces healthy states. Other common health practices of patients of Asian descent include use of acupuncture, herbal remedies, and heat. All such beliefs and practices need to be considered—especially when patients value their use more highly than the use of medications. Many of these beliefs are strongly grounded in religion. The Asian and Pacific Island racial/ethnic group also includes people who are Thai, Vietnamese, Filipino, Korean, and Japanese, among others.

Indigenous peoples in Canada live in diverse geographical areas. They maintain a diverse variety of rituals, symbols, and practices, which may vary by region. Some may follow traditional religious practices exclusively or follow a mix of

Fig. 4.2 Indigenous Medicine Wheel. Medicine wheels embody the concepts of direction and alignment and emphasize physical, emotional, mental, and spiritual truths. (Beaulieu, K. J. (2019). The seven lessons of the medicine wheel. *Sky Magazine*. Retrieved from <https://saymag.com/the-seven-lessons-of-the-medicine-wheel/>)

Christian and traditional practices, while others may choose Indigenous practices. Their spirituality is deeply connected to the land, including animals and plants, and life is seen as interconnected. Traditional medicines and practices remain an important part of the lives of Inuit, Métis and First Nations people in Canada. Some First Nations people follow the medicine wheel (see Fig. 4.2). The medicine wheel has distinct parts in honour of the number 4 (a number sacred to the First Nations people), which includes 4 directions, 4 seasons, and the 4 aspects of health (physical, emotional, intellectual, and spiritual). These aspects are connected to Mother Earth. Medicine wheels may include the colours red, black, white, and red, as well as white, yellow, red, and green. In addition, the medicine wheel may also include different animals, such as the wolf, eagle, buffalo, or grizzly bear. Indigenous people believe in preserving harmony with nature or keeping a balance between the four aspects of the medicine wheel. When one area is not functioning well, the other three areas are affected. Illness results from a neglected or oppressed spirit or an imbalance. Many use a traditional Indigenous healer or sacred medicines. Medicine is distinguished from healing, which goes beyond mere treatment of sickness. Traditional healing includes a wide range of activities, from physical cures using herbal medicines (such as tobacco, sage, sweetgrass, and cedar [see [Ethnocultural Implications](#)]) and other remedies to the promotion of psychological and spiritual well-being using ceremony, counselling, and the accumulated wisdom of elders (Beaulieu, 2019). The drum is considered a symbol of the living relationship between Indigenous people and the land. The traditional healer for this culture is not only the medicine man or woman but may also include a spiritualist and herbalist, among others. Healing occurs through a variety of methods, including the sweat lodge, healing lodges and circles, and the continuous journey toward Bimaadiziwin, or “the good life.” “Smudging” is a common ceremony used to cleanse the body spiritually and physically. An herb such as sage or sweetgrass is burned and the smoke is rubbed or brushed over the body.

Ayurveda and Unani, traditional healing methods commonly practised by South Asians, emphasize a balance between a person’s behaviour, lifestyle, environment, and mind. For example, South Asians believe that the body’s digestive forces maintain

the bodily humours, and an imbalance in bodily humours leads to physical and psychological illnesses. Muslims believe that ill health occurs due to the will of Allah. It is important to remember that these beliefs vary from patient to patient; therefore, consult with the patient rather than assume that the patient holds certain beliefs because of belonging to a certain ethnic group.

Barriers to adequate health care for the ethnoculturally diverse Canadian patient population include language, poverty, access, pride, and beliefs regarding medical practices. Medications may have a different meaning to different cultures, as would any form of medical treatment. Therefore, before any medication is administered, complete a thorough ethnocultural assessment. This assessment includes questions in regard to the following:

- Languages spoken, written, and understood; need for an interpreter
- Health beliefs and practices
- Past uses of medicine
- Use of herbal treatments, folk remedies, home remedies, or natural health products
- Use of over-the-counter (OTC) drugs
- Usual responses to illness
- Responsiveness to medical treatment
- Religious practices and beliefs (e.g., many Christian Scientists believe in taking no medications at all)
- Support from the patient’s ethnocultural community that may provide resources or assistance as needed, such as religious connections, leaders, family members, or friends
- Dietary habits

Ethnocultural Nursing Considerations and Drug Therapy

It is important to be knowledgeable about drugs that may elicit varied responses in culturally diverse patients or those from different racial or ethnic groups. Varied responses may include differences in therapeutic dosages and adverse effects, so that some patients may have therapeutic responses at lower dosages than are typically recommended. For example, in patients of Asian descent who take traditional antipsychotics, symptoms may be managed effectively at lower dosages than the usual recommended dosage range. Also, patients of Chinese descent may require lower doses of antidepressants.

Another aspect of cultural care as it relates to drug therapy is the recognition that patterns of communication may differ based on a patient’s race or ethnicity. Communication includes the use of language, tone, and volume of the voice, as well as spatial distancing, touch, eye contact, greetings, and naming format. It is important to assess and apply these aspects of cultural and racial or ethnic variations to patient care and to drug therapy and the nursing process. Precise instructions must be included in patient education about medication(s) and how to best and safely take them. Avoiding the use of contractions such as *can’t*, *won’t*, and *don’t* is important with patients who speak other languages to prevent confusion. Instead, use of *cannot*, *will not*, and *do not* is recommended to improve understanding.

❖ NURSING PROCESS

◆ ASSESSMENT

◆ Pediatric Considerations

Before any medication is administered to a pediatric patient, obtain a thorough health history and medication history with assistance from the parent, caregiver, or legal guardian. The following are areas to be included:

- Age
- Age-related concerns about organ functioning
- Allergies to drugs and food
- Baseline values for vital signs
- Physical assessment findings
- Height in centimetres and feet/inches
- Weight in kilograms and pounds
- Medical and medication history (including adverse drug reactions); current medication and related dosage forms and routes, and the patient's tolerance of the forms and routes
- Use of prescription and OTC medications in the home setting
- Level of growth and development and related developmental tasks
- Motor and cognitive responses and their age-appropriateness
- Age-related fears
- State of anxiety of the patient or family members or caregiver
- Usual method of medication administration, such as use of a calibrated spoon or needleless syringe
- Usual response to medications
- Resources available to the patient and family

The prescriber will determine the medication to be delivered. However, the nurse is responsible for detecting any errors in calculation of dosage, as well as for preparing the medication and administering the drug. The nurse needs to be aware that pediatric dosages are often less than 1 mL and require accurate medication dosage calculations that are checked several times. The Ten Rights of medication administration must be followed, of which correct dose is one right. In addition to an assessment of the patient, an assessment of the drug-related information is needed, focusing specifically on the drug's purpose, dosage ranges, routes of administration, cautions, and contraindications. Children are more sensitive than adults to medications because of their weight, height, physical condition, immature systems, and metabolism. Older children's body surface areas and weights are still lower than those of adults, so extreme caution is continually needed when giving them medications. Immature organ and system development will influence pharmacokinetics and thus affect the way pediatric patients respond to drugs. Organ function may be determined through laboratory testing. The following studies may be ordered by the prescriber before beginning drug therapy as well as during and after drug therapy: liver and kidney function studies, red blood cell and white blood cell counts, and measurement of hemoglobin levels, hematocrit, and protein levels.

◆ Older Adult Considerations

Assessment data to be gathered in older adults may include the following:

- Age
- Past and present medical history
- Allergies to drugs and food
- Dietary habits
- History of smoking and use of alcohol with notation of amount, frequency, and years of use
- Sensory, visual, hearing, cognitive, and motor-skill deficits
- Laboratory testing results, especially those that assess kidney and liver function
- List of all health-related care providers, including physicians; dentists; optometrists and ophthalmologists; podiatrists; alternative medicine health care practitioners, such as osteopathic physicians; chiropractors; and nurse practitioners
- Listing of medications, past and present, including prescription drugs, OTC medications, and natural health products
- Existence of polypharmacy (the use of more than five medications)
- Self-medication practices
- Risk situations resulting from drug therapy as identified by the Beers Criteria (see [Evidence in Practice](#) box on page 55)

The patient's insight into his or her own medical problems is a beneficial piece of information in developing a plan of care. It is also important for the nurse to realize that although older adults may be able to provide the required information themselves, many may be confused or poorly informed about their medications or health condition. In such cases, consult with a more reliable historian, such as a significant other, family member, or caregiver. Older adults may also have sensory deficits that require the nurse to speak slowly, loudly, and clearly, while facing the patient. Currently in Canada, drug information systems are being used in about 50% of Canada's emergency rooms and 3% of community pharmacies, resulting in safer use of medications and fewer adverse drug events. Access to electronic health care records for older adults is a significant step to improving the availability of information, quickly, as well as the quality of and access to health care ([Canada Health Infoway, 2013](#)).

One way to collect data about the various medications or drugs being taken by older adults is to use the brown-bag technique to obtain that information from the patient or caregiver. This is an effective means of identifying various drugs that the patient is taking, regardless of the patient's age, and may be used in conjunction with a complete review of the patient's medical history or record. The brown-bag technique requires the patient or caregiver to place all medications used in a bag and bring them to the health care provider. All medications need to be brought in their original containers. A list of medications with generic names, dosages, routes of administration, and frequencies is then compiled and the list is then compared with what is prescribed and what the patient states is actually being taken. Medication reconciliation procedures are performed in health care facilities when

BOX 4.1 Cultural Assessment Tools and Related Weblinks

- Madeline Leininger's Sunrise Model focuses on seven major areas of cultural assessment, including educational; economic; familial and social; political; technological; religious and philosophical; and cultural values, beliefs, and practices.
- Other comprehensive cultural assessment tools include those developed by Andrews and Bowls, 2008; Friedman, Bowles, and Jones, 2003; Giger and Davidhizar, 2002; and Purnell and Paulanka, 1998. Rani Srivastava's (2006) model, found in *The Healthcare Professional's Guide to Clinical Cultural Competence* (Healthcare Professional's Guides), contains further discussion on how populations are viewed by health care workers and not through the use of ethnocultural or religious labels.

assessing and tracking medications taken by the patient (see Chapter 6).

With older adults, thoroughly assess support systems and the patient's ability to take medications safely. Other data to collect include information about acute or chronic illnesses, nutritional problems, heart problems, respiratory illnesses, and gastrointestinal tract disorders. Laboratory tests that are often ordered for older adults include hemoglobin and hematocrit levels, red blood cell and white blood cell counts, serum electrolyte levels, protein and serum albumin levels, blood urea nitrogen level, serum and urine creatinine levels, and urine specific gravity.

◆ Ethnocultural Considerations

A thorough ethnocultural assessment is needed for the provision of ethnoculturally competent nursing care. A variety of assessment tools and resources to incorporate into nursing care are provided in Box 4.1. However, various factors must be assessed and then applied to nursing care, specifically drug therapy and the nursing process. Some of the specific questions to consider about the patient's physical, mental, and spiritual health include the following:

Maintaining Health

- For physical health: Where are special foods and clothing items purchased? What types of health education are of the patient's ethnoculture? Where does the patient usually obtain information about health and illness? Folklore? Where are health services obtained? Who are the health care providers (e.g., physicians, nurse practitioners, community services, health departments, healers)?
- For mental health: What are examples of ethnoculturally specific activities for the mind and for maintaining mental health, as well as beliefs about rest, relaxation, and reducing stress?
- For spiritual health: What resources are used to meet spiritual needs?

◆ Protecting Health

- For physical health: Where are special clothing and everyday essentials purchased? What are examples of the patient's symbolic clothing, if any?

- For mental health: Who within the family and community teaches the roles in the patient's specific ethnoculture? Are there rules about avoiding certain persons or places? Are there special activities that must be performed?
- For spiritual health: Who teaches spiritual practices and where can special protective symbolic objects such as crystals or amulets be purchased? Are they expensive and how available are they for the patient when needed?

◆ Restoring Health

- For physical health: Where are special remedies purchased? Can individuals produce or grow their own remedies, herbs, and so on? How often are traditional and nontraditional services obtained? Is the process and medication ethnoculturally safe for this patient?
- For mental health: Who are the traditional and nontraditional resources for mental health? Are there ethnoculture-specific activities for coping with stress and illness?
- For spiritual health: How often and where are traditional and nontraditional spiritual leaders or healers accessed?

◆ NURSING DIAGNOSES: AGE-RELATED

- Imbalanced nutrition, less than body requirements, resulting from the impact of age and drug therapy and possible adverse effects
- Inadequate knowledge resulting from information about drugs and their adverse effects or about when to contact the prescriber
- Potential for injury resulting from adverse effects of medications or from the method of drug administration
- Potential for injury resulting from idiosyncratic reactions to drugs as a result of age-related drug sensitivity

◆ PLANNING

◆ Goals

- Patient (caregiver, parent, or legal guardian) will state measures to enhance nutritional status due to age- and drug-related factors, as well as any adverse drug effects on everyday nutrition.
- Patient (caregiver, parent, or legal guardian) will state the importance of adhering to the prescribed drug therapy (or will take medication as prescribed with assistance).
- Patient will contact the prescriber when appropriate, such as when unusual effects occur during drug therapy.
- Patient (caregiver, parent, or legal guardian) will identify ways to minimize complications, adverse effects, reactions, and injury associated with the therapeutic medication regimen.

◆ Expected Patient Outcomes

- Patient (caregiver, parent, or legal guardian) lists recommended caloric and protein intake as well as examples of all the major food groups with the assistance of nutritional consultation.

- Patient (caregiver, parent, or legal guardian) identifies when to contact the prescriber if nausea, vomiting, loss of appetite, diarrhea, constipation, or other problems arise during medication therapy.
- Patient (caregiver, parent, or legal guardian) states rationale for medication as well as importance in the timing, dosage, and duration of therapy and is able to identify what the specific medication looks like.
- Patient (caregiver, parent, or legal guardian) describes intended therapeutic effects of the medication(s), such as improvement in condition with decrease in symptoms and with limited adverse effects.
- Patient (caregiver, parent, or legal guardian) demonstrates safe method of self- or assisted medication administration, such as use of a week-long pill mechanism (e.g., blister pack or a dosette medication box) with day of week and associated times, and has all medications safely labelled.
- Patient (caregiver, parent, or legal guardian) follows instructions specific to the route of administration for the medication ordered, while also demonstrating (if appropriate) techniques, such as special application of an ointment as prescribed, measuring and taking liquid medication, and taking medication with proper food or fluids, for the duration of treatment.
- Patient (caregiver, parent, or legal guardian) lists the most frequent adverse effects and possible toxicity associated with medication regimen, while also stating when to contact the health care provider, such as occurrence of fever, pain, vomiting, rash, diarrhea, difficulty breathing, or worsening of the condition being treated.
- Patient (caregiver, parent, or legal guardian) reports safe medication administration upon return appointment after beginning prescribed therapy.
- Patient (caregiver, parent, or legal guardian) minimizes adverse effects and danger to self by taking medication(s) as prescribed, at the right time, with right dosing, and with attention to intake of proper amount of fluids (120 to 180 mL of water with oral dosages) and with or without food, as indicated, while remaining aware of safety measures appropriate to specific drug regimen.

◆ IMPLEMENTATION

It is always important to emphasize and practise the Ten Rights of medication administration (see Chapter 1) and follow the prescriber's order and medication instructions. Check all drugs three times against the Ten Rights and the prescriber's order before the drug is given to the patient. This usually applies in acute care and long-term care inpatient and outpatient situations. For pediatric patients, some specific nursing actions are as follows: (1) If needed, mix medications in a substance or fluid other than essential foods (e.g., milk, orange juice, cereal) to avoid causing the child to develop a dislike for the essential food in the future. Instead, use a liquid or food item that may be used to make the medication(s) taste better, such as sherbet or flavoured ice cream. Use this intervention only if the patient cannot swallow the dosage form or if the taste needs to be made more palatable. (2) Do not add drug(s) to fluid in

a cup or bottle because the amount of drug consumed would then be impossible to calculate if the entire amount of fluid is not consumed. (3) Always document special techniques of drug administration so that others involved in the patient's care may benefit from the suggestion. For example, if the child takes an unpleasant-tasting pill, liquid, or tablet after eating a frozen Popsicle, then this information would be valuable to another caregiver. (4) Unless contraindicated, add small amounts of water or fluids to elixirs to enhance the child's tolerance of the medication. Remember that it is essential for the child to take the entire volume, so remain cautious with this practice and use only an amount of fluid mixture that you know the child will tolerate. (5) Avoid using the word *candy* in place of *drug* or *medication*. Medications must be called *medicines* and their dangers made known to children. Taking medications is not a game, and children must understand this for their own safety. (6) Keep all medications out of the reach of children of all ages. Be sure that parents and other family members in the same household understand this information and request child-protective lids or tops for their medications from the pharmacy. Also, childproof locks or closures may be used on cabinets holding medications. (7) Inquire about how the child usually takes medication (e.g., preference of liquid versus pill or tablet dosage forms) and whether there are any methods from the family or caregiver that may be helpful. See [Special Populations: Children](#) box, on page 49, for recommendations and further information on medication administration, beginning with infancy through adolescence. For more information about dosage calculations for medication administration in pediatric patients, visit the TestandCalc website, which provides examples and programs to help with pediatric drug dosage calculations (<http://www.testandcalc.com>).

Encourage older adult patients to take medications as directed and not to discontinue them or double up on doses unless recommended or ordered to do so by their health care provider or prescriber. The patient or caregiver must understand the treatment- and medication-related instructions, especially those resulting from safety measures such as keeping all medications out of the reach of children. Transdermal patches provide a different challenge in that if they fall off onto the floor or bedding, a child or infant in that environment may have accidental exposure to the effects of the medication. Serious adverse reactions have been reported concerning the accidental adhering of a transdermal patch to a child or infant while crawling or playing on the floor or carpet. Toxic and even fatal reactions may occur, depending on the medication and dosage. Provide written and verbal instructions concerning the drug name, action, purpose, dose, time of administration, route, adverse effects, safety of administration, storage, interactions, and any cautions about or contraindications to its use. Remember that simple is always best. Always try to find ways to make the patient's therapeutic regimen easy to understand. Always be alert to polypharmacy and be sure the patient or caregiver understands the dangers of multiple drug use. Patient education may prove to be helpful in preventing or minimizing problems associated with polypharmacy. If a nurse advocate or a nurse practitioner with prescription

privileges has the opportunity to review the patient's chart, she or he must provide simplified written instructions outlining the purpose of the drug, how to best take the medication(s), and a list of drug interactions and adverse effects. Information must be provided in bold, large print. The Beers Criteria have proven helpful in promoting medication safety in older adults (see [Evidence In Practice box](#) on page 55). These criteria provide a systematic way of identifying prescription medications that are potentially harmful to older adults. The prescriber and nurse must constantly remember that clinical judgement and knowledge base are important in making critical decisions about a patient's care and drug therapy. In addition, keeping abreast of evidence-informed nursing practice, such as the application of the Beers Criteria, is important for the nurse to remain current in clinical nursing practice. Specific guidelines for medication administration by different routes are presented in detail in Chapter 10.

In summary, drug therapy across the lifespan must be well thought out, with full consideration to the patient's age, gender, ethnocultural background, medical history, and medication profile. When all phases of the nursing process and the specific lifespan considerations discussed in this chapter are included, there is a better chance of decreasing adverse effects, reducing risks to the patient, and increasing drug safety.

◆ EVALUATION

When dealing with lifespan issues resulting from drug therapy, observation and monitoring for therapeutic effects as well as adverse effects are critical to safe and effective therapy. The nurse must know a patient's profile and history just as well as information about the drug. The drug's purpose, specific use in the patient, simply stated actions, dose, frequency of dosing, adverse effects, cautions, and contraindications need to be listed and kept available at all times. This information will allow more comprehensive monitoring of drug therapy, regardless of the age of the patient.

◆ NURSING DIAGNOSES: ETHNOCULTURAL

- Sleep deprivation resulting from a lack of adherence to cultural practices for encouraging stress release and sleep induction
- Inadequate knowledge (drug therapy) resulting from lack of experience and information about prescribed drug therapy
- Potential for injury resulting from adverse and unpredictable reaction to drug therapy due to racial or ethnic cultural factors

◆ PLANNING

◆ Goals

- Patient will state the need for assistance with nonpharmacological management of sleep deficit.
- Patient will request written and verbal education about medication therapy.

CASE STUDY

Polypharmacy and Older Adults

Rhonda, a 77-year-old retired librarian, sees several physician specialists for a variety of health problems. She uses the pharmacy at a large discount store but also has prescriptions filled at a nearby pharmacy, which she uses when she does not feel like going into the larger store. Her medication list is as follows:

Thiazide diuretic, prescribed for peripheral edema
Potassium tablets, prescribed to prevent hypokalemia

beta blocker, prescribed for hypertension

Warfarin sodium, taken every evening because of a history of deep vein thrombosis

Thyroid replacement hormone for hypothyroidism

Multivitamin tablet for seniors

1. What medications may cause problems for Rhonda? Explain your answer.

2. What measures can be taken to reduce these problems?

Rhonda visits the pharmacy to pick up some medications for a cold. She has chosen a popular OTC decongestant, an antihistamine preparation, and a nonsteroidal anti-inflammatory drug for her "aches and pains."

3. Should she use these medications? If not, what advice would you give her about choosing OTC medications?

For answers see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

- Patient will state need for information about the influence of racial or ethnic cultural factors upon specific drug therapy, with emphasis on safety measures.

◆ Expected Patient Outcomes

- Patient describes specific measures to enhance sleep patterns, such as regular sleep habits, decrease in caffeine, meditation, relaxation therapy, and journaling sleep patterns and noting those measures that enhance or take away sleep.
- Patient lists the various medication(s) with their therapeutic and adverse effects, dosage routes, and specific methods of adequate self-administration, drug interactions, and any other special considerations.
- Patient describes the impact of racial or ethnic influences (e.g., metabolic enzyme differences) on specific medications and the resulting potential for increase in adverse effects, toxicity, or increased or decreased effectiveness (medication therapy).

◆ IMPLEMENTATION

There are numerous interventions for implementation of ethnoculturally competent nursing care, but one important requirement is that nurses remain current in the knowledge of various ethnocultures and related activities and practices of daily living, health beliefs, as well as emotional and spiritual health practices and beliefs. Specifically, knowledge about medications that may elicit varied responses due to racial or ethnic variations is most important, along with application of concepts of culturally competent care and ethnopharmacology for each patient care situation.

Information of significance is the impact of cytochrome P450 liver enzymes on certain phases of drug metabolism.

Specific examples of differences in certain cytochrome P450 enzymes can be found. Consider additional factors, including the patient's verbal and nonverbal communication patterns; the patient's health belief systems; identification of health care providers or alternate healers; and the patient's interpretation of space, time, and touch. For example, cost may be a consideration in regard to adherence with the treatment regimen. Other lifestyle decisions (e.g., use of tobacco or alcohol) may also affect responses to drugs and must be considered during drug administration. In addition, a patient's ethnocultural background and associated socioeconomic status may create a situation that leads the patient to skip pills, split doses, and not obtain refills. This culture of poverty may be a causative factor in nonadherence and requires astute attention and individualized nursing actions.

EVALUATION

Ethnoculturally competent nursing care regarding drug therapy may be evaluated through adherence (or nonadherence) to the medication regimen(s). Safe, effective, and therapeutic self-administration of drugs with minimal to no adverse or toxic effects will be present only when the patient is treated as an individual and has a thorough understanding of the medication regimen.

KEY POINTS

- There are many age-related pharmacokinetic effects that lead to dramatic differences in drug absorption, distribution, metabolism, and excretion in young people and older adults. At one end of the lifespan is the pediatric patient, and at the other is older adult patients, both of whom are sensitive to the effects of drugs.
- For pediatrics, most common dosage calculations use the milligrams per kilogram formula pertaining to age; however, BSA is also used for drug calculations, and organ maturity is considered. It is important for the nurse to know that many elements besides the mathematical calculation contribute to safe dosage calculations. Safety must remain the number one concern, with consideration of the Ten Rights of medication administration (see [Chapter 1](#)).
- The percentage of the population older than 65 years of age continues to grow, and polypharmacy remains a concern with the increasing number of older adult patients. For older adults, a current list of all medications and drug allergies must always be on their person or with their family/caregiver.
- The nurse's responsibility is to act as a patient advocate as well as to be informed about growth and developmental principles and the effects of various drugs during the lifespan and in various phases of illness.
- A variety of culturally based assessment tools are available for use in patient care and drug therapy.
- Drug therapy and subsequent patient responses may be affected by racial and ethnic variations in levels of specific enzymes and metabolic pathways of drugs.

EXAMINATION REVIEW QUESTIONS

1. The nurse is reviewing factors that influence pharmacokinetics in the neonatal patient. Which factor puts the neonatal patient at risk as related to drug therapy?
 - a. Immature renal system
 - b. Hyperperistalsis in the gastrointestinal tract
 - c. Irregular temperature regulation
 - d. Smaller circulatory capacity
2. The physiological differences in the pediatric patient compared with the adult patient affect the amount of drug needed to produce a therapeutic effect. The nurse is aware that one of the main differences is that infants have which of the following?
 - a. Increased protein in circulation
 - b. Fat composition less than 0.001%
 - c. More muscular body composition
 - d. Water composition of approximately 75%
3. While teaching 76-year-old Rahul about the adverse effects of his medications, the nurse encourages him to keep a journal of the adverse effects he experiences. This intervention is important for older adult patients because of which alterations in pharmacokinetics?
 - a. Increased kidney excretion of protein-bound drugs
 - b. More alkaline gastric pH, resulting in more adverse effects

CASE STUDY

Otitis Media in a Child

A parent brings her 2-year-old son, Bryson, to the community health clinic with reports of fussiness and tugging at his left ear for the past 48 hours. He has been coughing and has had a runny nose for 4 days that has been treated with saline nose sprays and use of a humidifier. He had a low-grade fever of 38.4°C axillary for the past 48 hours. It has now risen to 39°C. Bryson attends day care and both parents smoke cigarettes. Bryson's past medical history is significant for bilateral ear infections, with his last

episode 5 months ago, which was treated with amoxicillin. His immunizations are up to date, including 13-valent pneumococcal conjugate vaccine. He is diagnosed with acute otitis media and prescribed amoxicillin and ibuprofen.

1. What characteristics of pediatric patients may have a significant effect on dosage calculation?
2. What pharmacokinetic factors may affect the administration of the ordered drugs for Bryson?
3. Bryson's mother is concerned that he has had a few episodes of otitis media. What health teaching would the nurse undertake with Bryson's mother?
4. Bryson weighs 11.5 kg. The recommended dose of amoxicillin to treat otitis media is 75 to 90 mg/kg/day divided bid. What dose range is appropriate for Bryson?

For answers see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

- c. Decreased blood flow to the liver, resulting in altered metabolism
 - d. Less adipose tissue to store fat-soluble drugs
4. The nurse is reviewing a list of medications taken by Huang, an 88-year-old patient. Huang says, “I get dizzy when I stand up.” She also states that she has nearly fainted “a time or two” in the afternoons. Her systolic blood pressure drops 15 points when she stands up. Which type of medications may be responsible for these effects?
 - a. NSAIDs
 - b. Cardiac glycosides
 - c. Anticoagulants
 - d. Antihypertensives
 5. A woman who is pregnant asks the nurse at the health care clinic how to know which drugs are safe to take during pregnancy. What is the nurse’s best response?
 - a. “Continue to take any drugs previously prescribed by your health care provider as there are few studies to establish which drugs are safe to take during pregnancy.”
 - b. “It is safe to continue taking the over-the-counter drugs that you are currently taking.”
 - c. “It is advisable not to take any prescription or over-the-counter drugs while pregnant.”
 - d. “It is best to consult with your health care provider about taking any prescription or over-the-counter drugs.”
 6. The nurse is preparing to administer an injection to a preschool-age child. Which approaches are appropriate for this age group? (Select all that apply.)
 - a. Explain to the child in advance about the injection.
 - b. Provide a brief, concrete explanation about the injection.
 - c. Encourage participation in the procedure.
 - d. Make use of magical thinking.
 - e. Provide comfort measures after the injection.
 7. Yuri, a patient of Japanese descent, describes a family trait that manifests frequently—she says that members of her family often have “strong reactions” after taking certain medications, but her friends who are not of Japanese descent have no problems with the same dosages of the same medications.
 - a. Yuri may need lower dosages of the medications prescribed.
 - b. Yuri may need higher dosages of the medications prescribed.
 - c. Yuri should not receive these medications because of potential problems with metabolism.
 - d. These situations vary greatly, and Yuri’s accounts may not indicate a valid cause for concern.
 8. Which factors does the nurse consider when evaluating polymorphism and medication administration? (Select all that apply.)
 - a. Nutritional status
 - b. Drug route
 - c. Patient’s ethnicity
 - d. Cultural beliefs
 - e. Patient’s age
 9. The nurse is preparing to give an oral dose of acetaminophen (Tylenol®) to a child who weighs 12 kg. The dose is 15 mg/kg. How many milligrams will the nurse administer for this dose?
 10. An 82-year-old patient is admitted to the hospital after an episode of confusion at home. The nurse is assessing the current medications he is taking at home. Which method is the best way to assess his home medications?
 - a. Ask the patient what medications he takes at home.
 - b. Ask the patient’s wife what medications he takes at home.
 - c. Ask the patient’s wife to bring his medications to the hospital in their original containers.
 - d. Contact the patient’s pharmacy for a list of the patient’s current medications.

CRITICAL THINKING ACTIVITIES

1. A mother calls the clinic to ask how to give a tablet to her 4-year-old son. He is refusing to swallow it and will not chew it because it “tastes icky.” The mother says she is ready to force her son to take this medication. What is the nurse’s priority action?
2. A woman in her third trimester of pregnancy is having a checkup and asks for acetylsalicylic acid (ASA) for a headache. What is the nurse’s best response?
3. A 22-year-old woman has brought her 16-month-old daughter to see the nurse practitioner because the toddler has symptoms of a sinus infection. After examining the toddler, the nurse practitioner writes a prescription for an antibiotic. The mother says, “Oh, I have tetracycline suspension at home that I took for an infection. Can’t I just use that and save money?” What is the nurse’s best answer?

For answers see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Gene Therapy and Pharmacogenomics

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Identify the significance of the basic terms related to genetics and drug therapy.
2. Briefly discuss the major concepts of genetics as an evolving segment of health care, such as principles of genetic inheritance; deoxyribonucleic acid (DNA), ribonucleic acid (RNA), and their functioning; the relationship of DNA to protein synthesis; and the importance of amino acids.
3. Describe the basis of the Human Genome Project and its impact on the role of genetics in health care.
4. Discuss the gene therapies currently available.
5. Differentiate between the direct and indirect forms of gene therapy.
6. Identify the regulatory and ethical issues resulting from gene therapy as well as nursing and health care providers.
7. Briefly discuss pharmacogenomics and pharmacogenetics.
8. Discuss the evolving role of professional nurses and gene therapy.

KEY TERMS

Acquired disease Any disease triggered by external factors and not directly caused by a person's genes (e.g., an infectious disease, noncongenital cardiovascular diseases). (p. 68)

Alleles The two alternative forms of a gene that can occupy a specific locus (location) on a chromosome (see *chromosome*). (p. 68)

Chromatin A collective term for all of the chromosomal material within a given cell. (p. 69)

Chromosome Structure in the nuclei of cells that contains threads of deoxyribonucleic acid (DNA), which transmit genetic information, and that are associated with ribonucleic acid (RNA) molecules and synthesis of protein molecules. (p. 68)

Gene The biological unit of heredity; a segment of a DNA molecule that contains all of the molecular information required for the synthesis of a biological product such as an RNA molecule or an amino acid chain (protein molecule). (p. 68)

Gene therapy New therapeutic technologies that directly target human genes in the treatment or prevention of illness. (p. 70)

Genetic disease Any disorder caused by a genetic mechanism. (p. 68)

Genetic material DNA or RNA molecules or portions of them. (p. 68)

Genetic polymorphisms Variants that occur in the chromosomes of 1% or more of the general population (i.e., too frequently to be caused by a random recurrent mutation). (p. 71)

Genetic predisposition The presence of certain factors in a person's genetic makeup, or genome (see next page), that increases the likelihood of developing one or more diseases. (p. 68)

Genetics The study of the structure, function, and inheritance of genes. (p. 69)

Genome The complete set of genetic material of any organism. It may be contained in multiple chromosomes (groups of DNA or RNA molecules) in higher organisms; in a single chromosome, as in bacteria; or in a single DNA or RNA molecule, as in viruses. (p. 69)

Genomics The study of the structure and function of the genome, including DNA sequencing, mapping, and expression, and the way genes and their products work in both health and disease. (p. 69)

Genotype The particular alleles present at a given site (locus) on the chromosomes of an organism that determine a specific genetic trait for that organism (compare *phenotype*). (p. 68)

Heredity The characteristics and qualities that are genetically passed from one generation to the next through reproduction. (p. 69)

Inherited disease Genetic disease that results from defective alleles passed from parents to offspring. (p. 68)

Nucleic acids Molecules of DNA or RNA in the nucleus of every cell. DNA makes up the chromosomes and encodes the genes. (p. 68)

Personalized medicine The use of molecular-level and genetic characterizations of both the disease process and the patient for the customization of drug therapy. (p. 71)

Pharmacogenetics The study of the genetic basis for variations in the body's response to drugs, with a focus on variations resulting from a single gene. (p. 71)

Pharmacogenomics A branch of pharmacogenetics (see earlier) that involves the survey of the entire genome to detect multigenic (multiple-gene) determinants of drug response. (p. 71)

Phenotype The expression in the body of a genetic trait that results from a person's particular genotype (see earlier) for that trait. (p. 68)

Proteome The entire set of proteins produced from the information encoded in an organism's genome. (p. 69)

Proteomics The detailed study of the proteome, including all biological actions of proteins. (p. 69)

Recombinant DNA (rDNA) DNA molecules that have been artificially synthesized or modified in a laboratory setting. (p. 70)

OVERVIEW

Genetic processes are a highly complex part of physiology and are far from being completely understood. Genetic research is one of the most active branches of science today, involving many types of health care providers, including nurses. Expected outcomes of this research include a deeper knowledge of the genetic influences on disease, along with the development of gene-based therapies. The practice of nursing requires an understanding of genetic concepts as well as genetically related health issues and therapeutic techniques. The goal of this chapter is to introduce some of the major concepts of this complex and emerging branch of health science. In 1996, in the United States, the National Coalition for Health Professional Education in Genetics (NCHPEG) was founded. Although NCHPEG closed in 2013, its purpose was to promote the education of health professionals and the public regarding advances in applied genetics. The Jackson Laboratory (JAX) now runs and maintains all NCHPEG education materials and the website and has adopted the baseline competencies ([The Jackson Laboratory, 2019](#)).

Since the 1960s, published literature has described the role of nursing in genetics and genetic research. The Genetics Nursing Network was formed in 1984 and later became the International Society of Nurses in Genetics (ISONG). The Canadian Nurses Association recognized the importance of knowledge of genetics in nursing in 2005, yet it is still not an official nursing specialty. The growing understanding of genetics is quickly creating demand for clinicians in all fields who can educate patients and provide clinical care that tailors health care services to each patient's inherent genetic makeup. This reality also calls for increasing the level of genetics education in nursing school curricula as well as in continuing nursing education. Interestingly, the study of genetics has become commonplace in secondary and even primary education.

BASIC PRINCIPLES OF GENETIC INHERITANCE

Nucleic acids are biochemical compounds consisting of two types of molecules: deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). DNA molecules make up the **genetic material** that is passed between all types of organisms during reproduction. In some viruses (e.g., human immunodeficiency virus [HIV]), it is actually RNA molecules that pass the virus's genetic material between generations; however, this is an exception to the norm. A **chromosome** is a long strand of DNA contained in the nuclei of cells. DNA molecules, in turn, act as the template for the formation of RNA molecules, from

which proteins are made. Humans normally have 23 pairs of chromosomes in each of their somatic cells, which are the cells in the body other than the sex cells (sperm cells or egg cells), which have 23 single (unpaired) chromosomes. One pair of chromosomes in each cell is termed the sex chromosomes, which can be designated as either X or Y. The sex chromosomes are normally XX for females and XY for males. One member of each pair of chromosomes in somatic cells comes from the father's sperm cell and one from the mother's egg. **Alleles** are the alternative forms of a **gene** that can vary in regard to a specific genetic trait. Genetic traits can be desirable (e.g., lack of allergies) or undesirable (e.g., predisposition toward a specific disease). Alleles are dominant or recessive. Each person has two alleles for every gene-coded trait—one allele from the mother, the other from the father. An allele may be dominant or recessive for a given genetic trait. The particular combination of alleles, or **genotype**, for a given trait determines whether or not a person manifests that trait, or the person's **phenotype**. Genetic traits that are passed on differently to male and female offspring are said to be sex-linked traits because they are carried on either the X or Y chromosome. For example, hemophilia genes are carried by females but manifest as a bleeding disorder only in males. Hemophilia is an example of an **inherited disease**; that is, a disease caused by passage of a genetic defect from parents to offspring. A more general term is **genetic disease**, which is any disease caused by a genetic mechanism. Note, however, that not all genetic diseases are inherited. Chromosomal abnormalities (aberrations) can also occur spontaneously during embryonic development. In contrast, an **acquired disease** is any disease that develops in response to external factors and is not directly resulting from a person's genetic makeup. Genetics can play an indirect role in acquired disease, however. For example, atherosclerotic heart disease is often acquired in middle or later life. Many people have certain genes in their cells that increase the likelihood of this condition. This is known as a **genetic predisposition**. In some cases, a person may be able to offset a genetic predisposition through lifestyle choices, such as consuming a healthy diet and exercising to lessen the risk of developing heart disease.

Current literature differentiates “old genetics,” which focused on single-gene inherited diseases such as hemophilia, from “new genetics.” The new genetic perspective recognizes that common diseases, including Alzheimer's disease, cancer, and heart disease, are the product of complex relationships between genetic and environmental factors. These environmental factors, such as diet or toxic exposures, can initiate or worsen disease processes. Research into disease treatment is beginning to look at genetically tailored therapy.

DISCOVERY, STRUCTURE, AND FUNCTION OF DNA

Genetics is the study of the structure, function, and inheritance of genes. **Heredity** refers to the qualities that are genetically transferred from one generation to the next during reproduction.

A major turning point in the current understanding of genetics came in 1953, when Drs. James Watson and Francis Crick first reported the chemical structures of human genetic material and named the primary biochemical compound *deoxyribonucleic acid* (DNA). They later received a Nobel Prize for their discovery.

It is now recognized that DNA is the primary molecule in the body that serves to transfer genes from parents to offspring. It exists in the nucleus of all body cells as strands of chromosomes, collectively called **chromatin**. As described in [Chapter 40](#), DNA molecules contain four different organic bases, each of which has its own alphabetical designation: *adenine* (A), *guanine* (G), *thymine* (T), and *cytosine* (C). These bases are linked to a type of sugar molecule known as *deoxyribose*. In turn, these sugar molecules are linked to a “backbone” chain of phosphate molecules, which results in the classic double-helix structure of two side-by-side, spiral macromolecular chains. An important related biomolecule is *ribonucleic acid* (RNA). RNA has a chemical structure similar to that of DNA, except that its sugar molecule is the compound *ribose* instead of deoxyribose, and it contains the base uracil (U) in place of thymine. RNA more commonly occurs as a single-stranded molecule, although in some genetic processes it can also be double stranded. In double-stranded structures, the base of each strand binds (via hydrogen bonds) to that of the other strand in the space between the two strands. This binding is based on complementary base pairing determined by the chemistry of the base molecules themselves. Specifically, adenine can bind only with thymine or uracil, whereas cytosine can bind only with guanine.

A nucleotide is the structural unit of DNA and consists of a single base and its attached sugar and phosphate molecules. A nucleoside is the base and attached sugar without the phosphate molecule. A relatively small sequence of nucleotides is called an *oligonucleotide* (the prefix *oligo-* means “a small number”). Certain new drug therapies involve synthetic analogues of both nucleosides and nucleotides (see [Chapters 45, 49, 50, and 51](#)). A related field is targeted drug therapy. Targeted drug therapy focuses on modifying the function of immune system cells (T cells and B cells) and biochemical mediators of immune response (cytokines). However, it is expected to focus on modifying specific genes as well. Current examples of targeted drug therapy are presented in [Chapters 49, 50, 52, and 53](#). One of these drugs, the ophthalmic antiviral drug fomivirsen (not available in Canada), is an oligonucleotide with a chemical structure that is opposite (complementary) to that of a critical part of the messenger RNA (mRNA) of the cytomegalovirus. For this reason, it is called an *antisense* oligonucleotide, and it is the first of this new class of drugs. Other types of antisense oligonucleotide drugs are anticipated in the near future as one type of gene therapy.

An organism’s entire DNA structure is its **genome**. This word is a combination of the terms *gene* and *chromosome*, and it refers to all the genes in an organism taken together. **Genomics** is the relatively new science of determining the location (mapping), structure (DNA base sequencing), identification (genotyping), and expression (phenotyping) of individual genes among the entire genome, and determining their functions in both health and disease processes.

Protein Synthesis

Protein molecules drive the functioning of all biochemical reactions. Protein synthesis is the primary function of DNA in human cells. There is a direct relationship between DNA nucleotide sequences and corresponding amino acid sequences. This relationship allows for precision in protein synthesis. Interestingly, it is estimated that only 2 to 3% of the human genome is involved in protein synthesis. Amino acid sequences control the shape of protein molecules, which ultimately affects their ability to function in the body. Mutations, undesired changes in DNA sequence, can affect the shape of protein molecules and impair or destroy their functioning.

In the cell nuclei, the double strands of DNA uncoil and separate, and a strand of mRNA forms on each strand through complementary base pairing, as described earlier in the chapter. This process is called *transcription* of the DNA. These mRNA molecules then detach from their corresponding DNA strands, leave the cell nucleus, and enter the cytoplasm, where they are then “read,” or translated, by the ribosomes. Ribosomes are composed of a second type of RNA, known as *ribosomal RNA* (rRNA), as well as several accessory proteins. Individual sequences of three bases along the mRNA molecule serve to code for specific amino acid molecules. This translation process involves molecules of a third type of RNA, transfer RNA (tRNA). The tRNA molecules transport the corresponding amino acid molecules to the site of ribosomal translation along the mRNA strand in sequence, according to the three-base codes along the mRNA strand. This in turn results in the creation of chains of multiple amino acid molecules (polypeptide chains), which are known as *protein molecules*. The specificity of this code is important for proper protein synthesis and the process is similar for all living organisms—plant and animal.

There are countless specific amino acid sequences (polypeptides) that result in the synthesis of many thousands of types of protein molecules. Proteins include hormones, enzymes, immunoglobulins, and numerous other biochemical molecules that regulate processes throughout the body. They are involved in both healthy physiological processes and the pathophysiological processes of many diseases. Biomedical researchers continue to identify and describe many proteins that are part of disease processes. Manipulation of genetic material, as in gene therapy (see later in this chapter), can theoretically modify the synthesis of these proteins and therefore aid in the treatment of disease. This emerging science continues to give rise to novel terminology. The entire set of proteins produced by a genome is now known as the **proteome**. **Proteomics** is the study of the proteome, including protein expression, modification, localization, and function, as well as the protein–protein interactions

that are part of biological processes. This science is expected to provide new drug therapies in the future. Furthermore, most clinically approved drugs interact with body proteins such as cell membrane receptors, hormones, and enzymes.

Human Genome Project

In 1990, an unprecedented genetic research project began, known as the Human Genome Project (HGP). This project was a worldwide research initiative coordinated by the U.S. Department of Energy and the National Institutes of Health (NIH). The project was completed in 2003, 2 years ahead of schedule. The goals of this project were to identify the estimated 30 000 genes—3 billion base pairs—in the DNA of an entire human genome. Additional goals included developing new tools for genetic data analysis and storage, transferring newly developed technologies to the private sector, and addressing the inherent ethical, legal, and social issues involved in genetic research and clinical practice. However, the ultimate goal was to develop improved prevention, treatment, and cures for disease. When the HGP began, there were 100 known human, disease-related genes. By its completion, there were 1 400.

GENE THERAPY

Background

Gene therapy is an experimental technique that uses genes to treat or prevent disease. It allows doctors to treat a disorder by inserting a gene into a patient's cells instead of using drugs or surgery. Researchers are testing several approaches to gene therapy, including the following:

- Replacing a mutated gene with a healthy copy of the gene
- Introducing a new gene into the body to help fight a disease
- Inactivating a mutated gene that is functioning improperly

Gene therapy research is based on the ongoing discovery of new details regarding cellular processes, including biochemical processes that occur at the molecular level. In addition, the increased understanding of allelic variation and its role in disease susceptibility can be used to guide attempts at preventive therapy based on a person's genotypic risk factors.

Although numerous gene therapy clinical trials have been approved by Health Canada, no gene therapy to date has been approved for routine treatment of disease. The goal of gene therapy is to transfer exogenous genes that will either provide a temporary substitute for, or initiate permanent changes in the patient's own genetic functioning to treat a given disease. Originally projected to provide treatment primarily for inherited genetic diseases, gene therapy techniques are now being researched for the treatment of acquired illnesses such as cancer, cardiovascular diseases, diabetes, infectious diseases, and substance misuse. In the future, in-utero gene therapy may be used to prevent the development of serious diseases as part of the prenatal care for the unborn fetus.

Description

During gene therapy, segments of DNA are injected into the patient's body in a process called *gene transfer*. These artificially produced DNA splices are also known as **recombinant DNA (rDNA)** and must usually be inserted into some kind of carrier

Fig. 5.1 Gene therapy for adenosine deaminase (ADA) deficiency attempts to correct this immunodeficiency state. The viral vector containing the therapeutic gene is inserted into the patient's lymphocytes. These cells can then make the ADA enzyme. From Lewis, S. M., Dirksen, S. R., Heitkemper, M. M., et al. (2014). *Medical-surgical nursing in Canada: Assessment and management of clinical problems* (3rd ed.). (Canadian Eds. S. Goldsworthy, M. Barry, & D. Goodridge). Toronto, ON: Elsevier Mosby.)

or vector for the gene transfer process. Vectors currently being evaluated include spherical lipid compounds known as *liposomes*, free DNA splices known as *plasmids*, DNA conjugates in which DNA splices are linked (conjugated) to either protein or gold particles, and various types of viruses. Viruses are the most widely studied rDNA vectors thus far. One commonly used group of viruses is that of the adenoviruses, which includes human influenza viruses.

Limitations

Viruses used for gene transfer can also induce viral disease and be immunogenic in the human host. The proteins produced by such artificial methods can be immunogenic. Even in the absence of significant virus-induced disease, the positive effects (e.g., supplemented protein synthesis) may be only temporary, and further treatments may be required. As a result, viruses must be carefully chosen and modified in an effort to optimize therapeutic effects while minimizing undesirable adverse effects. The determination of an ideal gene transfer method remains a major challenge for gene therapy researchers. **Figure 5.1** provides a clinical example of the potential use of gene therapy.

Current Application

One well-established, indirect form of gene therapy is called *rDNA technology*. It involves the use of rDNA vectors in the laboratory to make recombinant forms of drugs, especially biologic drugs such as hormones, vaccines, antitoxins, and monoclonal antibodies. The most common example is the use of the *Escherichia coli* bacterial genome to manufacture a recombinant form of human insulin. When the human insulin gene is inserted into the genome of bacterial cells, the resulting culture artificially generates human insulin on a large scale. Although

this insulin must be isolated and purified from its bacterial culture source, the majority of the world's medical insulin supply has been produced by this method for well over a decade.

Regulatory and Ethical Issues of Gene Therapy

Gene therapy research is inherently complex and can also carry great risks for its recipients. Thus, the issue of patient safety becomes significant. Research subjects who receive gene therapy often have a life-threatening illness, such as cancer, which may justify the risks involved. However, case reports of deaths in gene therapy trials have underscored these risks and raised awareness of patient safety. The Biologics and Genetic Therapies Directorate (BGTD) of Health Canada was assigned responsibility for oversight of gene therapy research in Canada. It reviews clinical trials involving human gene transfer. The BGTD must also review and approve all human clinical gene therapy trials, as it does with any type of drug therapy.

Any institution that conducts any type of research involving human subjects must have a research ethics board, whose purpose is to protect research subjects from unnecessary risks. An institutional biosafety committee is also required for gene therapy research. The role of this committee is to ensure compliance with the Medical Council of Canada (MCC)'s *Guidelines for the Handling of Recombinant DNA Molecules and Animal Viruses and Cells*.

A major ethical issue resulting from gene therapy techniques is that of eugenics. Eugenics is the intentional selection before birth of some genotypes that are considered more desirable than others. For similar reasons, the prospect of being able to manipulate genes in human germ cells (sperm and eggs) is also a potential ethical hazard of gene therapy. Theoretically, even cosmetic modifications could be attempted using such techniques as a part of routine family planning. Because of ethical concerns such as these, Canadian gene therapy research is limited to somatic cells only—gene therapy in germ line (reproductive) cells is currently not approved for funding in Canada. This limitation remains despite arguments from those who believe that human germ cell research could potentially yield cures for many serious chronic illnesses and disabilities, such as Parkinson's disease and spinal paralysis.

PHARMACOGENETICS AND PHARMACOGENOMICS

Pharmacogenetics is a general term for the study of genetic variations in drug response and focuses on single-gene variations. A related science that pertains more directly to the HGP is **pharmacogenomics**. Pharmacogenomics is the combination of two scientific disciplines: pharmacology and genomics. Pharmacogenomics involves how genetics (genome) affect the body's response to drugs. Pharmacogenomics offers physicians the opportunity to individualize drug therapy based on a patient's genetic makeup, rather than giving the "standard" dose to all patients. The ultimate goal is to predict patient drug response and proactively tailor drug selection and dosages for optimal treatment outcomes. Warfarin sodium is an anticoagulant drug that is used to prevent blood clots (see [Chapter 27](#)). Research has shown that people with certain genetic variations (CYP2C9*2 or CYP2C9*3 alleles) are at increased risk of

bleeding and require lower doses than those without the variation. In addition, variations in the gene that encodes VKORC1 may make a patient more or less sensitive to warfarin sodium. This genetic variation occurs most frequently in the Asian population.

Individual differences in alleles that occur in at least 1% of the population are known as **genetic polymorphisms**. The word *polymorphism* literally means "many forms." Polymorphisms are considered too frequent to result from random genetic mutations. Polymorphisms that alter the amount or actions of drug-metabolizing enzymes can alter the body's reactions to medications. Known examples include those polymorphisms that affect the metabolism of certain antimalarial drugs, the antituberculosis drug isoniazid, and the variety of drugs that are metabolized by several subtypes of cytochrome enzymes. They can also alter the functioning of drug receptor proteins, cell membrane ion channels and drug transport proteins, and intracellular second messenger proteins (which carry out drug actions after a drug molecule binds to a cell membrane receptor).

Differences in cytochrome enzymes (see [Chapter 2](#)) are the best studied polymorphism effects thus far. Depending on their existing genes for these enzymes, patients can be genetically classified as "poor" or "rapid" metabolizers of CYP-metabolized drugs such as warfarin sodium, phenytoin, codeine sulphate, and quinidine. With warfarin sodium and phenytoin, a rapid metabolizer may require a higher dose of medication for the same effect, whereas a lower dose may be best for a poor metabolizer. With codeine sulphate, a poor metabolizer may actually need a higher dose to get the same analgesic effect that occurs when codeine sulphate is metabolized to morphine sulphate. In contrast, a rapid metabolizer may convert codeine sulphate to morphine sulphate too quickly, resulting in oversedation, and a lower dose may be sufficient. A similar situation is also likely to occur with quinidine. Because cytochrome enzymes are known to vary among racial and ethnic groups, the principle of "cultural safety" becomes one of the imperatives for routine gene-based drug dosing.

Studying both the genome of the patient and the genetics features of the pathology (e.g., tumour cells, infectious organisms) before treatment could allow for customized drug selection and dosing. Such analysis could permit the avoidance of drugs not likely to be effective as well as optimization of drug doses to minimize the risk of adverse drug effects. These applications of pharmacogenomics are examples of **personalized medicine**.

DNA Microarray Technology

Most drug dosage changes are still usually made on a trial-and-error basis, by monitoring patient response. Researchers have developed an analytical tool known as a *high-density microarray*. This technology uses tiny microchip plates that contain thousands of microscopic DNA samples. A patient's blood can then be screened for thousands of corresponding DNA sequences that bind from the patient's blood sample to the sequences on the chip. This allows determination of the presence or absence of various genes, such as those resulting from drug metabolism. For example, the enzymes in the cytochrome system help metabolize from 25 to 30% of currently available drugs. Over 40 specific cytochrome genes have been identified thus far. The first DNA microchip for clinical use is

the AmpliChip Microarray. It is used to screen blood samples for the individual's cytochrome enzyme profile. Although this type of genotypic profiling is not yet practical for widespread use, it will eventually become a standard in clinical practice.

Table 5.1 lists several other examples of current clinical applications of pharmacogenomics.

CASE STUDY

Genetic Counselling

During the nurse's assessment of Darla, a newly admitted 38-year-old patient, Darla tells the nurse, "I'm allergic to codeine. Whenever I take it, it just knocks me out!" She tells the nurse that codeine does the same thing to all of her sisters.

The next day, the patient's oncologist comes in and explains the results of a genetic test that was performed on an outpatient basis. Darla agrees to allow the nurse to sit in on the conversation. The oncologist tells the patient that she has a type of gene that indicates that she has a strong chance of developing breast cancer within the next 5 years. The oncologist recommends that she undergo a bilateral mastectomy soon to avoid the possibility of developing breast cancer and suggests that she share this information with her sisters and her daughter, who is 18 years old. After the oncologist leaves, Darla tells the nurse, "I don't know what to do. I haven't talked to one of my sisters for years and I just know she won't believe me. I also don't want to worry my daughter. She is so young, and I'm sure she's too young to get cancer."

1. Does Darla have an actual allergy to codeine? What else could be happening?
2. Should the nurse tell Darla's sister and daughter? Explain your answer.
3. What is the best way for the nurse to handle this situation?

For answers see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

APPLICATION OF GENETIC PRINCIPLES AS A RESULT OF DRUG THERAPY AND THE NURSING PROCESS

As noted previously, the recognition that genetic factors contribute, at some level, to most diseases continues to grow. Thus, genetic influences on health, including the interaction of genetic and environmental (nongenetic) factors, will routinely affect nursing care delivery. In general, it is expected that in the next few years genetic research will move from the laboratory to more clinical practice settings.

Nurses in general practice settings will not be expected to perform in-depth genetic testing or counselling. Nurses—or other health care providers—with specialty certification in the field of genetics will conduct genetic testing and counselling. However, all nurses will need to have a working knowledge of relevant genetic principles. In this era of the "new genetics" paradigm, nurses are fully aware that nearly all diseases have a genetic component. Conditions such as myocardial infarction, cancer, mental health disorders, diabetes, and Alzheimer's disease are now viewed in a different light because of the known complex interactions between a number of factors, including the influence of one or more genes and a variety of environmental exposures for patients.

There are several other applicable skills regarding genetics for nurses in general practice settings. Assessment is the first step of the nursing process, and during the assessment the nurse may uncover factors that point to a potential for genetic disorders. During the initial assessment, the nurse obtains a patient's personal and family history. The family history is most effective if it covers at least three generations and includes the current and past health status of each family member. Assessment of factors possibly indicating an increased potential for genetic disorders is also important. A few examples of such factors are a higher incidence of a particular disease or disorder in the patient's family than in the general population; diagnosis of a disease in family members at an unusually young age; or diagnosis of a family member with an unusual form of cancer or with more than one type of cancer.

It is also important to inquire about any unusual reactions to a drug on the part of the patient, family members, significant others, and/or caregivers. An unusual or other than expected reaction to a drug in family members may point to a difference in the patient's ability to metabolize certain drugs. As indicated earlier in the chapter (as well as in Chapter 2), genetic factors may alter a patient's metabolism of a particular drug, resulting in either increased or decreased drug action. Every time a medication is administered, the patient's response to that drug must be assessed. Any unusual medication responses in a patient may point to a need for further investigation. Once a genetic variation is known, drug therapy may be adjusted accordingly.

As DNA chip technology becomes more affordable and accessible, it will be possible for patients to know in advance their relative risks for different diseases in later life. Genotype testing to identify a patient's drug-metabolizing enzymes will help prescribers better predict a patient's response to drug therapy.

Teaching about genetic testing and counselling may be another responsibility of the nurse. Patients will have questions and concerns about genetic testing and other issues. Nurses in general practice are not experts in genetic issues. However, the nurse may help with suggestions about genetic counselling, if appropriate. If genetic testing is ordered, the nurse may be a part of the testing process and will need to ensure that the informed decision making and consent procedure has been carried out correctly.

Maintaining privacy and confidentiality is of utmost importance during genetic testing and counselling. The patient is the one who decides whether to include or exclude any family members from the discussion and from knowledge of the results of the testing. Patients need to be reminded that undergoing the genetic test is not required and that they have the right to disclose or withhold test results from anyone. Nurses must protect against improper disclosure of information to other family members, friends of the family, other health care providers, and insurance providers. Nurses share the responsibility with other health care providers to protect patients and their families against the misuse of patients' genetic information.

Other responsibilities of the professional nurse may include development of clinical and social policy such as genetic non-discrimination and prenatal testing policies, testing of genetic products for reliability, and tasks in genetic informatics to meet the challenge of sifting through a continually expanding body of knowledge.

TABLE 5.1 Clinical Applications of Pharmacogenomics

Genetic Technique	Application
Genotyping for presence of the CYP2D6 isoenzyme and CYP2D6 alleles, determining whether patients are poor, intermediate, extensive, or ultrarapid metabolizers resulting from these enzymes (under study)	<i>Psychiatry and general medicine:</i> Helps guide the prescribing of selected medications such as anticoagulants, immunosuppressants, antidepressants, antipsychotics, anticonvulsants, β -blockers, and antidysrhythmics
Genotyping for presence of the p-glycoprotein drug transport protein (under study)	<i>Cardiology, infectious diseases, oncology, and other practice areas:</i> Assists in drug selection and dosing for drugs such as digoxin, antiretrovirals, and antineoplastics
Genotyping for presence of thiopurine methyltransferase enzyme	<i>Oncology:</i> Used to temper toxicity through more careful dosing of the cancer drug 6-mercaptopurine, in children with leukemia
Genotyping for variations in β -adrenergic receptors (under study)	<i>Pulmonology:</i> Determines which patients with asthma are more or less responsive to β -agonist therapy (e.g., albuterol) and which patients might benefit from other types of drug therapy
Genotyping for presence of the Philadelphia chromosome	<i>Oncology:</i> Identifies those patients with chronic myelogenous leukemia who may be stronger candidates for the cancer drug imatinib mesylate (Gleevec®)
Genotyping for presence of the <i>HER2/neu</i> proto-oncogene	<i>Oncology:</i> Identifies a subset of patients with breast cancer whose tumours express this gene, which indicates their suitability for treatment with the cancer drug trastuzumab (Herceptin®)
Viral genotyping of hepatitis C viruses (under study)	<i>Infectious diseases:</i> Can determine whether a particular infection warrants 26 versus 48 weeks of drug therapy (thereby reducing both costs and adverse drug effects)
Genotyping for the presence of factor V gene mutation	<i>Women's health:</i> Identifies women with a 7 to 100 times greater risk of thrombosis with oral contraceptive use compared to women without the mutation
Muscle biopsy test for patients with a family history of malignant hyperthermia	<i>Surgery:</i> Assesses the patient's risk of this adverse effect known to occur with administration of various inhalation anaesthetics and intraoperative paralyzing drugs
Genotyping for the presence of sodium channels associated with renin-angiotensin receptors and adrenal gland receptors	<i>Cardiology:</i> Allows refined antihypertensive drug selection
Race-based drug selection	<i>Cardiology:</i> Indicates use of the drug isosorbide dinitrate/hydralazine (BiDil®) for treatment of hypertension in patients of African descent due ultimately to genotypic variations in this patient population. This drug is not currently available in Canada.

CYP2D6, cytochrome enzyme subtype 2D6.

SUMMARY

Increasing scientific understanding of genetic processes is expected to revolutionize modern health care in many ways. The artificial manipulation and transfer of genetic material, although not a standard treatment for disease, is the focus of over 300 human clinical gene therapy trials. The spectrum of diseases that may eventually be treatable by gene therapy includes inherited diseases that are present from birth, disabilities such as paralysis from spinal cord injuries, life-threatening illnesses such as cancer, and even chronic illnesses acquired later in life for which a person may have a genetic predisposition. The

science of pharmacogenomics has already identified some of the genetic nuances in how different individuals' bodies metabolize drugs to their benefit or harm. Continued study in this area is expected to result in proactive customization of drug therapy to promote therapeutic benefits while minimizing or eliminating toxic effects. Genetic procedures and therapeutic techniques will likely become an increasing part of nursing practice as well as health care delivery in general. As the role and impact of genetics and genetically based drug therapy increase, so will their role in the nursing process.

KEY POINTS

- Genetic processes are a highly complex facet of human physiology, and genetics is becoming an integral part of health care that holds much promise in the form of new treatments for alterations in health.
- The Human Genome Project (HGP) described in detail the entire genome of a human individual.
- Basic genetic inheritance is carried by 23 pairs of chromosomes in each of the somatic cells; one pair of chromosomes

in each cell is called the *sex chromosomes*, identified as XX for females and XY for males.

- Applicable skills for general nurses include taking thorough patient, family, and drug histories; recognizing situations that may warrant further investigation through genetic testing; identifying resources for patients; maintaining confidentiality and privacy; and ensuring that informed consent is obtained for genetic testing and counselling.

EXAMINATION REVIEW QUESTIONS

- Which is the most appropriate example of a product formed by an indirect form of gene therapy?
 - Stem cells
 - Insulin
 - Antigen substitution
 - Platelet inhibitors or stimulators
- The nurse is providing teaching to a client about the goal of gene therapy. Which of the following would the nurse expect as the result?
 - To change the patient's own genetic functioning to treat a given disease
 - To improve drug metabolism
 - To prevent genetic disorders in the patient's future children
 - To stimulate the growth of stem cells
- What is the responsibility of research ethics boards?
 - Approving all forms of human clinical gene therapy
 - Identifying all major risks to the human subjects in a specific research protocol
 - Reviewing clinical trials involving human gene transfer
 - Analyzing genomes and determining whether they appear mutagenic
- The presence of certain factors in a person's genetic makeup that increase the likelihood of eventually developing one or more diseases is known as
 - Genetic mutation
 - Genetic polymorphism
 - Genome predisposition
 - Genotype
- The nurse is reviewing gene therapy. Which is a commonly studied adenovirus?
 - Hepatitis A and C virus
 - Genovirus
 - Human influenza virus
 - Pallodium
- Which of the following activities would be general responsibilities of a nurse working in a genetics clinic: (Select all that apply.)
 - Assessing the patient's personal and family history
 - Referring the patient to a genetic counsellor or other genetic specialist
 - Communicating the results of genetic tests to the patient and family
 - Maintaining privacy and confidentiality during the testing process
 - Answering questions about genetic test results
- The nurse is assessing a patient for a possible increased potential for genetic disorders. Which of these, if present, may indicate an increased potential for a genetic disorder? (Select all that apply.)
 - Having a brother who died of a myocardial infarction at age 29
 - Having a family member diagnosed with more than one type of cancer
 - Having an uncle who was diagnosed with prostate cancer at age 73
 - A history of allergy to shellfish and iodine
 - Having a maternal grandmother, two maternal aunts, and a sister who were diagnosed with colon cancer

CRITICAL THINKING ACTIVITIES

- You are working on a medical–surgical unit as a newly graduated nurse. During an assessment, your patient states, “My doctor told me that I need to have genetic testing. I just don't understand. If they change my genes, then it will change the way I look!” What is the priority as you answer the patient's concerns?
- An indirect form of gene therapy is already seen in contemporary health care practice. Explain this statement and provide examples.
- Analyze the process for producing human insulin, and suggest a few theoretical examples of how this same process could be used in other areas of health care.

For answers see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Medication Errors: Preventing and Responding

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Compare the following terms regarding drug therapy in the context of professional nursing practice: adverse drug event, adverse drug reaction, allergic reaction, idiosyncratic reaction, medical error, and medication error.
2. Describe the most commonly encountered medication errors.
3. Develop a framework for professional nursing practice for prevention of medication errors.
4. Identify potential physical and emotional consequences of a medication error.
5. Discuss the impact of culture and age on the occurrence of medication errors.
6. Analyze the various ethical dilemmas concerning professional nursing practice associated with medication errors.
7. Identify agencies concerned with prevention of and response to medication errors.
8. Discuss the possible consequences of medication errors for professional nurses and other members of the health care team.

KEY TERMS

Adverse drug event (ADE) Any undesirable occurrence concerning administration of or failure to administer a prescribed medication. (p. 76)

Adverse drug reactions (ADRs) Unexpected, unintended, or excessive responses to medication given at therapeutic dosages (as opposed to overdose); one type of adverse drug event. (p. 76)

Allergic reaction An immunological hypersensitivity reaction resulting from an unusual sensitivity of a patient to a particular medication; a type of adverse drug event and a subtype of adverse drug reactions. (p. 76)

Idiosyncratic reaction Any abnormal and unexpected response to a medication, other than an allergic reaction, that is peculiar to an individual patient. (p. 76)

Malpractice Improper or unethical conduct or unreasonable lack of skill that results in harm and where compensation

may be sought. All malpractice involves negligence. (p. 84)

Medical errors Any errors at any point of patient care that cause or have the potential to cause a patient harm. (p. 75)

Medication errors (MEs) Any preventable adverse drug events involving inappropriate medication use by a patient or health care provider; may or may not cause the patient harm. (p. 76)

Medication reconciliation A procedure implemented by health care providers to maintain an accurate and up-to-date list of medications for all patients between all phases of health care delivery. (p. 82)

Negligence Unintentional harm that results from conduct that does not meet a standard of care established by law. (p. 84)

GENERAL IMPACT OF ERRORS ON PATIENTS

Medical errors, and medication errors (MEs) in particular, have received much national attention. The study that brought medical errors to the public was the landmark study done in 1999 by the Institute of Medicine (IOM). According to this study, the number of patient deaths from medical errors in hospitals in the United States ranged from 44 000 to 98 000 annually, based on data from two large-scale studies. The IOM conducted a similar study in 2006 and found that medical errors harm at least 1.5 million people per year, including 117 000 hospitalizations at a cost of over \$4 billion. A follow-up study in 2010 showed 25.1 “harm” per 100 admissions

to the hospital. This study showed no significant change in rates of preventable errors since the IOM study. The landmark study of adverse events in Canadian hospitals undertaken in 2004 found that between 9 000 and 24 000 patients die each year because of adverse events or errors. Another Canadian study found that adverse drug-related events are responsible for 12% of emergency department visits. Of these, 68% were considered preventable (Zed, Abu-Laban, Balen, et al., 2008). A more recent report found that in 2007, 17% of Canadian adults (4.2 million) believed that a medical error had occurred to them when receiving health care in the previous 2 years (O'Hagan, MacKinnon, Persaud, et al., 2009). In this study,

factors contributing to medical errors such as numerous prescriptions, a chronic condition, and insufficient time with the physician were cited.

In the 2016 Canadian Institute of Health Information report entitled *Measuring Patient Harm in Canadian Hospitals* (https://secure.cihi.ca/free_products/cihi_cpsi_hospital_harm_en.pdf), authors found that harm in some form, including medication incidents, occurred in 1 in every 18 hospital stays (or 138 000 hospitalizations) between 2014 and 2015 (CIHI, 2016). The three most common medication incidents reported were with insulin (9%), hydromorphone hydrochloride (7%), and heparin (4%). The authors also indicated that the most common contributing factor reported (27%) was distraction or interruptions during the act of medication administration.

Numerous health institutions have made prevention of medical errors a top priority. The most important change to recognize is that reporting of errors should not be punitive toward the reporter. In fact, all health care providers are encouraged to report errors. It has been shown that reporting of errors can prevent errors from occurring. Increasingly, however, the literature reflects a shift in focus away from the individual nurse as the source of the ME to a consideration of the broader context. This concept has been taken a step further and has created “just culture.” Just culture recognizes that systems are generally at fault when an error occurs, but that when professionals do not follow policies or have repeated errors, those professionals need remedial education and must be held accountable. In addition to professional acknowledgement of personal error, remediation factors including workplace culture, reporting structure, and management behaviour may be organizational barriers to reporting (Vrbnjak, Denieffe, O’Gorman, et al., 2016).

Medical errors can occur during all phases of health care delivery and involve all categories of health care providers. Some of the more common types of error include misdiagnosis, patient misidentification, lack of patient monitoring, wrong-site surgery, and MEs. Most studies have looked at medical errors occurring in hospitals; however, many serious MEs occur in the home. Errors occurring in homes can be quite harmful, as potent drugs once used only in hospitals are now being prescribed for outpatients. The majority of fatal errors at home involve the mixing of prescription drugs with alcohol or other drugs. Intangible losses resulting from adverse outcomes include patient dissatisfaction with, and loss of trust in, the health care system. This loss of trust, in turn, can lead to adverse health outcomes because patients are afraid to seek health services. This chapter focuses on the issues concerning MEs and ways to prevent and respond to these errors.

MEDICATION ERRORS

An **adverse drug event (ADE)** is a general term that encompasses all types of clinical problems resulting from medication use. These errors include **medication errors (MEs)** and **adverse drug reactions (ADRs)**. The various subsets of ADEs and their

Fig. 6.1 Diagram illustrating the classes and subclasses of adverse drug events. ADRs, adverse drug reactions; AEs, adverse effects; ARs, allergic reactions; IRs, idiosyncratic reactions.

interrelationships are illustrated in Fig. 6.1. Adverse drug reactions are reactions that occur with the use of a particular drug. Two types of ADRs are **allergic reaction** (often predictable) and **idiosyncratic reaction** (usually unpredictable). MEs are a common cause of adverse health care outcomes and can range from having no significant effect to directly causing patient disability or death.

It is important to consider all of the steps involved in the medication use system when discussing MEs. Identifying, responding to, and ultimately preventing MEs require an examination of the entire medication use process. Attention must be focused on all people and all steps involved in the medication use process, including the prescriber, the transcriber of the order, nurses, pharmacists, and any other ancillary staff involved. A systems approach takes the Ten Rights one step further and examines the entire health care system, the health care providers involved, and any other factor that has an impact on the error.

Drugs commonly involved in severe MEs include central nervous system drugs, anticoagulants, and chemotherapeutic drugs. “High-alert” medications have been identified as those that, because of their potentially toxic nature, require special care when prescribing, dispensing, or administering. High-alert medications are not necessarily involved in more errors than other drugs; however, the potential for patient harm is higher. The Institute for Safe Medication Practices (ISMP’s) high-alert medications are listed in Table 6.1. MEs also result due to the large numbers of drugs with similarities in spelling or pronunciation (i.e., look-alike or sound-alike names). Several acronyms have been created to refer to these drugs, including SALAD (sound-alike, look-alike drugs) and LASA (look-alike, sound-alike). Mix-ups between such drugs are most dangerous when two drugs from different therapeutic classes have similar names. This can result in patient effects that are grossly different from those intended as part of the drug therapy. For a list of examples of commonly confused drug names, see Preventing Medication Errors: Institute for Safe Medication Practices: Examples of Look-Alike, Sound-Alike (LASA) Commonly Confused Drug Names box below. More information on high-alert medications and SALADs can be found on the Institute for Safe Medication Practices Canada website at <http://www.ismp-canada.org>.

TABLE 6.1 Examples of High-Alert Medications**Classes/Categories of Drugs**

- Adrenergic agonists, IV (e.g., **EPINEPH**rine, phenylephrine, norepinephrine)
- Adrenergic antagonists, IV (e.g., propranolol, metoprolol, labetalol)
- Anaesthetic agents, general, inhaled, and IV (e.g., propofol, ketamine)
- Antiarrhythmics, IV (e.g., lidocaine, amiodarone)
- Antithrombotic agents, including:
 - anticoagulants (e.g., warfarin, low-molecular-weight heparin, IV unfractionated heparin)
 - Factor Xa inhibitors (e.g., fondaparinux)
 - Direct thrombin inhibitors (e.g., argatroban, bivalirudin, dabigatran etexilate, lepirudin)
 - Thrombolytics (e.g., alteplase, reteplase, tenecteplase)
 - Glycoprotein IIb/IIIa inhibitors (e.g., eptifibatide)
- Cardioplegic solutions
- Chemotherapeutic agents, parenteral and oral
- Dextrose, hypertonic, 20% or greater
- Dialysis solutions, peritoneal and hemodialysis
- Epidural or intrathecal medications
- Hypoglycemics, oral
- Inotropic medications, IV (e.g., digoxin, milrinone)
- Insulin, subcutaneous and IV
- Liposomal forms of drugs (e.g., liposomal amphotericin B) and conventional counterparts (e.g., amphotericin B deoxycholate)
- Moderate sedation agents, IV (e.g., dexmedetomidine, midazolam)
- Moderate sedation agents, oral, for children (e.g., chloral hydrate)
- Narcotics/opioids
- IV
- Transdermal
- Oral (including liquid concentrates; immediate and sustained-release formulations)
- Neuromuscular blocking agents (e.g., succinylcholine, rocuronium, vecuronium)
- Parenteral nutrition preparations
- Radiocontrast agents, IV
- Sterile water for injection, inhalation, and irrigation (excluding pour bottles) in containers of 100 mL or more
- Sodium chloride for injection, hypertonic, greater than 0.9% concentration

Specific Drugs

- Epoprostenol (Flolan®), IV
- Magnesium sulphate injection
- Methotrexate, oral, non-oncological use
- Opium tincture
- Oxytocin, IV
- Nitroprusside sodium for injection
- Potassium chloride for injection concentrate
- Potassium phosphates injection
- Promethazine, IV
- Vasopressin, IV or intraosseous

ISMP List of High Alert Medications in Community/Ambulatory Health Care

Classes/Categories of Medications	Specific Medications
Antiretroviral agents (e.g., efavirenz, lami VUD ine, raltegravir, ritonavir, combination antiretroviral products)	car BAM azepine
Chemotherapeutic agents, oral (excluding hormonal agents) (e.g., cyclophosphamide, mercaptopurine, temozolomide)	chloral hydrate liquid, for sedation of children
Antihyperglycemic drugs, oral	heparin sodium, including unfractionated and low-molecular-weight heparin
Immunosuppressant agents (e.g., aza THIO prine, cyclo SPORINE , tacrolimus)	met FORMIN
Insulin, all formulations	methotrexate, non-oncological use
Opioids, all formulations	midazolam liquid, for sedation of children
Pediatric liquid medications that require measurement	propylthiouracil
Pregnancy category X drugs (e.g., bosentan, ISO retinoin)	warfarin sodium

⚡ PREVENTING MEDICATION ERRORS

Institute for Safe Medication Practices: Examples of Look-Alike, Sound-Alike (LASA) Commonly Confused Drug Names

Names of Medications	Comments
carboplatin vs. cisplatin	Two different antineoplastic drugs
Celebrex® vs. Celexa® vs. Cerebyx	Anti-inflammatory drug versus antidepressant drug versus antiepileptic drug
dopamine vs. dobutamine	Vasopressor drugs of markedly different strengths; dobutamine is also a strong inotropic, affecting the heart
fentanyl vs. sufentanil	Both are injectable anaesthetics but with a significant difference in potency and duration of action
Humulin® vs. Humalog®	Short-acting versus rapid-acting insulin
Lamictal® vs. Lamisil®	Anticonvulsant/mood stabilizer versus antifungal drug
Losec® vs. Lasix®	Proton pump inhibitor versus diuretic
metronidazole vs. metformin	Antibiotic versus antidiabetic drug
Paxil® vs. Plavix®	Antidepressant versus antiplatelet drug
trazodone® vs. tramadol®	Antidepressant versus analgesic

The application of TALLman lettering (combinations of uppercase and lowercase letters, rather than all uppercase or all lowercase lettering) is one of several techniques and strategies to differentiate similar drug names and optimize medication safety during all stages of the medication-use process. TALLman lettering creates a mental alert by changing the shape of words that look similar when seen in uppercase letters only. ISMP Canada, the Canadian Association of Provincial Cancer Agencies, and the International Medication Safety Network endorsed a list of sound-alike look-alike drug names used in oncology, where TALLman lettering is applied (e.g., VinCRISTine/VinBLASTine). For a full list of look-alike/sound-alike drug names with recommended TALLman lettering, see <http://www.ismp-canada.org>.

It is widely recognized that most MEs result from weaknesses in the systems within health care organizations rather than from individual shortcomings. System weaknesses include failure to create a “just culture” or nonpunitive work atmosphere for reporting errors, excessive workload with minimal time for preventive education for staff, interruptions during medication preparation and administration, and lack of interdisciplinary communication and collaboration. All hospitals are required to analyze MEs and implement ways to prevent them. Nurses must take the time to report errors because without reporting, no changes can be made. When errors are reported, trends can be identified and processes can be changed to prevent the errors from occurring again.

ISSUES CONTRIBUTING TO ERRORS

Organizational Issues

Various strategies have been used to detect and document MEs in hospitals. MEs can occur at any step in the medication process: procuring, prescribing, transcribing, dispensing,

administering, and monitoring. Prescribing faults and prescription errors are major problems among MEs. Most prescribing errors can be caught by the pharmacist before order entry or by nurses prior to administration. Administration is the next most common point in the process at which MEs occur, followed by dispensing errors and transcription errors. It is important for nurses to have good relationships with pharmacists, because the two professions, working together, can have a major impact in preventing MEs. Hospital pharmacists are usually available 24/7 and serve as great resources when the nurse has any question regarding drug therapy. In more rural areas, having a pharmacist or physician always available may not always be possible or feasible. In these circumstances, it is recommended that nurses work with the agency to develop policies and processes that outline what steps to take in the event of a potential ME. Patient involvement in patient safety is widely advocated. Patients who are involved and share in decision making in their health care have better outcomes when they take on the responsibility of asking questions and seeking more information when they need it. They learn more about their illnesses and the care provided, and they can advocate for their own safety at each health care encounter. Safer Healthcare Now! and the Canadian Patient Safety Institute function to raise awareness and promote best practices in patient safety. As part of the World Health Organization (WHO) and Pan American Health Organization initiative, Patients for Patient Safety Canada advocates for patient-centred care and patient safety strategies to improve patient safety (2012).

Effective use of technologies such as computerized prescriber order entry and bar coding of medication packages has also been shown to reduce MEs. In 2008, ISMP Canada and the Canadian Patient Safety Institute sponsored a roundtable to discuss and seek consensus on a national initiative for pharmaceutical manufacturers concerning the use of standardized bar codes for labelling pharmaceutical medications approved for use in Canada. By 2012, the GS1 global Automatic Identification and Data Capture application standard — a global bar code standard for pharmaceuticals — was adopted for Canada. In 2010, bar code verification was being used for only 8% of institutional beds and 33% of dispensing and compounding practices within hospital pharmacies in Canada ([Institute for Safe Medication Practices Canada, 2013](#); [Canadian Patient Safety Institute, 2013](#)). Cost is a barrier to technological improvements in general. The cost of implementing current technology, including automated drug dispensing cabinets with electronic charting and computerized order entry, is often prohibitive, ranging from hundreds of thousands of dollars to millions. Nonetheless, these various technological advances have been shown to reduce MEs. For example, computerized order entry (also known as computerized physician order entry [CPOE]) eliminates handwriting and standardizes many prescribing functions. Bar coding of medications allows the nurse to use electronic devices for verification of correct medication at the patient's bedside. Computer programs are used in the pharmacy to screen for potential drug interactions. Despite all the benefits technology has to offer, workload issues (i.e., nursing staff shortage), inadequate education in the use of the equipment, or difficulties in mastering

the use of complex technology can prevent the technology from eliminating errors as it was designed to do. Self-medication by patients (e.g., patient-controlled analgesia) has been shown to reduce errors, provided patients have adequate cognitive ability and mental alertness. The WHO has developed information about patient safety concerns, safety initiatives, and patient safety solutions (see [Box 6.1](#)).

Educational System Issues and Their Potential Impact on Medication Errors

All health care providers have an obligation to double-check any necessary medication information before proceeding. This includes stopping to check medication orders and being comfortable with one's knowledge of the drug *before* administering it. Numerous drug information guides are available for the nurse's use. Access to electronic references at the point of care

are improving. Many institutions subscribe to online databases such as Lexicomp or UpToDate that provide quick and easy access to drug information.

Patient safety begins in the educational process, with nursing students and faculty members. Nurses are pivotal to the medication administration process and must therefore demonstrate safe and reliable practice. It is critically important for nurse educators to employ teaching strategies that address a just culture of safety, one that allows students to begin their careers with greater confidence and a healthy habit of self-monitoring. Commonly reported student nurse errors involve the following situations: unusual dosing times, medication administration record issues (unavailability of the record, failure to document doses given resulting in administration of extra doses, failure to review the record before medicating patients), administration of discontinued or "held" medications, failure to monitor vital signs or laboratory results, administration of oral liquids as injections, preparation of medications for multiple patients at the same time, and dispensing of medications in different doses from those ordered (e.g., tablets that need to be split in half).

BOX 6.1 World Health Organization Initiatives About Medications and Health

The World Health Organization (WHO) posts information on its website regarding initiatives to promote patient safety in medication administration and other aspects of health care. As the WHO notes, no adverse event should ever occur, anywhere in the world, if the knowledge exists to prevent it from happening. Knowledge is of little use, however, if it is not applied in practice. The WHO Collaborating Centre for Patient Safety Solutions has developed patient safety initiatives that can serve as a guide in redesigning the patient care process to prevent the inevitable errors from ever reaching patients. *Patient safety solutions* are defined by the WHO as any system design feature or intervention that has demonstrated the ability to prevent or mitigate patient harm arising from the health care process. Information about the first group of patient safety solutions (2008/2009) approved by the WHO centre is available at <https://www.who.int/patientsafety/topics/solutions/en/>. These patient safety concerns include avoiding confusion of medications with look-alike, sound-alike names; ensuring correct patient identification; enhancing communication during patient "handovers" between care units or care teams; ensuring performance of the correct procedure at the correct body site; maintaining control of concentrated electrolyte solutions; ensuring medication accuracy at transition points in care; avoiding catheter and tubing misconnections; and promoting single use of injection devices and improved hand hygiene to prevent health care-associated infections.

More information about patient safety and safety initiatives is provided in a national initiative—Safer Healthcare Now! (SHN). SHN is the flagship program of the Canadian Patient Safety Institute (CPSI). The overarching goal of the program is to reduce preventable injuries and deaths resulting from adverse events. They have identified four priority areas: infection prevention and control, medication safety, surgical care, and home care. Canadian Patient Safety Week is a national annual campaign launched by the CPSI to raise awareness of patient safety issues common to all health care organizations. For example, the 2013 message was "Don't hold back—Good healthcare starts with good communication." The theme was "Ask. Listen. Talk." and encouraged all health care providers, patients, and their families to ASK questions, LISTEN to the answers, and TALK openly about their concerns in order to improve patient safety. [Patients for Patient Safety Canada \(2012\)](#) is a patient-led program of the CPSI. These initiatives encourage patients to take a role in preventing health care errors by becoming more active, involved, and informed regarding all aspects of their health care. For more information on these programs, visit <http://www.patientsafetyinstitute.ca/> or visit <https://www.patientsafetyinstitute.ca/en/About/Programs/SHN/Pages/default.aspx>.

Medication Errors and Related Sociological Factors

Effective communication among all members of the health care team contributes to improved patient care. Workplace bullying among nurses is becoming an increasing issue. Bullying is different from horizontal violence in that a real or perceived power differential between the initiator and recipient must be present (Einarsen, Hoel, Zapf, et al., 2011). The perpetrator's and target's gender can also play a role to heighten and promote downward bullying (McCormack, Djurkovic, Nsubuga-Kyobe, et al., 2018). Disruptive interprofessional team behaviour and workplace bullying, and a lack of institutional response to it, are significant factors affecting nurse job satisfaction and nursing staff retention, as well as the erosion of personal health and professional well-being. Disruptive behaviours can potentially result in communication breakdown and lack of collaboration among physicians, nurses, and other health care workers that can lead to medical errors, adverse events, and near misses, resulting in reduced patient care quality. It can also lead to recruitment and retention issues, impact workers' health and well-being, patient safety, organization outcomes, and societal outcomes.

Fortunately, communication between prescribers and other members of the interprofessional health care team has improved over the years, with newer generations of prescribers. This is due in large part to more progressive approaches in medical education that emphasize a team orientation and zero tolerance to any form of violence. One progressive approach has been to include the Canadian Interprofessional Health Collaborative (CIHC) national interprofessional core competencies (CIHC, 2010) into health professional education and institutions (https://www.cihc.ca/files/CIHC_IPCompetencies_Feb1210.pdf). Such approaches recognize the ever-increasing complexities of health care delivery and the reality that no one team member can know every fact and provide for all patient care needs.

PREVENTING, RESPONDING TO, REPORTING, AND DOCUMENTING MEDICATION ERRORS: A NURSING PERSPECTIVE

Preventing Medication Errors

MEs are considered to be any preventable event that could lead to inappropriate medication use or harm. The major categories of ME according to the Canadian Medication Incident Reporting and Prevention System (2011) are (1) near miss or close call where an event could result in unwanted consequences but does not, (2) no-harm event where an incident occurs but results in no injury to the patient, (3) ME that causes harm, and (4) critical incident resulting in serious harm. MEs may be prevented through a variety of strategies, including the following: (1) Multiple systems of checks and balances should be implemented to prevent MEs. (2) Prescribers should write legible orders that contain correct information, or orders

should be written electronically if the technology is available. (3) Authoritative resources, such as pharmacists or current drug literature, should be consulted if there is any area of concern, beginning with the medication order and continuing throughout the entire medication administration process. (4) Nurses should always check the medication order three times before giving the drug and consult with authoritative resources (see [Chapter 3](#)) if any questions or concerns exist. Faculty members should not be the student's research source regarding medications, and the safe practice of using appropriate resources should begin early in the educational process. (5) The rights of medication administration should be used consistently; this practice has been shown to substantially reduce the likelihood of an ME. See Preventing Medication Errors: How to Prevent Medication Errors box below, for a more concise and detailed listing of ways to help prevent MEs. See Special Populations: Children box on page 81 for a discussion of MEs in pediatric patients and special considerations for this age group.

PREVENTING MEDICATION ERRORS

How to Prevent Medication Errors

- As the first step to defend against errors, assess information about drug allergies, vital signs, and laboratory test results.
- Use two patient identifiers before giving medications.
- Never give medications that you have not drawn up or prepared yourself.
- Minimize the use of verbal and telephone orders. If verbal or telephone orders are used, be sure to repeat the order to confirm with the prescriber. Speak slowly and clearly, and spell the drug name aloud.
- List the reason for use of each drug and any educational materials on the medication administration record.
- Avoid abbreviations, medical shorthand, and acronyms because they can lead to confusion, miscommunication, and risk of error (see Legal & Ethical Principles: Use of Abbreviations, Symbols, and Dose Designations on page 82).
- Never assume anything about a drug order or prescription, including route. If a medication order is questioned for any reason (e.g., dose, drug, indication), never assume that the prescriber is correct. Always be the patient's advocate and investigate the matter until all ambiguities are resolved.
- Do not try to decipher illegibly written orders; instead, contact the prescriber for clarification. Illegible orders fall below applicable standards for quality medical care and endanger patient safety. If in doubt about any part of an order, always check with the prescriber. Compare the medication order against what is on hand by checking for the right drug, right dose, right time, right patient, and right route.
- *Never* use trailing zeros (e.g., 1.0 mg) in writing and/or transcribing medication orders. Use of trailing zeros is associated with increased occurrence of overdose. For example, "1.0 mg warfarin sodium" could be misread as "10 mg warfarin sodium," a 10-fold dose increase. Instead, use "1 mg" or even "one mg."
- Failure to use leading zeros can also lead to overdose. For example, .25 mg digoxin could be misread as 25 mg digoxin, a dose that is 100 times the dose ordered. Instead, write "0.25 mg."
- Carefully read all labels for accuracy, expiration dates, dilution requirements, and warnings.
- Remain current with new techniques of administration and new equipment.
- Encourage the use of generic names.
- Listen to and honour any concerns expressed by patients. If the patient voices a concern about being allergic to a medication or states that a pill is not what the patient usually takes, STOP, listen, and investigate.
- Strive to maintain your own health so you remain alert, and never be too busy to stop, learn, and inquire. In addition, engage in ongoing continuing education.
- Become a member of professional nursing organizations to network with other nursing students or professional nurses to advocate for improved working conditions and to stand up for the rights of nurses and patients.
- Know where to find the latest information on which dosage forms can be or should not be crushed or opened (e.g., capsules), and educate patients accordingly.
- Safeguard any medications that the patient had on admission or transfer so that additional doses are not given or taken by mistake. In such situations, safeguarding is accomplished by compiling a current medication history and resolving any discrepancies rather than ignoring them.
- Always verify new medication administration records if they have been rewritten or re-entered for any reason, and follow policies and procedures about this action.
- Make sure the weight of the patient is always recorded before carrying out a medication order, to help decrease dosage errors.
- Provide for mandatory recalculation of every drug dosage for high-risk drugs (e.g., highly toxic drugs), or high-risk patients (e.g., pediatric or older adults) because there is a narrow margin between therapeutic serum drug levels and toxic levels (e.g., for chemotherapeutic drugs or digitalis drugs, or in the presence of altered liver or kidney function in a patient).
- Always suspect an error whenever an adult dosage form is dispensed for a pediatric patient.
- Seek translators when appropriate—never guess what patients are trying to say.
- Educate patients to take an active role in ME prevention, both in the hospital setting and at home.
- Involve yourself politically in advocating for legislation that improves patient safety.

Medication Errors

Of all the ways a pediatric patient may be harmed during medical treatment, MEs are the most common. As with older adult patients, when MEs occur, there is a higher risk of death in children. MEs involving inpatient pediatric patients occur frequently, estimated at a rate of 4.5 to 5.7 errors per 100 drugs used. The most common MEs in pediatrics are dosing errors. Research has begun to identify some of the groups of pediatric patients who are at highest risk of MEs (see Evidence in Practice box). These include the following patients: (1) those younger than 2 years of age, (2) those in intensive care units, specifically the neonatal intensive care unit, (3) those in the emergency department, where there is high patient turnover and there are diverse and unpredictable patient needs, (4) those receiving intravenous or chemotherapeutic drugs, immunosuppressive medications, lipid/total parenteral nutrition or opioids (Maaskant, Eskes, van Rijn-Bikker, et al., 2013), and (5) those whose weight has not been determined or recorded. The risk of harm is compounded when a high-alert medication is involved. The top five high-alert medications reported as causing harm or potential harm in Canadian pediatric health care settings are morphine sulphate, potassium chloride, insulin, fentanyl, and salbutamol (Institute for Safe Medication Practices Canada, 2009). Mathematical dosage calculations for pediatric patients are also problematic. Once the drug has been ordered, in determination of the correct dosage, the problems of most concern include the following: (1) inability of the nurse to understand/perform the correct calculation or dilution, (2) infrequent use of calculations, and (3) decimal point misplacement, with potential overdosing or underdosing.

The following are some of the actions that can be taken to prevent pediatric MEs:

- Report all MEs, because this information is part of the practice of professional nursing and helps in identifying causes of ME.
- Know the drug thoroughly, including its on- and off-label uses, action, adverse effects, dosage ranges, routes of administration, high-alert drug status cautions (see Table 6.1), and contraindications (e.g., Is it recommended for use in pediatric patients?).
- Confirm information about the patient each and every time a dose is given, and check three times before giving the drug, by comparing the drug order with the patient's medication profile and verifying for the right drug, right dose, right time, right route, and right patient.
- Double-check and verify information on handwritten orders that may be incomplete, unclear, or illegible.
- Avoid verbal telephone orders in general. When they are unavoidable, always repeat them back to the prescriber over the telephone. Insist that the prescriber sign off any emergency in-person verbal orders before leaving the unit.
- Avoid distractions while giving medications.
- Communicate with everyone (e.g., parent, caregiver) involved in patient care.
- Make sure all orders are clear and understood when patients are handed over to other nurses with shift changes.
- Adopt standard concentrations of opioid solutions (high-alert classification) intended for continuous intravenous infusion.
- Limit the number of concentrations and strengths of high-alert medications available on a unit.
- Use authoritative resources such as drug handbooks, Lexicomp, *Pediatric & Neonatal Dosage Handbook*, *Compendium of Pharmaceuticals and Specialties*, or information from the Health Canada Drug Product Database website (<http://www.hc-sc.gc.ca/dhp-mps/prodpharma/databasdon/index-eng.php>).

EVIDENCE IN PRACTICE

Canadian Pediatric Adverse Events Study

Review

Numerous adult studies have been conducted to investigate the harm associated with adverse events. The Canadian Adverse Effects Study conducted by Baker, Norton and colleagues in 2004 highlighted the significance of hospital-related harm in the adult population. This landmark study found that 7.5% of adults admitted to hospital experience adverse events (AEs). This information provided the foundation for improved safety of health care delivery for adults. Although some recent epidemiological studies have contributed to the knowledge base of pediatric safety in acute care hospitals, the scope of the problem in this vulnerable population was limited. The lack of a comprehensive pediatric trigger tool limited the scope of the full burden of health care-associated harm. In response to this gap, Matlow, Baker, Flintoft, and colleagues (2012) conducted the Canadian Paediatric Adverse Events Study discussed in the following Types of Evidence section.

Type of Evidence

This cross-sectional study used a retrospective chart review of 3 669 charts from April 2008 to March 2009 across four age groups: 0 to 28 days; 29 days to 1 year; older than 1 year to 5 years; and older than 5 years to 18 years). The validated Canadian Paediatric Trigger Tool was used to identify AEs in children admitted to 7 academic pediatric centres and 15 large community hospitals across 7 Canadian provinces. The purpose of the study was to determine the epidemiology (incidence and prevention) of AEs in the pediatric population.

Results of the Study

Two hundred and thirty-seven patients (9.2%) experienced an AE resulting in death, disability, prolonged hospital stay, or readmission. Children in the pediatric academic settings experienced more AEs (11.2%) than those in community hospitals (3.3%). More nonpreventable AEs occurred in academic settings, while the incidence of preventable AEs was comparable in both settings.

The reason for hospitalization and the age of the patient also influenced the occurrence of an adverse event. Neonates aged 0 to 28 days were more likely to experience an adverse event. Neonates admitted to the intensive care unit for at least 1 day were 10 times more likely to experience an AE. Patients over the age of 28 days admitted to surgical units were two times as likely to experience an AE as those on medical units. Surgical errors were the most frequent overall. Children under 12 months of age experienced more AEs from medical procedures and clinical care. Children 12 months and older experienced more AEs from medication and diagnostic errors.

Errors in surgical units and intensive care units in academic settings were the most common overall compared to emergency services and maternal/obstetrical units in community settings.

Link of Evidence to Nursing Practice

These data inform health care providers that children hospitalized in health care settings across Canada are vulnerable to harm. Children cannot advocate for safe care, so health care providers and decision makers must be informed of the various dangers in pediatric health care delivery. The range and burden of health care-associated injuries established from this study is key to transformation of the system to make health care safer.

LEGAL & ETHICAL PRINCIPLES

Use of Abbreviations, Symbols, and Dose Designations

Medication errors often occur as a result of misinterpretation of abbreviations, symbols, and dose designations. The Institute for Safe Medication Practices Canada, Accreditation Canada, and the Canadian Patient Safety Institute support the elimination of dangerous abbreviations, symbols, and dose designations in health care to enhance the safety of Canadian patients and recommend that abbreviations be written out in full. As part of Accreditation Canada Required Organizational Practices, organizations are required to identify and implement a list of abbreviations, dose designations, and symbols that are not to be used in the organization. This list is inclusive of the following Institute for Safe Medication Practices Canada “Do Not Use” chart on page 84.

Note: In Canada, the trend is now toward using “mcg” in practice, so it is important to note the difference between “mcg” and “mg” in orders.

It is the philosophy of the authors of this textbook to avoid abbreviations whenever possible.

In 2018, the Institute for Safe Medication Practices reaffirmed the *Do Not Use; Dangerous Abbreviations, Symbols and Dose Designations* list. (<https://www.ismp-canada.org/download/safetyBulletins/2018/ISMPCSB2018-05-DoNotUseList.pdf>).

Responding to, Reporting, and Documenting Medication Errors

Responding to and reporting MEs are part of the professional responsibilities for which nurses are accountable. If a ME does occur, it must be reported, regardless of whether the error was made by a nursing student or a professional nurse. Follow facility policies and procedures for reporting and documenting the error closely and cautiously. Once the patient has been assessed and urgent safety issues have been addressed, report the error immediately to the appropriate prescriber and nursing management, for example, the nurse manager or supervisor. If the patient cannot be left alone due to deterioration of the patient's condition or the need for close monitoring after the ME, a fellow nurse or other qualified health care provider should remain with the patient and provide appropriate care while the prescriber is contacted. Follow-up procedures or tests may be ordered or an antidote prescribed. These orders should be implemented as indicated by the prescriber. Remember that the nurse's highest priority at all times during the medication administration process and during a ME is the patient's physiological status and safety.

When a ME has occurred, complete all appropriate forms—including an incident report—as per the facility's policies and procedures, and provide appropriate documentation. Document the ME by providing only factual information about the error. Documentation should always be accurate, thorough, and objective. Avoid using judgemental words such as *error* in the documentation. Instead, chart factual information such as the medication that was administered, the actual dose given, and other details regarding the order (e.g., wrong patient, wrong route, wrong time). Also note any observed changes in the patient's physical and mental status. In addition, document the fact that

the prescriber was notified and any follow-up actions or orders that were implemented. Patient monitoring should be ongoing.

Most facilities require additional documentation when an ME occurs, consisting of an incident report or unusual occurrence report. Always follow facility policies and procedures or protocols in completing an incident report. Documentation should include only factual information about the error as well as all corrective actions taken. Complete any additional sections of the form to help with the investigation of the incident. Because these forms are forwarded to the facility's risk management department, this complete and factual information may help prevent errors in the future. Do not document on the patient's chart that an incident report was filled out, and do not keep a copy of the incident report; incident reports are not to be placed in the patient's chart. The reporting of actual and suspected MEs should offer the option of anonymity. This may help to foster improved error reporting and safe medication practices. Internal, facility-based systems of error tracking may generate data to help customize policy and procedure development. All institutional pharmacy departments are required to have an adverse drug event monitoring program.

Nurses as well as health care facilities may also be involved in external reporting of MEs. There are nationwide confidential reporting programs that collect and disseminate safety information on a larger scale. One such program is the Canadian Medication Incident Reporting and Prevention System (<https://www.cmiprs-scdpim.ca/?lang=en>), which collects incident reports of MEs. The Canada Vigilance Program is Health Canada's postmarket surveillance program that collects and assesses reports of suspected adverse reactions to health products marketed in Canada. The Health Canada website (<http://www.hc-sc.gc.ca/dhp-mps/medeff/vigilance-eng.php>) is a valuable source of adverse reaction information. The Canada Vigilance Adverse Reaction Online Database (http://www.hc-sc.gc.ca/dhp-mps/medeff/databasdon/conditions_search-recherche-eng.php) is a nationwide database of adverse reactions that has existed since 1965. Adverse reaction reports are submitted by health care providers and consumers on a voluntary basis, online or by telephone. MedEffect e-Notice, provided by Health Canada, sends health product advisories and recalls, and the *Health Product Info Watch* and MedEffect content updates are available for free by email (<http://www.hc-sc.gc.ca/dhp-mps/medeff/subscribe-abonnement/index-eng.php>). ISMP Canada, Safer Healthcare Now!, and Accreditation Canada also provide useful information to health care providers aimed at safety enhancement.

Performing Medication Reconciliation

Communicating effectively about medications is a critical component of delivering safe care. **Medication reconciliation** (also called *MedRec*) is a formal process in which medications are “reconciled” at all points of entry and exit to and from a health care entity. Medication reconciliation requires a best possible medication history (BPMH) and entails a more systematic and comprehensive review of all the medications a patient is taking. The prescriber is then to assess those medications and decide if they are to be continued upon hospitalization. Medication reconciliation was designed to ensure that there are no discrepancies between what patients were taking at home and what they

take in the hospital. Medication reconciliation should occur at entry into the facility, upon transfer from surgery, into or out of the intensive care unit, and at discharge.

Although this seems to be an easy process, numerous problems have been encountered since its inception in 2005. The first problem is that often patients do not know exactly what medications they are taking and may report, for example, that they take a “blue pill for blood pressure.” Sometimes the patient may have a list of medications but some of the medications were discontinued prior to admission, and often they fail to provide this vital piece of information. The patient or family may not be involved in the medication history-taking process. This can lead to the prescriber continuing a medicine based on faulty information. System and communication factors may also impact medication reconciliation, such as inadequate hospital policies for medication management upon transfer and lack of systems to verify that medications are properly documented, ordered, or transcribed. There may also be communication issues between physicians, about changes to medication orders or discrepancies, or poor communication between physicians and other team members. Hospitals throughout the country are working hard to figure out ways to avoid the problems described; this is an ongoing process. Medication reconciliation has been part of the Accreditation Canada program since 2006; however, due to the problems encountered, it scaled back its requirements in 2008 (Accreditation Canada, Canadian Institute for Health Information, Canadian Patient Safety Institute, et al., 2012).

Medication reconciliation involves three steps:

1. Verification: Collection of the patient’s medication information with a focus on medications currently used (including prescription drugs as well as over-the-counter medications and natural health products)
2. Clarification: Professional review of this information to ensure that all medications and dosages are appropriate for the patient
3. Reconciliation: Further investigation of any discrepancies and documentation of relevant communications and changes in medication orders

To ensure ongoing accuracy of medication use, the steps listed below should be repeated at each stage of health care delivery:

- a. Admission
- b. Status change (e.g., from critical to stable). It is the role of the health care provider to evaluate current medications and specify in writing which medications are to be continued or discontinued with any status change, transfer, or discharge.
- c. Patient transfer within or between facilities or health care provider teams
- d. Discharge. (The latest medication list should be provided to the patient to take to the next health care provider, or this information should be otherwise forwarded to the health care provider; applicable confidentiality guidelines should be followed.)

Following are some applicable assessment and education tips regarding medication reconciliation:

1. Ask the patient open-ended questions and gradually move to yes–no questions to help determine specific medication information. (Details are important and sometimes even critical.)
2. Avoid the use of medical jargon unless it is clear that the patient understands and is comfortable with such language.
3. Prompt the patient to try to remember all applicable medications (e.g., patches, creams, eye drops, inhalers, professional samples, injections, natural health products). If the patient does provide a medication list, make a copy for the patient’s chart.
4. Clarify unclear information to the extent possible (e.g., by talking with the home caregiver or the outpatient pharmacist who fills the patient’s prescriptions, if needed).
5. Record the aforementioned information in the patient’s chart as the first step in the medication reconciliation process.
6. Emphasize to the patient the importance of always maintaining a current and complete medication list and bringing it to each health care encounter (e.g., as a wallet card or other list). Many patients use their own computers for this. Also encourage patients to learn the names and current dosages of their medications.

OTHER ETHICAL ISSUES

Notification of Patients Regarding Errors

A landmark article published in the *Journal of Clinical Outcomes Management* in 2001 recognized the obligation of institutions and health care providers to provide full disclosure to patients when errors have occurred in their care. The article not only emphasized the ethical basis for this practice but also addressed the legal implications and was a starting point for understanding the issue of notification of patients about MEs. The Disclosure Working Group of the Canadian Patient Safety Institute (2011) recommended a just culture of disclosure. Apology legislation that has been introduced in eight Canadian provinces and one territory adds a legal component to meaningful apology and disclosure of a harmful event. The provinces and territory where this legislation exists provide statutory protection that any apology they make to a patient cannot be used against them in subsequent court proceedings as evidence to establish fault or liability. Critical to disclosure is honesty and transparency. Accreditation Canada includes disclosure in its Required Organizational Practice, which includes developing a formal, transparent organizational policy and process of disclosure to patients. This includes support for the patient, family, and health care worker. It is recommended that the term *error* be avoided in the context of disclosure because of the complex interplay of factors involved in patient safety incidents, as noted previously. The working group prefers the term *patient safety incident*. There are three types of patient safety incidents: (1) harmful incident (replaces the term *preventable adverse drug event*) that results in harm to the patient; (2) near miss, which did not reach the patient and results in no harm; and, (3) no-harm incident, which reaches the patient but no harm results. This terminology is an effort by the World Health Organization (2016) to standardize key concepts and to improve safety worldwide. Health care organizations offer needed financial support for reasonable expenses (e.g., travel expenses, temporary loss of wages) in regard to the disclosure process. As well, support is recommended for health care providers involved in the disclosure proceedings. The process of disclosure is outlined in the document available at <http://www.patientsafety-institute.ca/en/toolsResources/disclosure/Documents/CPSI%20Canadian%20Disclosure%20Guidelines.pdf>.

Possible Consequences of Medication Errors for Nurses

The possible effects of MEs on patients range from no significant effect to permanent disability or even death in the most extreme cases. However, MEs may also affect health care providers, including nurses and student nurses, in a number of ways. An error that involves significant patient harm or death may take an emotional toll on the nurse involved in the error. Nurses may be named as defendants in malpractice litigation, with possibly serious financial consequences. In nursing, **negligence** is “conduct that does not meet a standard of care established by law” (Potter, Perry, Ross-Kerr, et al., 2014, p. 9). It is characterized chiefly by inattention or thoughtlessness. Examples of negligent acts in nursing include MEs that result in injury, errors in instrument counts in surgical cases, and failure to monitor a client’s condition adequately. **Malpractice** is improper or unethical conduct or unreasonable lack of skill that results in harm, and compensation may be sought. All malpractice involves negligence. Charges against health care workers are rare in Canada; however, as patients have become more knowledgeable about their rights, they are more likely to seek compensation for negligence.

Many nurses choose to carry personal malpractice insurance, also known as *professional liability protection*, although nurses working in publicly funded institutional settings are usually covered by the institution’s liability insurance policy. Nurses should obtain clear written documentation of any institutional coverage provided before deciding whether to carry individual malpractice insurance. The Canadian Nurses Protective Society (CNPS), established in 1988, is a not-for-profit society that offers legal advice, risk management services, legal assistance, and professional liability protection concerning nursing practice to eligible nurses. These services are available to nurses who are members in a provincial or territorial professional organization or college (the sole exception is Quebec). Administrative responses to MEs vary from institution to institution. One possible response is a directive to the nurse involved to obtain continuing education or refresher training. Depending on the severity of the error, disciplinary action, including suspension or termination of employment, may also occur. However, hospitals have created a more proactive, open, and nonpunitive culture in the approach to MEs. Nurses who have violated regulations of the provincial or territorial standards of nursing practice may also be counselled or disciplined by the provincial or territorial regulatory bodies, which may suspend or permanently revoke their nursing licence. Student nurses are also held responsible and accountable for the quality of their clinical work. When in doubt about the correct course of action, students should consult with clinical instructors or more experienced staff nurses. If a student nurse realizes that an error has been committed, the student should notify the responsible clinical instructor immediately. The patient may require additional monitoring or medication, and the prescriber may also need to be notified. Although such events are preferably avoided, they can ultimately be useful, though stressful, learning experiences for the student nurse.

SUMMARY

The increasing complexity of nursing practice also increases the potential for MEs. Widely recognized and common causes of errors include misunderstanding of abbreviations, illegibility of prescriber handwriting, miscommunication during verbal or telephone orders, and confusing drug nomenclature. The structure of various organizational, educational, and sociological systems involved in health care delivery may also contribute directly or indirectly to the occurrence of MEs. Understanding these influences can help the nurse take proactive steps to improve these systems. Such actions can range from fostering improved communication with other health care team members, including students, to advocating politically for safer conditions for both patients and staff. The first priority when an error does occur is to protect the patient from further harm, whenever possible. All errors should serve as red flags that warrant further reflection, detailed analysis, and future preventive actions on the part of nurses, other health care providers, and possibly even patients themselves.

CASE STUDY

Preventing Medication Errors

During your busy clinical day as a student nurse, the staff nurse assigned to your patient comes to you and says, “Would you like to give this injection? We have a ‘now’ order for octreotide acetate 200 mcg subcutaneously. I’ve already drawn it up; 200 mcg equals 2 mL. It needs to

be given as soon as possible, so I drew it up to save time.” She hands you a syringe that has 2 mL of a clear fluid in it, and the patient’s medication administration record (MAR).

1. Should you give this medication “now,” as ordered? Why or why not?

You decide to check the order that is handwritten on the MAR with the order written on the chart. The physician wrote, “Octreotide, 200 mcg now, subcut, then 100 mcg every 8 hours as needed.” Before you have a chance to find your instructor, the nurse returns and says, “Your instructor probably won’t let you give the injection unless you can show the medication ampoules. Here are the ampoules I used to draw up the octreotide. Be quick—your patient needs it now!” You take the order, the MAR, the two ampoules, and the syringe to your instructor. Together, you read the order and then check the ampoules. Each ampoule is marked “Sandostatin (octreotide acetate) 500 mcg/mL.”

2. If the nurse drew up 2 mL from those two ampoules, how much octreotide acetate is in the syringe? How does that amount compare with the order?

The nurse is astonished when you point out that the ampoules read “500 mcg/mL.” She goes into the automated medication dispenser and sees two identical boxes of Sandostatin® next to each other in the refrigerated section. One box is labelled “100 mcg/mL” and the other box is labelled “500 mcg/mL.” She then realizes she chose an ampoule of the wrong strength of drug and drew up an incorrect dose.

3. What would have happened if you had given the injection?

4. What should be done at this point? What contributed to this potential ME, and how can it be prevented in the future?

Note: High-alert drugs include adrenal drugs (corticosteroids), analgesics (e.g., acetaminophen), anti-infectives and antibiotics, antihistamines, antineoplastics, asthma drugs, bronchodilators, heart drugs, electrolytes, vitamins, minerals, insulin, opioids, and sedatives.

For answers see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

DO NOT USE

DANGEROUS ABBREVIATIONS, SYMBOLS AND DOSE DESIGNATIONS

The abbreviations, symbols, and dose designations found in this table have been reported as being frequently misinterpreted and involved in harmful medication errors. They should NEVER be used when communicating medication information.

Abbreviation	Intended Meaning	Problem	Correction
U	unit	Mistaken for "0" (zero), "4" (four), or cc.	Use "unit".
IU	international unit	Mistaken for "IV" (intravenous) or "10" (ten).	Use "unit".
Abbreviations for drug names		Misinterpreted because of similar abbreviations for multiple drugs; e.g., MS, MSO ₄ (morphine sulphate), MgSO ₄ (magnesium sulphate) may be confused for one another.	Do not abbreviate drug names.
QD QOD	Every day Every other day	QD and QOD have been mistaken for each other, or as 'qid'. The Q has also been misinterpreted as "2" (two).	Use "daily" and "every other day".
OD	Every day	Mistaken for "right eye" (OD = oculus dexter).	Use "daily".
OS, OD, OU	Left eye, right eye, both eyes	May be confused with one another.	Use "left eye", "right eye" or "both eyes".
D/C	Discharge	Interpreted as "discontinue whatever medications follow" (typically discharge medications).	Use "discharge".
cc	cubic centimetre	Mistaken for "u" (units).	Use "mL" or "millilitre".
µg	microgram	Mistaken for "mg" (milligram) resulting in one thousand-fold overdose.	Use "mcg".
Symbol	Intended Meaning	Potential Problem	Correction
@	at	Mistaken for "2" (two) or "5" (five).	Use "at".
> <	Greater than Less than	Mistaken for "7" (seven) or the letter "L". Confused with each other.	Use "greater than"/"more than" or "less than"/"lower than".
Dose Designation	Intended Meaning	Potential Problem	Correction
Trailing zero	ℵ.0 mg	Decimal point is overlooked resulting in 10-fold dose error.	Never use a zero by itself after a decimal point. Use "ℵ mg".
Lack of leading zero	. ℵ mg	Decimal point is overlooked resulting in 10-fold dose error.	Always use a zero before a decimal point. Use "0.ℵ mg".

Practices Canada
Institut pour l'utilisation sécuritaire
des médicaments du Canada

KEY POINTS

- To prevent MEs from misinterpretation of the prescriber's orders, avoid abbreviations. MEs include giving the drug to the wrong patient, confusing sound-alike and look-alike drugs, administering the wrong drug or the wrong dose, giving the drug by the wrong route, or giving the drug at the wrong time.
- Measures to help prevent MEs include being prepared and knowledgeable and taking time always to triple-check for the right patient, drug, dosage, time, and route. It is also important for nurses always to be aware of the entire medication administration process and to take a system analysis approach to MEs and their prevention.
- Encourage patients to ask questions about their medications and to question any concern about the drug or any component of the medication administration process.
- Encourage patients to always carry drug allergy information on their persons and to keep a current list of medications in their wallets or purses and on their refrigerators. This list should include the drug's name, reason the drug is being used, usual dosage range and dosage prescribed, expected adverse effects and possible toxicity of the drug, and the prescriber's name and contact information.
- Report MEs. It is important to include in this documentation the assessment of the patient status before, during, and after the ME, as well as specific orders carried out in response to the error.

EXAMINATION REVIEW QUESTIONS

1. Which measures does the nurse keep in mind to reduce the risk of MEs?
 - a. When questioning a drug order, keep in mind that the prescriber is correct.
 - b. Be careful about questioning the drug order a board-certified physician has written for a patient.
 - c. Always double-check the many drugs with sound-alike and look-alike names because of the high risk of error.
 - d. If the drug route has not been specified, use the oral route.
2. During the medication administration process, it is important that the nurse remembers which guideline?
 - a. When in doubt about a drug, ask a colleague about it before giving the drug.
 - b. Ask what the patient knows about the drug before giving it.
 - c. When giving a new drug, be sure to read about it after giving it.
 - d. If a patient expresses a concern about a drug, stop, listen, and investigate the concerns.
3. If a student nurse realizes that a drug error has been made, the instructor should remind the student of what concept?
 - a. The student bears no legal responsibility when giving medications.
 - b. The major legal responsibility lies with the health care institution at which the student is placed for nursing practice experience.
 - c. The major legal responsibility for drug errors lies with the faculty members.
 - d. Once the student has committed an ME, the responsibility is to the patient and to being honest and accountable.
4. The nurse is giving medications to a newly admitted patient who is to receive nothing by mouth (NPO status) and finds an order written as follows: "Digoxin, 250 mcg stat." Which action is appropriate?
 - a. Give the medication immediately (stat) by mouth because the patient has no intravenous (IV) access at this time.
 - b. Clarify the order with the prescribing physician before giving the drug.
 - c. Ask the charge nurse what route the physician meant to use.
 - d. Start an IV line and then give the medication IV so that it will work faster, because the patient's status is NPO at this time.
5. The nurse is reviewing medication orders. Which digoxin dose is written correctly?
 - a. Digoxin .25 mg
 - b. Digoxin .250 mg
 - c. Digoxin 0.250 mg
 - d. Digoxin 0.25 mg
6. The nurse is administering medications. Examples of high-alert medications include (Select all that apply):
 - a. Insulins
 - b. Antibiotics
 - c. Opiates
 - d. Anticoagulants
 - e. Potassium chloride for injection
7. Convert 250 micrograms to milligrams. Be sure to depict the number correctly according to the guidelines for decimals and zeroes.
8. The nurse is performing medication reconciliation during a patient's admission assessment. Which question by the nurse reflects medication reconciliation?
 - a. "Do you have any medication allergies?"
 - b. "Do you have a list of all the medications, including over-the-counter, you are currently taking?"
 - c. "Do you need to take anything to help you to sleep at night?"
 - d. "What pharmacies do you use when you fill your prescriptions?"

CRITICAL THINKING ACTIVITIES

1. The health care provider has ordered a stat IV vancomycin infusion, but when the bag comes up from the pharmacy, the nurse notices that the dose is incorrect. It takes 2 hours for the pharmacy to send up an IV bag with the correct dose. While checking the medication, the nurse checks the medication rights and notes that it has been 2 hours since it was ordered stat. What are the priority actions of the nurse, if anything, before giving this medication?
 2. Just after the nurse administers an oral antihypertensive drug, the patient asks, “Wasn’t that supposed to be a half-tablet? I just took the whole tablet!” The nurse realizes that the patient was given twice the ordered amount; the order was for 25 mg, a half-tablet, and the entire 50-mg tablet was given. At this time, what would the nurse need to say to the patient? What are the nurse’s priority actions?
 3. The nurse is reviewing the orders on a newly admitted patient and reads this order: “Humalog insulin, 4 units daily.” What problems, if any, would the nurse identify in this order?

Patient Education and Drug Therapy

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Discuss the importance of patient education in the safe and efficient administration of drugs (e.g., prescription drugs, over-the-counter drugs, natural health products).
2. Summarize the various teaching and learning principles appropriate to patient education and drug therapy across the lifespan, as applicable to any health care setting.
3. Identify the impact of the various developmental phases (as described by Erikson) on patient education as it relates to drug therapy.
4. Develop a complete patient education plan as part of a comprehensive collaborative plan of care for drug therapy for the adult patient.

KEY TERMS

Affective domain The most intangible domain of the learning process. It involves affective behaviour, which is conduct that expresses feelings, needs, beliefs, values, and opinions; the feeling domain. (p. 89)

Cognitive domain The domain involved in the learning and storage of basic knowledge. It is the thinking portion of the learning process and incorporates a person's previous experiences and perceptions; the learning or thinking domain. (p. 89)

Health literacy The degree to which individuals have the capacity to obtain and then process and understand

basic health information and services needed to make appropriate health decisions (p. 90)

Learning The acquisition of knowledge or skill that involves a change in behaviour. (p. 89)

Psychomotor domain The domain involved in the learning of a new procedure or skill; often called the *doing domain*. (p. 89)

Teaching A system of directed and deliberate actions intended to induce learning. (p. 89)

OVERVIEW

Given the constant change in today's health care climate and increased consumer awareness, the role of the nurse as an educator continues to increase and remains a significant part of patient care, both in and out of the hospital environment. Patient education is essential in any health care setting and is a critical component of quality and safe health care. Patient education is a necessary nursing practice standard that meaningfully impacts a patient's health and quality of life. Without patient education, the highest quality and safest care cannot be provided. Patient education is a process, much like the nursing process; it provides patients with a framework of knowledge that assists in the learning of healthy behaviours and assimilation of these behaviours into a lifestyle. Patient education is also crucial for assisting patients, family, significant others, and caregivers to adapt to illness, prevent illness, maintain wellness, and provide self-care. Being well informed provides patients with the opportunity to be more actively involved participants and advocates in their own health care needs. However, successful outcomes are often dictated by the willingness and capacity of

patients to self-manage their health behaviours. The challenge is to develop strategies to engage patients in their own health care (Conn, 2015).

Patient education may be one of the more satisfying aspects of nursing care because it is essential to improved health outcomes. In fact, in the current era of increasing acuteness of patient conditions and the need to decrease length of stays in hospitals, patient education and family teaching become even more essential to effectively and efficiently meet outcome criteria. Patient education has also been identified as a valued and satisfying activity for the professional nurse as the nurse develops a therapeutic relationship and the trust of the patient, caregiver, and family. Nurses may often cite the lack of time and resources to adequately teach patients; however, while there may not always be optimum time for teaching, nurses need to consider how they can most effectively and efficiently teach in the time available.

Contributing to the effectiveness of patient education is an understanding of and attention to the three domains of learning: the cognitive, affective, and psychomotor domains. It is recommended that one or a combination of these domains be

addressed in any patient educational session. The **cognitive domain** refers to the level at which basic knowledge is learned and stored. It is the thinking portion of the learning process and incorporates a person's previous experiences and perceptions. Previous experiences with health and wellness influence the learning of new materials, and prior knowledge and experience can serve as the foundation for adding new concepts. Thus, the learning process begins with identifying the experiences the person has had with the subject matter or content. However, it is important to remember that thinking involves more than the delivery of new information because a patient must build relationships between prior and new experiences to formulate new meanings. At a higher level in the thinking process, the new information is used to question something that is uncertain, recognize when to seek additional information, and make decisions during real-life situations.

The **affective domain** is the most intangible component of the learning process. Affective behaviour is conduct that expresses feelings, needs, beliefs, values, and opinions. It is well known that individuals view events from different perspectives and often choose to internalize feelings rather than express them. Nurses must be willing to approach patients in a non-judgemental manner, listen to their concerns, recognize the nonverbal messages being communicated, and assess patient needs with an open mind. Being successful in gaining the trust and confidence of patients and family members may have a powerful effect on their attitudes and thus on the learning process.

The **psychomotor domain** involves the learning of a new procedure or skill and is often called the *doing domain*. Learning is generally accomplished by demonstration of the procedure or task using a step-by-step approach, with return demonstrations by the learner to verify that the procedure or skill has been mastered. Using a teaching approach that engages these domains—whether one, two, or a combination of all three—certainly adds to the quality and effectiveness of patient education sessions and subsequent learning.

The result of effective patient education is learning. **Learning** is defined as a change in behaviour, and **teaching** as a sharing of knowledge. Although you may never be certain that patients will take medications as prescribed, you may carefully assess, plan, implement, and evaluate the teaching you provide to help maximize outcome criteria. Just like the nursing process, the medication administration process and the teaching–learning process provide systematic frameworks for professional nursing practice. The remainder of this chapter provides a brief look at patient education regarding drug therapy.

ASSESSMENT OF LEARNING NEEDS REGARDING DRUG THERAPY

The patient education process is similar to the nursing process. An important facet of the patient education process is a thorough assessment of learning needs. This assessment should be completed before patients begin any form of drug therapy. When considering patient education and drug therapy, a thorough assessment should include gathering subjective and objective data about the following:

BOX 7.1 Strategies to Enhance Patient Education and Reduce Barriers to Learning

- Work with available educational resources in nursing and pharmacy to collect or order and distribute materials about drug therapy. Make sure that written materials are available to all individuals and are prepared at a reading level that is most representative of the geographical area, such as a Grade 8 reading level. Most acute care and other health care facilities have electronic resources, so that printing educational materials is easy.
- Be sure that written and verbal instructions are available in the language most commonly spoken in the facility's patient population. Identify resources within the facility and in the community that can provide assistance with translation, such as nurses or other health care providers who are proficient in languages other than one of the official languages. Have the information available so that education is carried out in a timely and effective manner.
- Perform a cultural assessment that includes questions about level of education, learning experiences, past and present successes of therapies and medication regimens, language(s) spoken, core beliefs, value system, meaning of health and illness, perceived cause of illness, family roles, social organization, and health practices or lack thereof.
- Make sure that written materials are available on the most commonly used medications and that all materials are updated annually to ensure that information is current.
- Have available information for patients on how they can prevent medication errors. The Institute for Safe Medication Practices Canada offers informative pamphlets on the patient's role in preventing medication errors as well as web-based resources such as alerts for consumers with the proper citation.
- Work collaboratively in the health care setting, inpatient and outpatient, to develop a listing of medications that may be considered error prone, such as cardiac drugs, chemotherapeutic drugs, low-molecular-weight heparin sodium, digoxin, metered-dose inhaled drugs, and acetaminophen. Lack of time for patient education is often a concern for nurses, but efforts should be undertaken to make materials available and review these with patients and those involved in their care. Use all available resources, such as videos, verbal instructions, pictures, and other health care providers.
- Educate the health care consumer about the accuracy or quality of online information and provide suggested reliable sites.
- For the adolescent, be sure to provide clear and simple directions for each medication, including clarification of information that may well be misinterpreted. For example, adolescent girls may have the false idea that oral contraceptives prevent them from contracting sexually transmitted infections.

- Adaptation to any illnesses
- Age
- Barriers to learning (Box 7.1)
- Cognitive abilities
- Coping mechanisms
- Cultural background (see Ethnocultural Implications: Patient Education box)
- Developmental status for age group, with attention to cognitive and mental processing abilities
- Education level, including highest grade level completed and literacy level
- Emotional status
- Environment at home and at work
- Folk medicine, home remedies, or use of alternative/complementary therapies (e.g., physiotherapy, chiropractic therapy, osteopathic medicine, meditation, yoga, aromatherapy)

BOX 7.2 A Brief Look at Health Literacy

- According to ABC Life Literacy Canada (2018), 60% of adults and 88% of seniors have some difficulty understanding health-related information, which is associated with poor health outcomes (<https://www.newswire.ca/news-releases/health-literacy-still-an-issue-in-canada-694482791.html>). In regard to patient education, assessing and addressing health literacy is only one aspect, though an important aspect, of health communication and the cognitive domain of learning.
- Studies have shown that poor health literacy is associated with issues of nonadherence to treatment regimens and disease complications, as well as difficulty accessing health care, contributing to poor health as well as higher health care costs (Remshardt, 2011; Roter, Rude, & Comings, 1998).
- Poor health literacy has been associated with less education, lower socioeconomic status, decrease in sensorial abilities, and multiple disease processes, so assessment of these factors is important to individualized patient education.
- Other areas to assess about health literacy include reading level, ability to follow directions/instructions, as well as ability to manage everyday living activities such as self-care, grocery shopping, and meal preparation.
- Assessment of health literacy must be done with much sensitivity and relates not only to education but also to levels of stress or difficulty coping with a new diagnosis or process and new and complex information (i.e., patients with higher levels of education but who are stressed and unable to process information because of a disturbing diagnosis).

BOX 7.3 Erikson's Stages of Development

- Infancy (birth to 1 year of age): Trust versus mistrust. Infant learns to trust self, others, and the environment; learns to love and be loved.
- Toddlerhood (1 to 3 years of age): Autonomy versus shame and doubt. Toddler learns independence; learns to master the physical environment and maintain self-esteem.
- Preschool age (3 to 6 years of age): Initiative versus guilt. Preschooler learns basic problem solving; develops conscience and sexual identity; initiates activities as well as imitates.
- School age (6 to 12 years of age): Industry versus inferiority. School-age child learns to do things well; develops a sense of self-worth.
- Adolescence (12 to 18 years of age): Identity versus role confusion. Adolescent integrates many roles into self-identity through imitation of role models and peer pressure.
- Young adulthood (18 to 45 years of age): Intimacy versus isolation. Young adult establishes deep and lasting relationships; learns to make commitment as spouse, parent, or partner.
- Middle adulthood (45 to 65 years of age): Generativity versus stagnation. Adult learns commitment to community and world; is productive in career, family, and civic interests.
- Older adulthood (over 65 years of age): Integrity versus despair. Older adult appreciates life role and status; deals with loss and prepares for death.

- Family relationships
- Financial status
- **Health literacy** (see Box 7.2)
- Psychosocial growth and developmental level, according to Erikson's stages (see Box 7.3)
- Health beliefs, including beliefs about health, wellness, and illness
- Information the patient understands about past and present medical condition, medical therapy, and medications
- Language(s) spoken

- Level of knowledge about any medication(s) being taken
- Limitations (physical, psychological, cognitive, and motor)
- Medications currently taken (including over-the-counter [OTC] drugs, prescription drugs, and natural health products)
- Misinformation about drug therapy
- Mobility and motor skills
- Motivation
- Nutritional status
- Past and present health behaviours
- Past and present experience with drug regimens and other forms of therapy, including levels of adherence
- Race or ethnicity
- Religion or religious beliefs
- Self-care ability
- Sensory status
- Social support

ETHNOCULTURAL IMPLICATIONS

Patient Education

Every health care encounter provides an opportunity to have a positive effect on patient health. Health care providers can maximize this potential by learning more about patients' cultures so they can respond in a respectful manner and be responsive to the preferences of each patient, with the goal of an individualized approach to nursing care. Culture is dynamic and multidimensional and may include gender, religion, sexual orientation, profession, values and beliefs, age, socioeconomic status, disability, ethnicity, and race. For example, the Indigenous peoples of Canada are a unique culture that all health care providers must understand in order to improve health care outcomes. In Canada, the Indigenous population is made up of First Nations people, Métis, and Inuit. The Indigenous people have experienced brutal colonization, including government-imposed policies related to land, residential schools, "Indian" hospitals, as well as ongoing racism and discrimination. Some of this colonization also includes the expectation to forego traditional healing practices in favour of the Canadian medical system.

Indigenous people value their traditional healing practices and are varied across Canada's Indigenous groups. All elders hold an honoured position in the Indigenous culture as most are healers and knowledgeable in traditional medicine. Elders bring experience and tradition to gatherings and usually serve as valued teachers and leaders to guide members through healing and other spiritual ceremonies. The Indigenous peoples value the medicine wheel, a powerful symbol that honours the number four by representing the four directions, the four seasons, and the four aspects of health. Their belief systems about health address spiritual, mental, physical, and emotional aspects that enable members to seek balance and harmony. The focus is on balancing life, health, and community values.

During the assessment of learning needs, be astutely aware of the patient's verbal and nonverbal communication. Often a patient will not divulge true feelings to the nurse as the environment may not be conducive to a private conversation. Although it might be challenging to do so, the nurse should attempt to find a private area for the discussion. A seeming discrepancy is an indication that the patient's emotional or physical state may need to be further assessed in relation to readiness and motivation for learning. Use of open-ended questions is encouraged, because they stimulate more discussion and greater clarification from the

patient than closed-ended questions, which require only a “yes” or “no” answer. Ask questions about the following: (1) What do the patient and family know about the purpose, dose, and adverse effects of the medications? (2) Can the patient demonstrate how the treatments are done at home?, and (3) How confident are the patient and the family that the treatments can be carried out at home? Assess level of anxiety, because mild levels of anxiety have been identified as motivating, whereas moderate to severe levels may be obstacles. In addition, if there are physical needs that are not being met, such as relief from pain, vomiting, or other physical distress, these needs become obstacles to learning and must be managed appropriately before any patient teaching occurs.

NURSING DIAGNOSES REGARDING LEARNING NEEDS AND DRUG THERAPY

Some of the most commonly used nursing diagnoses regarding patient education and drug therapy are as follows:

- Inadequate knowledge
- Readiness for enhanced knowledge
- Falls, potential for
- Inadequate self-health management
- Readiness for enhanced health management
- Reduced memory
- Injury, potential for
- Nonadherence
- Readiness for enhanced communication
- Readiness for enhanced power
- Readiness for enhanced decision making
- Sleep deprivation

As an example of how nursing diagnoses regarding patient education are derived, the nursing diagnosis of *Inadequate knowledge* refers to a situation in which the patient, caregiver, or significant other has a limited knowledge base or skills regarding the medication or medication regimen. A nursing diagnosis of *Inadequate knowledge* develops out of objective or subjective data showing that there is limited understanding, no understanding, or misunderstanding of the medication and its action, indications, adverse reactions, toxic effects, drug–drug or drug–food interactions, cautions, and contraindications. This diagnosis may also reflect decreased cognitive ability or reduced motor skill needed to perform self-medication. Inadequate knowledge differs from nonadherence; nonadherence is when the patient does not take the medication as prescribed or at all—in other words, the patient does not adhere with the instructions given about the medication. Nonadherence is usually a patient’s choice. A nursing diagnosis of *nonadherence* is made when data collected from the patient show that the condition or symptoms for which the patient is taking the medication have recurred or were never resolved because the patient did not take the medication per the prescriber’s orders or did not take it at all. It is critical to assess factors to determine the cause of the nonadherence (e.g., lack of ability of the patient, family, or caregiver to administer the medication or other physical, emotional, or socioeconomic factors). These factors are associated with the nursing diagnosis of *Inadequate health maintenance* and provide a patient-centred approach to the plan of care.

PLANNING REGARDING LEARNING NEEDS AND DRUG THERAPY

The planning phase of the teaching and learning process occurs as soon as a learning need has been assessed and then identified in the patient, family, or caregiver. With mutual understanding, the nurse and patient identify goals and outcome criteria that are associated with the identified nursing diagnosis and are able to relate them to the specific medication the patient is taking. The following is an example of a measurable goal with an outcome criterion regarding a nursing diagnosis of *readiness for enhanced knowledge* for a patient who is self-administering an oral antihyperglycemic drug and has many questions about the medication therapy. *Sample goal:* The patient safely self-administers the prescribed oral antihyperglycemic drug within a given time frame. *Sample outcome criterion:* The patient remains without signs or symptoms of overmedication while taking an oral antihyperglycemic drug, such as hypoglycemia with tachycardia, palpitations, diaphoresis, hunger, and fatigue. When drug therapy goals and outcome criteria are developed, appropriate time frames for meeting outcome criteria should also be identified (see [Chapter 1](#) for more information on the nursing process). In addition, goals and outcome criteria need to be realistic; based on patient needs; stated in patient terms; and include behaviours that are measurable, such as list, identify, demonstrate, self-administer, state, describe, and discuss.

IMPLEMENTATION REGARDING DRUG THERAPY

After the nurse has completed the assessment phase, identified nursing diagnoses, and created a plan of care, the implementation phase of the teaching–learning process begins. Nurses have a responsibility to address patients’ needs but have an equal responsibility to teach. Providing “care” means ensuring that patients are fully educated about their conditions and their proposed treatments so that they are able to make informed decisions about them. This phase includes conveying specific information about the medication to the patient, family, or caregiver. Teaching–learning sessions must incorporate clear, simple, concise written instructions ([Box 7.4](#)); oral instructions; and written pamphlets, pictures, videos, or any other learning aids that will help ensure patient learning. The nurse may have to conduct several brief teaching–learning sessions with multiple strategies, depending on the needs of the patient. Several changes regarding the growth and aging of patients (although they may also apply to other age groups experiencing chronic diseases) may affect teaching–learning. Age-associated changes are most pronounced in people of advanced age—85 years or older. [Table 7.1](#) lists educational strategies for accommodating these changes in a plan of care. The nurse may also need to identify aids to help the patient in the safe administration of medications at home, such as the use of medication day and time calendars, pill reminder stickers, daily medication containers with alarms, weekly pill containers with separate compartments for different dosing times for each day of the week, or a method of documenting doses taken to avoid overdose or omission of

BOX 7.4 General Teaching and Learning Principles

- Make learning patient-centred and individualized to each patient's needs, including the patient's learning needs. This includes assessment of the patient's ethnocultural beliefs, educational level, previous experience with medications, level of growth and development (to best select a teaching–learning strategy), age, gender, family support system, resources, preferred learning style, and level of sophistication with health care and health care treatment.
- Assess the patient's motivation and readiness to learn.
- Assess the patient's ability to use and interpret label information on medication containers.
- It is estimated that 42% of Canadian adults between the ages of 16 and 65 have low literacy skills. Fifteen percent have serious problems reading printed materials and 27% have only simple reading skills. Less than 20% of individuals with the lowest literacy skills are employed ([Canadian Literacy and Learning Network, 2015](#)). Sixty percent of immigrants have low literacy, compared with 37% of native-born Canadians ([Life Literacy Canada, 2015](#)). It is estimated that between 55 and 60% of adults and 88% of seniors over the age of 65 in Canada are not health literate ([Public Health Agency of Canada, 2014](#)). Indigenous people are also at risk for poor health literacy, many of whom have less than a Grade 9 education ([Canadian Nurses Association, 2015](#)). It is therefore important to ensure that educational strategies and materials are at a level the patient is able to understand, while taking care not to embarrass the patient.
- Patients who are illiterate still need to be instructed on safe medication administration; use pictures, demonstrations, and return demonstrations to emphasize instructions.
- Consider, assess, and appreciate language and ethnicity during patient teaching. Make every effort to educate non-English-speaking patients in their native languages. Ideally, the patient should be instructed by a health provider familiar with the patient's clinical situation who also speaks the patient's native language. At the least, provide the patient with detailed written instructions in the patient's native language.
- Assess the family support system for adequate patient teaching. Family living arrangements, financial status, resources, communication patterns, the roles of family members, and the power and authority of different family members should always be considered.
- Make the teaching–learning session simple, easy, fun, thorough, effective, and not monotonous. Make it applicable to daily life, and schedule it at a time when the patient is ready to learn. Avoid providing extraneous information that may be confusing or overwhelming to the patient.
- Remember that learning occurs best with repetition and periods of demonstration and with the use of audiovisuals and other educational aids.
- Patient teaching must focus on the various processes in the cognitive, affective, or psychomotor domains (see earlier discussion).
- Consult online resources for help in obtaining the most up-to-date and accurate patient teaching materials and information.
- Technology advances have increased the variety of methods available for teaching. For example, recorded information by telephone, telephone help-lines, videos, podcasts, websites, text messaging, webinars, and social networking are some of the options for creative approaches to teaching. In addition, there are various language translator applications, such as Google Translate. Smartphone and tablet applications are also essential tools to aid in patient education.

doses. Many pharmacies now package a week's supply of pills, with a blister pack for each time of day. Medical technology companies are developing smart technology systems to assist patients to take and keep track of medications—for example, an ingestible sensor that when swallowed is activated by stomach

fluids, initiating a heartbeatlike signal picked up by a patch worn on the chest. The patch records data from the sensor, such as that the patient has ingested the medication, and additional information, such as heart rate. There are also patient-tracking apps that remind patients to take their medications. Certainly, there is a need for a large portfolio of technologies, from simple to complex, in order to meet the needs of all patients.

Special issues arise when the patient has limited ability to speak (or does not speak) one of the official languages of Canada—English and French. If at all possible, the nurse should communicate with the patient in the patient's native language. If the nurse is not able to communicate in the patient's native language, including in sign language, a translator needs to be made available to prevent communication problems, minimize errors, and help boost the patient's level of trust and understanding. In practice, this translator may be another nurse or health care provider; a nonprofessional member of the health care team; or a layperson, family member, adult friend, or religious leader or associate. However, it is best to avoid using family members as translators if possible because of issues with bias and misinterpretation, as well as potential confidentiality issues. It is important to remember that some of these individuals may not be competent in or comfortable with communicating technical clinical information, and other resources must be used if this is the case. Canada has experienced a rapid growth in minority populations, and our health care system has seen a staggering increase in the percentage of non-English/French-speaking patients. Demographic changes will be significant, with the numbers of visible minority groups doubling by 2031. This growth in cultural diversity will continue to demand that nursing and related health care providers offer patient education materials in English, French, and Southeast Asian and East Asian languages (as well as other prominent languages). Publications provided for non-English/French-speaking patients may enable the nurse to convey a sufficient amount of information in the patient's language to help effectively educate the patient and also allow the nurse to share materials with family members and caregivers for their use. Companies now also publish a variety of patient education materials for the discharge process in both English and French and other languages.

Non-English/French-speaking patients tend to notice and appreciate their health care providers' efforts to speak their language and will often help teach them new words or phrases, if the nurse shows enthusiasm and interest. This experience may lead to significantly greater rapport, put patients at ease, and show respect for their culture or race/ethnicity. Obtaining and keeping available a foreign language dictionary for languages that are widely spoken in that geographical area may be helpful. Keeping notes about newly learned words, phrases, or sentences may be helpful, too. Even if the professional does not use the correct verb tenses, communication with the patient may often be sufficient to meet the immediate need. As one begins to learn a foreign language, a major challenge may be to speak with a patient over the telephone. The important goal is to try to increase one's *listening* speed to match the *speaking* speed of the patient. With effort, this can be accomplished. If one can grasp even a few words of what the patient is saying, one may be able, with continued conversation with the patient, to determine and

TABLE 7.1 Strategies to Educate Older Adults With Age-Related Changes

Changes Related to Aging	Educational Strategy
Reduced Memory	
Slowed cognitive functioning	Slow the pace of the presentation and attend to the patient's verbal and nonverbal cues to verify understanding.
Decreased short-term memory	Provide smaller amounts of information at one time. Repeat information frequently. Provide written instructions for home use.
Decreased ability to think abstractly	Use examples to illustrate information. Use a variety of methods, such as audiovisuals, props, videos, large-print materials, materials with vivid colours, return demonstrations, and practice sessions.
Decreased ability to concentrate. Increased reaction time (slower to respond)	Decrease external stimuli as much as possible. Always allow sufficient time and be patient. Allow more time for feedback.
Altered Sensory Perception	
Hearing	
Diminished hearing	Perform a baseline hearing assessment. Use tone- and volume-controlled teaching aids; use bright, large-print material to reinforce learning.
Decreased ability to distinguish sounds (e.g., words beginning with S, Z, T, D, F, and G)	Face the patient. Speak distinctly and slowly, and articulate carefully.
Decreased conduction of sound	If the learner has decreased hearing in one ear, sit on the side of the learner's "best" ear, but always make sure the patient can see your face as you speak.
Loss of ability to hear high-frequency sounds	Do not shout; speak in a normal voice but lower voice pitch.
Partial to complete loss of hearing	Face the patient so that lip reading is possible. Use visual aids to reinforce verbal instruction. Reinforce teaching with easy-to-read materials. Provide teaching in a room with no distractions and extraneous noise. If the patient uses sign language to communicate, find a sign language interpreter. If the patient uses a hearing aid(s), make sure the aid is/are in place and that batteries are functioning. Use community resources for the hearing impaired.
Vision	
Decreased visual acuity	Ensure that the patient's glasses are clean and in place and that the prescription is current.
Decreased ability to read fine detail	Use large-print, clear, brightly coloured material.
Decreased ability to discriminate among blue, violet, and green: tendency for all colours to fade, with red fading the least	Use high-contrast materials, such as black on white. Avoid the use of blue, violet, and green in type or graphics; use red instead.
Thickening and yellowing of the lenses of the eyes, with decreased accommodation	Use nonglare lighting and avoid contrasts of light (e.g., darkened room with single light). Use additional lighting and avoid harsh lights, direct sunlight, and glossy paper.
Decreased depth perception	Adjust teaching to allow for the use of touch to gauge depth.
Decreased peripheral vision	Keep all teaching materials within the patient's visual field.
Touch and Vibration	
Decreased sense of touch	Allow more time for the teaching of psychomotor skills, the number of repetitions, and the number of return demonstrations.
Decreased sense of vibration	Teach patient to palpate more prominent pulse sites (e.g., carotid and radial arteries).

Modified from Mullen, E. (2013). Health literacy challenges in the adult population. *Nursing Forum*, 48(4), 248–255; Speros, C. I. (2009). More than words: Promoting health literacy in older adults. *The Online Journal of Issues in Nursing*, 14(3). <https://doi.org/10.3912/OJIN.Vol14No03Man05>

respond to the patient's needs. However, be aware that patients who are native English or French speakers may also have challenges learning about their medications and treatment regimens for other reasons—for example, learning deficits or difficulties, hearing and speech disorders, lack of education, or minimal previous exposure to treatment regimens and medication use.

The teaching of manual skills for specific medication administration is also part of the teaching–learning session. Sufficient time must be allowed for the patient to become familiar with any equipment and to perform several return demonstrations to the

nurse or another healthcare provider. Teaching and learning needs will vary from patient to patient. Make every effort to include family members, significant others, or caregivers in the teaching sessions for reinforcement purposes. Audiovisual aids may be incorporated and should be based on findings from the learning needs and nursing assessment. One online resource for information about medications is the Pharmasave medication library (<http://www.pharmasave.com/default/0/medications.aspx>), which provides information for the public. Another good resource is the *Compendium of Pharmaceuticals and Specialties*

(CPS): *The Canadian Drug Reference for Health Professionals*, which has an Information for the Patient component, written in lay language, that is easier for patients to understand yet provides helpful advice and how-to information for patients on many drugs. This section is available only in the e-CPS. This type of resource may be helpful to the patient when seeking information about a medication (e.g., purpose, adverse effects, method of administration, drug interactions) and helpful to the nurse in developing a patient teaching plan. Create a safe, non-threatening, nondistracting environment for learning needs, and be open and receptive to the patient's questions. The following strategies may help ensure an effective teaching-learning session:

- Begin the teaching-learning process upon the patient's admission to the health care setting (see the Legal & Ethical Principles box).
- Individualize the teaching session to the patient.
- Provide positive rewards or reinforcement for accurate return demonstration of a procedure, technique, or skill during the teaching session (e.g., a sticker or badge for a child).
- Complete a medication calendar that includes the names of the drugs to be taken, along with the dosage and frequency. Allow the patient to see what the medications look like, for future reference.
- Use audiovisual aids.
- Involve family members or significant others in the teaching session, as deemed appropriate.
- Keep the teaching on a level that is most meaningful to the given patient; general research on reading skills has shown that written materials must be written at a Grade 8 reading level.

Box 7.4 lists some general teaching and learning principles to consider in providing patient education.

Upon completion of any teaching-learning process or patient education session, complete the documentation and include notes about the content provided, strategies used, and patient response to the teaching session and an overall evaluation of learning. Because of the significance of patient education regarding drug therapy and the nursing process, this textbook integrates patient education into each chapter in the implementation phase of the nursing process. In addition, a Patient Teaching Tips section is included at the end of most chapters.

EVALUATION OF PATIENT LEARNING REGARDING DRUG THERAPY

Evaluation of patient learning is a critical component of safe and effective drug administration. To verify the success—or lack of success—of patient education, ask specific questions about patient outcomes and request that the patient repeat information or give a return demonstration of skills. The patient's behaviour, such as adherence to the schedule for medication administration with few or no complications, is one key to determining whether or not teaching was successful and learning occurred. If a patient's behaviour is characteristic of nonadherence or an inadequate level of learning, develop, implement, and evaluate a new plan of teaching.

LEGAL & ETHICAL PRINCIPLES

Discharge Teaching

The safest practices for discharge teaching include the following:

- Always follow the health care facility's policy on discharge teaching, focusing on how much information to impart to the patient.
- Do not assume that any patient has received adequate teaching before interacting with you.
- Always begin discharge teaching as soon as possible, when the patient is ready.
- Minimize any distractions during the teaching session.
- Evaluate any teaching of the patient and significant others by having the individuals repeat the instructions you have given them.
- Contact the institution's social service department or the discharge planner if there are any concerns regarding the learning capacity of the patient.
- Document what you taught, who was present with the patient during the teaching, what specific written instructions you gave, what the responses of the patient and significant other or caregiver were, and what your nursing actions were, such as specific demonstrations or referrals to community resources.
- Document teaching and learning strategies, such as videotapes and pamphlets.
- Case managers need to make sure patients have a follow-up phone call and the name and number of someone to contact if they have questions, can't get their medication, or have symptoms.

CASE STUDY

Patient Education and Anticoagulant Therapy

Martin, an 82-year-old retired civil servant, has developed atrial fibrillation. As part of his medical therapy, he is started on the oral anticoagulant warfarin sodium (Coumadin®). His wife reports that he has some trouble hearing yet refuses to consider getting hearing aids. In addition, this is his first illness, and his wife states that he has "always hated taking medications. He's read about herbs and folk healing and would rather try natural therapy." The nurse is planning education about oral anticoagulant therapy, and Martin says that he'll "give it a try" for now, but he "knows nothing about this drug."

1. What will the nurse assess, including possible barriers to learning, before teaching?
2. Formulate an education-related nursing diagnosis for this patient based on the information given above. In addition, provide a goal and one example of an outcome criterion for the nursing diagnosis.
3. What education strategies will the nurse plan to use, considering any age-related changes the patient may have?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

SUMMARY

Patient education is a critical part of patient care, and patient education about medication administration, therapies, or regimens is no exception. From the time of initial contact with the patient and throughout the time the nurse works with the patient, he or she is entitled to all information about medications prescribed as well as other aspects of patient care.

Evaluation of patient learning and adherence with the medication regimen remain a continuous process—be willing to listen to patients about any aspects of their drug therapy. Professional nurses are teachers and serve as patient advocates and thus have a responsibility to facilitate learning for patients, families, significant others, and caregivers. Accurate assessment of learning needs and readiness to learn always requires a look at the whole patient, including cultural values, health practices, and level of literacy. Every effort needs to be made to see that the patient learns effectively to ensure successful outcomes in regard to drug therapy—and all parts of the patient's health care.

It is important to consult resources mentioned earlier, as well as the Institute for Safe Medication Practices Canada (ISMP)

(at <http://www.ismp-canada.org/>). ISMP Canada provides nurses with a wealth of information about patient education, safety, and prevention of medication errors. As a nonprofit organization, this institute works closely with nurses, prescribers, regulatory agencies, and professional organizations to provide education about medication errors and their prevention, and is a premier resource in all matters pertaining to safe medication practices in health care organizations.

Other resources available are medication checks. For example, in Ontario, any Ontario resident with a chronic condition and taking three or more prescription medications, or anyone living with type 1 or type 2 diabetes, may qualify for a MedsCheck service. Such a service provides a 20- to 30-minute, one-to-one meeting with a community pharmacist to ensure that medications are being taken safely and appropriately. A similar program is available in New Brunswick, called PharmaCheck.

PATIENT TEACHING TIPS

- Teaching needs to focus on the cognitive, affective, or psychomotor domain or a combination of all three. The cognitive domain may involve recall for synthesis of facts, with the affective domain involving behaviours such as responding, valuing, and organizing. The psychomotor domain includes teaching someone how to perform a procedure.
- Realistic patient teaching goals and outcome criteria must be established with the involvement of the patient, caregiver, or significant other.
- Keep patient teaching on a level that is most meaningful to the individual. Most research indicates that reading materials need to be written at a Grade 8 reading level but adjusted according to patient assessment.
- Follow teaching and learning principles when developing and implementing patient education.
- Be sure to control the environmental factors, such as lighting, noise, privacy, and odours. Provide dignified care while preparing the patient for teaching, and respect personal space. If there are distractions, such as television, radio, cellphone, or computer, work with the patient and family members to safely and appropriately reduce these distractions during teaching sessions.
- Make sure that all patient education materials are organized and at hand. If the patient wears glasses or hearing aids, be sure they are made available prior to providing education.

KEY POINTS

- The effectiveness of patient education relies on an understanding of and attention to the cognitive, affective, and psychomotor domains of learning. Once the assessment phase, identified nursing diagnoses, and plan of care are completed, the implementation phase of the teaching–learning process begins; re-evaluation of the teaching plan must occur frequently and as needed. The growth in cultural diversity in Canada, in particular the increase in the Asian and Southeast Asian population, demands that nursing and other health care providers make patient education materials available not only in English and French but also in other languages.
- Patients need to receive information through as many senses as possible, such as aurally and visually (e.g., pamphlets, videos, diagrams), to maximize learning. Information should also be at the patient's reading level and in the language the patient speaks most fluently. For example, a person may be from Thailand but speaks French and not English. Teaching, therefore, would be appropriate in French, not Thai. Information should also be suitable for the patient's level of cognitive development (see Erikson's stages in [Box 7.3](#)).
- Teaching and learning principles also must be integrated into patient education plans. Evaluation of patient learning is a critical component of safe and effective drug administration.
- To verify the success—or lack of success—of patient education, nurses need to be clear and specific in their questions about patient outcomes and request that the patient repeat information or perform a return demonstration of skills, if appropriate.

EXAMINATION REVIEW QUESTIONS

1. Lucas, a 47-year-old patient with diabetes, is being discharged home on insulin injections twice a day. Which concepts should the nurse keep in mind when considering patient teaching?
 - a. Teaching needs to begin at the time of diagnosis or admission and is individualized to the patient's reading level.
 - b. The nurse can assume that because Lucas is in his forties he will be able to read any written or printed documents provided.
 - c. The majority of teaching can be done with pamphlets that Lucas can share with family members.
 - d. A thorough and comprehensive teaching plan designed for a Grade 11 reading level needs to be developed.
2. The nurse is developing a discharge plan regarding a patient's medication. Which statement about the discharge plan is true? The teaching will:
 - a. Be done right before the patient leaves the hospital.
 - b. Be developed only after the patient is comfortable or after pain medications are administered.
 - c. Include videos, demonstrations, and instructions written at least at a Grade 5 level.
 - d. Be individualized and based on the patient's level of cognitive development.
3. The nurse is responsible for preoperative teaching for a patient who is mildly anxious about receiving narcotics postoperatively. The nurse acknowledges that this level of anxiety may:
 - a. Impede learning because anxiety is always a barrier to learning.
 - b. Lead to major emotional unsteadiness.
 - c. Result in learning by increasing the patient's motivation to learn.
 - d. Reorganize the patient's thoughts and lead to inadequate potential for learning.
4. What action by the nurse is the best way to assess a patient's learning needs?
 - a. Quiz the patient daily on all medications.
 - b. Begin with validation of the patient's present level of knowledge.
 - c. Assess family members' knowledge of the medication even if they are not involved in the patient's care.
 - d. Ask the caregivers what the patient knows about the medications.
5. Which technique would be most appropriate for teaching a patient who does not understand English?
 - a. Obtain an interpreter who can speak in the patient's native tongue for teaching sessions.
 - b. Use detailed and lengthy explanations, speaking slowly and clearly.
 - c. Assume that the patient understands the information presented if the patient has no questions.
 - d. Provide only written instructions.
6. A nursing student is identifying situations that involve the psychomotor domain of learning as part of a class project. Which are examples of learning activities that involve the psychomotor domain? (Select all that apply.)
 - a. Teaching a patient how to self-administer eye drops
 - b. Having a patient list the adverse effects of an antihypertensive drug
 - c. Discussing what foods to avoid while taking antilipemic drugs
 - d. Teaching a patient how to measure the pulse before taking a beta blocker
 - e. Teaching a family member how to give an injection
 - f. Teaching a patient the rationale for checking a drug's blood level
7. The nurse is instructing an older adult patient on how to use his walker. Which education strategies are appropriate? (Select all that apply.)
 - a. Speak slowly and loudly.
 - b. Ensure a quiet environment for learning.
 - c. Repeat information frequently.
 - d. Allow for an increased number of return demonstrations.
 - e. Provide all the information in one teaching session.
8. You are reviewing newly prescribed medications with the wife of a patient who will be discharged today on a liquid diet after jaw surgery. She will be giving the patient his medications. There is a prescription for liquid metoclopramide (Reglan), 10 mg PO before breakfast, lunch, and dinner. The medication is available in a strength of 5 mg/mL. How many mL will she need to give for each dose?

CRITICAL THINKING ACTIVITIES

1. Ed, a 65-year-old patient with diabetes mellitus type 2, is to begin treatment with insulin injections. Using the guidelines and principles for patient education discussed in this chapter of your textbook, develop a 10-minute teaching plan for Ed on the basics of subcutaneous self-administration of insulin.
2. A nurse has been trying to communicate with a patient, Narinder, who does not speak English, but so far none of the

communication techniques has been successful. What are the best strategies the nurse can use to develop a plan of care that addresses Narinder's need for medication information on the cardiac drug digoxin and also focuses on the potential for toxicity? (Note: You may need to look up the drug in the textbook if you are not familiar with it.)

3. A patient has had hip replacement surgery and will be going home in a few days. The surgeon has requested that the

nurses teach the patient and a family member how to give subcutaneous injections of the low-molecular-weight heparin that will be prescribed for him after his discharge. What is the priority regarding this patient's education? Explain your answer.

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Over-the-Counter Drugs and Natural Health Products

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Discuss the differences between prescription drugs, over-the-counter (OTC) drugs, and natural health products.
2. Briefly discuss the differences between the federal legislation governing the promotion and sale of prescription drugs and the legislation governing OTC drugs and natural health products.
3. Describe the advantages and disadvantages of the use of OTC drugs and natural health products.
4. Discuss the role of nonprescription drugs, specifically natural health products and dietary supplements, in the integrative (often called *alternative* or *complementary*) approach to nursing and health care.
5. Discuss the potential dangers associated with the use of OTC drugs and natural health products.
6. Develop a collaborative plan of care for the patient who uses OTC drugs or natural health products.

KEY TERMS

Alternative medicine Herbal medicine, natural health approaches, chiropractic, acupuncture, massage, reflexology, and any other therapies that are not part of conventional medicine yet are popular with many patients. (p. 102)

Cannabis Regulations Guidelines regarding access to marijuana for medical purposes that define the circumstances and the manner in which marijuana can be purchased or produced. (p. 104)

Complementary medicine Alternative medicine used simultaneously with conventional medicine. (p. 102)

Conventional medicine The practice of medicine by medical doctors and allied health providers to treat symptoms and diseases. Also referred to as *allopathic medicine* and *Western medicine*. (p. 102)

Dietary supplement A product that contains an ingredient intended to supplement the diet, including vitamins, minerals, herbs or other botanicals, amino acids, and substances such as enzymes, organ tissues, glandular preparations, metabolites, extracts, and concentrates. (p. 102)

Herbal medicine The practice of using herbs to heal. (p. 102)

Herbs Plant components including bark, roots, leaves, seeds, flowers, fruit of trees, and extracts of these plants and

materials that are valued for their savoury, aromatic, or medicinal qualities. (p. 102)

Homeopathy A popular form of alternative medicine that uses microdoses of active ingredients, usually plants or minerals, for the treatment of disease. (p. 102)

Iatrogenic effects Unintentional adverse effects caused by the actions of a prescriber or other health care provider or by a specific treatment. (p. 102)

Integrative medicine Simultaneous use of both conventional and alternative medicine. (p. 102)

Natural health products (NHPs) Umbrella term for products that includes vitamins and minerals, herbal remedies, homeopathic medicines, traditional medicines such as traditional Chinese medicines, probiotics, and other products such as amino acids and essential fatty acids. (p. 101)

Over-the-counter (OTC) drugs Medications that are legally available without a prescription. (p. 98)

Phytochemicals The pharmacological active ingredients in herbal remedies. (p. 104)

Phytomedicine The application of scientific research to the practice of herbal medicine. (p. 102)

OVER-THE-COUNTER DRUGS

Health care consumers are increasingly involved in the diagnosis and treatment of common ailments. This has led to a great increase in the use of nonprescription or **over-the-counter (OTC) drugs**. There are approximately 40 000 OTC medications currently available on the Canadian market (Ramsay,

2009). Over 80 therapeutic classes of OTC drugs exist, marketed to treat a variety of illnesses, including pain relievers, cold and allergy medications, laxatives, and weight control medications. Over the course of a year, 83% of adult Canadians take OTC medications, 59% take multivitamins or minerals, and 27% take herbal remedies (Ramsay, 2009). Clearly, OTC medications comprise a large percentage of all medications used in Canada.

In 2014, Health Canada launched Regulations Amending the Food and Drug Regulations (Labelling, Packaging and Brand Names of Drugs for Human Use), a “plain language labelling initiative,” requiring a new, stricter “drug facts” table for OTC products, in an easy-to-read format. The regulations include information on the following: purpose and uses of the product, storage information, dosage instructions, inactive ingredients, specific warnings and adverse effects that could occur, when the product should not be used under any circumstances, and when it is appropriate to consult a doctor or pharmacist. This labelling also requires information to facilitate adverse event reporting and quality reporting, as well as evidence that drug names would not be confused with other products. In addition, manufacturers would be required to submit a mock-up drug label and packaging to regulators for review. In June 2015, all

Drug ingredients can also be switched from prescription to nonprescription status. This used to involve a lengthy application process, taking 14 to 20 months from proposing a regulatory amendment to removing the ingredient from Schedule F. Schedule F of Health Canada's Food and Drug Regulations has been eliminated and replaced with the Prescription Drug List (see [Chapter 3](#)). Now, switches from prescription to nonprescription status are initiated by a request from a company in the form of a drug submission. After reviewing these data, Health Canada may determine that the ingredient should be available by prescription only, or that nonprescription sale is appropriate. Once the federal decision has been made, the provinces and territories may further restrict the conditions of sale of these products. The intent of the new process is to make nonprescription drugs available faster. The application must contain information and data about the safety, quality, and efficacy of the drug. The drug usually has been marketed in Canada and other countries long enough to demonstrate that it can be used safely by consumers on their own. Generally, to be switched from prescription to nonprescription status, a drug must meet the three criteria listed in [Box 8.1](#). This information is obtained from clinical-trial results and postmarketing safety surveillance data, which are submitted to Health Canada by the manufacturer.

Reclassifying a prescription drug to an OTC drug may increase out-of-pocket costs for many patients because third-party health insurance plans usually do not cover OTC products.

BOX 8.1 Criteria for Over-the-Counter Status

I. Indications for Use

Consumer must be able to easily:

- Diagnose condition
 - Monitor effectiveness
- Benefits of correct usage must outweigh risks.

II. Safety Profile

Drugs must have:

- Favourable adverse event profile
- Limited interaction with other drugs
- Low potential for misuse
- High therapeutic index*

III. Practicality for Over-the-Counter Use

Drugs must be:

- Easy to use
- Easy to monitor

* Ratio of toxic to therapeutic dosage.

BOX 8.2 Reclassified OTC Products

Analgesics

acetaminophen,
acetylsalicylic acid,
ibuprofen (Advil®, Motrin®)
naproxen sodium (Aleve®, Anaprox®, Naprelan®, Naproxen®)

Histamine Blockers

H1 Receptors

cetirizine (Aller-Relief®, Reactine®)
chlorpheniramine maleate (Chlor-Tripolon®)
diphenhydramine hydrochloride (Benadryl®)
loratadine (Claritin®)

Protein Pump Inhibitors

omeprazole (Prilosec®)
esomeprazole (Nexium®)

Intranasal steroids

fluticasone Propionate (Flonase®)
triamcinolone acetonide (Nasacort®)

H2 Receptors

famotidine (Pepcid®)
ranitidine (Zantac®)

Smoking Deterrents

nicotine gum (Nicorette®)
nicotine transdermal patch (Nicoderm®, Habitrol®)

Topical Medications

clotrimazole (Canesten®)
miconazole nitrate (Micazole®, Monistat®)
minoxidil (Minox®, Rogaine®)

The importance of patient education cannot be overemphasized. Many patients are inexperienced in interpreting medication labels, which results in misuse of the products. This lack of experience and possibly lack of information or knowledge may lead to adverse events or drug interactions with prescription medications, other OTC medications, or NHPs. Small print on OTC package labels often complicates the situation, especially for older patients. In one study, parents gave children incorrect doses of OTC antipyretics over 50% of the time, and another 15% administered subtherapeutic doses of acetaminophen or ibuprofen (Sullivan & Farrar, 2011). Use of OTC medications can be hazardous for patients with various chronic illnesses, including diabetes, liver, kidney disease (including acute kidney injury and chronic kidney disease), enlarged prostate, hypertension, cardiovascular disease, and glaucoma. Patients are encouraged to read labels carefully and consult a qualified health care provider when in doubt.

Another common problem associated with OTC drugs is that their use may postpone effective management of serious or life-threatening disorders. The OTC medication may relieve symptoms without necessarily addressing the cause of the disorder. This situation is often complicated when patients are afraid to visit a health care provider, are uninsured or underinsured, have inadequate health literacy (see Chapter 7), lack access to a family physician or clinic, or perhaps wish to avoid visiting a health care provider and hope for a “quick fix” for themselves or their children.

OTC medications also have their own toxicity profiles. For example, cough and cold products usually include one or more of the following ingredients: nasal decongestants (for stuffy nose), expectorants (for loosening chest mucus), antihistamines (for sneezing and runny nose), and antitussives (for cough). In 2008, Health Canada issued recommendations that OTC cough and cold medicines (CCMs) not be used in children younger than 6 years of age. This action followed numerous case reports of symptoms such as oversedation, seizures, tachycardia, and even death in toddlers medicated with such products. There is also evidence that such medications are simply not efficacious in young children. Numerous studies have shown a dramatic decrease in visits of young children to emergency departments since the recommendation (Hampton, Nguyen, Edwards, et al., 2013; Shehab, Schaefer, Kegler, et al., 2010). Health Canada continues to evaluate the safety and efficacy of cough and cold products for children but has issued no guidelines to date. Parents are advised to be mindful of how much medication they give to their children and to be careful not to give two products that contain the same active ingredient(s).

Two other examples of OTC drug dangers include products containing acetaminophen (e.g., Tylenol) and nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen (e.g., Advil®, Motrin®), naproxen (e.g., Aleve®). Hepatic toxicity is associated with excessive doses of acetaminophen and is a leading cause of liver failure. Acetaminophen doses are not to exceed a total of 4 grams (4 000 mg) per day for patients with normal liver function (this dosage was reviewed and recommended by Health Canada in 2016; see Chapter 11 for more detail). The use of NSAIDs is associated with gastrointestinal ulceration, myocardial infarction, and stroke. Patients may sometimes choose excessive dosages of these and other OTC medications out of lack of knowledge or simply in hopes of easing their symptoms. Health Canada finalized regulations requiring specific labelling

However, overall health care costs tend to decrease when products are reclassified as OTC, due to a direct reduction in drug costs, elimination of physician office visits, and avoidance of pharmacy dispensing fees. Some examples of drugs that have been reclassified as OTC products appear in Box 8.2.

for acetaminophen (in 2009) and aspirin (in 2013) to enhance consumer awareness of these risks. The most current guidance document for NSAIDs is from 2006. In addition, Johnson and Johnson, the manufacturers of Tylenol in Canada, developed a website with specific information for consumers on dosages, adverse effects, drug interactions and related information (<http://www.tylenol.ca/adult-pain-relief>).

Misuse can also be a potential hazard with the use of OTC drug products. Pseudoephedrine is found in a variety of cough and cold products (see [Chapter 37](#)); however, this drug is also used to manufacture the widely misused street drug, methamphetamine. Because of the potential for misuse, products containing pseudoephedrine must be sold from behind the pharmacy counter. Many patients become addicted to OTC nasal sprays because they can cause rebound congestion and dependency. Dextromethorphan (used as a cough suppressant) is also commonly misused. It is known by the brand name Robitussin, and misusing it is called *Robotripping*.

Several other OTC products can cause specific problems. The use of sympathomimetics (e.g., epinephrine, pseudoephedrine; see [Chapter 19](#)) can cause adverse effects in patients with type 1 diabetes (elevated plasma glucose levels), hypertension, or angina (e.g., dysrhythmias). Aspirin is not to be used in children as it can cause a rare condition called Reye's syndrome (see [Chapter 27](#)). Long-term use of antacids can result in constipation or impaction (see [Chapter 39](#)).

Normally, OTC medications should be used for only short-term treatment of common minor illnesses. An appropriate medical evaluation is recommended for all chronic health conditions, even if the final decision is to prescribe OTC medications. Patient assessment includes questions on OTC drug use, including on what conditions are being treated. Such questions may help uncover more serious ongoing medical problems. Inform patients that OTC drugs, including NHPs, are still

medications. Their use may have associated risks, depending on the specific OTC drugs or NHPs used, concurrent prescription medications, and the patient's overall health status and disease state.

Health care providers have an excellent opportunity to prevent common problems associated with the use of OTC drugs. Up to 60% of patients consult a health care provider when selecting an OTC product. Provide patients with information about choice of an appropriate product, correct dosing, common adverse effects, and drug interactions with other medications. For specific information on OTC drugs, see the appropriate drug chapters later in this text (see [Table 8.1](#) for a cross-reference to these chapters).

NATURAL HEALTH PRODUCTS

History

In Canada, natural health products are subject to the *Food and Drugs Act* and Food and Drug Regulations. Internationally, the regulation of natural health products varies. There are many differences in how countries approach the regulation of health products. In Canada, as in European Union countries, natural health products are considered drugs, whereas in the United States, many natural health products are classified as "dietary supplements." Under the Natural Health Products Regulations, **natural health products (NHPs)** is the umbrella term that includes vitamin and mineral supplements; herbal remedies; homeopathic preparations; traditional Chinese, Ayurvedic, and other traditional medicines; probiotics; and other products such as amino acids and essential fatty acids ([Health Canada, 2018b](#)).

The language surrounding NHPs can be confusing. For example, in the United States, dietary supplements are considered to be food products. In Canada, they were considered NHPs and were regulated as such. However, in 2013, Health

TABLE 8.1 Common OTC Drugs Discussed in This Book

Type of OTC Drug	Example	Where Discussed in This Book
Acid-controlling drugs (H ₂ blockers, proton pump inhibitors) and antacids	famotidine (Pepsid AC®), omeprazole (heart burn control®), ranitidine hydrochloride (Zantac®); aluminum- and magnesium-containing products (Maalox®, Mylanta®), calcium-containing products (Tums®)	Chapter 39 : Acid-Controlling Drugs
Antifungal drugs (topical)	clotrimazole (Canesten®), miconazole nitrate (Micozole®, Monistat®)	Chapter 56 : Dermatological Drugs
Antihistamines and decongestants	brompheniramine maleate (Dimetane®, Dimetapp®) cetirizine hydrochloride (Reactine®) chlorpheniramine maleate (Advil Cold and Sinus®, Chlor-Tripolon®, Triaminic®) diphenhydramine hydrochloride (Benadryl, Nadril®) fexofenadine hydrochloride (Allerga®) guaifenesin (Balminil®) loratadine (Claritin®) desloratidine (Aerius®, Allernix), pseudoephedrine hydrochloride (Actifed®)	Chapter 37 : Antihistamines, Decongestants, Antitussives, and Expectorants
Eye drops	Artificial tears (Murine®)	Chapter 57 : Ophthalmic Drugs
Hair growth drugs (topical)	minoxidil (Rogaine®)	Chapter 56 : Dermatological Drugs
Pain-relieving drugs (analgesics)	acetaminophen (Tylenol®)	Chapter 11 : Analgesic Drugs
Pain-relieving drugs (NSAIDs)	aspirin ibuprofen (Advil®, Motrin®) naproxen sodium (Aleve®, Naprelan®)	Chapter 49 : Anti-Inflammatory and Anti-gout Drugs

Canada announced that it would transition products that more appropriately fit the definition of a food away from the Natural Health Products Regulations. To clarify the differences in language and terminology, a brief discussion of the forms and history of various NHPs follows. Basic definitions are provided here to ensure complete understanding and to prevent confusion in how these terms are used.

Dietary supplement is a broad term for orally administered alternative medicines and includes the category of herbal supplements. Although there are differences in what is considered a dietary supplement, they are products intended to augment the diet and include ingredients such as vitamins, minerals, herbs or other botanicals, amino acids, dietary substances that supplement the diet by increasing the total dietary intake, concentrates, metabolites, constituents, or extracts (Health Canada, 2012). Dietary supplements are produced in many forms, such as tablets, capsules, softgels, gels, liquids, and powders. These supplements may also be found in nutritional, breakfast, snack, or health food bars; drinks; and shakes.

Herbs come from nature and include the leaves, bark, berries, roots, gums, seeds, stems, and flowers of plants. They have been used for thousands of years to help maintain good health. Herbs have been an integral part of society because of their culinary and medicinal properties. About 30% of all modern drugs are derived from plants (Table 8.2). In Canada, Indigenous peoples have been using sacred herbs and the medicine wheel (see Chapter 4) for centuries. Herbs, including tobacco, sage, cedar, and sweetgrass, are used by First Nations, Métis, and Inuit populations. Both sacred herbs and the medicine wheel are important elements to support Indigenous people and their families to embrace all four health aspects of Indigenous culture (spiritual, mental, physical, and emotional).

In the early nineteenth century, scientific methods became more advanced, and the development and mass production of chemically synthesized drugs revolutionized health care in most parts of the world. During this time, the practice of botanical healing was dismissed as quackery. Nonetheless, **herbal medicines** (or the practice of **phytomedicine**) are now in great demand in the developing world for primary health care because they are inexpensive and have better cultural acceptability, are reasonably safe and effective, and have

advantageous compatibility and minimal adverse effects (World Health Organization, 2015). However, use of traditional medicine is not limited to developing countries, and during the past two decades, public interest in natural therapies has increased greatly in industrialized countries, with expanding use of ethnobotanicals. Indeed, in the future, traditional herbal medicine research may play a critical role in global health.

Herbs and plants can be processed and ingested in numerous ways and forms. This includes whole herbs, teas, essential oils, ointments, salves, syrup, tinctures, rubs, capsules, and tablets that contain a ground or powdered form of a raw herb or its dried extract. Plant and herb extracts vary in the solvent used for extraction, temperature, and extraction time and include alcoholic extracts (tinctures), vinegars (acetic acid extracts), hot water extracts (tisanes), long-term boiled extracts, usually roots or bark (decoctions), and cold infusion of plants (macerates). There is no standardization, and components of an herbal extract or a product are likely to vary significantly between batches and producers (Benzie & Wachtel-Galor, 2011). Herbs are generally to be taken intermittently, not in continuous daily dosing.

In the 1960s, concerns were expressed over the **iatrogenic effects** of (medicine taught in the West). These concerns, along with a desire for more self-reliance, led to a renewed interest in “natural health,” and as a result, the use of NHPs, including the use of herbal products, increased. In 1974, the World Health Organization (WHO) encouraged developing countries to use traditional plant medicines. In 1978, the German equivalent of Health Canada published a series of herbal recommendations known as the *Commission E Monographs*. These monographs focus on herbs whose effectiveness for specific indications is supported by the research literature. Recognition of the rising use of herbal medicines and other nontraditional remedies, known as **alternative medicine**, led to the establishment of the Office of Alternative Medicine by the National Institutes of Health, in 1992. This office was later renamed the National Center for Complementary and Alternative Medicine (NCCAM), and in 2014, it was again renamed, now to the National Center for Complementary and Integrative Health (NCCIH). **Complementary medicine** refers to the simultaneous use of both conventional and alternative medicine. This practice is also referred to as **integrative medicine**. NCCIH classifies complementary health approaches into three categories: 1) natural products, 2) mind and body practices, and 3) other complementary health approaches. A popular form of alternative medicine is **homeopathy**. Homeopathy is based on the belief that a disease can be treated by the administration of a microdose of a substance thought to cause the physical signs of that disease. Homeopathy is thought to stimulate the body's immune defences.

Many controversies remain about the safety and the control of NHPs, although they continue to be used in Canada and abroad. Their uses and touted advantages are widely publicized. As a result, these products are marketed and placed in grocery stores, pharmacies, health food stores, and fitness gyms and can even be ordered through television and radio ads and over the internet. Adverse effects are considered minimal by the public

TABLE 8.2 Conventional Medicines Derived From Plants

Medicine*	Plant
atropine	<i>Atropa belladonna</i>
capsaicin	<i>Capsicum frutescens</i>
cocaine	<i>Erythroxylon coca</i>
codeine	<i>Papaver somniferum</i>
digoxin	<i>Digitalis purpurea</i>
paclitaxel	<i>Taxis brevifolia</i>
quinine	<i>Cinchona officinalis</i>
scopolamine	<i>Datura fastuosa</i>
senna	<i>Cassia acutifolia</i>
vincristine	<i>Catharanthus roseus</i>

*Includes both OTC and prescription drugs

as well as by the companies and businesses that sell these supplements. However, this belief has created a false sense of security because the public's view tends to be that if a product is "natural" then it is safe. The information provided in this book regarding NHPs does not imply author or publisher endorsement of such products.

Concerns over the accessibility and regulation of all NHPs led the Health Canada Directorate to establish the Advisory Panel on Natural Health in 1997. After consultations with interested stakeholders, the Minister of Health tabled *Natural Health Products: A New Vision*, which provided the framework for the development of the Office of Natural Health Products. This office would later be renamed the Natural and Non-prescription Health Products Directorate (NNHPD). In 2004, the Natural Health Products Regulations came into effect. Manufacturers must obtain a product licence from Health Canada to sell their products in Canada. If the product meets the NNHPD criteria, then a Natural Product Number (NPN) will be issued. The Licensed Natural Health Products Database (LNHPD), managed by Health Canada, provides information on licensed NHPs. These include vitamin and mineral supplements, herb- and plant-based remedies, traditional medicines (e.g., traditional Chinese medicines or Ayurvedic [Indian] medicines), omega-3 and essential fatty acids, probiotics, homeopathic medicines, and numerous consumer products, such as certain toothpastes, antiperspirants, shampoos, facial products, and mouthwashes. This database can be accessed at <http://www.hc-sc.gc.ca/dhpm-prod-natur/applications/licen-prod/lnhpd-bdpsnh-eng.php>.

Homeopathic medicines (HMs) receive a Drug Identification Number (DIN)-HM, followed by a product number. Extensive product labelling must meet specific requirements regarded as essential to risk management. Based on information from the WHO, the European Scientific Cooperative on Phytotherapy, and the German Commission E, the NNHPD developed the Compendium of Monographs. The regulations also impose standard labelling requirements to ensure that consumers can make informed choices about NHPs. Labels contain such details as the product name, the quantity of the product in the container, and the recommended conditions for use, which include recommended use or purpose and dose, warnings, cautionary statements, contraindications, and possible adverse reactions. With such regulations, Canada, similar to Germany, France, and the United Kingdom, enforces standards for the assessment of natural-product quality and safety.

Consumer Use of Natural Health Products

Consumer use of NHPs is growing. In 2016, approximately 79% of Canadians used an alternative therapy during their lifetime (Fraser Institute, 2017). An estimated 73% of Canadians use some form of alternative medicine and regularly take NHPs, such as vitamins and minerals, herbal products, and homeopathic medicines (Health Canada, 2015), even though 12% who use them experience adverse reactions and only 41% who experience adverse effects report them. Canadians who take NHPs and prescription drugs are six times as likely to suffer unwanted adverse effects as those who use only drugs (Necyk, Barnes,

Tsuyuki, et al., 2013). Consumers select NHPs for the treatment and prevention of diseases and, proactively, to preserve health and wellness and boost the immune system (e.g., to reduce cardiovascular risk factors, increase liver and immune system functions, increase feelings of wellness). In addition, herbs may be used as adjunct therapy to support conventional pharmaceutical therapies.

Some products may be used to treat minor conditions and illnesses (e.g., coughs, colds, stomach upset) in much the same manner as conventional Health-Canada-approved OTC non-prescription drugs are used. As the number of NHPs on the market increases, nurses will need to respond to patient educational needs about these products.

Safety

NHPs, particularly herbal medicines, are often perceived as natural and therefore healthier than conventional drugs; however, this is not always the case. There are examples of allergic reactions, toxic reactions, and adverse effects caused by herbs. Some herbs have been shown to have possible mutagenic effects and to interact with drugs (see Natural Health Products: Selected Natural Health Products and their Possible Drug Interactions box). It is thought that many patients using NHPs do not disclose this to their health care providers. Patients are reluctant to disclose use for fear of disapproval by their health care providers, that they will not give their full attention to the topic, and because typically most health care providers have limited understanding of NHPs (Walji, Boon, Barnes, et al., 2010; Barry, 2018). In addition, there are concerns about the level of consumer knowledge of these products and their risks, even among regular users. These factors demonstrate the need for health care providers to develop a clinical knowledge base regarding these products and know where to find key information as the need arises. Because of under-reporting, present knowledge may represent but a small fraction of potential safety concerns.

There are few published scientific data regarding the safety of NHPs. Two recent examples indicating some of the growing concerns with specific herbal remedies include Health Canada warnings about possible liver toxicity with the use of kava root and possible cardiovascular and stroke risks with the use of ephedra. Ephedra remains on the market and in 2012, after a 10-year ban, Health Canada regulated kava root as a new drug. Also, many herbal products are best avoided in patients with cardiovascular diseases as there is risk for drug interactions and possible contamination or substitution with other medications, and there is no evidence to support any clinical improvement with use (Tachjian, Vigar, & Jahanjir, 2010; Liperoti, Vetrano, Bernabei, et al., 2017). Herbal products can increase bleeding risk with warfarin sodium (see Chapter 26), potentiate digoxin toxicity (see Chapter 25), increase the effects of antihypertensive agents (see Chapter 23), and cause heart block or dysrhythmias (see Chapter 26).

In order to improve the NHP vigilance system, Health Canada has put in place several initiatives that are available to both consumers and health care providers. The Canada

NATURAL HEALTH PRODUCTS

Selected Natural Health Products and Their Possible Drug Interactions

Natural Health Product	Possible Drug Interaction
Chamomile	Increased potential for bleeding with anticoagulants
Cranberry	Decreased elimination of many drugs excreted by the kidneys
Echinacea	Possible interference with or counteraction to immunosuppressant drugs and antivirals
Evening primrose	Possible interaction with antipsychotic drugs
Garlic	Possible interference with hypoglycemic therapy and the anticoagulant warfarin sodium (Coumadin®)
Ginkgo biloba	May increase risk of bleeding with use of anticoagulants (warfarin sodium, heparin sodium) and antiplatelets (aspirin, clopidogrel)
Ginger root	At high dosages, possible interference with cardiac, antidiabetic, or anticoagulant drugs
Grapefruit	Decreases metabolism of drugs used for erectile dysfunction Decreases metabolism of estrogens and some psychotherapeutic drugs (benzodiazepines, sertraline) Increases risk of toxicity of immunosuppressants, HMG-CoA reductase inhibitors, and of some psychotherapeutic drugs (pimozide, escitalopram)
Hawthorn	Increases intensity and duration of effects of caffeine
Kava	May lead to toxic levels of cardiac glycosides (e.g., digitalis)
Saw palmetto	May increase the effect of barbiturates and alcohol
St. John's wort	May change the effects of hormones in oral contraceptive drugs, patches, or hormonal replacement therapies May lead to serotonin syndrome if used with other serotonergic drugs (e.g., selective serotonin reuptake inhibitors [see Chapter 17])
Valerian	Strong CYP 3A4 inducer, resulting in decreased concentrations of many drugs Increases central nervous system depression if used with sedatives

Modified from Bailey, D. G., Dresser, G., & Arnold, J. M. O. (2013). Grapefruit–medication interactions: Forbidden fruit or avoidable consequences? *Canadian Medical Association Journal*, 185(4). doi: 10.1503/cmaj.120951; Seden, K., Dickinson, L., Khoo, S., et al. (2010). Grapefruit-drug interactions. *Drugs*, 70(18): 2373–2407.

Vigilance Program is Health Canada's postmarket surveillance program that maintains an online database of suspected adverse reactions submitted by both consumers and health care providers. The database provides information only. Through the MedEffect program, consumers and health care providers can report adverse effects from NHPs via web, phone, fax, or mail. Also available is the Health Product Info Watch, published monthly, with health product advisories and summary safety information about marketed health products and information on new health product safety. Other authoritative references that can be utilized for herbal information include Pharmacist's Letter, Prescriber's Letter, and Natural Medicines (formerly Natural Medicines Comprehensive Database and Natural Standard), all available at <http://www.naturalstandard.com/>. Health care providers need to be on the alert for announcements about the safe and effective use of NHPs as well as their reported adverse effects. The discriminating and proper use of some products may provide some therapeutic benefits, but the indiscriminate or excessive use of NHP supplements can be dangerous (see Ethnocultural Implications box).

Level of Use

There are approximately 16 000 NHPs currently licensed for use in Canada, with many new products introduced annually. A great deal of public interest in the use of NHPs remains. Estimates of the prevalence of use differ greatly.

The many different herbs in these preparations contain a wide variety of active **phytochemicals** (plant compounds). Herbal medicine is based on the premise that plants contain natural substances that can promote health and alleviate illness. Some of the more common ailments and conditions treated with herbs are anxiety, arthritis, colds, constipation, cough, depression, fever, headache, infection, insomnia, intestinal disorders, premenstrual syndrome, menopausal symptoms, stress, ulcers, and weakness.

NHPs constitute the largest growth area in retail pharmacy, and their use is increasing, exceeding the growth in the use of conventional drugs. Some of the most commonly used natural health herbal remedies are aloe, black cohosh, chamomile, echinacea, feverfew, garlic, ginger, Ginkgo biloba, ginseng, goldenseal, hawthorn, St. John's wort, saw palmetto, and valerian.

Medical Use of Marijuana

Marijuana is an herb with a long history of use for its therapeutic and medicinal qualities. On October 17, 2018, cannabis and related products including marijuana became legal in Canada and are regulated under the Cannabis Act and **Cannabis Regulations**. Both the Cannabis Act and Cannabis Regulations replaced the Access to Cannabis for Medical Purposes Regulations (ACMPR). In 2003, prior to legalization, Health Canada implemented the Marijuana Medical Access Regulations (MMAR) to allow access to and

possession of marihuana for individuals suffering from specific grave and debilitating illnesses, while protecting public safety. These regulations were repealed in 2014, and the Marihuana for Medical Purposes Regulations (MMPRs) came into effect. In 2015, the Supreme Court of Canada ruled against the federal government to expand the definition of medical marihuana beyond the “dried” form and allow the consumption of medical marihuana as well as use other extracts and derivatives (Do, 2015).

Individuals who use marihuana for medical reasons can access marihuana for medical purposes after registering with the federal government. Once authorized by their health care provider, patients can access medical marihuana by purchasing direct from a seller licensed by the federal government, registering with Health Canada in order to produce a prescribed amount of cannabis in their home, or by appointing an agent or designate to produce cannabis on their behalf (Government of Canada, 2018). See Box 8.3 for discussion of the use of marihuana (also known as *cannabis*) for medical purposes.

❖ NURSING PROCESS

◆ ASSESSMENT

◆ Over-the-Counter Drugs

Nursing assessments are always important to perform, but they are especially important in situations in which the patient is self-medicating. Reading level, cognitive level, motor abilities, previous use of OTC drugs, successes versus failures with drug therapies and self-medication, and caregiver support are just a few of the variables to be assessed, as deemed appropriate. Other assessment data include questioning about allergies to any of the drug's ingredients or additives (e.g., dyes, preservatives, or fillers). Include a list of *all* medications and substances used by the patient in the medication history, including OTC drugs, prescription drugs, herbal products, vitamins, and minerals. Also note use of alcohol, tobacco, and caffeine. Assess past and present medical history so that possible drug interactions, contraindications, and cautions are identified. Screen patients carefully before recommending an OTC drug because patients often assume that if a drug is sold OTC it is completely safe to take and without potential negative consequences. This is not true—OTC drugs can be just as lethal or problematic as prescription drugs if they are not taken properly or are taken in high dosages and without regard to directions (see discussion earlier in the chapter).

Assessment of the patient's knowledge about the components of self-medication, including the positive and negative consequences of the use of a given OTC drug, must be included. Assessment of the patient's (or caregiver's or family member's) level of knowledge and experience with OTC self-medication is critical to the patient's safety, as is assessment of attitudes toward and beliefs about their use. This is especially true if a casual attitude is combined with a lack of knowledge, which could result in overuse, overdose, and

ETHNOCULTURAL IMPLICATIONS

Drug Responses and Ethnocultural Factors

Responses to drugs, including OTC drugs and NHPs, may be affected by beliefs, values, and genetics as well as by culture, race, and ethnicity. As one example of the impact of culture on drug response and use, if patients who are Japanese experience nausea, vomiting, or bowel changes as adverse effects of OTC drugs or NHPs, these often are not mentioned. The reason is that individuals in this culture find it unacceptable to report gastrointestinal symptoms and they may remain unreported to the point of causing risk to the patient.

NHPs, specifically herbal and alternative therapies, may also be used more extensively in some cultures than in others. Wide acceptance of herbal use without major concern for the effects on other therapies may be problematic because of the many interactions of conventional drugs with herbs and dietary supplements. For example, the Chinese herb ginseng may inhibit or accelerate the metabolism of a specific medication and significantly affect the drug's absorption or elimination.

One genetic factor that has an influence on drug response is acetylation polymorphism; that is, prescription drugs, OTC drugs, and NHPs may be metabolized in different ways that are genetically determined and vary with race or ethnicity. For example, populations of European or African descent contain approximately equal numbers of individuals showing rapid and slow acetylation (which affects drug metabolism), whereas Japanese and Inuit populations may contain more rapid acetylators. See Chapter 4 for a more in-depth discussion of these specific genetic attributes.

Source: Modified from Munoz, C., & Hilgenberg, C. (2005). Ethnopharmacology, *Am J Nurs* 105(8):40–49.

potential complications. See Chapter 7 for more information on patient education.

For the most part, laboratory tests are not ordered before the use of OTC drugs because these drugs are self-administered and self-monitored. However, there are situations in which patients may be taking certain medications that react adversely with OTC drugs, and laboratory testing may be needed. Some patient groups are also at higher potential for adverse reactions to OTC drugs (as to most drugs in general), including pediatric and older adult patients; patients with single and/or multiple acute and chronic illnesses; those who are frail or in poor health, debilitated and whose diets are nutritionally inadequate; and those with suppressed immune systems. OTC drugs must also be used with caution and may be contraindicated in patients with a history of kidney, liver, heart, or vascular dysfunction. More assessment information for OTC drugs and NHPs can be found in other chapters in this textbook, where relevant (see Table 8.1 on page 101). It is important to remember that consumer/patient safety and quality of care regarding drug therapy of any kind begins with education. Thus, the best way for patients to help themselves is for them to learn how to assess each situation, weigh all the factors, and find out all they can about any OTC drugs they wish to take *before* taking them.

◆ Natural Health Products

Many NHPs, including herbs, probiotics, and dietary supplements, are readily available in pharmacies, health food stores, and grocery stores, as well as in gardens, kitchens, and

BOX 8.3 Cannabis

Cannabis sativa, or cannabis from the hemp plant, is widely used for recreational purposes. After tobacco, it is the most frequently smoked substance worldwide. Cannabinoids are the psychoactive ingredients of marihuana, of which 1- Δ^9 -trans-tetrahydrocannabinol (THC), concentrated in the bud of the female plant, is the main psychoactive substance. When marihuana is smoked, the effect is almost immediate and lasts for one to three hours. THC is absorbed by most tissues and organs in the body; however, it is primarily found in fat tissues. The body attempts to eliminate the foreign chemical by chemically transforming THC into metabolites. The half-life of THC for an infrequent user is approximately 1.3 days and for frequent users 5 to 13 days (Sharma, Murthy, & Bharath, 2012). THC metabolites can be found in the urine, the preferred sample, for up to one week after smoking marihuana. Metabolites can also be detected retrospectively, in hair. Once incorporated into the growing hair, the drug can be detected for 90 days after it has been eliminated from more conventional samples, such as blood and urine (Khajuria & Nayak, 2014). THC acts on cannabinoid receptors on brain cells and triggers a series of chemical reactions that ultimately lead to the “high” that users experience. Cannabinoid receptors are found in areas of the brain that influence pleasure, memory, thought, concentration, sensory and time perception, and coordinated movement. There is evidence that THC acts on neurotransmitters and exerts either excitatory or inhibitory effects.

Cannabidiol (CBD) is the major nonpsychotropic cannabinoid found in marihuana. It has shown antiepileptic, anti-inflammatory, antiemetic, muscle relaxing, anxiolytic, neuroprotective, and antipsychotic activity; inhibits colon cancer cell proliferation; and reduces the psychoactive effects of THC (Romano, Borrelli, Pagano, et al., 2014). The mode of action of cannabidiol is not fully understood.

While there is sociopolitical concern around the medical use of marihuana, and the clinical therapeutic potential for marihuana has not yet been proven in controlled clinical trials beyond 6 weeks, there is anecdotal evidence that it may be beneficial in a variety of disorders. In Canada, marihuana is legal and is authorized based on promising clinical evidence for use as an adjunctive treatment for neuropathic pain in adults with multiple sclerosis and as adjunctive analgesic treatment in adult patients with advanced cancer, for acquired immunodeficiency syndrome (AIDS)-related anorexia associated with weight loss, as well as for severe nausea and vomiting associated with cancer chemotherapy.

medicine cabinets. As noted earlier in the chapter, among the more commonly used herbals are aloe, echinacea, feverfew, garlic, ginger, Ginkgo biloba, ginseng, goldenseal, hawthorn, St. John's wort, saw palmetto, and valerian. Although patients generally self-administer these products and do not perform an assessment, in various settings, the health care provider may be able to assess the patient through a head-to-toe physical examination, medical and nursing history, and medication history. Share with the patient assessment data, factors, and variables to consider, for the patient's safety. This sharing of assessment information allows the health care provider to be sure that the patient is taking the NHP in as safe a manner as possible.

Many NHPs may lead to a variety of adverse effects. For example, some may cause dermatitis when used topically, whereas some taken systemically may be associated with kidney disorders such as nephritis. Therefore, for example, patients with existing skin problems or kidney dysfunction must seek medical advice before using certain herbal products. It is also

crucial to patient safety to consider any other contraindications, cautions, and potential drug–drug and drug–food interactions. See Natural Health Products on page 104 for more information on drug interactions.

◆ NURSING DIAGNOSES

Nursing diagnoses appropriate for the patient who is taking OTC drugs or NHPs include the following (without related causes because these are too numerous to include):

1. Inadequate physical mobility
2. Reduced memory
3. Inadequate urinary elimination
4. Acute pain or persistent pain
5. Fatigue
6. Activity intolerance
7. Insomnia
8. Inadequate health maintenance
9. Potential for injury
10. Readiness for enhanced self-care
11. Readiness for enhanced knowledge

◆ PLANNING

◆ Goals

1. Patient will be able to increase mobility as tolerated and without distress.
2. Patient will experience increased alertness and improved short-term and long-term memory with continued use of the NHP.
3. Patient will maintain normal elimination patterns during NHP use.
4. Patient will experience pain relief or relief of the symptoms of the disease process or injury.
5. Patient will experience an increase in energy and function (or both).
6. Patient's tolerance for activity will remain within normal limits or improve during OTC drug or therapy.
7. Patient will experience limited sleep pattern disturbance while on OTC drug or NHP therapy.
8. Patient will seek healthy maintenance behaviours, with questions about the OTC drug or NHP (or both), as well as its action, therapeutic effects versus adverse effects, toxicity, cautions, contraindications, drug–drug or drug–food interactions, and appropriate dosage formulation administration.
9. Patient will remain free from injury while taking the OTC drug or NHP (or both).

◆ Expected Patient Outcomes

- Patient states that the actions of the OTC drug or NHP have been beneficial, with relief of symptoms and increased physical mobility.
- Patient experiences improving overall well-being and health status, with minimal adverse effects or complications.
- Patient reports any change in orientation to person, place, or time or in short-term or long-term memory immediately and seeks appropriate directions regarding discontinuing therapy.

- Patient describes nonpharmacological approaches to the treatment of acute and persistent pain, such as the use of hot or cold packs, physiotherapy, massage, relaxation therapy, biofeedback, imagery, and hypnosis.
- Patient identifies measures to increase urinary elimination and enhance urinary elimination patterns, such as increasing fluid intake to six to eight glasses of water per day, unless contraindicated, and taking time to void at regular intervals.
- Patient takes measures to minimize fatigue through the use of NHPs, sleeping 6 to 8 hours per night; increasing fluid intake; and maintaining an intake of recommended daily amounts of food, calories, and protein.
- Patient states that the actions of the OTC drug or NHP (or both) have been beneficial, with relief of symptoms and subsequent increased ability to participate in activities of daily living (ADLs) as well as increased participation in other physical activities.
- Patient states increased hours of sleep (i.e., 6 to 8 hours of sleep) and less difficulty with onset of sleep while using OTC drugs, herbal products, or dietary supplements.
- Patient experiences healthier behaviours as a result of health maintenance, by being more knowledgeable about self-medication administration with OTC drugs or NHPs.
- Patient inquires of pharmacist or health care provider about the safe, daily, healthy maintenance behaviour of taking NHPs and deciphers information appropriately.
- Patient states the importance of taking drugs as directed and of immediately reporting any severe adverse effects or complications associated with the use of an OTC drug or NHP to the health care provider and pharmacist and contacting the poison control centre, if needed.
- Patient is able to self-administer OTC drugs or NHPs as directed and with proper administration technique (e.g., transdermal patch, suppository, liquid, quick-dissolve tablet), with minimal adverse effects and a decrease in potential for self-injury.

◆ IMPLEMENTATION

With OTC drugs and NHPs, patient education is an important strategy to enhance patient safety. Patients need to receive as

much information as possible about the safe use of these products and to be informed that, even though these are not prescription drugs, they are *not* completely safe and are not without toxicity. Include in the patient instructions information about safe use, frequency of dosing and dose specifics about how to take the medication (e.g., with food or at bedtime), as well as strategies to prevent adverse effects, drug interactions, and toxicity. Another consideration is the dosage form, because a variety of dosage forms are available, such as liquids, tablets, enteric-coated tablets, transdermal patches, gum, and quick-dissolve tablets or strips. Instructions must be provided and the need to recheck dosage emphasized. For transdermal patches (e.g., for smoking cessation), it is important to emphasize proper use and application. As previously mentioned, many consumers believe that there are no risks if a medication is available OTC or is a “natural” substance. See [Box 8.1](#) for more information about the criteria for moving a drug from prescription to OTC status. The fact that a drug is an NHP does not mean that it can be safely administered to children, infants, pregnant or lactating women, or patients with certain health conditions that put them at risk.

◆ EVALUATION

Patients taking OTC drugs or NHPs need to carefully monitor themselves for unusual or adverse reactions and therapeutic responses to the medication to prevent overuse and overdosing. The range of therapeutic responses will vary, depending on the specific drug and the indication for which it is used. Therapeutic responses also vary depending on the drug’s action—a few examples include decreased pain; decreased stiffness and swelling in joints; decreased fever; increased ease of carrying out ADLs; increased hair growth; increased ease in breathing; decreased constipation, diarrhea, bowel irritability, or gastrointestinal reflux or hyperacidity; resolution of allergic symptoms; decreased vaginal itching and discharge; increased healing; increased sleep; and decreased fatigue or improved energy.

For more specific nursing diagnoses, planning with goals and outcome criteria, implementation, and evaluation regarding various OTC drugs and NHPs, see the appropriate chapters later in the textbook; [Table 8.1](#) provides cross-references to these chapters.

CASE STUDY

Over-the-Counter Drugs and Natural Health Products

Jag, a 28-year-old graduate student, is at the student health clinic for a physical examination that is required before he goes on a research trip out of the country. As he completes the paperwork, he says to the nurse, “The form is asking about my medications. I don’t have any prescribed medicines, but I take several herbal products and OTC medicines. Do you need to know about these?”

1. How should the nurse answer Jag?

On the form, Jag lists the following items:

- 1 low-dose (81 mg) aspirin daily to prevent blood clots
- Sleepwell® herbal product with valerian at night, if needed
- Benadryl®, as needed for allergies, especially at night
- Stress Away® herbal product with ginseng, as needed

Generic ibuprofen, 3 or 4 tablets three times a day for muscle aches from working out

Memory Boost® herbal product with Ginkgo biloba every morning

2. Examine the products on Jag’s list, and state whether there are any concerns with interactions or adverse effects. It may be necessary to refer to descriptions of the individual herbal products (see the inside back cover of this textbook for a complete listing of Natural Health Products boxes located throughout the textbook) or to the appropriate drug chapters for more information.

3. Upon further questioning, Jag remembers that he has had problems with “acid stomach” for about a year and takes Maximum Strength Pepcid® AC-OTC, as needed, to manage this problem. What concerns, if any, are there about this?

For answers see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

PATIENT TEACHING TIPS

- Provide verbal and written information about how to choose an appropriate OTC drug or NHP, as well as information about correct dosing, common adverse effects, and possible interactions with other medications.
- Many patients believe that there are no risks if a medication is herbal and “natural” or if it is sold OTC, so provide adequate education about the drug or product as well as all of the advantages and disadvantages of its use because this is crucial to patient safety.
- Provide instructions on how to read OTC and NHP labels. Encourage patients to read the ingredients if using more than one product, as an ingredient or chemical may occur in both products. For example, a multivitamin supplement may contain ginseng, and taking additional ginseng supplements may lead to toxicity. Another example is with products containing acetaminophen (Tylenol). If patients take acetaminophen and then also take a cold/flu product, there may also be acetaminophen in that product, and consequently the risk of adverse effects and toxicity increases.
- Emphasize the importance of taking all OTC drugs, herbals, and dietary supplements with extreme caution and being aware of all the possible interactions and concerns associated with the use of these products.
- Instruct patients that all health care providers (e.g., nurses, dentists, osteopathic and chiropractic physicians) need to be aware of the use of any OTC drugs and NHPs (and, of course, any prescription drug use).
- Encourage journalling of any improvement of symptoms noted with the use of a specific OTC drug or NHP.
- Encourage the use of appropriate and authoritative resources for patient information, such as a registered pharmacist, literature provided from the drug company or pharmacist, and web-based information from reliable sites, at an appropriate reading level for patients (e.g., www.Webmd.com).
- Instruct patients that all medications, including OTC drugs and NHPs, should be kept out of the reach of children and pets.
- Provide thorough instructions regarding the various dosage forms of OTC drugs and NHPs.
- Provide specific instructions, such as how to mix powders and how to properly use transdermal patches, inhalers, ointments, lotions, nose drops, ophthalmic drops, elixirs, suppositories, vaginal suppositories or creams, and all other dosage forms (see [Chapter 10](#)); also provide information about proper storage and cleansing of any equipment.

KEY POINTS

- Consumers use NHPs therapeutically for the treatment of diseases and pathological conditions, prophylactically for long-term prevention of disease, and proactively as agents for the maintenance of health and wellness.
- Health Canada has established the MedEffect program to track adverse events or problems as a result of drug therapy. The toll-free number is 1-866-678-6789 for marketed health products, including prescription and nonprescription medications and NHPs. Consumers and health care providers may report adverse events anonymously and without consequence.
- NHPs are approved by Health Canada, with specific labelling requirements to provide adequate instructions for use and warnings.
- The fact that a drug is an NHP or an OTC medication is no guarantee that it can be safely administered to children, infants, pregnant or lactating women, or patients with certain health conditions that may put them at risk.

EXAMINATION REVIEW QUESTIONS

1. Which statement is true about current Canadian legislation regarding NHPs?
 - a. Herbals were regulated in the early 1900s in reference to their efficacy and toxicity.
 - b. The Natural and Non-prescription Health Products Directorate (NNHPD) regulates the safety, efficacy, and quality of NHPs.
 - c. The Marihuana for Medical Purposes Regulations allow access to and possession of marihuana for individuals.
 - d. The NNHPD was specifically designed to encourage the freedom of choice and philosophical and ethnocultural diversity of NHPs.
2. What information about NHPs is important for the nurse to communicate to patients?
 - a. Natural health and OTC products are not approved by Health Canada and are under strict regulation.
 - b. These products are scrutinized for safety and tested repeatedly by Health Canada.
 - c. No adverse effects are associated with these agents because they are “natural” and may be purchased without a prescription.
 - d. Labelling is not 100% reliable for the provision of proper instructions or warnings, and the products should be taken with caution.
3. A nurse is taking a patient’s drug history and questions the patient about the use of OTC medications. The patient responds by saying, “Oh, I frequently take something for my headaches, but I didn’t mention it because aspirin is nonprescription.” Which of the following would be the best response from the nurse to the patient?
 - a. “That’s true; OTC drugs are generally not harmful.”
 - b. “Aspirin is one of the safest drugs out there.”

- c. “Although aspirin is over the counter, it is still important to know why you take it, how much you take, and how often.”
 - d. “We need you to be honest about the drugs you are taking. Are there any others that you haven’t told us about?”
4. When making a home visit to a patient who was recently discharged from the hospital, the nurse notes that the patient has a small pack over her chest and that the pack has a strong odour. She also is drinking herbal tea. When asked about the pack and the tea, the patient indicates that “My grandmother never used medicines from the doctor. She told me this plaster and tea were all I would need to fix things.” Which of the following responses by the nurse would be most appropriate?
 - a. “You really should listen to what the doctor told you if you want to get better.”
 - b. “What’s in the plaster and the tea? When do you usually use them?”
 - c. “These herbal remedies rarely work, but if you want to use them, then it is your choice.”
 - d. “It’s fine if you want to use this home remedy, as long as you use it with your prescription medicines.”
 5. The nurse is taking a health history from a patient. The patient reports taking an herbal supplement that contains kava, to help with relaxation. The nurse notes that the patient’s skin and sclera have a yellow tinge. Which of the following nursing actions would be most appropriate?
 - a. Report this incident to MedEffect.
 - b. Notify the provincial or territorial pharmaceutical association.
 - c. Contact the supplement manufacturer.
 - d. No other action is needed.
 6. The nurse is reviewing a patient’s drug history, and during the interview, the patient asks, “Why are some drugs over the counter and others are not?” Which of the following criteria for OTC status would be most appropriate for the nurse to consider when planning her response to the patient? (Select all that apply.)
 - a. The condition must be diagnosed by a health care provider.
 - b. The benefits of correct usage of the drug outweigh the risks.
 - c. The drug has limited interaction with other drugs.
 - d. The drug is easy to use.
 - e. The drug company sells OTC drugs at lower prices.
 7. A patient comes to the clinic reporting elbow pain after an injury. He states that he has been taking two pain pills, eight times a day, for the past few days. The medication bottle contains acetaminophen, 325-mg tablets. Calculate how much medication he has been taking per day. Is this a safe dose of this medication?
 8. The nurse is reviewing definitions for a pharmacology review class. Which of these products would be categorized as “prescription drugs”? (Select all that apply.)
 - a. Acetaminophen (Tylenol®)
 - b. Warfarin (Coumadin)
 - c. Ginkgo biloba
 - d. Morphine sulphate
 - e. Diphenhydramine (Benadryl®)

CRITICAL THINKING ACTIVITIES

1. The nurse is discussing OTC drugs and NHPs with neighbours. One neighbour comments, “Oh, OTC drugs and NHPs are safe. As long as you use the recommended amounts, there won’t be any bad side effects.” What is the best response from the nurse?
2. The nurse is teaching a patient about pain control at home with OTC products. What teaching points are priorities during the discussion with the patient?
3. A patient tells the clinic nurse that he has been taking a “blood thinner” for several months and wants to ask about

taking Ginkgo biloba to prevent memory loss. He says his sister uses it and it “works wonders.” He also says, “I think it would be safe because I can buy it at the grocery store. They wouldn’t sell harmful drugs.” What is the nurse’s best response to this patient? (You may need to look up the drug warfarin and the herbal product elsewhere in the textbook.)

Vitamins and Minerals

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Discuss the importance of the various vitamins and minerals to the normal functioning of the human body.
2. Briefly describe the various acute and chronic disease states and conditions that may lead to various imbalances in vitamin and mineral imbalances.
3. Discuss the pathologies that result from vitamin and mineral imbalances.
4. Describe the treatment of these vitamin and mineral imbalances.
5. Identify mechanisms of action, indications, cautions, contraindications, drug interactions, dosages, recommended daily allowances, and routes of administration of each of the vitamins and minerals.
6. Develop a collaborative plan of care regarding the use of vitamins and minerals that includes all phases of the nursing process.

KEY TERMS

Beriberi A disease of the peripheral nerves caused by a dietary deficiency of thiamine (vitamin B₁). Symptoms include fatigue, diarrhea, weight loss, edema, heart failure, and disturbed nerve function. (p. 119)

Coenzyme A nonprotein substance that combines with a protein molecule to form an active enzyme. (p. 112)

Enzymes Specialized proteins that catalyze chemical reactions. (p. 112)

Fat-soluble vitamins Vitamins that can be dissolved (i.e., are soluble) in fat. (p. 112)

Minerals Inorganic substances that are ingested and attach to enzymes or other organic molecules. (p. 112)

Pellagra A disease resulting from a deficiency of niacin or a metabolic defect that interferes with the conversion of tryptophan to niacin (vitamin B₃). (p. 119)

Rhodopsin The purple pigment in the rods of the retina, formed by the protein opsin and a derivative of retinol (vitamin A). (p. 114)

Rickets A condition caused by a deficiency of vitamin D. (p. 116)

Scurvy A condition caused by a deficiency of ascorbic acid (vitamin C). (p. 123)

Tocopherols Biologically active chemicals that make up vitamin E compounds. (p. 117)

Vitamins Organic compounds essential in small quantities for normal physiological and metabolic functioning of the body. (p. 111)

Water-soluble vitamins Vitamins that can be dissolved (i.e., are soluble) in water. (p. 112)

DRUG PROFILES

magnesium, p. 126

OVERVIEW

For the body to grow and maintain itself, it needs the essential building blocks provided by carbohydrates, fats, and proteins. Vitamins and minerals are needed to efficiently utilize these nutrients. **Vitamins** are organic molecules needed in small quantities for normal metabolism and other biochemical functions, such as growth and repair of tissue. Equally important are **minerals**, inorganic elements found naturally in the earth. **Enzymes** are proteins secreted by cells; they act as catalysts to induce chemical changes in other substances. A **coenzyme** is a substance that enhances or is necessary for the action of enzymes. Many enzymes are useless without the appropriate vitamins and minerals that cause them to function properly. Both vitamins and minerals act primarily as coenzymes, binding to enzymes (or other organic molecules) to activate anabolic (tissue-building) processes in the body. For example, coenzyme A is an important carrier molecule associated with the citric acid cycle, one of the body's major energy-producing metabolic reactions. However, it requires pantothenic acid (vitamin B₅) to complete its function in the citric acid cycle.

Vitamins and minerals are essential in our lives, whether or not we make conscious food choices. The 2019 Health Canada food guide (Health Canada, 2019a) recommends a variety of vegetables, fruits, proteins, and whole grain foods to help ensure that daily requirements of vitamins and minerals are met by ingestion of fluids and balanced meals. Ingesting food maintains adequate stores of essential vitamins and minerals, serves to preserve intestinal structure, provides chemicals for hormones and enzymes, and prevents harmful overgrowth of bacteria.

Various illnesses can cause acute or chronic deficiencies of vitamins, minerals, electrolytes, and fluids. These conditions require replacement or supplementation of these nutrients. Common examples include extensive burn injuries and acquired immune deficiency syndrome (AIDS). Excessive loss of vitamins and minerals may also be the result of poor dietary intake, an inability to swallow after cancer chemotherapy or radiation, or mental health disorders such as anorexia nervosa. Poor dietary absorption can also be caused by various gastrointestinal (GI) malabsorption syndromes such as celiac disease, Crohn's disease, or cystic fibrosis. In addition, drug and alcohol misuse are frequently associated with inadequate nutritional intake and absorption that warrants vitamin and mineral supplementation. Deficiencies in dietary protein, fat, and carbohydrates are also common. These nutrients are discussed in Chapter 42. Because of some of their distinct properties and functions in the body regarding blood formation, iron and folic acid (vitamin B₉) are discussed separately, in Chapter 55.

Vitamins

The human body requires vitamins in specific minimum amounts on a daily basis, and these can be obtained from both plant and animal food sources. In some cases, the body synthesizes some of its own vitamin supply. Supplemental amounts of vitamin B complex and vitamin K are synthesized by normal bacterial flora in the GI tract. Vitamin D can be synthesized by the skin when exposed to sunlight.

In Canada, vitamins and minerals are considered natural health products (NHPs) and are governed under the Natural Health

TABLE 9.1 Fat- and Water-Soluble Vitamins

FAT-SOLUBLE		WATER-SOLUBLE	
Designation	Alternate Name	Designation Vitamin B Complex	Alternate Name
vitamin A	retinol	vitamin B ₁	thiamine
vitamin D	D ₃ , cholecalciferol	vitamin B ₂	riboflavin
	D ₂ , ergocalciferol; dihydrotachysterol	vitamin B ₃	niacin
vitamin E	tocopherols	vitamin B ₅	pantothenic acid
vitamin K	K ₁ , phytonadione K ₂ , menaquinone	vitamin B ₆	pyridoxine
		vitamin B ₉	folic acid
		vitamin B ₁₂	cyanocobalamin
		vitamin B ₇	biotin
		vitamin C	ascorbic acid

Products Regulations. Health Canada requires mandatory detailed nutritional information to be listed on any packaged food product (Health Canada, 2019b). The values that appear on the labels are the percent daily values and indicate what percentage of the dietary reference intakes (DRIs) for a specific nutrient is met by a single serving of the food product. Information regarding DRIs and nutrition labelling is available from the following websites:

1. Health Canada Food and Nutrition: Dietary Reference Intakes (Health Canada, 2013)
2. Health Canada: Dietary References Intakes Tables: recommended intakes for individuals (Health Canada, 2019c), available at <http://www.hc-sc.gc.ca/fn-an/nutrition/reference/table/index-eng.php>

Vitamins are classified as either fat-soluble or water-soluble. **Water-soluble vitamins** can be dissolved in water and are easily excreted in the urine. **Fat-soluble vitamins** are dissolvable in fat. Because water-soluble vitamins (the B-complex group and vitamin C) cannot be stored in the body over long periods, daily intake is required to prevent the development of deficiencies. Conversely, fat-soluble vitamins (vitamins A, D, E, and K) do not need to be taken daily unless one is inadequate, because substantial amounts are stored in the liver and fatty tissues. Deficiencies of these vitamins occur only after prolonged deprivation from an adequate supply or from disorders that prevent their absorption. Table 9.1 lists the fat-soluble and water-soluble vitamins.

One controversial topic regarding vitamins is that of nutrient “megadosing,” as a strategy both for health promotion and maintenance and for treatment of various illnesses. Some patients with cancer elect to use supplemental megadosing of specific nutrients in hopes of strengthening their body's response to more conventional cancer treatments. *Megadosing* refers to taking doses of a nutrient that are 10 or more times the recommended amount. A related term was coined in 1968 by the Nobel prize-winning chemist, Linus Pauling. He defined *orthomolecular medicine* to be “the preventive or therapeutic use of high-dose vitamins to treat disease.” The best-known claim of Dr. Pauling was that megadoses of vitamin C (at more than 100 times the Canadian recommended

dietary allowance [RDA]) could prevent or cure the common cold and cancer. Many studies since have not substantiated this claim. However, there are some situations in which nutrient megadosing is known to be helpful, including the following:

- When concurrent long-term drug therapy depletes vitamin stores or otherwise interferes with the function of a vitamin. A common clinical example is the use of vitamin B₆ (pyridoxine) supplementation in patients receiving the drug isoniazid for the treatment of tuberculosis (see [Chapter 46](#)).
- In GI malabsorption syndromes such as those seen in patients with severe colitis and cystic fibrosis (all major nutrient classes, including protein, fat, carbohydrates, vitamins, and minerals).
- For the treatment of pernicious anemia, which results from vitamin B₁₂ (cyanocobalamin) deficiency. The GI tract uses a complex mechanism to drive cyanocobalamin absorption. Specifically, a glycoprotein known as *intrinsic factor* is secreted by the parietal cells of the gastric glands (see [Chapter 55](#)). Intrinsic factor facilitates absorption of cyanocobalamin in the intestine. When this process is compromised (e.g., by disease), administration of megadoses of cyanocobalamin can bypass this absorption mechanism by allowing a small amount of the vitamin to diffuse on its own through the intestinal mucosa.
- When the vitamin acts as a drug when megadosed. The most common example is niacin (vitamin B₃, also called *nicotinic acid*). At doses of up to 20 mg daily, it functions as a vitamin, but at dosages 50 to 100 times higher, it reduces blood levels of both triglycerides and low-density lipoprotein (LDL) cholesterol (see [Chapter 28](#)).

In contrast with the aforementioned examples, there are some situations in which nutrient megadosing is known to be harmful. For example, any excess of one or more nutrients can result in deficiencies of other nutrients because of their chemical “competition” for sites of absorption in the intestinal mucosa. This is likely to be the case with megadosing of minerals, such as with calcium, copper, iron, and zinc, and is less likely to result from vitamin megadosing. Vitamin megadosing can lead to toxic accumulation known as *hypervitaminosis*, especially with the fat-soluble vitamins, A, D, and K. Vitamin E appears safer, however, even at doses 10 to 20 times the recommended DRI. Hypervitaminosis is much less likely to occur with the water-soluble vitamins (B complex and C) because they are readily excreted through the urinary system. Nevertheless, it is known that megadosing with vitamin B₆ (pyridoxine) at 50 to 100 times the DRI can nonetheless cause nerve damage.

A person with an illness may be less tolerant of nutrient megadosing, although megadosing regimens are often prescribed to them. For example, megadosing may be more of a strain for a patient whose GI tract is already weakened by illness. Megadosing can interfere with chemotherapy drugs as well as with radiation treatments, because these therapies work to destroy cancer cells through oxidation processes. Nutritional supplementation with antioxidants may impede such treatment mechanisms. Patients need to tell their health care providers about any unusual nutritional regimens that they plan to try, especially if they have a serious illness.

Fat-Soluble Vitamins

Fat-soluble vitamins are not readily excreted in the urine and are stored in the body. Thus, daily ingestion of these vitamins

TABLE 9.2 Food Sources of Selected Nutrients

Vitamins/Minerals	Food Sources
vitamin A	Liver; fish; dairy products; egg yolks; dark green, leafy, yellow–orange vegetables and fruits
vitamin D	Dairy products, fortified cereals and fortified orange juice, liver, fish liver oils, saltwater fish, butter, eggs
vitamin E	Fish, egg yolks, meats, vegetable oils, nuts, fruits, wheat germ, grains, fortified cereals
vitamin K	Cheese, spinach, broccoli, Brussels sprouts, kale, cabbage, turnip greens, soybean oils
vitamin B ₁ (thiamine)	Yeast, liver, enriched whole-grain products, beans
vitamin B ₂ (riboflavin)	Meats, liver, dairy products, eggs, legumes, nuts, enriched whole-grain products, green leafy vegetables, yeast
vitamin B ₃ (niacin)	Liver, turkey, tuna, peanuts, beans, yeast, enriched whole-grain breads and cereals, wheat germ
vitamin B ₆ (pyridoxine)	Organ meats, meats, poultry, fish, eggs, peanuts, whole-grain products, vegetables, nuts, wheat germ, bananas, fortified cereals
vitamin B ₁₂ (cyanocobalamin)	Liver, kidney, shellfish, poultry, fish, eggs, milk, blue cheese, fortified cereals
vitamin C (ascorbic acid)	Broccoli, green peppers, spinach, Brussels sprouts, citrus fruits, tomatoes, potatoes, strawberries, cabbage, liver
calcium	Dairy products, fortified cereals and calcium-fortified orange juice, sardines, salmon
magnesium	Meats, seafood, milk, cheese, yogurt, green leafy vegetables, bran cereal, nuts
phosphorus	Milk, yogurt, cheese, peas, meats, fish, eggs
zinc	Red meats, liver, oysters, certain seafood, milk products, eggs, beans, nuts, whole grains, fortified cereals

is not necessary to maintain good health and, in fact, is more likely to result in hypervitaminosis.

The fat-soluble vitamins are A, D, E, and K. As a group, they share the following characteristics:

- They are present in both plant and animal foods.
- They are stored primarily in the liver.
- They exhibit slow metabolism or breakdown.
- They are excreted via the feces.
- They can reach toxic levels (*hypervitaminosis*) if excessive amounts are consumed. Owing to their ability to accumulate in the body, fat-soluble vitamins have a higher potential for toxicity than water-soluble vitamins do. Iron-containing vitamins are the most toxic.

[Table 9.2](#) lists the food sources for several nutrients.

Vitamin A

Vitamin A (retinol) is derived from animal fats such as those found in dairy products, eggs, meat, liver, and fish liver oils. It is also derived from carotenes, which are found in plants (green and

yellow vegetables, yellow fruits). Therefore, vitamin A is an exogenous substance for humans because it must be obtained from either plant or animal foods. There are more than 600 naturally occurring carotenoid compounds in plant-based foods. Of these, 40 to 50 occur commonly in the human diet. Beta carotene is the most prevalent of these, followed by alpha carotene and cryptoxanthin. These are known as *provitamin A carotenoids* because they are all metabolized to various forms of vitamin A in the body.

Mechanism of Action and Drug Effects

Vitamin A is essential for night vision and for normal vision because it is part of one of the major retinal pigments called **rhodopsin**. Beta carotene is metabolized in the body to retinal (retinaldehyde), and some of this retinal is reduced to the alcohol compound known as *retinol*. Retinol is involved in the maintenance of the integrity of mucosal and epithelial surfaces as well as cholesterol and steroid synthesis. The remainder of the retinal may be oxidized to the carboxylic acid compound, retinoic acid. Unlike retinal, retinoic acid has no direct role in vision, but it is essential for normal cell growth and differentiation and for the development of the physical shapes of the body's many parts—a process known as *morphogenesis*. It is also involved in the growth and development of bones and teeth and in other body processes, including reproduction, integrity of mucosal and epithelial surfaces, and cholesterol and steroid synthesis.

Indications

Supplements of vitamin A may be used to satisfy normal body requirements or an increased demand such as in infants and in pregnant and nursing women. A normal diet usually provides adequate amounts of vitamin A, but in cases of excessive need or inadequate dietary intake, vitamin A supplementation is indicated. Symptoms of vitamin A deficiency include night blindness, xerophthalmia, keratomalacia (softening of the cornea), hyperkeratosis of both the stratum corneum (outermost layer of the skin) and the sclera (outermost layer of the eyeball), reduced infant growth, generalized weakness, and increased susceptibility of mucous membranes to infection. Vitamin A–related compounds, such as isotretinoin, are also used to treat various skin conditions, including acne, psoriasis, and keratosis follicularis.

Contraindications

Contraindications to vitamin A supplementation include known allergy to the individual vitamin product; known current state of hypervitaminosis; and excessive supplementation beyond recommended guidelines, especially in oral malabsorption syndromes. Vitamin A is considered highly teratogenic in pregnancy, particularly in the first 8 weeks, with daily intake more than 10 000 units (Rosenbloom, 2014).

Adverse Effects

There are minimal acute adverse effects associated with normal vitamin A ingestion. Only after long-term excessive ingestion of vitamin A do symptoms appear. Adverse effects are usually noticed in bones, mucous membranes, the liver, and the skin. Table 9.3 lists some of the symptoms of long-term excessive ingestion of vitamin A.

TABLE 9.3 Vitamin A: Adverse Effects

Body System	Adverse Effects
Central nervous	Headache, increased intracranial pressure, lethargy, malaise
Gastrointestinal	Nausea, vomiting, anorexia, abdominal pain, jaundice
Integumentary	Dry skin, pruritus, increased pigmentation, night sweats
Metabolic	Hypomenorrhea, hypercalcemia
Musculoskeletal	Arthralgia, reduced growth

Toxicity and Management of Overdose. The major toxic effects of vitamin A result from ingestion of excessive amounts, which occurs most commonly in children. A few hours after administration of an excess dose of vitamin A, irritability, drowsiness, vertigo, delirium, coma, vomiting, or diarrhea may occur. In infants, excessive amounts of vitamin A can cause an increase in intracranial pressure, resulting in symptoms such as bulging fontanelles, headache, papilledema, exophthalmos (bulging eyeballs), and visual disturbances. Papilledema is the presence of edematous fluid, often including blood, in the optic disc. This is the portion of the eye in the back of the retina, where nerve fibres converge to form the optic nerve. Over several weeks, a generalized peeling of the skin and erythema (skin reddening) may occur. These symptoms seem to disappear a few days after discontinuation of the drug, which is the only treatment necessary in situations of overdose.

Interactions

Vitamin A is absorbed less when used together with lubricant laxatives and cholestyramine. In addition, the concurrent use of isotretinoin and vitamin A supplementation can result in additive effects and possible toxicity.

Dosages

For dosage information on vitamin A, refer to the table on p. 115.

DRUG PROFILE

There are three forms of vitamin A: retinol, retinyl palmitate, and retinyl acetate. Medications containing vitamin A may require a prescription, but many over-the-counter products, such as vitamin A–containing multivitamins, are also available. All vitamin A products are safe to use during pregnancy.

vitamin A

Vitamin A, also known as *retinol*, *retinyl palmitate*, and *retinyl acetate*, is available in a variety of oral forms. Doses for vitamin A are expressed as *retinol activity equivalents* (RAEs). One RAE is approximately equal to the following:

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	N/A	4 hr	50–100 days	Unknown

Dosages

Selected Vitamins*

Drug	Pharmacological Class	Usual Dosage Range	Indications/Uses
Vitamin D–Active Compounds			
calcifediol	Fat-soluble	<i>Adults and children</i> PO: 50 mcg once daily	Hypocalcemia in patients receiving hemodialysis
calcitriol	Fat-soluble	<i>Adults and children 6 yr and older</i> PO/IV: 0.25–1 mcg/day	Hypoparathyroidism; hypocalcemia in patients receiving hemodialysis
cholecalciferol (vitamin D ₃)	Fat-soluble	<i>Adults and children older than 9 yr</i> 600–800 units/day (max 4 000 units/day) <i>Children 4–8 yr</i> 600 units/day (max 3 000 units/day) <i>Children aged 0–4 yrs</i> 400–600 units/day (max 1 000–3 000/day)	Vitamin D deficiency
Vitamin B–Active Compounds			
vitamin B ₁ (thiamine)	Water-soluble, B complex group	<i>Adults</i> 100 mg/day until normal dietary intake is established <i>Children</i> 5–30 mg/day × 30 days	Alcohol-induced deficiency Beriberi
vitamin B ₂ (riboflavin)	Water-soluble, B complex group	<i>Adults</i> PO: 5–30 mg/day <i>Children</i> 3–10 mg/day	Deficiency
vitamin B ₃ (niacin, niacinamide)	Water-soluble, B complex group	<i>Adults</i> PO: 1.5–6 g/day 300–500 mg/day <i>Children</i> IV: Up to 300 mg/day	Dyslipidemia Pellagra (deficiency) Deficiency
vitamin B ₆	Water-soluble, B complex group	<i>Adults</i> PO/IV: 2.5–10 mg/day <i>Children</i> PO/IV: 5–25 mg/day × 3 wk, then give multivitamin product <i>Adults</i> PO/IV: 100–200 mg/day <i>Children</i> PO: 100–200 mg/kg/day	Deficiency Drug-induced neuritis (e.g., isoniazid for tuberculosis) Anemia
vitamin B ₁₂ (cyanocobalamin)	Water-soluble, B complex group	<i>Adults and children</i> IM/Subcut: 100 mcg/mo PO: 50–100 mcg/day	Deficiency; anemia
Vitamins A, C, E, and K			
vitamin A	Fat-soluble	<i>Adults</i> 100,000 units/day IM × 3 days then 50,000 units/day IM for 2 weeks (deficiency) <i>Children 1–18 yr</i> PO: 30–3 000 mcg RAE/day	Deficiency
vitamin C (ascorbic acid)	Water-soluble	<i>Adults</i> PO/IV/IM/SC: 100–250 mg daily, bid × 3 wk <i>Children</i> PO/IV: 100–300 mg/day	Deficiency (scurvy)
vitamin E	Fat-soluble	<i>Adults</i> PO: 60–75 units/day	Deficiency
vitamin K (phytonadione)	Fat-soluble	<i>Adults</i> IM/Subcut: 2.5–10 mg single dose For reversal of warfarin, the ORAL route is preferred in non-bleeding patients depending on their INR (usual dose is 1-5mg PO) <i>Infants and children</i> IM/Subcut: 2.5–10 mg single dose; may repeat in 4–6 hr <i>Infants</i> IM/Subcut: 1 mg single dose	Deficiency; warfarin-induced hypoprothrombinemia Hemorrhagic disease of newborn

*Adequate dietary intake is always preferred over supplementation to prevent vitamin deficiencies.

- 1 mcg of retinol (either dietary or supplemental)
- 2 mcg of supplemental β -carotene
- 12 mcg of dietary β -carotene
- 24 mcg of dietary carotenoids

Vitamin D

Vitamin D, also called the *sunshine vitamin*, is responsible for the proper utilization of calcium and phosphorus in the body. The two most important members of the vitamin D family are vitamin D₂ (ergocalciferol) and vitamin D₃ (cholecalciferol). They have different sites of origin but similar functions in the body. Ergocalciferol is plant derived and is therefore obtained through dietary sources. The natural form of vitamin D produced in the skin by ultraviolet irradiation from the sun is chemically known as 7-dehydrocholesterol. It is more commonly referred to as *cholecalciferol*. This endogenous synthesis of vitamin D₃ usually produces sufficient amounts to meet daily requirements. Vitamin D is obtained through both endogenous synthesis and consumption of vitamin D₂-containing foods such as fish oils, salmon, sardines, and herring; fortified milk, bread, and cereals; and animal livers, tuna fish, eggs, and butter. Normal serum levels are 50 nmol/L.

Mechanism of Action and Drug Effects

The basic function of vitamin D is to regulate the absorption and subsequent utilization of calcium and phosphorus. It is also necessary for the normal calcification of bone. Vitamin D, in coordination with parathyroid hormone and calcitonin, regulates serum calcium levels by increasing calcium absorption from the small intestine and extracting calcium from the bone. Ergocalciferol and cholecalciferol are inactive and require transformation into active metabolites for biological activity. Both vitamin D₂ and vitamin D₃ are biotransformed in the liver by the actions of the parathyroid hormone. The resulting compound, calcifediol, is then transported to the kidney, where it is converted to calcitriol, which is believed to be the most physiologically active form of vitamin D. Calcitriol promotes the intestinal absorption of calcium and phosphorus and the deposition of calcium and phosphorus into the structure of teeth and bones.

The drug effects of vitamin D are similar to those of vitamin A and essentially all vitamin and mineral compounds. It is used as a supplement to satisfy normal daily requirements or an increased demand, as in infants and in pregnant and nursing women.

Indications

Vitamin D can be used either to supplement dietary intake of vitamin D or to treat a deficiency of vitamin D. When used to supplement dietary intake, it is given prophylactically to prevent deficiency-related problems, and it is recommended for breastfed infants. Vitamin D may also be used to treat and correct the results of a long-term deficiency that leads to such conditions as infantile rickets, tetany (involuntary sustained muscular contractions), and osteomalacia (softening of bones). **Rickets** is specifically a vitamin D deficiency state. Symptoms include soft, pliable bones, which causes deformities such as bowlegs and knock-knees; nodular enlargement on the ends and sides of the bones; muscle pain; enlarged skull; chest deformities; spinal curvature; enlargement of the liver and

TABLE 9.4 Vitamin D: Adverse Effects

Body System	Adverse Effects
Cardiovascular	Hypertension, dysrhythmias
Central nervous	Fatigue, weakness, drowsiness, headache
Gastrointestinal	Nausea, vomiting, anorexia, cramps, metallic taste, dry mouth, constipation
Genitourinary	Polyuria, albuminuria, increased blood urea nitrogen level
Musculoskeletal	Decreased bone growth, bone pain, muscle pain

spleen; profuse sweating; and general tenderness of the body when touched. Vitamin D can also help promote the absorption of phosphorus and calcium. For this reason, its use is important in preventing osteoporosis. Because of the role of vitamin D in the regulation of calcium and phosphorus, it may be used to correct deficiencies of these two elements. Other uses include dietary supplementation and treatment of osteodystrophy, hypocalcemia, hypoparathyroidism, pseudohypoparathyroidism, and hypophosphatemia. Many patients have vitamin D deficiency, and it is common to see doses of 1 000 to 2 000 or more units daily prescribed.

There were some early indications that maintaining adequate levels of vitamin D may have a protective effect and lower the risk of developing multiple sclerosis. However, there have been no current, evidence-informed studies to support this theory.

Contraindications

Contraindications to vitamin D products include known allergy to the product, hypercalcemia, kidney dysfunction, kidney stones, and hyperphosphatemia.

Adverse Effects

Few acute adverse effects are associated with normal vitamin D ingestion. Only after long-term excessive ingestion of vitamin D do symptoms appear. Such effects are usually noticed in the GI tract or the central nervous system (CNS) and are listed in [Table 9.4](#).

Toxicity and Management of Overdose. The major toxic effects from ingesting excessive amounts of vitamin D occur most commonly in children. Discontinuation of vitamin D and reduced calcium intake reverse the toxic state. Toxicity occurs because vitamin D is fat-soluble and is stored in the body's fat supply. The amount of vitamin D considered to be toxic varies considerably among individuals. In adults, a dose of 50 000 IU per day of vitamin D can eventually increase blood levels to more than 374 nmol/L; at these concentrations, abnormal levels of calcium and phosphorus can also build up in the blood. However, 10 000 to 14 000 units daily have not produced toxic effects.

The toxic effects of vitamin D are those associated with hypertension, such as weakness, fatigue, headache, anorexia, dry mouth, metallic taste, nausea, vomiting, ataxia, and bone pain. If not recognized and treated, these symptoms can progress to impairment of kidney function and osteoporosis.

Interactions

Reduced absorption of vitamin D occurs with the concurrent use of lubricant laxatives and cholestyramine.

Dosages

For dosage information on vitamin D, refer to the table on p. 115.

DRUG PROFILES

vitamin D

There are four forms of vitamin D: calcifediol, calcitriol, dihydrotachysterol, and ergocalciferol. Vitamin D is available in over-the-counter preparations—such as multivitamin products—or by prescription. Vitamin D is considered safe to use during pregnancy as long as the patient is not dosed at higher levels than recommended.

calcitriol

Calcitriol (Rocaltrol®), a steroid hormone, is the 1,25-dihydroxylated form of cholecalciferol (vitamin D₃). It is a vitamin-D analogue used for the management of hypocalcemia in patients with chronic kidney failure, on dialysis, and for the management of secondary hyperparathyroidism in patients not yet on dialysis. Calcitriol is also used in the treatment of hypoparathyroidism and pseudohypoparathyroidism, vitamin D-dependent rickets, hypophosphatemia, and hypocalcemia in premature infants. Calcitriol is available for oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Less than 3 hr	3–6 hr	3–6 hr	3–5 days

dihydrotachysterol

Dihydrotachysterol is a vitamin-D analogue that is administered orally, once daily, for the treatment of any of the previously mentioned conditions. It is available orally in combination with calcium carbonate.

ergocalciferol

Ergocalciferol (Osto-D₂®) is vitamin D₂. It is indicated for use in patients with GI, liver, or biliary disease associated with malabsorption of vitamin-D analogues. It is available orally.

PHARMACOKINETICS (ERGOCALCIFEROL, VITAMIN D₂)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	30 days	Unknown	19 days	Months to years

Vitamin E

Four biologically active chemicals, called **tocopherols** (alpha [α], beta [β], gamma [γ], and delta [δ]), make up the vitamin E compounds. Alpha-tocopherol is the most biologically active, natural form of vitamin E and can come from plant and animal sources.

Mechanism of Action and Drug Effects

Vitamin E is a powerful biological antioxidant and an essential component of the diet. Its exact nutritional function has not been fully demonstrated. The only recognized significant

TABLE 9.5 Vitamin E: Adverse Effects

Body System	Adverse Effects
Central nervous	Fatigue, headache, blurred vision
Gastrointestinal	Nausea, diarrhea, flatulence
Genitourinary	Increased blood urea nitrogen level
Musculoskeletal	Weakness

deficiency syndrome for vitamin E occurs in premature infants. In this situation, vitamin E deficiency may result in irritability, edema, thrombosis, and hemolytic anemia.

The drug effects of vitamin E are not as well defined as those of the other fat-soluble vitamins. It is believed to protect polyunsaturated fatty acids, a component of cellular membranes. It has also been shown to hinder the deterioration of substances such as vitamin A and ascorbic acid (vitamin C), two substances that are highly oxygen sensitive and readily oxidized; thus, it acts as an antioxidant.

Indications

Vitamin E is most commonly used as a dietary supplement to augment current daily intake or to treat a deficiency. Premature infants are at greatest risk of complications from vitamin E deficiency. Vitamin E has received much attention for its function as an antioxidant. Free radical damage contributes to the early stages of atherosclerosis and may also contribute to cancer, heart disease, and numerous other chronic diseases. Early studies such as the Nurses' Health Study showed promise for vitamin E's role as a scavenger for the damaging free radicals, with beneficial effects for patients with cancer, heart disease, Alzheimer's disease, premenstrual syndrome, and sexual dysfunction. Results from the Heart Outcomes Prevention Evaluation (HOPE) trial also showed no benefit of 4 years of vitamin E supplementation among the 9 500 men and women already diagnosed with heart disease or at high potential for it. In fact, when the HOPE trial was extended for an additional 4 years, researchers found a higher risk of heart failure in those subjects. [The Heart and Stroke Foundation \(2019\)](#) recommends a healthy diet that includes vitamin E (e.g., pecans, walnuts, almonds) (<https://www.heartandstroke.ca/get-healthy/healthy-eating/fats-and-oils>). As well, vitamin E supplement use has no immediate or long-term effects on cancer risk ([Chan, 2015](#)).

Free radicals can also damage collagen and cause skin dryness, fine lines, and wrinkles. Vitamin E is available in many skin creams and ointments; it is thought to provide protection against ultraviolet radiation.

Contraindications

Contraindications for vitamin E include known allergy to a specific vitamin E product. There are currently no approved injectable forms of this vitamin.

Adverse Effects

Few acute adverse effects are associated with normal vitamin E ingestion, because it is relatively nontoxic. Adverse effects are usually noticed in the GI tract or CNS and are listed in [Table 9.5](#).

Dosages

For dosage information on vitamin E, refer to the table on p. 115.

DRUG PROFILE

vitamin E

Vitamin E is available as an over-the-counter medication. It has four forms: alpha (α), beta (β), gamma (γ), and delta (δ) tocopherol. It is available in many multivitamin preparations and is also available by prescription. Vitamin E products are usually contraindicated only in cases of known drug allergy. Vitamin E (AquaSol E[®]) activity is generally expressed in US Pharmacopeia (USP) or international units. It is available for oral and injection use.

Vitamin K

Vitamin K is the last of the four fat-soluble vitamins (A, D, E, and K). There are three types of vitamin K: phytonadione (vitamin K₁), menaquinone (vitamin K₂), and menadione (vitamin K₃). The body does not store large amounts of vitamin K; however, vitamin K₂ is synthesized by the intestinal flora, which provides an endogenous supply. Vitamin K is essential for the synthesis of blood coagulation factors, which takes place in the liver. Vitamin K–dependent blood coagulation factors are factors II, VII, IX, and X. Other names for these clotting factors are as follows: factor II (prothrombin), factor VII (proconvertin), factor IX (Christmas factor), and factor X (Stuart-Prower factor). Minimum daily requirements have been estimated at 1 to 5 mcg/kg for infants and 0.03 mcg/kg for adults. There is no commercially available oral formulation of vitamin K₁; however, the injectable formulation has been used orally. It is usually administered by intramuscular or subcutaneous route, but the intravenous route can be used cautiously.

Vitamin K also plays a role in converting osteocalcin, a non-collagen protein found in the bone, into its active form. Osteocalcin, once activated, serves to anchor calcium into place within the bone.

Mechanism of Action and Drug Effects

Vitamin K activity is essential for effective blood clotting because, as noted earlier, it facilitates the liver biosynthesis of factors II, VII, IX, and X. Vitamin K deficiency results in coagulation disorders caused by hypoprothrombinemia. Coagulation defects affecting these clotting factors can be corrected with administration of vitamin K. Vitamin K deficiency is rare because intestinal flora is normally able to synthesize sufficient amounts. If a deficiency develops, it can be corrected with vitamin K supplementation.

Indications

Vitamin K is indicated for dietary supplementation and for treatment of deficiency states. Although rare, deficiency states can develop with inadequate dietary intake or inhibition

TABLE 9.6 Vitamin K: Adverse Effects

Body System	Adverse Effects
Central nervous	Headache, brain damage (large doses)
Gastrointestinal	Nausea, decreased liver enzyme levels
Hematological	Hemolytic anemia, hemoglobinuria, hyperbilirubinemia
Integumentary	Rash, urticaria

of the intestinal flora resulting from the administration of broad-spectrum antibiotics. Deficiency states can also be seen in newborns because of malabsorption attributable to inadequate amounts of bile. For this reason, infants born in hospitals are often given a prophylactic intramuscular dose of vitamin K on arrival to the nursery. Vitamin K may also be used to reverse excessive anti-coagulation if the patient has evidence of bleeding (as measured by the international normalized ratio [INR]).

Vitamin K deficiency can also result from the administration and pharmacological action of the oral anticoagulant warfarin sodium (see [Chapter 27](#)). Warfarin sodium's anti-coagulant effects occur by inhibiting vitamin K–dependent clotting factors II, VII, IX, and X in the liver. Administration of vitamin K overrides the mechanism by which the anticoagulant inhibits production of vitamin K–dependent clotting factors. Thus, vitamin K can be used to reverse the effects of warfarin sodium. It is important to note that when vitamin K is used in this manner, the patient becomes unresponsive to warfarin sodium for approximately 1 week after vitamin K administration. When vitamin K₁ is reduced, it can lead to inadequate mineralization of the bone due to diminished functioning of osteocalcin. Osteoporosis increases one's risk of fracture. It has been shown that the greater the deficiency in vitamin K, the greater the severity of the fracture.

Contraindications

The only usual contraindication to treatment with vitamin K is known drug allergy.

Adverse Effects

Vitamin K is relatively nontoxic and thus causes minimal adverse effects. Severe reactions limited to hypersensitivity or anaphylaxis have occurred rarely, during or immediately after intravenous administration. Adverse effects usually result from injection-site reactions and hypersensitivity. See [Table 9.6](#) for a list of such major effects by body system.

Toxicity and Management of Overdose. Toxicity is limited primarily to use in the newborn. Hemolysis of red blood cells (RBCs) can occur, especially in infants with low levels of glucose-6-phosphate dehydrogenase (G6PD). In severe cases, replacement with blood products may be indicated.

Dosages

For dosage information on vitamin K, refer to the table on p. 115.

DRUG PROFILE

The most commonly used form of vitamin K is phytonadione (vitamin K₁), which is available by prescription, only in parenteral form. Menadione (vitamin K₃) is not available in Canada and is contraindicated in patients with a known hypersensitivity, in patients who are in the last few weeks of pregnancy, and in patients with severe liver disease. Vitamin K must be used with caution in patients taking warfarin sodium.

vitamin K₁

Vitamin K₁ (phytonadione) is available in injectable form and is usually administered by the intramuscular or subcutaneous route. Because of its potential to cause anaphylaxis (due to the formulation), for intravenous use it is usually diluted and given over 30 to 60 minutes. When used to reverse the effects of warfarin sodium, Vitamin K is given IV and not intramuscularly.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	1–2 hr	12–14 hr	1.2 hr	24 hr
PO	6–10 hours	24–48 hours	10 hrs (+/– 6hrs)	12–24hrs

Water-Soluble Vitamins

The water-soluble vitamins include the vitamin B complex and vitamin C (ascorbic acid). They are present in a variety of plant and animal food sources. The vitamin B complex is a group of 10 vitamins that are often found together in food, although they are chemically dissimilar and have different metabolic functions. Because the B vitamins were originally isolated from the same sources, they were grouped together as B-complex vitamins. Vitamin C (ascorbic acid), the other principal water-soluble vitamin, is concentrated in citrus fruits and is not classified as part of the B complex. The numeric subscripts associated with the various B vitamins reflect the order in which they were discovered. In clinical practice, some B vitamins are more often referred to by their common name, whereas others are more often referred to by their numeric designation.

For example, *vitamin B₁₂* is used more often in clinical practice than the corresponding common name, *cyanocobalamin*. However, *folic acid* is rarely referred to as *vitamin B₉*, although this would also be correct. The most commonly used B-complex vitamins, as well as vitamin C, are listed in [Table 9.1](#). Folic acid (vitamin B₉) has a special role in hematopoiesis and therefore is described further in [Chapter 55](#).

Water-soluble vitamins are a chemically diverse group sharing only the characteristic of being dissolvable in water. Like fat-soluble vitamins, they act primarily as coenzymes or oxidation-reduction agents in important metabolic pathways. Unlike fat-soluble vitamins, water-soluble vitamins are not stored in the body in appreciable amounts. Their water-soluble properties promote urinary excretion and reduce their half-life in the body. Therefore, dietary intake must be adequate and regular or deficiency states will develop. The body excretes what it does not need, which makes toxic reactions to water-soluble vitamins rare.

Vitamin B₁

A deficiency of vitamin B₁ (thiamine) results in the classic disease **beriberi** or Wernicke's encephalopathy (cerebral beriberi). Common findings in beriberi include brain lesions, polyneuropathy of peripheral nerves, serous effusions (abnormal collections of fluids in body tissues), and cardiac anatomical changes. Vitamin deficiency can result from poor diet, extended fever, hyperthyroidism, liver disease, alcoholism, malabsorption, and pregnancy and breastfeeding. Normal serum levels are 0.75–222 nmol/L.

Mechanism of Action and Drug Effects

Vitamin B₁ (thiamine) is an essential precursor for the formation of thiamine pyrophosphate. When thiamine combines with adenosine triphosphate (ATP), the result is thiamine pyrophosphate coenzyme. This is required for the citric acid cycle (Krebs cycle), a major part of carbohydrate metabolism, as well as several other metabolic pathways. In addition, thiamine plays a key role in the integrity of the peripheral nervous system, cardiovascular system, and GI tract.

Indications

The essential role of thiamine in many metabolic pathways makes it useful in treating a variety of metabolic disorders. These include subacute necrotizing encephalomyelopathy, maple syrup urine disease, and lactic acidosis associated with pyruvate carboxylase enzyme deficiency and hyper-β-alaninemia. Some of the deficiency states treated by thiamine are beriberi, Wernicke's encephalopathy syndrome, peripheral neuritis associated with **pellagra** (niacin deficiency), and neuritis of pregnancy. Thiamine is used as a dietary supplement to prevent or treat deficiency in cases of malabsorption, such as that induced by alcoholism, cirrhosis, or GI disease. Other situations in which thiamine may have therapeutic value are poor appetite, ulcerative colitis, chronic diarrhea, and cerebellar syndrome or ataxia (inadequate muscular coordination). Although it has been suggested, studies do not support the use of oral vitamin B as an insect repellent.

Contraindications

The only usual contraindication to any of the B-complex vitamins is known allergy to a specific vitamin product.

Adverse Effects

Adverse effects are rare but include hypersensitivity reactions, nausea, restlessness, pulmonary edema, pruritus, urticaria, weakness, sweating, angioedema, cyanosis, and cardiovascular collapse. Administration by intramuscular injection can produce local tenderness, and intravenous injections can produce anaphylaxis.

Interactions

Thiamine is incompatible with alkaline- and sulfite-containing solutions.

Dosages

For dosage information on vitamin B₁, refer to the table on p. 115.

DRUG PROFILE

thiamine

Thiamine is contraindicated in individuals with a known hypersensitivity to it. It is available for both oral (in combination) and parenteral use. It is safe to use during pregnancy.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Unknown	1–2 hr	1.2 hr	24 hr

Vitamin B₂

A deficiency of vitamin B₂ (riboflavin) results in cutaneous, oral, and corneal changes that include cheilosis (chapped or fissured lips), seborrheic dermatitis, and keratitis.

Mechanism of Action and Drug Effects

Riboflavin serves several important functions in the body. Riboflavin is converted into two coenzymes (flavin mononucleotide and flavin adenine dinucleotide) that are essential for tissue respiration. Riboflavin also plays an important part in carbohydrate catabolism. Another B vitamin, vitamin B₆ (pyridoxine), requires riboflavin for activation. Riboflavin is also needed to convert tryptophan into niacin and to maintain erythrocyte integrity. Deficiency is rare and does not usually occur in healthy people.

Indications

Riboflavin is used primarily as a dietary supplement and for treatment of deficiency states. Patients who may experience riboflavin deficiency include those with long-standing infections, liver disease, alcoholism, or malignancy and those taking probenecid. Riboflavin supplementation may also be beneficial in the treatment of microcytic anemia; acne; migraine headache; congenital methemoglobinemia (presence in the blood of an abnormal, nonfunctional hemoglobin pigment); muscle cramps; and Gopalan's syndrome, a symptom of suspected riboflavin (and possibly pantothenic acid [vitamin B₅]) deficiency that involves a sensation of tingling in the extremities (for this reason, it is also called *burning feet syndrome*).

Contraindications

The only usual contraindication to riboflavin is known allergy to a given vitamin product.

Adverse Effects

Riboflavin is a safe and effective vitamin; to date, no adverse effects or toxic effects have been reported. In large doses, riboflavin will discolor urine to yellow–orange.

Dosages

For dosage information on riboflavin, refer to the table on p. 115.

DRUG PROFILE

riboflavin

Riboflavin (vitamin B₂) is needed for normal respiratory reactions. It is a safe, nontoxic water-soluble vitamin with almost no adverse effects. It is available for oral and parenteral use. It is safe to use during pregnancy.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Unknown	Unknown	66–84 min	24 hr

Vitamin B₃

The body is able to produce a small amount of vitamin B₃ (niacin) from dietary tryptophan, an essential amino acid occurring in dietary proteins and some commercially available nutritional supplements. A dietary deficiency of niacin will produce the classic symptoms known as *pellagra*. Symptoms of pellagra include various psychotic disorders; neurasthenic syndrome; crust- ing, erythema, and desquamation of the skin; scaly dermatitis; inflammation of the oral, vaginal, and urethral mucosa, including glossitis (inflamed tongue); and diarrhea or bloody diarrhea.

Mechanism of Action and Drug Effects

The metabolic actions of niacin (vitamin B₃) are not because of niacin in the ingested form but rather its metabolic product, nicotinamide. Nicotinamide is required for numerous metabolic reactions, including those involved in carbohydrate, protein, purine, and lipid metabolism, as well as tissue respiration (Fig. 9.1). A key example involves two compounds, nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP), both of which are necessary for the carbohydrate pathway known as *glycogenolysis* (the breakdown of stored glycogen to usable glucose). The parent compound, niacin, also has a pharmacological role as an antilipemic drug (see Chapter 28). The doses of niacin required for its antilipemic effect are substantially higher than those required for the nutritional and metabolic effects.

Indications

Niacin is indicated for the prevention and treatment of pellagra, a condition caused by a deficiency of vitamin B₃ that is most commonly the result of malabsorption. It is also used for management of certain types of dyslipidemia (see Chapter 28). Niacin also has a beneficial effect in peripheral vascular disease.

Contraindications

Niacin, unlike certain other B-complex vitamins, has additional contraindications besides drug allergy. These include liver disease, severe hypotension, arterial hemorrhage, and active peptic ulcer disease.

Adverse Effects

The most frequent adverse effects associated with the use of niacin are flushing, pruritus, and GI distress. These usually subside with continued use and are most frequently seen when larger

Fig. 9.1 Niacin, once in the body, is converted to nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP), which are coenzymes needed for many metabolic processes.

TABLE 9.7 Niacin: Adverse Effects

Body System	Adverse Effects
Cardiovascular	Postural hypotension, dysrhythmias
Central nervous	Headache, dizziness, anxiety
Gastrointestinal	Nausea, vomiting, diarrhea, peptic ulcer
Genitourinary	Hyperuricemia
Hepatic	Abnormal liver function tests, hepatitis
Integumentary	Flushing, dry skin, rash, pruritus, keratosis
Metabolic	Decreased glucose tolerance

doses of niacin are used in the treatment of dyslipidemia. [Table 9.7](#) lists adverse effects by body system.

Dosages

For dosage information on niacin, refer to the Drug Profile box below.

DRUG PROFILE

niacin

Niacin is used to treat pellagra, dyslipidemias, and peripheral vascular disease. Its use must be monitored closely in patients who have a history of coronary artery disease, gallbladder disease, jaundice, liver disease, or arterial bleeding. Niacin is available for oral use. It is safe to use during pregnancy.

PHARMACOKINETICS (NIACIN, VITAMIN B₃)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	30–60 min	45 min	45 min	Variable

Vitamin B₆

Vitamin B₆ (pyridoxine) is composed of three compounds: pyridoxine, pyridoxal, and pyridoxamine. Deficiency of vitamin B₆ can lead to a type of anemia known as *sideroblastic anemia*, neurological disturbances, seborrheic dermatitis, cheilosis, and xanthurenic aciduria (formation of xanthine crystals or “stones” in urine). It may also result in convulsions, especially in neonates and infants; hypochromic microcytic anemia; and glossitis (inflamed tongue) and stomatitis (inflamed oral mucosa). Pyridoxine deficiency also affects the peripheral nerves, skin, and mucous membranes. Inadequate intake or poor absorption of pyridoxine causes the development of these conditions.

TABLE 9.8 Pyridoxine (Vitamin B₆): Adverse Effects

Body System	Adverse Effects
Central nervous	Paresthesias, flushing, warmth, headache, lethargy

Vitamin B₆ deficiency may occur as a result of uremia, alcoholism, cirrhosis, hyperthyroidism, malabsorption syndromes, and heart failure. It may also be induced by various drugs, such as isoniazid and hydralazine.

Mechanism of Action and Drug Effects

Pyridoxine, pyridoxal, and pyridoxamine are all converted in erythrocytes to the active coenzyme forms of vitamin B₆, pyridoxal phosphate and pyridoxamine phosphate. These compounds are necessary for many metabolic functions in the body, such as protein, carbohydrate, and lipid utilization. They also play an important part in the conversion of amino acid tryptophan to niacin (vitamin B₃) and the neurotransmitter serotonin. They are essential in the synthesis of gamma-aminobutyric acid (GABA), an inhibitory neurotransmitter in the CNS. They are important in the synthesis of heme and the maintenance of the hematopoietic system. In addition, these substances are necessary for the integrity of the peripheral nerves, skin, and mucous membranes.

Indications

Pyridoxine is used to prevent and treat vitamin B₆ deficiency. This includes deficiency that can result from therapy with certain medications, including isoniazid (for tuberculosis) and hydralazine (for hypertension). Although vitamin B₆ deficiency is rare, it can occur in conditions of inadequate intake or poor absorption of pyridoxine. Seizures that are unresponsive to usual therapy, morning sickness during pregnancy, and metabolic disorders may respond to pyridoxine therapy.

Contraindications

The only usual contraindication to pyridoxine use is known drug allergy.

Adverse Effects

Adverse effects with pyridoxine use are rare and usually do not occur at normal dosages; high dosages and long-term use may produce the adverse effects listed in [Table 9.8](#). Toxic

Fig. 9.2 Cyanocobalamin is a Required Coenzyme for Many Body Processes.

effects are a result of large dosages sustained for several months. Neurotoxicity is the most likely result, but this will subside upon discontinuation of the pyridoxine.

Interactions

Pyridoxine reduces the activity of levodopa; therefore, vitamin formulations containing B₆ must be avoided in patients taking levodopa alone. However, the overwhelming majority of patients with Parkinson's disease take a combination of levodopa and carbidopa, and this interaction does not occur with combination therapy.

Dosages

For dosage information on vitamin B₆, refer to the table on p. 115.

DRUG PROFILE

pyridoxine

Pyridoxine is a water-soluble B-complex vitamin composed of three components: pyridoxine, pyridoxal, and pyridoxamine. It has several vital roles in the body but is primarily responsible for the integrity of peripheral nerves, skin, mucous membranes, and the hematopoietic system. It is available only for oral use. It is safe to use in pregnancy.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Unknown	30–60 min	15–20 days	Unknown

Vitamin B₁₂

Vitamin B₁₂ (cyanocobalamin) is a water-soluble B-complex vitamin that contains cobalt (hence, its name; *cyan-* means “blue”). It is synthesized by microorganisms and is present in the body as two different coenzymes: adenosylcobalamin and methylcobalamin. Cyanocobalamin is a required coenzyme for many metabolic pathways, including fat and carbohydrate metabolism and protein synthesis. It is also required for growth, cell replication, hematopoiesis, and nucleoprotein and myelin synthesis (Fig. 9.2).

Vitamin B₁₂ deficiency results in GI lesions, neurological changes that can result in degenerative CNS lesions, and megaloblastic anemia. The major cause of cyanocobalamin deficiency is malabsorption. Other possible but less likely causes are poor diet, chronic alcoholism, and chronic hemorrhage. Normal serum levels are 118–701 pmol/L.

Mechanism of Action and Drug Effects

Humans must have an exogenous source of cyanocobalamin because it is required for nucleoprotein and myelin synthesis,

Fig. 9.3 Oral absorption of cyanocobalamin requires the presence of intrinsic factor, which is secreted by gastric parietal cells.

cell reproduction, normal growth, and the maintenance of normal erythropoiesis. The cells that have the greatest requirement for vitamin B₁₂ are those that divide rapidly, such as epithelial cells, bone marrow, and myeloid cells.

Reduced sulfhydryl (-SH) groups are required to metabolize fats and carbohydrates and synthesize protein. Cyanocobalamin is involved in maintaining SH groups in the reduced form. Cyanocobalamin deficiency can lead to neurological damage that begins with an inability to produce myelin and is followed by gradual degeneration of the axon and nerve head.

Cyanocobalamin activity is identical to the activity of the antipernicious anemia factor present in liver extract, called *extrinsic factor* or *Castle factor*. The oral absorption of cyanocobalamin (extrinsic factor) requires the presence of intrinsic factor, which is a glycoprotein secreted by gastric parietal cells. A complex is formed between the two factors, which is then absorbed by the intestines. This mechanism is depicted in Fig. 9.3.

Indications

Cyanocobalamin is used to treat deficiency states that develop because of an insufficient intake of the vitamin. It is also included in multivitamin formulations that are used as dietary supplements. Deficiency states are most often the result of malabsorption or poor dietary intake, including consumption of a strict vegetarian diet, because the primary source of cyanocobalamin is foods of animal origin. The most common manifestation of untreated cyanocobalamin deficiency is pernicious anemia. The use of vitamin B₁₂ to treat pernicious anemia and other megaloblastic anemias results in the rapid conversion of megaloblastic bone marrow to normoblastic bone marrow. The preferred route of administration of vitamin B₁₂ in treating megaloblastic anemias is deep intramuscular injection. If not treated, deficiency states can lead to megaloblastic anemia and

TABLE 9.9 Cyanocobalamin: Adverse Effects

Body System	Adverse Effects
Cardiovascular	Heart failure, peripheral vascular thrombosis, pulmonary edema
Central nervous	Flushing, optic nerve atrophy
Gastrointestinal	Diarrhea
Integumentary	Pruritus, rash, pain at injection site
Metabolic	Hypokalemia

irreversible neurological damage. Cyanocobalamin is also useful in the treatment of pernicious anemia caused by an endogenous lack of intrinsic factor.

Contraindications

The only usual contraindication to cyanocobalamin (vitamin B₁₂) is known drug product allergies. This may include sensitivity to the chemical element cobalt, which is part of the structure of cyanocobalamin. Another contraindication is hereditary optic nerve atrophy (Leber's disease).

Adverse Effects

Vitamin B₁₂ is nontoxic, and large doses must be ingested to produce adverse effects, which include itching, transitory diarrhea, and fever. Other adverse effects are listed by body system in Table 9.9.

Interactions

Concurrent use with anticonvulsants, aminoglycoside antibiotics, or long-acting potassium preparations decreases the oral absorption of vitamin B₁₂.

Dosages

For dosage information on vitamin B₁₂, refer to the table on p. 115.

DRUG PROFILE

cyanocobalamin

Cyanocobalamin is a water-soluble B-complex vitamin required for maintenance of body fat and carbohydrate metabolism and protein synthesis. It is also needed for growth, cell replication, blood cell production, and the integrity of normal nerve function. Cyanocobalamin is available both as an over-the-counter preparation and by prescription. Most of the over-the-counter, cyanocobalamin-containing products are multivitamin preparations, whereas many of the prescription cyanocobalamin-containing products contain large doses for parenteral injection and are available by prescription only. Cyanocobalamin is safe for use during pregnancy.

PHARMACOKINETICS (CYANOCOBALAMIN, VITAMIN B₁₂)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Unknown	8–12 hr	6 days	Unknown

Vitamin C

Vitamin C (ascorbic acid) can be used in many therapeutic situations. Prolonged ascorbic acid deficiency results in the nutritional disease **scurvy**, which is characterized by weakness, edema, gingivitis and bleeding gums, loss of teeth, anemia, subcutaneous hemorrhage, bone lesions, delayed healing of soft tissues and bones, and hardening of leg muscles. Scurvy has been recognized for several centuries, especially among sailors. In 1795, the British navy ordered ingestion of limes to prevent the disease.

Mechanism of Action and Drug Effects

Vitamin C is reversibly oxidized to dehydroascorbic acid and acts in oxidation-reduction reactions. It is required for several important metabolic activities, including collagen synthesis and the maintenance of connective tissue; tissue repair; maintenance of bone, teeth, and capillaries; and folic acid metabolism (specifically, the conversion of folic acid into its active metabolite). It is also essential for erythropoiesis. Vitamin C enhances the absorption of iron and is required for the synthesis of lipids, proteins, and steroids. It has also been shown to aid in cellular respiration and resistance to infections.

Indications

Vitamin C is used to treat diseases associated with vitamin C deficiency and as a dietary supplement. It is most beneficial in patients who have larger daily requirements because of pregnancy, lactation, hyperthyroidism, fever, stress, infection, trauma, burns, smoking, exposure to cold temperatures, and the consumption of certain drugs (e.g., estrogens, oral contraceptives, barbiturates, tetracyclines, and salicylates). Because vitamin C is an acid, it can also be used as a urinary acidifier. The benefits of other uses of vitamin C are undocumented. For example, taking vitamin C to prevent or treat the common cold is common practice, but most large, controlled studies have shown that ascorbic acid has little or no value as a prophylactic for the common cold.

Contraindications

The only usual contraindication for vitamin C use is known allergy to a specific vitamin product.

Adverse Effects

Vitamin C is usually nontoxic unless excessive dosages are consumed. Megadoses can produce nausea, vomiting, headache, and abdominal cramps and will acidify the urine, which can result in the formation of cystine, oxalate, and urate kidney stones. Furthermore, individuals who discontinue taking excessive daily doses of ascorbic acid can experience scurvylike symptoms.

Interactions

Ascorbic acid has the potential to interact with many classes of drugs. However, clinical experience concerning interactions is inconclusive. Coadministration with acid-labile drugs such as penicillin G or erythromycin must be avoided. Large doses of vitamin C can acidify the urine but may enhance the excretion of basic (opposite of acidic) drugs and delay the excretion of acidic drugs.

Dosages

For dosage information on vitamin C, refer to the table on p. 115.

DRUG PROFILE

ascorbic acid

Ascorbic acid is a water-soluble vitamin required for the prevention and treatment of scurvy. It is also required for erythropoiesis and the synthesis of lipids, protein, and steroids. It is available both in over-the-counter preparations such as multivitamin products and by prescription. Ascorbic acid is available in many oral dosage forms as well as an injectable form. It is safe to use during pregnancy.

Minerals

Minerals are essential nutrients that are classified as inorganic compounds. They act as building blocks for many body structures and thus are necessary for a variety of physiological functions. They are also needed for intracellular and extracellular body fluid electrolytes. Iron is essential for the production of hemoglobin, which is required for transport of oxygen throughout the body (see [Chapter 55](#)). Minerals are necessary for muscle contraction and nerve transmission and are required components of essential enzymes.

Mineral compounds are composed of metallic and non-metallic elements that are chemically combined with ionic bonds. When these compounds are dissolved in water, they separate (dissociate) into positively charged metallic cations and electrolytes or negatively charged nonmetallic anions and electrolytes ([Fig. 9.4](#)). Ingestion of minerals provides essential elements necessary for vital bodily functions. Elements that are required in larger amounts are called *macrominerals*; those required in smaller amounts are called *microminerals* or *trace elements*. [Table 9.10](#) classifies these nutrient elements as either *macrominerals* or *microminerals* and as *metal* or *nonmetal*.

Calcium

Calcium is the most abundant mineral element in the human body, accounting for approximately 2% of the total body weight. The highest concentration of calcium is in bones and teeth. The efficient absorption of calcium requires adequate amounts of vitamin D. According to [Health Canada \(2019c\)](#), calcium intake of Canadians is inadequate. Approximately one quarter (23%) of children ranging from 4 to 8 years, 44% of boys (9–18 years), and up to 70% of girls (9–18 years) had inadequate intake of calcium. In Canadian adults, depending on the age group, approximately 27–80% of men and 48–87% of women have a high prevalence of inadequate intake of calcium.

Calcium deficiency results in hypocalcemia and can affect many bodily functions. Causes of calcium deficiency include inadequate calcium intake and insufficient vitamin D to facilitate absorption; hypoparathyroidism; and malabsorption syndrome, especially in older individuals. Calcium deficiency-related disorders include infantile rickets, adult osteomalacia, muscle cramps, osteoporosis (especially in postmenopausal females), hypoparathyroidism, and kidney dysfunction. [Table 9.11](#) lists

Fig. 9.4 When Mineral Compounds are Dissolved in Water, they Separate Into Positively Charged Metallic Cations and Electrolytes or Negatively Charged Nonmetallic Anions and Electrolytes.

the possible causes of calcium deficiency and the resulting disorders. Normal serum levels are 2.05 to 2.55 mmol/L.

Mechanism of Action and Drug Effects

Calcium participates in a variety of essential physiological functions and is a building block for body structures. Specifically, it is involved in the proper development and maintenance of teeth and skeletal bones. It is an important catalyst in many of the coagulation pathways in the blood. Calcium acts as a cofactor in clotting reactions involving the intrinsic and extrinsic pathways of thromboplastin. It is also a cofactor in the conversion of prothrombin to thrombin by thromboplastin and the conversion of fibrinogen to fibrin. Calcium is essential for the normal maintenance and function of the nervous, muscular, and skeletal systems and for cell membrane and capillary permeability. It is an important catalyst in many enzymatic reactions, including

TABLE 9.11 Calcium Deficiency: Causes and Disorders

Cause	Disorder
Inadequate intake	Infantile rickets
Insufficient vitamin D	Adult osteomalacia
Hypoparathyroidism	Muscle cramps
Malabsorption syndrome	Osteoporosis

transmission of nerve impulses; contraction of cardiac, smooth, and skeletal muscles; renal function; respiration; and, as noted earlier, blood coagulation. Calcium also plays a regulatory role in the release and storage of neurotransmitters and hormones, in white blood cell (WBC) and hormone activity, in the uptake and binding of amino acids, and in intestinal absorption of cyanocobalamin (vitamin B₁₂) and gastrin secretion.

Indications

Calcium salts are used for the treatment or prevention of calcium depletion in patients for whom dietary measures are inadequate. Calcium requirements are also high for growing children and women who are pregnant or breastfeeding. Many conditions may be associated with calcium deficiency, including the following:

- Achlorhydria
- Alkalosis
- Chronic diarrhea
- Hyperphosphatemia
- Hypoparathyroidism
- Menopause
- Pancreatitis
- Pregnancy and lactation
- Premenstrual syndrome
- Kidney failure
- Sprue
- Steatorrhea
- Vitamin D deficiency

Calcium is also used to treat various manifestations of established deficiency states, including adult osteomalacia, hypoparathyroidism, infantile rickets or tetany, muscle cramps, and osteoporosis. In addition, it is used as a dietary supplement for women during pregnancy and lactation.

More than 12 different selected calcium salts are available for treatment or nutritional supplementation. Each calcium salt contains a different amount of elemental calcium per gram of calcium salt. [Table 9.12](#) lists seven available salts and their associated elemental calcium contents.

Contraindications

Contraindications for administration of exogenous calcium include hypercalcemia, ventricular fibrillation, and known allergy to a specific calcium drug product.

Adverse Effects

Although adverse effects and toxicity are rare, hypercalcemia can occur. Symptoms include anorexia, nausea, vomiting, and

TABLE 9.12 Calcium Salts: Elemental Calcium Content

Calcium Salt	Elemental Calcium Content (Per Gram)
carbonate*	400 mg (9.96 mmol)
chloride	273 mg (13.5 mmol)
acetate	253 mg (6.3 mmol)
citrate*	211 mg (5.26 mmol)
gluconate*	93 mg (2.32 mmol)
gluceptate	82 mg (2.04 mmol)
glubionate	66 mg (1.64 mmol)

*Most commonly used forms for the prevention of osteoporosis.

TABLE 9.13 Calcium Salts: Adverse Effects

Body System	Adverse Effects
Cardiovascular	Hemorrhage, rebound hypertension
Gastrointestinal	Constipation, obstruction, nausea, vomiting, flatulence
Genitourinary	Kidney dysfunction, kidney stones, kidney failure
Metabolic	Hypercalcemia, metabolic alkalosis

constipation. In addition, when calcium salts are administered by intramuscular or subcutaneous injection, mild to severe local reactions, including burning, necrosis and sloughing of tissue, cellulitis, and soft tissue calcification, may occur. Venous irritation may occur with intravenous administration. Other adverse effects associated with both oral and parenteral use of calcium salts are listed in [Table 9.13](#).

Toxicity and Management of Overdose. Long-term excessive calcium intake can result in severe hypercalcemia, which can cause heart irregularities, delirium, and coma. Management of acute hypercalcemia may require hemodialysis, whereas milder cases will respond to discontinuation of calcium intake.

Interactions

Calcium salts will chelate (bind) with tetracyclines and quinolones to produce an insoluble complex. If hypercalcemia is present in patients taking digoxin, serious cardiac dysrhythmias can occur. Calcium may interfere with the absorption of thyroid replacement medications; therefore, it is recommended to take the thyroid medication 2 hours before taking calcium.

Dosages

For dosage information on calcium and other selected minerals, refer to the table on p. 127.

DRUG PROFILE

calcium

Calcium salts are primarily used in the treatment or prevention of calcium depletion in patients in whom dietary measures are inadequate. Many calcium salts are available, all with a different content of elemental calcium per gram of salt.

Calcium is available in both oral and parenteral (injectable) forms. Numerous calcium preparations are available that have different names and provide different dosages. Consult manufacturer instructions for recommended dosages. The pharmacokinetics of calcium is highly variable and depends on individual patient physiology and the characteristics of the specific drug product used. Medication errors and confusion are common with calcium products because the amount of salt is not the same as the amount of elemental calcium. For example, calcium carbonate 1 250 mg is equal to 500 mg of elemental calcium. Depending on the manufacturer, the drug may be profiled as 1 250 mg when the tablet is labelled as 500 mg. Additional confusion occurs with the injectable forms, calcium chloride and calcium gluconate. Calcium chloride provides about three times as much elemental calcium as calcium gluconate, but they are both ordered as 1 g or 1 ampule. Calcium chloride can cause severe problems if it infiltrates from the intravenous line. For that reason, it is recommended that it be diluted or given through a central line if it is given by intravenous push. Adding to the confusion is calcium acetate (acetic acid), which is used not for calcium replacement but to bind phosphate in patients with kidney disease. Calcium products are considered safe to use during pregnancy.

Magnesium

Magnesium is one of the principal cations present in the intracellular fluid. It is an essential part of many enzyme systems associated with energy metabolism. Magnesium deficiency (hypomagnesemia) is usually caused by (1) malabsorption, especially in the presence of high calcium intake; (2) alcoholism; (3) long-term intravenous feeding; (4) diuretic use; and (5) metabolic disorders, including hyperthyroidism and diabetic ketoacidosis. Symptoms associated with hypomagnesemia include cardiovascular disturbances, neuromuscular impairment, and mental health disorders. Dietary intake from vegetables and other foods will usually prevent magnesium deficiency. However, magnesium is required in greater amounts in individuals with diets high in protein-rich foods, calcium, and phosphorus. Normal serum levels are 0.65 to 1.05 mmol/L.

Mechanism of Action and Drug Effects

The precise mechanism for the effects of magnesium has not been fully determined. Magnesium is a known cofactor for many enzyme systems. It is required for muscle contraction and nerve function. Magnesium produces an anticonvulsant effect by inhibiting neuromuscular transmission for selected convulsive states.

Indications

Magnesium is used for treatment of magnesium deficiency and as a nutritional supplement in total parenteral nutrition and multivitamin preparations. It is used as an anticonvulsant in magnesium deficiency-induced seizures; to manage complications of pregnancy, including pre-eclampsia and eclampsia; as a tocolytic drug for inhibition of uterine contractions in premature labour; for treatment of acute nephropathy in children;

for management of various cardiac dysrhythmias; and for short-term treatment of constipation.

Contraindications

Contraindications to magnesium administration include known drug product allergy, heart block, kidney failure, adrenal gland failure (Addison's disease), and hepatitis.

Adverse Effects

Adverse effects of magnesium are due to hypermagnesemia, which results in tendon reflex loss, difficult bowel movements, CNS depression, respiratory distress and heart block, and hypothermia.

Toxicity and Management of Overdose. Toxic effects are extensions of symptoms caused by hypermagnesemia, a major cause of which is the long-term use of magnesium products (especially antacids in patients with kidney dysfunction). Severe hypermagnesemia is treated with intravenous calcium salt, administered intravenously, and possibly the diuretic furosemide.

Interactions

The use of magnesium with neuromuscular blocking agents and CNS depressants produces additive effects.

DRUG PROFILE

magnesium

Magnesium is a mineral that has a variety of dosage forms and uses. It is an essential part of many enzyme systems. When absent or diminished in the body, cardiovascular, neuromuscular, and mental health disorders can occur. Magnesium sulphate is the most common form of magnesium used as a mineral replacement. It is available in injectable form. It is safe to use in pregnancy.

Phosphorus

Phosphorus is widely distributed in foods, and thus a dietary deficiency is rare. Deficiency states are primarily due to malabsorption, extensive diarrhea or vomiting, hyperthyroidism, liver disease, and long-term use of aluminum or calcium antacids. Normal serum levels are 0.74 to 1.52 mmol/L.

Mechanism of Action and Drug Effects

Phosphorus in the form of the phosphate group or anion (PO_4^{3-}) is a required precursor for the synthesis of essential body chemicals and an important building block for body structures. Phosphorus is required as a structural unit for the synthesis of nucleic acid and the adenosine phosphate compounds (adenosine monophosphate [AMP], adenosine diphosphate [ADP], and adenosine triphosphate [ATP]) responsible for cellular energy transfer. It is also necessary for the development and maintenance of the skeletal system and teeth. Bones contain up to 85% of the phosphorus content of the body. In addition, phosphorus is required for the proper utilization of many B-complex vitamins, and it is an essential component of physiological buffering systems.

Dosages

Selected Minerals

Drug	Pharmacological Class	Usual Dosage Range	Indications/ Uses
calcium carbonate (Rolaids®, TUMS®)	Mineral salt	PO: 500 mg 2–4 times daily	Antacid, nutritional-calcium supplementation, hyperphosphatemia associated with chronic kidney failure

Indications

Phosphorus is used for treatment of deficiency states and as a dietary supplement in many multivitamin formulations.

Contraindications

Contraindications to phosphorus or phosphate administration include hyperphosphatemia and hypocalcemia.

Adverse Effects

Adverse effects are usually associated with the use of phosphorus replacement products. These effects include diarrhea, nausea, vomiting, and other GI disturbances. Other adverse effects include confusion, weakness, and breathing difficulties.

Toxicity and Management of Overdose. Toxic reactions to phosphorus are extremely rare and usually occur after ingestion of the pure element.

Interactions

Antacids can reduce the oral absorption of phosphorus.

DRUG PROFILES

phosphorus

Phosphorus is a mineral that is essential to our well-being. It is needed to make energy in the form of ADP and ATP for all bodily processes. Phosphorus is present in a large number of drug formulations and appears as a phosphate salt (PO_4). Phosphorus should be used with caution in patients with kidney impairment.

zinc

The metallic element zinc is often taken orally in the form of the sulphate salt as a mineral supplement. Normally a dietary trace element, zinc plays a crucial role in the enzymatic metabolic reactions involving both proteins and carbohydrates. This makes it especially important for normal tissue growth and repair. It therefore also has a major role in wound repair.

tests such as hemoglobin, hematocrit, WBC and RBC counts, serum albumin, and total protein levels. Assess the patient's dietary intake, dietary patterns, menu planning, grocery shopping/food practices and habits, and ethnocultural influences prior to giving any supplemental therapy. Assess contraindications, cautions, and drug interactions before giving any supplemental therapy. For vitamin A deficiencies, perform a baseline vision assessment, including night vision, and conduct a thorough examination of the skin and mucous membranes and document the findings. Assess for contraindications to vitamin A such as known allergy as well as a current state of excessive supplementation or hypervitaminosis. Additionally, assess for drug interactions with laxatives and cholestyramine leading to possible decreased absorption of the vitamin. Baseline assessment and documentation of level of consciousness, GI functioning and concerns, vision, condition of the skin, and musculoskeletal status are also important due to the adverse effects and signs and symptoms of toxicity associated with overdosage of vitamin A (see the pharmacology discussion and Table 9.3).

For patients who have reduced vitamin D serum levels, perform a baseline assessment of skeletal formation with attention to any deformities. Serum vitamin D (35 to 150 nmol/L) and calcium levels are usually ordered as baseline and then during therapy. It is also important to assess for known contraindications such as kidney dysfunction and hypercalcemia or hyperphosphatemia. Assess for drug interactions with laxatives and cholestyramine leading to possible decreased absorption of the vitamin.

Before vitamin E is administered, assess patients for hypoprothrombinemia because this condition may occur secondary to vitamin E deficiency. Document any baseline bleeding or hematological problems and conduct a thorough skin assessment with attention to skin integrity, presence of any edema, muscle weakness, easy bruising, or bleeding.

The last of the fat-soluble vitamins, vitamin K, is associated with clotting function; therefore, prior to its use, measure and document the patient's prothrombin time, INR, and platelet counts. Assess the skin for bruises, petechiae, and erythema. Examine the gums for gingival bleeding. Assess urine and stool for the presence of blood. Also assess vital signs with attention to blood pressure and pulse rate. If intravenous dosage forms are prescribed, baseline assessment must include vital signs because of the risk of anaphylactic reactions. This is particularly important for vitamin K_1 injection because of an associated higher risk of anaphylaxis. Assessment of liver function is also important. It is critical to patient safety to remember that fat-soluble vitamins are all stored in the body tissue when excessive quantities are consumed and may become toxic if taken in large doses. Assess and document baseline values of vitamin K; normal ranges are 0.29 to 2.64 nmol/L.

Vitamin B_1 (thiamine) hypersensitivity may cause skin rash and wheezing; therefore, document the presence of any allergic reactions to vitamin B compounds. Also document baseline assessment of vital signs. Because it is rare for a deficiency of only one B-complex vitamin to occur, rule out deficiencies of all the B vitamins before treatment begins. The normal vitamin B_1 (thiamine) level is 0.75 nmol/L, and vitamin B_{12} (cyanocobalamin) levels range from 118 to 701 pmol/L. Urinary thiamine

NURSING PROCESS

ASSESSMENT

Before administering vitamins, assess the patient for nutritional disorders by reviewing the results of various laboratory

levels may also be ordered (in adults, urinary thiamine levels of less than 27 mcg/dL indicate deficiency). Vitamin B₁ deficiency may result in Wernicke's encephalopathy (see the pharmacology discussion); thus, there is a need for a thorough mental status assessment. Thoroughly assess the medication order for accuracy and for route of administration. Drug interactions include alkaline and sulfite-containing solutions, so be sure to assess for drugs being administered at the same time. Vitamin B₂ (riboflavin) has no major toxic effects or drug interactions, but assessing for known allergy to any vitamin product is important. Vitamin B₃ (niacin) has several important indications. Assess for contraindications such as liver disease, severe hypotension, and active peptic ulcer disease. With vitamin B₆ (pyridoxine), perform a thorough neurological assessment due to associated neurotoxicity with large dosages. Levodopa is a significant drug interaction to assess for with pyridoxine because the vitamin reduces the action of levodopa. Vitamin B₁₂ (cyanocobalamin) requires thorough assessment of the medication order. Note the route of administration because the preferred route is deep IM injection. Drug interactions to assess for include anticonvulsants, aminoglycoside antibiotics, and long-acting potassium supplements because they decrease the oral absorption of vitamin B₁₂.

Vitamin C (ascorbic acid) is usually well tolerated; however, assess the patient for any history of nutritional deficits or problems with dietary intake as well as any allergies to a specific product. Assess for drug interactions that include acid-labile drugs such as penicillin G or erythromycin. Additionally, it is important to note that large doses of vitamin C may increase the excretion of many basic (opposite of acidic) drugs and delay the excretion of acidic drugs.

With the minerals calcium and magnesium, include in the baseline assessment allergies, nutritional status, use of medications, medical history, contraindications, cautions, and drug interactions. Laboratory studies that may be prescribed include serum calcium (2.05 to 2.55 mmol/L), magnesium (0.65 to 1.05 mmol/L), hemoglobin, hematocrit, and RBC and WBC counts. Calcium interacts with many medications, as described previously, so a thorough assessment of the patient's medication history is important to patient safety. The specific interaction of calcium is that of chelation or binding with the drug and, in this case, it is with levothyroxine, tetracycline and quinolone antibiotics. The chelation then forms an insoluble complex, rendering the antibiotic inactive. Another significant interaction occurs when a patient is hypercalcemic and takes digitalis, with the result of serious cardiac dysrhythmias. If there is a history of cardiac disease, a baseline electrocardiogram recording may be ordered prior to calcium therapy. Because of the various calcium preparations with different names and doses, always thoroughly assess the medication order and be certain that the right product is being given. Also note that the injectable forms of calcium (i.e., calcium chloride and calcium gluconate) may be easily confused, so be cautious. Assess patency of the intravenous site, if intravenous dosage forms are ordered, because infiltrates may lead to severe irritation of the vein and surrounding tissue.

Magnesium is also associated with several drug interactions. Review for potential interactions before drug therapy is initiated, such as with CNS depressants and neuromuscular blocking drugs. Assess the patient's kidney, heart, and liver functioning. It is important to document neurological functioning and grading of deep tendon reflexes prior to giving magnesium. Hyporeflexia may indicate toxicity. It is also important to assess the health care provider's order for completeness and reason for use to fully understand why the drug is being given (e.g., for replacement, antacid, or laxative purposes). In addition, thoroughly assess any order for the use of calcium, magnesium, or zinc within total parenteral nutrition infusions.

◆ NURSING DIAGNOSES

- Inadequate physical mobility resulting from poorly developed muscles from vitamin D or vitamin E deficiency or from fatigue resulting from poor nutrition and vitamin B deficiency
- Inadequate tissue integrity resulting from vitamin C deficiency and subsequent decreased healing
- Potential for injury as a result of possible night blindness or altered vision due to vitamin A deficiency

◆ PLANNING

◆ Goals

- Patient will regain or maintain normal or near-normal physical mobility and musculoskeletal functioning.
- Patient will maintain intact skin and tissue integrity.
- Patient will remain free from injury.

◆ Expected Patient Outcomes

- Patient increases mobility daily with performance of activities of daily living and usual exercise regimen or as prescribed.
- Patient states measures to increase energy, stamina, and strength, such as increase in dietary consumption of well-balanced diet and fluids with vitamin or mineral supplementation.
- Patient states measures to minimize injury and maximize intactness of skin and mucous membranes, such as performing frequent mouth care, keeping skin clean and dry and applying moisturizers as needed, as well as drinking at least 180 to 240 mL of water per day.
- Patient states measures to prevent injury, such as minimizing obstacles in the home setting, removing area or throw rugs, and adding night lights.
- Patient states measures to replace vitamin A deficiencies through replacement therapy and dietary intake, such as increased intake of liver, fish, dairy products, egg yolks, and yellow-orange vegetables and fruits.

◆ IMPLEMENTATION

Before administering vitamin A or any vitamin or supplement, document the patient's dietary intake for the preceding 24 hours. Document any signs and symptoms of hypervitaminosis and hypercarotenemia (excess vitamin A). Vitamin D is available in over-the-counter products (e.g., multivitamins)

or by prescription (10 000 units), but attention to the product prescribed is important to patient safety. Combination intramuscular dosage forms are available for those with GI, liver, biliary, or malabsorptive syndromes. During therapy, advise the patient to report any palpitations or unresolved nausea, vomiting, constipation, or muscle pain. Instruct the patient to take vitamin B₁ (thiamine) as directed. Vitamin B₂ (riboflavin) is not associated with any adverse or toxic effects but it is important to note that in large doses it may turn the urine yellowish-orange. Tell patients to take vitamin B₃ (niacin) with milk or food to decrease GI upset. Niacin is often used for dyslipidemia (see [Chapter 28](#)) and in much larger doses. Vitamin B₆ (pyridoxine) is more commonly used to treat drug-induced B₆ deficiencies. Two examples of this are with the antituberculin drug isoniazid (INH) and the anti-hypertensive drug hydralazine hydrochloride. Vitamin B₁₂ (cyanocobalamin) is administered orally with meals to increase its absorption. Intranasal gel and sublingual tablets are other dosage forms available. If given for megaloblastic anemia, deep IM injection is the preferred route of administration. Give vitamin C (ascorbic acid) orally, and if an oral effervescent form is used, instruct the patient to dissolve it in at least 180 mL of water or juice. If vitamin C is administered for acidification of urine, it is important for the nurse to frequently assess urinary pH.

Various oral calcium products are available and, because of the differences in the amount of elemental calcium they provide (e.g., calcium carbonate 1 250 mg is equal to only 500 mg of elemental calcium), medication errors may occur and confusion may arise about the various dosages available OTC. A list of the various calcium salts available is found in [Table 9.12](#). Instruct the patient to take oral dosage forms of calcium 1 to 3 hours after meals. Injectable dosage forms of calcium may also be confusing. Follow the medication order carefully and check policies and standards regarding infusions (see previous discussion in the pharmacology section and the Preventing Medication Errors box below). Because of problems with venous irritation, give intravenous calcium via an intravenous infusion pump and with proper dilution. Giving intravenous calcium too rapidly may precipitate severe hypercalcemia with subsequent heart irregularities, delirium, and coma. Administer intravenous calcium slowly, as ordered, and within the manufacturer guidelines (e.g., usually less than 1 mL/min). Patients need to remain recumbent for 15 minutes after the infusion to prevent further problems. Should extravasation of the intravenous calcium solution occur, the nurse should discontinue the infusion immediately and leave the IV catheter in place. The prescriber may then order an injection of 1% procaine or other antidotes or fluids to reduce vasospasm at the site and dilute the effects of the calcium on surrounding tissue. However, follow all facility policies and procedural guidelines and manufacturer insert information, as appropriate. In addition, include the appearance of the intravenous site (e.g., erythema, swelling, and any drainage) in the documentation.

PREVENTING MEDICATION ERRORS

All Calcium Forms Are Not the Same!

When calcium is given, it is essential to use the correct form. Calcium chloride has many uses, including treatment of cardiac arrest and hypocalcemic tetany. Both calcium carbonate (Rolaids®, TUMS®) and calcium citrate are used as antacids, and they are also used to treat or prevent calcium deficiency. Be cautious when giving calcium—the different forms are not interchangeable.

Administer magnesium according to manufacturer guidelines and as ordered. Always give intravenous magnesium sulphate cautiously; use an infusion pump, and follow manufacturer guidelines for dosage and dilution concentration. During intravenous magnesium infusion, monitor the patient's ECG and vital signs, and rate patellar (knee-jerk) reflexes. Reduced reflexes are used as an indication of drug-related CNS depressant effects. Central nervous system depression may quickly lead to respiratory or cardiac depression; thus, perform frequent monitoring. Document intravenous magnesium infusion and record each set of vital sign measurements with ratings of reflexes. If there is a decrease in the strength of reflexes or a decrease in respirations to less than 10 breaths per minute, contact the prescriber immediately, stop the infusion, and monitor the patient. Other signs that require immediate attention are confusion, irregular heart rhythm, cramping, unusual fatigue, lightheadedness, and dizziness. Calcium gluconate must be readily accessible for use as an antidote to magnesium toxicity. Administer oral dosage forms of magnesium as ordered and in the exact dosage prescribed. See the Patient Teaching Tips for more information concerning the use of vitamins, minerals, and trace elements.

EVALUATION

In the patient's evaluation, always review whether goals and outcome criteria have been met. Monitor for therapeutic responses and adverse effects of each vitamin or mineral. Therapeutic responses to vitamin A therapy include restoration of normal vision and intact skin; adverse effects of vitamin A include lethargy, headache, nausea, and vomiting (see [Table 9.3](#)). Therapeutic responses to vitamin D include improved bone growth and formation and an intact skeleton, with decreased or no pain compared with baseline musculoskeletal deformity, weakness, and discomfort; adverse effects include hypertension, dysrhythmias, fatigue, weakness, headache, and decreased bone growth (see [Table 9.4](#)). Therapeutic responses to vitamin E include improved muscle strength, improved skin integrity, and α -tocopherol levels within normal limits; adverse effects are listed in [Table 9.5](#). Therapeutic responses to vitamin K include return to normal clotting; adverse effects include headache, nausea, and hemolytic anemia (see [Table 9.6](#)). Therapeutic responses to vitamin B₁ (thiamine) include improved mental status and reduction in confusion. Therapeutic responses to vitamin B₂ (riboflavin) include improved skin integrity, normal vision, improved mental status, and normal RBC, hemoglobin,

and hematocrit. Adverse effects from vitamin B₃ (niacin) are rare, but they are associated with postural hypotension, dysrhythmias, headache, and nausea (see Table 9.7 for complete listing). Vitamin B₆ (pyridoxine) adverse effects include flushing, paresthesias, lethargy, and headache. Vitamin B₁₂ (cyanocobalamin) has the adverse effects of heart failure, flushing, diarrhea, itching, and hypokalemia. Therapeutic responses to vitamin C include improvements in capillary intactness, integrity of the skin and mucous membrane, healing, energy level,

and mental health state. Therapeutic responses to calcium include improved deficiency states. Adverse effects are listed in Table 9.13. Therapeutic effects of magnesium include bolstering of many enzymatic functions in the body with other uses as an anticonvulsant, treatment of pre-eclampsia and eclampsia, and management of various dysrhythmias. Adverse effects include loss of deep tendon reflexes, CNS depression, constipation, respiratory distress, and heart block.

CASE STUDY

Vitamin Supplements

Brian, 49 years of age, was found unconscious in a vacant house and was brought to the emergency department. He had an elevated blood alcohol level and eventually manifested delirium tremens. Now, a week later, he is in stable condition on a medical-surgical unit. He is weak and malnourished, and he cannot remember how he got to the hospital. The nurse is reviewing his medication list and notes that several vitamin supplements are ordered.

1. Based on Brian's history, what vitamin deficiencies are possible?
2. Which vitamin supplement is especially used to treat complications associated with alcoholism? Explain your answer.
3. Brian is receiving large doses of several vitamins, and the nurse is concerned about vitamin toxicities. Which type of vitamin, water-soluble or fat-soluble, carries the risk of toxicities? Explain your answer.
4. Because of Brian's long-term malnourished state, the prescriber is concerned about the condition of his bones and starts Brian on phosphorus and calcium supplementation, along with vitamin D. Explain the rationale behind the addition of vitamin D.

For answers see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

PATIENT TEACHING TIPS

- Educate the patient about the best dietary sources of both water- and fat-soluble vitamins (vitamins A, B, C, D, E, and K), as well as about the best sources of elements and minerals. See Table 9.2 for the nutrient content of select food items.
- Monitor any patient taking vitamins or minerals closely for therapeutic and adverse effects. Encourage patients to monitor self-progress on how well they feel and to note any improvement in the related condition or health status. Encourage intake of fluids with all vitamin and mineral therapy.
- Inform patients who have had a gastrectomy or ileal resection and those with pernicious anemia of the necessity for vitamin B₁₂ injections. In the community, an oral supplementation may be used.
- Educate the patient taking up to 600 mg/day of vitamin C that there may be a slight increase in daily urination and that diarrhea is associated with intake of more than 1 g of vitamin C per day.
- Stress that patients taking calcium therapy and magnesium (see Table 9.10) must take the medication as prescribed and with adequate amounts of fluids.
- Educate the patient about calcium therapy and about food items and drugs that will chelate (or bind) with calcium. For example, calcium binds with tetracycline antibiotics and decreases or negates the effect of the antibiotic.

KEY POINTS

- Over-the-counter use of vitamins and minerals may lead to serious problems and adverse effects and requires careful consideration prior to self-medication. A health care provider may be consulted prior to use if there are any questions or concerns.
- Incorporate the nutritional status of the patient into the collaborative plan of care to provide comprehensive care during vitamin or mineral therapy.
- Provide information about dietary needs and the body's need for vitamins and minerals as part of the patient's health promotion.
- Focus patient education regarding vitamin and mineral replacement on dietary sources of the specific nutrient, drug and food interactions, and adverse effects. Instruct the patient on when it is necessary to contact the health care provider.
- Vitamins and minerals can be dangerous to the patient if given without concern or caution for the patient's overall condition and underlying disease processes.
- Never assume that because the drug is a vitamin or mineral it does not have adverse reactions or toxicity.

EXAMINATION REVIEW QUESTIONS

1. The nurse is administering prescribed calcium to a patient intravenously. Which of the following adverse events should the nurse monitor for if calcium is given too fast?
 - a. Ototoxicity
 - b. Kidney damage
 - c. Tetany
 - d. Cardiac dysrhythmias
2. The nurse is to administer vitamin K to a client. Which of the following laboratory tests should the nurse assess prior to administration?
 - a. Prothrombin time and INR
 - b. Red blood cell and white blood cell counts
 - c. Phosphorus and calcium levels
 - d. Total protein and albumin levels
3. The nurse is caring for a patient who has gastrointestinal malabsorption. Which of the following vitamin deficiencies will the nurse monitor in the patient?
 - a. Vitamin A (retinol)
 - b. Vitamin B₁₂ (cyanocobalamin)
 - c. Vitamin B₆ (pyridoxine)
 - d. Vitamin E (tocopherols)
4. The nurse is performing wound care for a patient with a stage IV pressure ulcer. Which of the following supplements would the nurse understand could assist with wound healing?
 - a. Vitamin K
 - b. Vitamin B₁
 - c. Zinc
 - d. Calcium
5. The nurse is caring for a client with a history of alcoholism. Which of the following vitamins would the nurse expect to be ordered for this patient?
 - a. Vitamin B₁ (thiamine)
 - b. Vitamin B₆ (pyridoxine)
 - c. Vitamin C (ascorbic acid)
 - d. Vitamin A (retinol)
6. The nurse is to administer prescribed vitamin and mineral supplements. Which of the following nursing interventions would be most appropriate during administration of these medications? (Select all that apply.)
 - a. Not administering oral calcium tablets along with oral tetracyclines
 - b. Administering intravenous calcium via a rapid intravenous push infusion
 - c. Monitoring the heart rhythm (ECG) of a patient receiving an intravenous magnesium infusion
 - d. Giving oral niacin with milk or food to decrease gastrointestinal upset
 - e. Monitoring for the formation of kidney stones in patients taking large doses of vitamin C
7. The order reads, "Give vitamin K 0.5 mg IM within 1 hour of birth." The medication is available in a vial that contains 1 mg/0.5 mL. How many millilitres will the nurse draw up for the injection?
8. The nurse is assessing a patient who has been recently admitted to the hospital after living on the streets for over 1 year. The nurse notes that the patient has severely chapped and fissured lips. This could be a sign of which vitamin deficiency?
 - a. Vitamin B₂ (riboflavin)
 - b. Vitamin B₆ (pyridoxine)
 - c. Vitamin C (ascorbic acid)
 - d. Vitamin E (tocopherols)

CRITICAL THINKING ACTIVITIES

1. The nurse is about to administer calcium supplemental therapy to a patient with a history of cardiac disease. What is the most important assessment needed before the nurse gives the drug?
 2. A patient with a stage III pressure ulcer is receiving daily doses of vitamin C and zinc. A new nurse asks the medication nurse, "Why is this patient receiving these two particular supplements?" What is the nurse's best answer?
 3. A patient receiving a magnesium infusion has developed tendon reflex loss, CNS depression, and some respiratory distress. These problems are a result of what condition? What are the nurse's priority actions at this time?
- For answers see** <http://evolve.elsevier.com/Lilley/pharmacology/>.

Principles of Drug Administration

PREPARING FOR DRUG ADMINISTRATION

NOTE: This chapter is designed to illustrate general aspects of drug administration. For detailed instructions, please refer to a nursing fundamentals or skills book.

When giving medications, remember safety measures and correct administration techniques to avoid errors and to ensure optimal drug actions. Keep in mind the following key Rights for drug administration:

1. Right drug
2. Right dose
3. Right time
4. Right route
5. Right patient
6. Right reason

Refer to [Chapter 1](#) for additional Rights 7-10 (Box 1.3). It is important to note that health care professionals must adhere to medication administration Rights as per each province and territory's professional regulatory body. Other things to keep in mind when preparing to give medications are as follows:

- Remember to perform hand hygiene before preparing or giving medications (see [Box 10.1](#)).
- If unsure about a drug or dosage calculation, do not hesitate to double-check with a drug reference or pharmacist. **DO NOT** give a medication if you are unsure about it!
- Be punctual when giving drugs. Some medications must be given at regular intervals to maintain therapeutic blood levels.
- There are a variety of automated dispensing machines—decentralized medication distribution systems—that provide computer-controlled storage, dispensing, and tracking of medications. [Figure 10.1](#) shows one example of a computer-controlled drug-dispensing system. To prevent errors, obtain the drugs for one patient at a time.
- Remember to check the drug at least three times before giving it. The first check is when the medications are removed from the automated dispensing machine, the medication drawer, or whatever system is in place at a given institution. The nurse is responsible for checking medication labels against the transcribed medication order. In [Figure 10.2](#), the nurse is checking the drug against the medication administration record (MAR), after removing the drug from the dispenser drawer. The second check is when preparing the medications for administration. The drug should be checked

before opening the container, and again after opening it. It is recommended that some drugs (e.g., heparin sulphate and insulin) must be checked by two licensed nurses. Some agencies have specific policies regarding the two-nurse, double-check practice for certain medications. Always follow agency policy. The final check occurs at the patient's bedside, just before medications are given. This check also provides the opportunity to teach the patient about the medications.

BOX 10.1 Standard Precautions/Routine Practices

Always adhere to standard precautions/routine practices, including the following:

- Wear clean gloves when there is exposure or potential exposure to blood, body fluids, secretions, excretions, or any items that may contain these substances. Always wash hands immediately when there is direct contact with these substances or any item contaminated with blood, body fluids, secretions, or excretions. Follow agency policy about wearing gloves when giving injections and during medication preparation. Be sure to assess for latex allergies and use nonlatex gloves if indicated.
- Perform hand hygiene after removing gloves and between patient contacts. According to the World Health Organization (2009) and Centers for Disease Control and Prevention, the preferred method of hand decontamination is with an alcohol-based hand rub, but washing with an antimicrobial soap and water is an alternative to the alcohol rub. Use soap and water to wash hands when they are visibly dirty or visibly soiled with blood or other body fluids and after using the toilet.
- Perform hand hygiene in the following circumstances:
 - Before direct contact with patients
 - After contact with blood, body fluids, excretions, mucous membranes, wound dressings, or nonintact skin
 - After contact with a patient's skin (e.g., when taking a pulse or positioning a patient)
 - After removing gloves
- Wear a mask, eye protective gear, and a face shield during any procedure or patient care activity with the potential for splashing or spraying of blood, body fluids, secretions, or excretions. Use of a gown may also be indicated for these situations.
- When administering medications, once the exposure or procedure is completed and exposure is no longer a danger, remove contaminated protective garments or gear and perform hand hygiene.
- Never remove, cap, recap, bend, or break any used needle or needle system. Be sure to discard any disposable syringes and needles in the appropriate puncture-resistant container.

Fig. 10.1 Mobile computer-controlled medication workstation.

Fig. 10.2 Checking the medication against the order on the electronic medication administration record.

- Health care facilities have various means of checking the MAR when a new one is printed, so be sure that you are working from an MAR that has been checked or verified before giving the oral medication. If the patient's MAR has a new drug order on it, the best rule of practice is to double-check that order against the original medication order on the patient's chart.
- Check the expiration date of all medications. Medications used past the expiration date may be less potent or potentially harmful.
- Make sure that drugs that are given together are compatible. For example, bile acid sequestrants and antacids (see [Chapters 28 and 39](#)) must not be given with other drugs because they will interfere with drug absorption and action. Check with a pharmacist if unsure.
- Before administering any medication, check the patient's identification bracelet ([Figure 10.3](#)). If the patient is in an

Fig. 10.3 Always check the patient's identification and allergies before giving medications.

Fig. 10.4 Example of a hospital bar code.

isolation room, follow hospital policy regarding how to check patient identification. Also assess the patient's drug allergies. Some hospitals use a bar code system, shown in [Figure 10.4](#). Accreditation Canada standards require two patient identifiers (name and birthday, or name and account number, according to the facility policy). In some facilities, patient information is in a bar code system that is scanned. Advanced bar code technology allows the nurse to scan her badge, the patient's hospital identification band, and the medication, to assure that the right patient is receiving the correct medication in the correct dose and by the correct route.

- Assess the patient's physical condition prior to administering a medication. This may be focused on a specific system or value (e.g., plasma glucose level prior to the administration of insulin, blood pressure and heart rate prior to the administration of an antihypertensive, or a pain assessment prior to administering an analgesic). The prescriber may provide certain parameters for when to administer or withhold a medication. This assessment provides a baseline for post-medication evaluation.
- In addition, assess the patient's drug allergies before giving any medication. Be aware of medications that may have adverse effects, such as mental status changes or bronchospasm.

Fig. 10.5 One example of a medication administration record (MAR). (Courtesy Princess Margaret Hospital, Toronto, ON.)

- Be sure to take the time to explain to the patient and caregiver the purpose of each medication, its action, possible adverse effects, and any other pertinent information, especially drug–drug or drug–food interactions.
- Open the medication at the bedside into the patient's hand or into a medicine cup. Try not to touch the drugs with your hands. Leaving the drugs in their packaging until you get to the patient's room helps to avoid contamination and waste in case the patient refuses the drug.
- If the patient refuses a drug, the drug may be returned to the automated medication dispenser or to the pharmacy if the package is unopened. Check facility policy. Discard opened drugs per facility protocol. Scheduled drugs that are not given will need a witness if discarded. Note on the patient's record which drug was refused and the patient's reason for refusal.
- Discard any medications that fall to the floor or become contaminated by other means.
- Remain with the patient while the patient takes the drugs. Do not leave the drugs on the bedside table or the meal tray for the patient to take later.
- Chart the medication on the MAR as soon as it is given and before going to the next patient (Figure 10.5). Be sure to also document therapeutic responses, adverse effects (if any), and other concerns in the nurse's notes. Some facilities use manual documentation, and others use electronic documentation.
- Return to evaluate the patient's response to the drug. Remember that the expected response time will vary according to

Fig. 10.6 Some medications require special assessment before administration, such as measuring the apical pulse rate. (Shutterstock.)

the drug route. For example, responses to sublingual nitroglycerin or intravenous push medications need to be evaluated within minutes, but it may take an hour or more for a response to be noted after an oral medication is given.

- See Special Populations: Children: Pharmacokinetic Changes in Children box in Chapter 4 for age-related considerations when administering medication to infants and children.

ENTERAL DRUGS

Administering Oral Drugs

Always begin by washing your hands and maintain standard precautions/routine practices (see Box 10.1). When administering oral drugs, keep in mind the points outlined in the sections below.

Oral Medications

- Administration of some oral medications (and medications by other routes) requires special assessments. For example, it is recommended that the apical pulse be auscultated for 1 full minute before any digitalis preparation is given (Figure 10.6). Administration of other oral medications may require blood pressure monitoring. Be sure to document all parameters on the MAR. In addition, do not forget to check the patient's identification and allergies before giving any oral medication (or medication by any other route).
- If the patient is experiencing difficulty swallowing (dysphagia), some types of tablets can be crushed with a pill-crushing device (Figure 10.7) for easier administration. Crush one type of pill at a time, because if you mix together all the medications before crushing (instead of crushing them one at a time) and then spill some, there is no way to tell which drug has been wasted. Also, if all are mixed together, you cannot check the Five Rights three times before giving the drug. Mix the crushed medication in a small amount of soft food, such as applesauce or pudding. Be sure that the entire serving is consumed, and the pill-crushing device is clean before and after you use it. See Chapter 2 for more information on medications that should not be crushed.
- CAUTION: Be sure to verify whether a medication can be crushed by consulting a drug reference book or a pharmacist. Some oral medications, such as capsules, enteric-coated

Fig. 10.7 Using a pill-crushing device to crush a tablet. (From Perry, A. G., & Potter, P. A. (2010). *Clinical nursing skills and techniques* (7th ed.). St. Louis, MO: Mosby.)

Fig. 10.8 Enteric-coated tablets and long-acting medications should not be crushed. (From Rick Brady, Riva, MD.)

tablets, and sustained-release or long-acting drugs, must not be crushed, broken, or chewed (Figure 10.8). These medications are formulated to protect the gastric lining from irritation or to protect the drug from destruction from gastric acids or are designed to break down gradually to slowly release the medication. If these drugs, designated with labels such as sustained-release or extended-release, are crushed or opened, then the intended action of the dosage form is destroyed. As a result, gastric irritation may occur, the drug may be inactivated by gastric acids, or the immediate availability of a drug that was supposed to be released slowly may cause toxic effects. Check with the health care provider or pharmacist to see if an alternate form of the drug is needed.

- Be sure to position the patient in a sitting or side-lying position to make it easier to swallow oral medications and to avoid the risk of aspiration (Figure 10.9). Always provide aspiration prevention measures as needed.
- Offer the patient a full glass of water; 120 to 180 mL of water or other fluid is recommended for the best dissolution and absorption of oral medications.
- Age-related and fluid-restricted considerations: Children and older adults may not be able to drink a full glass of water but need to take enough fluid to ensure that the medication reaches the stomach. If the patient prefers another fluid, be sure to check

Fig. 10.9 Giving oral medications.

Fig. 10.10 Proper placement of a sublingual tablet. (From Rick Brady, Riva, MD.)

for interactions between the medication and the fluid of choice. If fluid restriction is ordered, be sure to follow the guidelines.

- If the patient requests it, you may place the pill or capsule in his or her mouth with your gloved hand.
- Lozenges are not chewed unless this instruction is specifically given.
- Effervescent powders and tablets should be mixed with water and then given immediately after they are dissolved.
- Remain with the patient until all medication has been swallowed. If you are unsure whether a pill has been swallowed, ask the patient to open his or her mouth so that you can inspect to see if it is gone. Assist the patient to a comfortable position after the medication has been taken.
- Document the medication given on the MAR (see Figure 10.5), and monitor the patient for a therapeutic response as well as for adverse reactions.

Sublingual and Buccal Medications

The sublingual and buccal routes prevent destruction of the drugs in the gastrointestinal tract and allow for rapid absorption into the bloodstream through the oral mucous membranes. Be sure to provide instruction to the patient before giving these medications.

- Sublingual tablets are placed under the tongue (Figure 10.10). Buccal tablets are placed between the upper or lower molar teeth and the cheek.

Fig. 10.11 A, Liquid medication in a unit-dose package. B, Liquid measured into a medicine cup from a multidose container. C, Liquid medicine in an oral-dosing syringe. (From Elkin, M. K., Perry, A. G., & Potter, P. A. (2012). *Nursing interventions and clinical skills* (5th ed.). St. Louis, MO: Mosby.)

- Be sure to wear gloves if you are placing the tablet into the patient's mouth. Adhere to standard precautions/routine practices (see [Box 10.1](#)).
- Instruct the patient to allow the drug to dissolve completely and not to swallow it.
- These drug forms are not taken with fluids. Instruct the patient not to drink anything until after the tablet has dissolved completely.
- Be sure to instruct the patient not to swallow the tablet; saliva should also not be swallowed until after the drug is dissolved.
- When using the buccal route, alternate sides with each dose to reduce possible oral mucosal irritation.
- Document the medication given on the MAR (see [Figure 10.5](#)), and monitor the patient for a therapeutic response as well as for adverse reactions.

Liquid Medications

- Liquid medications may be packaged as a single-dose (unit-dose) package, be poured into a medicine cup from a multidose bottle, or be drawn up in an oral-dosing syringe ([Figure 10.11](#)).
- When pouring a liquid medication from a container, first shake the bottle gently to mix the contents, if indicated. Remove the cap and place it on a paper towel on the counter, upside down. Hold the bottle with the label against the palm of your hand to keep any spilled medication from altering the label. Place the medicine cup at eye level, and fill to the proper level on the scale ([Figure 10.12](#)). Pour the liquid so that the base of the meniscus is even with the appropriate line measure on the medicine cup.
- If you overfill the medicine cup, discard the excess in an environmentally appropriate way according to agency policy. Do not pour it back into the multidose bottle. Before replacing the cap, wipe the rim of the bottle with a paper towel.
- Doses of medications that are less than 5 mL cannot be measured accurately in a calibrated medicine cup. For small volumes, use a calibrated syringe. Do not use a hypodermic

Fig. 10.12 Measuring liquid medication at eye level. (From Rick Brady, Riva, MD.)

syringe or a syringe with a needle or syringe cap. If hypodermic syringes are used, the drug may be inadvertently given parenterally, or the syringe cap or needle, if not removed from the syringe, may become dislodged and accidentally aspirated by the patient when the syringe plunger is pressed.

- Document the medication given on the MAR (see [Figure 10.5](#)), and monitor the patient for a therapeutic response as well as for adverse reactions.

Oral Medications for Infants and Children

- Liquids are usually ordered for infants and young children because they cannot swallow oral pills or capsules.
- A plastic, disposable oral-dosing syringe is recommended for measuring small doses of liquid medications. Use of an oral-dosing syringe prevents the inadvertent parenteral administration of a drug once it is drawn up into the syringe.
- Position the infant so that the head is slightly elevated, to prevent aspiration. Not all infants will be cooperative, and many may need to be partially restrained ([Figure 10.13](#)).
- Place the plastic dropper or syringe inside the infant's mouth, beside the tongue, and administer the liquid in small amounts while allowing the infant to swallow each time.
- A clean, empty nipple may be used to administer the medication. Place the liquid inside the empty nipple and allow the infant to suck the nipple. Add a few millilitres of water to rinse any remaining medication into the infant's mouth, unless contraindicated.
- Take great care to prevent aspiration. A crying infant can easily aspirate medication. If the infant is crying, wait until the infant is calmer before trying again to give the medication.
- Do not add medication to a bottle of formula; the infant may refuse the feeding or may not drink all of it.
- Make sure that all of the oral medication has been taken, and then return the infant to a safe, comfortable position.
- Never use honey on infants who reject bitter-tasting oral medications. Honey is *not* recommended because of the risk of botulism.

Fig. 10.13 Administering oral liquid medication to an infant. (Courtesy Oscar H. Allison, Jr. (2010). In Clayton, B. D., & Stock, Y. N. (Eds.). *Basic pharmacology for nurses* (15th ed.). St. Louis, MO: Mosby.)

- If infants or children reject oral medications that taste bitter, the drug may be mixed with 5 mL (1 teaspoon) of a sweet-tasting food such as jelly, applesauce, ice cream, or sherbet. Do not mix the medication in an essential food item, such as formula, milk, or orange juice, because the child may reject that food later. After the medication is taken, offer the child diluted juice, a flavoured frozen popsicle, or water.

Administering Drugs Through a Nasogastric or Gastrostomy Tube

Always begin by performing hand hygiene and maintain standard precautions/routine practices (see [Box 10.1](#)). Follow agency policy about wearing gloves during the procedure. When administering drugs via these routes, keep in mind the following points:

- Follow institution-specific protocols for medication administration through a nasogastric (NG) or gastrostomy tube. Institutions may require checking the placement of the NG tube and assessing gastric residual volumes (how much of the previous feeding is in the stomach). Reinstall gastric residual per institutional policy, and then clamp the tube ([Figure 10.14](#)).
- Before giving drugs via these routes, position the patient in a semi-Fowler's or high Fowler's position and leave the head of the bed elevated for at least 30 minutes afterward, to reduce the risk of aspiration ([Figure 10.15](#)).
- Assess whether fluid restriction or fluid overload is a concern. It will be necessary to give water along with the medications to flush the tubing.
- Check to see if the drug is recommended to be given on an empty or full stomach. In addition, some drugs are incompatible with enteral feedings. If the drug is to be taken on an empty stomach, or if incompatibility exists, the feeding may need to be stopped before and after giving the medication. Follow the guidelines for the specific drug if this is necessary.

Fig. 10.14 Check the gastric residual before administering medications.

Fig. 10.15 Elevate the head of the bed before administering medications through a nasogastric tube.

Examples of drugs that are not compatible with enteral feedings are phenytoin and carbidopa-levodopa. Whenever possible, give liquid forms of the drugs to prevent clogging of the tube.

- If tablets must be given, crush them individually into a fine powder. Administer the drugs separately ([Figure 10.16](#)). Keeping the drugs separate allows for accurate identification if a dose is spilled. Be sure to check whether the medication can be crushed; in general, do not administer sustained-release, chewable, long-acting, or enteric-coated tablets or capsules through an NG or gastrostomy tube. Check with a pharmacist if you are unsure.

Fig. 10.16 Medications given through gastric tubes should be administered separately. Dilute crushed pills in 15 to 30 mL of water before administration. (From Rick Brady, Riva, MD.)

Fig. 10.17 Pour liquid medication into the syringe. Then unclamp the tubing and allow it to flow in by gravity.

- Dilute a crushed tablet or liquid medication in 15 to 30 mL of warm water. Some capsules may be opened and dissolved in 30 mL of warm water; check with a pharmacist.
- Remove the piston from an adaptable-tip syringe and attach it to the end of the tube. Unclamp the tube and pinch the tubing to close it again. Add 30 mL of warm water and release the pinched tubing. Allow the water to flow in by gravity to flush the tube, and then pinch the tubing closed again before all the water is gone to prevent excessive air from entering the stomach. If a stopcock valve device is present on the enteral tube, open and close the stopcock instead of pinching the tubing to clamp it.
- Pour the diluted medication into the syringe and release the tubing to allow it to flow in by gravity ([Figure 10.17](#)). Flush between each drug with 10 mL of warm water. Be careful not to spill the medication mixture. Adjust fluid amounts if fluid

Fig. 10.18 Lubricate the suppository with a water-soluble lubricant.

restrictions are ordered, but sufficient fluid must be used to dilute the medication and to flush the tubing.

- If water or medication does not flow freely, you may apply gentle pressure with the plunger of the syringe or the bulb of the syringe. Do not try to force the medicine through the tubing.
- After the last drug dose, flush the tubing with 30 mL of warm water, and then clamp the tube. Resume the tube feeding when appropriate.
- Have the patient remain in a high Fowler's or slightly elevated right-side-lying position to reduce the risk of aspiration.
- Document the medications given on the MAR (see [Figure 10.5](#)), the amount of fluid given on the patient's intake and output record, and the patient's response in the patient's record.

Administering Rectal Drugs

Always begin by performing hand hygiene and maintain standard precautions/routine practices (see [Box 10.1](#)). Gloves must be worn. When administering rectal drugs, keep in mind the following points:

- Assess the patient for the presence of active rectal bleeding or diarrhea, which generally are contraindications for the use of rectal suppositories.
- Suppositories should not be divided to provide a smaller dose. The active drug may not be evenly distributed within the suppository base.
- Position the patient on the left side, unless contraindicated. The uppermost leg needs to be flexed toward the waist (Sims' position). Provide privacy and drape.
- Do not insert the suppository into stool. Gently palpate the rectal wall for presence of feces. If possible, have the patient defecate. DO NOT palpate the patient's rectum if the patient has had rectal surgery.
- Remove the wrapping from the suppository and lubricate the rounded tip with water-soluble gel ([Figure 10.18](#)).
- Insert the tip of the suppository into the rectum while having the patient take a deep breath and exhale through the mouth. With your gloved finger, quickly and gently insert the suppository into the rectum, alongside the rectal wall, at least 2.5 cm beyond the internal sphincter ([Figure 10.19](#)).

Fig. 10.19 Inserting a rectal suppository. (From Perry, A. G., & Potter, P. A. (2010). *Clinical nursing skills and techniques* (7th ed.). St. Louis, MO: Mosby.)

Fig. 10.20 Vaginal suppositories (right) are larger and more oval than rectal suppositories (left). (From Rick Brady, Riva, MD.)

- Have the patient remain lying on the left side for 15 to 20 minutes to allow absorption of the medication.
- Age-related considerations: With children, it may be necessary to gently but firmly hold the buttocks in place for 5 to 10 minutes until the urge to expel the suppository has passed. Older adults with loss of sphincter control may not be able to retain the suppository.
- If the patient prefers to self-administer the suppository, give specific instructions on its purpose and correct procedure. Be sure to tell the patient to remove the wrapper.
- Use the same procedure for medications administered by a retention enema, such as sodium polystyrene sulfonate (see [Chapter 40](#)). Drugs given by enemas are diluted in the smallest amount of solution possible. Retention enemas need to be held for 30 minutes to 1 hour before expulsion, if possible, for maximum absorption.
- Document the medication given on the MAR (see [Figure 10.5](#)), and monitor the patient for a therapeutic response as well as for adverse reactions.

Administering Vaginal Medications

Always begin by performing hand hygiene and maintain standard precautions/routine practices (see [Box 10.1](#)). Gloves must be worn. When administering vaginal preparations, keep in mind the following points:

- Vaginal suppositories are larger and more oval than rectal suppositories ([Figure 10.20](#)).

Fig. 10.21 Vaginal cream and suppository, with applicators. (From Rick Brady, Riva, MD.)

- [Figure 10.21](#) shows examples of a vaginal suppository in its applicator and vaginal cream in an applicator.
- Before giving these medications, explain the procedure to the patient, have her void to empty the bladder, and perform pericare.
- If possible, administer vaginal preparations at bedtime to allow the medications to remain in place for as long as possible.
- Some patients may prefer to self-administer vaginal medications. Provide specific instructions if necessary.
- Position the patient in the lithotomy position and elevate the hips with a pillow, if tolerated. Be sure to drape the patient to provide privacy.

Creams, Foams, or Gels Applied With an Applicator

- Fit the applicator to the tube of the medication, and then gently squeeze the tube to fill the applicator with the correct amount of medication.
- Lubricate the tip of the applicator with a water-soluble lubricant.
- Use your nondominant hand to spread the labia and expose the vagina. Gently insert the applicator as far as possible into the vagina ([Figure 10.22](#)).
- Push the plunger to deposit the medication. Remove the applicator and wrap it in a paper towel for cleaning.

Suppositories or Vaginal Tablets

- For suppositories or vaginal tablets, remove the wrapping and lubricate the suppository with a water-soluble lubricant. Be sure that the suppository is at room temperature.
- Using the applicator, insert the suppository or tablet into the vagina, and then push the plunger to deposit the suppository. Remove the applicator.
- If no applicator is available, use your dominant index finger to insert the suppository about 5 cm into the vagina ([Figure 10.23](#)).
- Have the patient remain in the supine position, with hips elevated for 5 to 10 minutes to allow the suppository to dissolve and the medication to absorb.
- If the patient desires, apply a perineal pad.
- If the applicator is to be reused, wash with soap and water and store in a clean container for the next use.

Fig. 10.22 Administering vaginal cream with an applicator. (From Elkin, M. K., Perry, A. G., & Potter, P. A. (2004). *Nursing interventions and clinical skills* (3rd ed.). St. Louis, MO: Mosby.)

Fig. 10.23 Administering a vaginal suppository. (From Elkin, M. K., Perry, A. G., & Potter, P. A. (2004). *Nursing interventions and clinical skills* (3rd ed.). St. Louis, MO: Mosby.)

- Document the medication given on the MAR (see [Figure 10.5](#)), and monitor the patient for a therapeutic response as well as for adverse reactions.

PARENTERAL DRUGS

According to the [World Health Organization \(2010\)](#), gloves are not usually recommended for injections if the skin is intact. Gloves do not protect against a needle-stick injury. Practice may vary among institutions/agencies and educational settings about the use of gloves to prepare and administer parenteral drugs. For the purpose of this text, the images reflect the use of gloves to prepare and administer parenteral drugs. It is always recommended to follow the agency policy.

Fig. 10.24 NEVER RECAP A USED NEEDLE! Always dispose of uncapped needles in the appropriate sharps container. Refer to [Box 10-1](#) for standard precautions/routine practices. (From Rick Brady, Riva, MD.)

Fig. 10.25 An UNUSED needle may need to be recapped before the medication is given to the patient. The “scoop method” is one way to recap an unused needle safely. Be sure not to touch the needle to the countertop or to the outside of the needle cap.

Preparing for Parenteral Drug Administration

[Figures 10.24 through 10.34](#) show equipment used for administering parenteral drugs.

Removing Medications from Ampoules

Always begin by performing hand hygiene and maintain standard precautions/routine practices (see [Box 10.1](#)). Gloves may be worn, especially if the medication is toxic. When performing these procedures, keep in mind the following points:

- Medication often rests in the top part of the ampoule. Tap the top of the ampoule lightly and quickly with your finger until all fluid moves to the bottom portion of the ampoule (see [Figure 10.35](#)).
- When removing medication from an ampoule, use a sterile filter needle, if available (see [Figure 10.34](#)). These needles

Fig. 10.26 Examples of several different types of needle-stick prevention syringes. (Courtesy Becton, Dickinson and Company.)

Fig. 10.27 The parts of a syringe and hypodermic needle. (Courtesy Chuck Dresner.)

Fig. 10.28 Close-up view of the bevel of a needle. (Courtesy Chuck Dresner.)

Fig. 10.29 Be sure to choose the correct size and type of syringe for the drug ordered. (From Potter, P. A., Perry, A. G., Stockert, P. A., et al. (2011). *Basic Nursing* (7th ed.). St. Louis, MO: Mosby.)

Fig. 10.30 Needles come in various gauges and lengths. The larger the gauge, the smaller the needle and often the shorter in length. Be sure to choose the correct needle—gauge and length—for the type of injection ordered. (From Rick Brady, Riva, MD.)

Figs. 10.31 and 10.32 Figure 10.31 is an example of prefilled low-molecular-weight heparin enoxaparin sodium. Figure 10.32 is an example of a saline lock prefilled syringe. After use, the syringe is disposed of in a sharps container. (For Figure 10.31: courtesy of Sandoz Novartis.) (For Figure 10.32: courtesy of Hospira Healthcare Corporation.)

Fig. 10.33 Ampoules containing medications come in various sizes. The neck of the ampoule must be broken carefully before the medication is withdrawn. (From Potter, P. A., & Perry, A. G. (2001). *Fundamentals of nursing* (5th ed.). St. Louis, MO: Mosby.)

Fig. 10.34 Use a filter needle when withdrawing medication from an ampoule. Filter needles help remove tiny glass particles that may result from breaking the ampoule. **DO NOT USE A FILTER NEEDLE for injecting medication into a patient!** Some institutions may also require the use of a filter needle to withdraw medications from a vial. (From Rick Brady, Riva, MD.)

Fig. 10.35 Tapping an ampoule to move the fluid below the neck. (From Rick Brady, Riva, MD.)

Fig. 10.36 Breaking an ampule. Carefully break the neck of the ampoule in a direction *away* from you and away from others near you. (From [A] and [B] from Rick Brady, Riva, MD.)

Fig. 10.37 Using a filter needle to draw medication from an ampoule. (From Rick Brady, Riva, MD.)

are designed to filter out glass particles that may be present inside the ampoule after it is broken. The filter needle **IS NOT** intended for administration of the drug to the patient.

- Place a small gauze pad or dry alcohol swab around the neck of the ampoule to protect your hand. Snap the neck quickly and firmly and break the ampoule away from your body and away from any other open areas or individuals (Figure 10.36). There are many varieties of ampoule breakers that are available to open ampoules and minimize the risk of potential injury from broken edges of glass. Many agencies also use a plastic sleeve that is placed over the neck of the ampoule. The ampoule is broken in the same manner as described above.
- To draw up the medication, either set the open ampoule on a flat surface or hold the ampoule upside down. Insert the filter needle (attached to a syringe) into the centre of the ampoule opening. Do not allow the needle tip or shaft to touch the rim of the ampoule (Figure 10.37).

- Gently pull back on the plunger to draw up the medication. Keep the needle tip below the fluid, within the vial; tip the ampoule to bring all of the fluid within reach of the needle. Avoid touching the inside of the plunger when pulling it back.
- If air bubbles are aspirated, do not expel them into the ampoule. Remove the needle from the ampoule, hold the syringe with the needle pointing up, and tap the side of the syringe with your finger to cause the bubbles to rise toward the needle. Draw back slightly on the plunger, and slowly push the plunger upward to eject the air. Do not eject fluid.
- Excess medication is disposed of into the sink. Hold the syringe vertically with needle tip up and slanted toward the sink. Slowly eject the excess fluid into the sink, and then recheck the fluid level by holding the syringe vertically.
- Remove the filter needle and replace with the appropriate needle for administration. NEVER use a filter needle to administer medications to a patient!
- Be sure to ensure the sterility of the injection needle throughout the process. Do not touch the open end of the needle hub, or the tip of the syringe, when attaching a needle to a syringe.
- Dispose of the glass ampoule pieces and the used filter needle into the appropriate sharps container.

Removing Medications from Vials

Always begin by performing hand hygiene and maintain standard precautions/routine practices (see [Box 10.1](#)). Gloves may be worn. When performing these procedures, keep in mind the following points:

- Vials can contain either a single dose or multiple doses of medications. Follow the institution's policy for using opened multidose vials, such as vials of insulin. Mark multidose vials with the date and time of opening and the discard date (per institution policy). If you are unsure about the age of an opened vial of medication, discard it and obtain a new one.
- Check institutional policies regarding which type of needle to use to withdraw fluid from a vial.
- With the exception of insulin, which must be withdrawn using an insulin syringe, fluid may be withdrawn from a vial using a blunt fill needle or a filter needle. Using a blunt fill needle reduces the chance of injury.
- If the vial is unused, remove the cap from the top of the vial and clean well with an alcohol swab.
- If the vial has been previously opened and used, wipe the top of the vial vigorously with an alcohol swab.
- Air must first be injected into a vial before fluid can be withdrawn. The amount of air injected into a vial needs to equal the amount of fluid to be withdrawn.
- Determine the volume of fluid to be withdrawn from the vial. Pull back on the syringe's plunger to draw an amount of air into the syringe that is equivalent to the volume of medication to be removed from the vial ([Figure 10.38](#)). Insert the syringe into the vial, preferably using a needleless system.
- Some vials are not compatible with needleless systems and therefore require a needle for fluid withdrawals. Use a blunt fill needle, if possible.

Figs. 10.38 and 10.39 Inject air into the vial before withdrawing medication (needleless system shown). Needleless vial adaptor shows a needleless system of vial access. (For [Figure 10.38](#): from Rick Brady, Riva, MD.) (For [Figure 10.39](#): courtesy of Healthmark Services Canada.)

Figs. 10.40 and 10.41 Using a needle and syringe to remove medication from a vial (needleless system shown on the right).

- [Figure 10.39](#) shows a needleless vial adaptor that may be used for safe and rapid transfer and reconstitution of drugs between vials and syringes. It can be used for a multidose vial. Adaptors are available in a variety of styles. Many have a blunt access device. Adaptors were created to reduce exposure to needle-stick injuries. To use the adaptor, remove the cover from the vial cap; on a firm surface, centre the needleless adaptor directly over the top of the vial and press the adaptor firmly onto the vial until it is sealed. The adaptor can be cleansed with an alcohol wipe and the drug removed similarly to the steps described below.
- While holding onto the plunger, invert the vial and remove the desired amount of medication ([Figure 10.40 and Figure 10.41](#)).

Fig. 10.42 Various needle angles. (Courtesy of Nadine Sokol.)

- Gently but firmly tap the syringe to remove air bubbles. Excess fluid, if present, should be discarded into a sink.
- When an injection requires two medications from two different vials, begin by injecting air into the first vial (without touching the fluid in the first vial), and then inject air into the second vial. Immediately remove the desired dose from the second vial. Change needles (if possible), and then remove the exact prescribed dose of drug from the first vial. Take great care not to contaminate the drug in one vial with the drug from the other vial. Check with a pharmacist to make sure the two drugs are compatible for mixing in the same syringe.
- For injections, if a needle has been used to remove medication from a vial, always change the needle before administering the dose. Changing needles ensures that a clean and sharp needle is used for the injection. It also avoids the risk of irritation to the patient's tissues caused by medication remaining on the outside of the needle. In addition, the needle may become dull if used to puncture a rubber stopper. However, some syringes, such as insulin syringes, have needles that are fixed onto the syringe and cannot be removed.
- Ensure the sterility of the injection needle throughout the process. Do not touch the open end of the needle hub, or the tip of the syringe, when attaching a needle to a syringe.

Injections Overview

Current best practice for the administration of injections varies throughout health care agencies and practice environments (Crawford & Johnson, 2012). Aspiration for intramuscular injections is one controversial topic—the literature is unclear as to whether it is best practice to aspirate or not aspirate for blood before medication injections. Evidence shows that no aspiration is required for the intramuscular injections of vaccines and immunizations and subcutaneous injections of heparin sulphate and insulin (Centers for Disease Control and Prevention, 2015; Crawford & Johnson, 2012).

Needle Insertion Angles for Intramuscular, Subcutaneous, and Intradermal Injections

- For any injection, if syringes are prepared at a medication cart or in a medication room, each parenteral medication should be prepared separately and a label identifying the patient, the medication, the dose, and the route placed on the barrel of the syringe before the nurse leaves the preparation area.
- For intramuscular (IM) injections, insert the needle at a 90-degree angle (see Figure 10.42). Intramuscular injections deposit the drug deep into muscle tissue, where the drug is

absorbed through blood vessels within the muscle. The rate of absorption of a drug given by the IM route is slower than that of drugs given by the intravenous route but faster than that of drugs given by the subcutaneous route. Intramuscular injections generally require a longer needle to reach the muscle tissue, but shorter needles may be needed for older patients, children, and adults who are malnourished. The site chosen will also determine the length of the needle needed. In general, aqueous drugs can be given with a 22- to 27-gauge needle; however, oil-based or more viscous (thick) drugs are given with an 18- to 25-gauge needle. Average needle lengths for children range from 16 mm to 25 mm, and needles for adults range from 25 mm to 38 mm. The nurse must choose the needle length based on the size of the muscle at the injection site, the age of the patient, and the type of drug used. For a normal, well-developed adult, 3 mL is the maximum amount used in a single injection. Follow agency policy. If more than 3 mL is needed for the ordered dose, then the drug will need to be given in two separate injections. However, if the patient is an older adult or thin, a smaller maximum volume, such as 2 mL, is recommended.

- For subcutaneous (subcut) injections, insert the needle at either a 45- or a 90-degree angle. Subcutaneous injections deposit the drug into the loose connective tissue under the dermis. This tissue is not as well supplied with blood vessels as the muscle tissue is; as a result, drugs are absorbed more slowly when given subcutaneously than when given intramuscularly. Doses are usually 0.5 to 1 mL. In general, use a 25-gauge, 12-mm to 16-mm needle (for insulin, a 6-mm or 8-mm needle is recommended). A 90-degree angle is used for a patient of average size; a 45-degree angle may be used for patients who are thin, emaciated, or cachectic and for children. To ensure correct needle length, grasp the skin fold with the thumb and forefinger, and choose a needle that is approximately one half the length of the skin fold from top to bottom.
- Intradermal (ID) injections are given into the outer layers of the dermis in tiny amounts, usually 0.01 to 0.1 mL. These injections are used mostly for diagnostic purposes, such as when testing for allergies or tuberculosis and for local anaesthesia. Little of the drug is absorbed systemically. In general, choose a tuberculin or 1-mL syringe with a 26- or 27-gauge needle that is 10 mm to 16 mm long. The angle of injection is 5 to 15 degrees.
- For specific information about giving injections to children, see Box 10.2.

Air-Lock Technique

- Some facilities recommend administering IM injections using the air-lock technique (Figure 10.43). Check institutional policy.
- After withdrawing the desired amount of drug into the syringe, withdraw an additional 0.2 mL of air. Be sure to inject using a 90-degree angle. The small air bubble that follows the medication during the injection may help prevent the medication from leaking through the needle track into the subcutaneous tissues.

BOX 10.2 Pediatric Injections

For pediatric injections, site selection is crucial. Factors to consider are the age of the child, the size of the muscle at the injection site, the type of injection, the thickness of the solution, and the ease with which the child can be positioned properly. There is no universal agreement in the literature on the best intramuscular injection site for children. For infants, the preferred site is the vastus lateralis muscle. The ventrogluteal site may also be used in children of all ages. For immunizations in toddlers and older children, the deltoid muscle may be used *if* the muscle mass is well developed. Intramuscular injections for older infants and small children should not exceed 1 mL in a single injection. Refer to facility policy.

Children are often extremely fearful of needles and injections. Even a child who appears calm may become upset and lose control during an injection procedure. For safety reasons, it is important to have another person available for positioning and holding the child.

Distraction techniques are helpful. Say to the child, "If you feel this you can ask me to take it out, please." Be quick and efficient when giving the injection.

Have a small, colourful adhesive bandage on hand to apply after the injection. If the child is old enough, have the child hold the bandage and apply it after the injection. If possible, offer a reward sticker after the injection.

After the injection, allow the child to express feelings about the injection. For young children, encourage parents to offer comfort with holding and cuddling. Older children respond better if they receive praise.

EMLA (lidocaine/prilocaine) cream or a vapocoolant spray, if available, may be used before the injection to reduce the pain from the needle insertion. However, because these agents do not absorb down into the muscle, the child may still experience pain when the medication enters the muscle. Apply EMLA cream to the site at least 1 hour and up to 3 hours before the injection. Vapocoolant spray is applied to the site immediately before the injection. Another option is to apply a wrapped ice cube to the injection site for a minute before the injection. Infants also experience pain with the administration of injections. Breastfeedings during the procedure or administering a glucose solution have both been effective strategies for pain management.

Fig. 10.43 Air-lock technique for intramuscular injections. (From Elkin, M. K., Perry, A. G., & Potter, P. A. (2012). *Nursing interventions and clinical skills* (5th ed.). St. Louis, MO: Mosby.)

Intradermal Injection

Always begin by performing hand hygiene and maintain standard precautions/routine practices (see [Box 10.1](#)). When giving an ID injection, keep in mind the following points:

- Be sure to choose an appropriate site for the injection. Avoid areas of bruising, rashes, inflammation, edema, or skin discoloration.

Figs. 10.44 and 10.45 Intradermal injection.

- Help the patient to a comfortable position. Extend and support the elbow and forearm on a flat surface.
- In general, three to four finger-widths below the antecubital space and one hand-width above the wrist are the preferred locations on the forearm. Areas on the back that are also suitable for subcut injections may be used if the forearm is not appropriate for the ID injection.
- Cleanse the site with an alcohol or antiseptic swab. Apply the swab at the centre of the site, and cleanse outward in a circular direction for about 5 cm; then let the skin dry. After cleansing the site, stretch the skin over the site with your nondominant hand.
- With the needle almost against the patient's skin, insert the needle, bevel up, at a 5- to 15-degree angle until resistance is felt, and then advance the needle through the epidermis, approximately 3 mm ([Figures 10.44 and 10.45](#)). The needle tip should still be visible under the skin.
- Do not aspirate. This area under the skin contains few blood vessels.
- Slowly inject the medication. It is normal to feel resistance, and a bleb that resembles a mosquito bite (about 6 mm in diameter) will form at the site if accurate technique is used.
- Withdraw the needle slowly, while gently applying a gauze pad at the site, but do not massage the site.
- DO NOT RECAP the needle. Dispose of the syringe and needle in the appropriate container. Perform hand hygiene after administering the medication.
- Provide instructions to the patient, as needed, for a follow-up visit for reading the skin testing, if applicable.

Fig. 10.46 Potential sites for subcutaneous injections. (From Perry, A. G., & Potter, P. A. (2010). *Clinical nursing skills and techniques* (7th ed.). St. Louis, MO: Mosby.)

Fig. 10.47 Before giving an injection, cleanse the skin with an alcohol or antiseptic swab.

- Document in the MAR the date of the skin testing and the date that results need to be read, if applicable.

Subcutaneous Injections

Always begin by performing hand hygiene and maintain standard precautions/routine practices (see [Box 10.1](#)). When giving a subcut injection, keep in mind the following points:

- Be sure to choose an appropriate site for the injection. Avoid areas of bruising, rashes, inflammation, edema, or skin discoloration as well as scars, moles, or hair roots ([Figure 10.46](#)).
- Ensure that the needle size is correct. Grasp the skin fold between your thumb and forefinger and measure from top to bottom. The needle should be approximately one half of this length.
- Cleanse the site with an alcohol or antiseptic swab. Apply the swab at the centre of the site, and cleanse outward in a circular direction for about 5 cm ([Figure 10.47](#)); then let the skin dry.

Fig. 10.48 Giving a subcutaneous injection at a 90-degree angle.

Fig. 10.49 When giving a subcutaneous injection in the abdomen, be sure to choose a site at least 5 cm away from the umbilicus.

- Tell the patient that he or she will feel a “stick” as you insert the needle.
- For a patient who is of average size, pinch the skin with your nondominant hand, and inject the needle quickly at a 45- or 90-degree angle ([Figure 10.48](#)).
- For a patient who is obese, pinch the skin and inject the needle at a 90-degree angle. Be sure the needle is long enough to reach the base of the skin fold.
- Age-related considerations: For a child or a thin patient, pinch the skin gently and be sure to use a 45-degree angle when injecting the needle.
- Injections given in the abdomen must be given at least 5 cm away from the umbilicus because of the surrounding vascular structure ([Figure 10.49](#)). The injection site must also be 5 cm away from any incisions, stomas, or open wounds, if present.
- After the needle enters the skin, grasp the lower end of the syringe with your nondominant hand. Move your dominant hand to the end of the plunger—be careful not to move the syringe.
- Aspiration of medication to check for blood return is not necessary for subcut injections or vaccinations (Public Health Agency of Canada, 2013). Heparin sulphate injections and insulin injections are NOT aspirated before injection and need to be injected at a 90-degree angle.
- With your dominant hand, slowly inject the medication.

- Withdraw the needle quickly and place a swab or sterile gauze pad over the site.
- Apply gentle pressure but do not massage the site. If necessary, apply a bandage to the site.
- DO NOT RECAP the needle. Dispose of the syringe and needle in the appropriate container. Perform hand hygiene after administering the injection.
- Document the medication given on the MAR (see Figure 10.5), and monitor the patient for a therapeutic response as well as for adverse reactions.
- For heparin sulphate or other subcut anticoagulant injections, follow the manufacturer's instructions for injection technique as needed. Many manufacturers recommend the area of the abdomen known as the "love handles" for injection of anticoagulants. DO NOT ASPIRATE before injecting, and DO NOT MASSAGE the site after injection. These actions may cause a hematoma at the injection site.
- Heparin doses are ordered in units, but it is important to note that units of heparin sulphate are not the same as units of insulin. Heparin sulphate is *never* measured with insulin syringes.
- Also available are prefilled syringes with air lock of low-molecular-weight heparin (e.g., enoxaparin sodium, dalteparin sodium). The air lock of 0.2 to 0.3 mL of air is left in the injector; when the drug is administered followed by the air, a lock is created where the needle is inserted to prevent the heparin from penetrating the skin. This reduces the possibility of developing a hematoma. In addition, all of the drug is pushed by the air into the subcutaneous tissue and the precise dose of the drug is administered.

Insulin Syringes

- Always use an insulin syringe to measure and administer insulin. When giving small doses of insulin, use an insulin syringe that is calibrated for smaller doses. Figure 10.50 shows insulin syringes with two different calibrations. Notice that in the 100-unit syringe, each line represents 2 units; on the 50-unit syringe, each line represents 1 unit. NOTE: One unit of insulin is NOT equivalent to one millilitre of insulin.
- Figure 10.51 shows several examples of devices (syringe, insulin pen) that can be used to help patients self-administer insulin. These devices feature a multidose container of insulin and easy-to-read dials for choosing the correct dose. The needle is changed with each use. These devices are for single-patient use only, due to the risk of blood contamination of the medication reservoir.
- When two different types of insulin are drawn up into the same syringe, always draw up the clear (fast-acting) insulin into the syringe first. An easy way to remember which insulin is drawn up first is by thinking "Fast/First."
- Disinfection of the site for insulin is usually not required; however, alcohol or antiseptic swabs are often used in the hospital or home care setting.

Intramuscular Injections

Always begin by performing hand hygiene and maintain standard precautions/routine practices (see Box 10.1). Gloves must

Fig. 10.50 Insulin syringes are available in 100-unit and 50-unit calibrations. (From Rick Brady, Riva, MD.)

Fig. 10.51 A variety of devices are available for insulin injections. (<http://www.mdtmag.com/articles/2014/08/advances-diabetes-drug-delivery>.)

be worn. When giving an IM injection, keep in mind the following points:

- Choose the appropriate site for the injection by assessing not only the size and integrity of the muscle but also the amount and type of injection. Palpate potential sites for areas of hardness or tenderness and note the presence of bruising or infection.
- The dorsogluteal injection site is no longer recommended for injections because of its close proximity to the sciatic nerve and major blood vessels. Injury to the sciatic nerve from an injection may cause partial paralysis of the leg. The dorsogluteal site is not to be used for IM injections; instead, the ventrogluteal site is the preferred IM injection site for adults and children.
- Assist the patient to the proper position and ensure the patient's comfort.
- Locate the proper site for the injection and cleanse the site with an alcohol or antiseptic swab. Apply the swab at the centre of the site, and cleanse outward in a circular direction for about 5 cm (see Figure 10.47); then let the skin dry. Keep a sterile gauze pad nearby for use after the injection.
- With your nondominant hand, pull the skin taut. Follow the instructions for the Z-track method (see below), if appropriate.

- Grasp the syringe with your dominant hand between thumb and index finger, as if holding a dart, and hold the needle at a 90-degree angle to the skin. Tell the patient to expect a “stick” feeling as you insert the needle.
- Insert the needle quickly and firmly into the muscle. Grasp the lower end of the syringe with the nondominant hand while still holding the skin back, to stabilize the syringe. With the dominant hand, pull back on the plunger for 5 to 10 seconds to check for blood return.
- If no blood appears in the syringe, inject the medication slowly, at the rate of 1 mL every 10 seconds. After injecting the drug, wait 10 seconds, and then withdraw the needle smoothly while releasing the skin.
- Apply gentle pressure at the site and watch for bleeding. Apply a bandage if necessary.
- If blood does appear in the syringe, remove the needle, dispose of the medication and syringe, and prepare a new syringe with the medication.
- DO NOT RECAP the needle. Dispose of the syringe and needle in the appropriate container. Remove gloves and perform hand hygiene.
- Document the medication given on the MAR (see Figure 10.5), and monitor the patient for a therapeutic response as well as for adverse reactions.

Z-Track Method

- The Z-track method is used for injections of irritating substances such as iron dextran and hydroxyzine hydrochloride. The technique reduces pain, irritation, and staining at the injection site. Some facilities recommend this method for all IM injections (Figures 10.52 and 10.53).
- After choosing and preparing the site for injection, use your nondominant hand to pull the skin laterally, and hold it in this position while giving the injection. When using this technique in the older adult population, it may not be necessary to pull the skin as much as in a younger adult because of loose skin turgor. Insert the needle at a 90-degree angle, aspirate for 5 to 10 seconds to check for blood return, and then inject the medication slowly. After injecting the medication, wait 10 seconds before withdrawing the needle. Withdraw the needle slowly and smoothly, and maintain the 90-degree angle.
- Release the skin immediately after withdrawing the needle to seal off the injection site. This technique forms a Z-shaped track in the tissue that prevents the medication from leaking through the more sensitive subcutaneous tissue from the muscle site of injection. Apply gentle pressure to the site with a dry gauze pad.

Ventrogluteal Site

- The ventrogluteal site is the preferred site for adults and children. It is considered the safest of all the sites because the muscle is deep and away from major blood vessels and nerves (Figure 10.54).
- Position the patient on one side, with knees bent and upper leg slightly ahead of the bottom leg. If necessary, the patient may remain in a supine position.

Figs. 10.52 and 10.53 The Z-track method for intramuscular injections. (From Perry, A. G., & Potter, P. A. (2010). *Clinical nursing skills and techniques* (7th ed.). St. Louis, MO: Mosby.)

Fig. 10.54 Finding landmarks for a ventrogluteal injection. (Modified from Potter, P. A., & Perry, A. G. (1993). *Fundamentals of nursing: Concepts, process, and practice* (3rd ed.). St. Louis, MO: Mosby.)

- Palpate the greater trochanter at the head of the femur and the anterosuperior iliac spine. As illustrated in Figure 10.55, use the left hand to find landmarks when injecting into the patient's right ventrogluteal, and the right hand to find landmarks when injecting into the patient's left ventrogluteal site. Place the palm of your hand over the greater trochanter and your index finger on the anterosuperior iliac

Figs. 10.55 and 10.56 Ventrogluteal intramuscular injection. (From Rick Brady, Riva, MD.)

spine. Point your thumb toward the patient's groin and your fingers toward the patient's head. Spread the middle finger back along the iliac crest, toward the buttocks, as much as possible.

- The injection site is the centre of the triangle formed by your middle and index fingers (see arrow in [Figure 10.55](#)).
- Before giving the injection, you may need to switch hands so that you can use your dominant hand to give the injection ([Figure 10.56](#)).
- Follow the general instructions for giving an IM injection.

Vastus Lateralis Site

- Generally, the vastus lateralis muscle is well developed and not located near major nerves or blood vessels. It is the preferred site of injection of drugs such as immunizations for infants ([Figure 10.57](#)). For specific information about giving injections to children, see [Box 10.2](#).
- The patient may be sitting or lying supine; if supine, have the patient bend the knee of the leg in which the injection will be given.
- To find the correct site of injection, place one hand above the knee and one hand below the greater trochanter of the femur. Locate the midline of the anterior thigh and the midline of the lateral side of the thigh. The injection site is located within the rectangular area ([Figures 10.58, 10.59, and 10.60](#)).

Fig. 10.57 Vastus lateralis intramuscular injection in an infant. (From Rick Brady, Riva, MD.)

Figs. 10.58, 10.59, and 10.60 Vastus lateralis intramuscular injection. (For [Figure 10.58](#): modified from Potter, P. A., & Perry, A. G. (1993). *Fundamentals of nursing: Concepts, process, and practice* (3rd ed.). St. Louis, MO: Mosby.) (For [Figure 10.59](#): from Rick Brady, Riva, MD.) (For [Figure 10.60](#): from Rick Brady, Riva, MD.)

Deltoid Site

- Even though the deltoid site (Figure 10.61) is easily accessible, it is not the first choice for IM injections because the muscle may not be well developed in some adults, and the site carries a potential for injury because the axillary nerve lies beneath the deltoid muscle. In addition, the brachial artery and radial, brachial, and ulnar nerves are also located in the upper arm. Always check medication administration policies, because some facilities do not use the deltoid site for IM injections. The deltoid site must be used only for giving immunizations to toddlers, older children, and adults (not infants) and only for small volumes of medication (0.5 to 1 mL).
- The patient may be sitting or lying down. Remove clothing to expose the upper arm and shoulder. Do not roll up tight-fitting sleeves. Have the patient relax the arm and slightly bend the elbow.
- Palpate the lower edge of the acromion process. This edge becomes the base of an imaginary triangle (Figure 10.62).
- Place three fingers below this edge of the acromion process. Find the point on the lateral arm in line with the axilla. The injection site will be in the centre of this triangle, three finger widths (2.5 to 5 cm) below the acromion process.
- Age-related considerations: In children and smaller adults, it may be necessary to bunch the underlying tissue together before giving the injection and use a shorter (16 mm) needle (Figure 10.63).
- To reduce patient anxiety, have the patient look away before you give the injection.

Figs. 10.61, 10.62, and 10.63 Deltoid intramuscular injection. (For Figure 10.61: modified from Potter, P. A., & Perry, A. G. (1993). *Fundamentals of nursing: Concepts, process, and practice* (3rd ed.). St. Louis, MO: Mosby.)

Preparing Intravenous Medications

Always begin by performing hand hygiene and maintain standard precautions/routine practices (see Box 10.1). Gloves may be worn for these procedures. Check the agency policy. When administering intravenous drugs, keep in mind the following points:

- The intravenous route for medication administration provides for rapid onset and faster therapeutic drug levels in the blood than other routes. However, the intravenous route is also potentially more dangerous. Once an intravenous drug is given, it begins to act immediately and cannot be removed. The nurse must be aware of the drug's intended effects and possible adverse effects. In addition, hypersensitivity (allergic) reactions may occur quickly.
- Most Canadian provinces (e.g., Alberta, Manitoba, Ontario, Saskatchewan) have passed laws or regulations pertaining to the use of safety-engineered devices (needleless systems for infusion lines).
- Before giving an intravenous medication, assess the patient's drug allergies, the intravenous line for patency, and the site for signs of phlebitis or infiltration.
- When more than one intravenous medication is to be given, check with the pharmacy for compatibility if medications are to be infused at the same time.
- Check the expiration date of both the medication and infusion bags.

- Age-related considerations: For children, infusion pumps must be used to prevent the risk of infusing the fluid and medication too fast.
- In many institutions, the pharmacy prepares the intravenous solutions and intravenous piggyback (IVPB) admixtures under a special laminar airflow hood. Most IVPB medications

Fig. 10.64 Two types of intravenous piggyback (IVPB) medication delivery systems. These IVPB medications must be activated before administration to the patient. (From Rick Brady, Riva, MD.)

come in vials that are added to the intravenous bag just before administration. When you dilute a drug for intravenous use, contact the pharmacist for instructions. Be sure to verify which type of fluid to use and the correct amount of solution for the dosage according to agency-specific guidelines or protocols for IV medication dilution and administration.

- Many IVPB medications are provided as part of an “add-a-vial” system that allows the intravenous medication vial to be attached to a small-volume minibag for administration. [Figure 10.64](#) shows two examples of IVPB medications attached to small-volume infusion bags.
- These IVPB medication set-ups allow for mixing of the drug and diluent immediately before the medication is given. Remember that if the seals are not broken and the medication is not mixed with the fluid in the infusion bag, then the medication stays in the vial. As a result, the patient does not receive the ordered drug dose; instead, the patient receives a small amount of plain intravenous fluid.
- It is important to choose the correct solution for diluting intravenous medications. For example, phenytoin must be infused with normal saline (NS), not dextrose solutions (see [Chapter 15](#)). Check with the pharmacist if necessary.
- One type of IVPB that needs to be activated before administration is illustrated in [Figure 10.65](#). To activate this type of IVPB system, snap the connection area between the intravenous infusion bag and the vial ([Figure 10.66](#)). Gently squeeze the fluid from the infusion bag into the vial and allow the medication to dissolve ([Figure 10.67](#)). After a few minutes, rotate the vial gently to ensure that all the powder is dissolved. When the drug is fully dissolved, hold the IVPB apparatus by the vial and squeeze the bag; fluid will enter the bag from the vial. Make sure that all the medication is returned to the IVPB bag.
- When hanging these IVPB medications, take care NOT to squeeze the bag. This may cause some of the fluid to leak back into the vial and alter the dose given.
- Always label the IVPB bag with the patient’s name and room number, the name of the medication, the dose, the date and time mixed, your initials, and the date and time the medication was given.

Fig. 10.65 Activating an IVPB infusion bag (step 1). (From Rick Brady, Riva, MD.)

Fig. 10.66 Activating an IVPB infusion bag (step 2). (From Rick Brady, Riva, MD.)

Fig. 10.67 Activating an IVPB infusion bag (step 3). (From Rick Brady, Riva, MD.)

- Some intravenous medications must be mixed using a needle and syringe. In many facilities, this procedure may be performed in the pharmacy. If you are mixing the IV medication, be sure to verify which type of fluid to use and the correct amount of solution for the dosage according to agency-specific guidelines or protocols for IV medication dilution and administration. After checking the order and the compatibility of the drug and the intravenous fluid, wipe the port of the intravenous bag with an alcohol swab (Figure 10.68).
- Carefully insert the needle into the centre of the port and inject the medication (Figures 10.69 and 10.70). Note how the medication remains in the lower part of the intravenous infusion bag. Turn the bag gently, end to end, to mix the fluid and added medication (Figure 10.71).
- Always add medication to a new bag of intravenous fluid, not to a bag that has partially infused. The concentration of the medication may be too strong if it is added to a partially full bag.
- Always label the intravenous infusion bag when a drug has been added (Figure 10.72). Label as per institution policy and include the patient's name and room number, the name of the medication, the date and time mixed, your initials, and the date and time the infusion was started. In addition, label all intravenous infusion tubing per institution policy.

Infusions of Intravenous Piggyback Medications

Always begin by performing hand hygiene and maintain standard precautions/routine practices (see Box 10.1). Gloves must be worn.

- Refrigerated medications may need to be left on the counter to warm to room temperature before administering. If you are infusing the IVPB medication for the first time, you will need to attach the medication bag to the appropriate tubing and “prime” the tubing by allowing just enough fluid through the tubing to flush out the air. Take care not to waste too much of the medication when flushing the tubing.
- If you are adding IVPB medication to an infusion that already has tubing, then use the technique of “backpriming” to flush the tubing (Figure 10.73). Backpriming allows for the administration of multiple intravenous medications without multiple disconnections, and thus reduces the risk of contamination of the intravenous tubing system.
- Backpriming allows the removal of the old medication fluid that has remained in the IVPB tubing from the previous dose of intravenous medication. After ensuring that the medication in the primary infusion (if any) is compatible with the medication in the IVPB bag, close the roller clamp on the primary infusion if the intravenous fluid is infusing by gravity flow (not necessary if an infusion pump is used). Remove the empty IVPB container from the intravenous pole, lower it to below the level of the primary infusion bag, and open the clamp on the IVPB tubing. This will allow fluid to flow from the primary intravenous bag into the empty IVPB bag. Then, close the clamp on the IVPB tubing and squeeze the fluid that is in the drip chamber into the old IVPB bag to remove the old medication fluid. At this point, you may attach the new dose of intravenous medication to the IVPB tubing.

Figs. 10.68, 10.69, and 10.70 Adding a medication to a full intravenous infusion bag with a needle and syringe (prior to initiating the infusion). (From Rick Brady, Riva, MD.)

Fig. 10.71 Mix the medication thoroughly before infusing. (From Rick Brady, Riva, MD.)

Fig. 10.72 Label the intravenous infusion bag when medication has been added. (From Rick Brady, Riva, MD.)

- Backpriming will not be possible if the primary intravenous infusion contains heparin sulphate, aminophylline, a vasopressor, or multivitamins. Check with a pharmacist if unsure about compatibility.
- Stopping intravenous infusions of medications such as vasopressors for an IVPB medication may affect a patient's blood pressure; stopping intravenous heparin may affect the patient's coagulation levels. Be sure to assess carefully before adding an IVPB medication to an existing infusion. A separate intravenous line may be necessary.
- [Figure 10.74](#) shows an IVPB medication infusion (also known as the *secondary infusion*) with a primary gravity

Fig. 10.73 Flush the intravenous piggyback (secondary) tubing by using the backpriming method. Fluid is drained through the tubing into the old intravenous piggyback bag, which is then discarded. The new dose of medication is then attached to the primed secondary tubing.

Fig. 10.74 Infusing an IVPB medication with a primary gravity intravenous infusion. (From Rick Brady, Riva, MD.)

infusion. When the IVPB bag is hung higher than the primary intravenous infusion bag, the IVPB medication will infuse until empty, and then the primary infusion will take over again.

- When beginning the infusion, attach the IVPB tubing to the upper port on the primary intravenous tubing. A back-check valve above this port prevents the medication from infusing up into the primary intravenous infusion bag.
- Fully open the clamp of the IVPB tubing and regulate the infusion rate with the roller clamp of the primary infusion tubing. Be sure to note the drip factor of the tubing and calculate the drops per minute count to set the correct infusion rate for the IVPB.

Fig. 10.75 Infusing an IVPB medication with the primary intravenous infusion on an electronic infusion pump. (From Rick Brady, Riva, MD.)

- Monitor the patient during the infusion. Observe for hypersensitivity and for adverse reactions. In addition, observe the intravenous infusion site for infiltration. Have the patient report if pain or burning occurs.
- Monitor the rate of infusion during the IVPB administration. Changes in arm position may alter the infusion rate.
- When the infusion is complete, clamp the IVPB tubing and check the primary intravenous infusion rate. If necessary, adjust the clamp to the correct infusion rate.
- [Figure 10.75](#) shows an IVPB medication infusion with a primary infusion that is running through an electronic infusion pump.
- When giving IVPB drugs through an intravenous infusion controlled by a pump, attach the IVPB tubing to the port on the primary intravenous tubing above the pump. Open the roller clamp of the IVPB medication tubing. Make sure that the IVPB bag is higher than the primary intravenous infusion bag.
- Following the manufacturer's instructions, set the infusion pump to deliver the IVPB medication. Entering the volume of the IVPB bag and the desired time frame of the infusion (e.g., over a 60-minute period) will cause the pump to automatically calculate the IVPB rate. Start the IVPB infusion as instructed by the pump.
- Monitor the patient during the infusion, as described earlier.
- When the infusion is complete, the primary intravenous infusion will automatically resume.
- Document the medication given on the MAR (see [Figure 10.5](#)), and monitor the patient for a therapeutic response as well as for adverse reactions.
- When giving intravenous medications through a saline (heparin) lock, follow the facility's guidelines for the flushing protocol before and after the medication is administered.

Fig. 10.76 Instructing the patient on the use of a patient-controlled analgesia (PCA) pump. (From Perry, A. G., & Potter, P. A. (2010). *Clinical nursing skills and techniques* (7th ed.). St. Louis, MO: Mosby.)

Fig. 10.77 An electronic smart pump. The two components on the right side are a patient-controlled analgesia pump. (From Perry, A. G., & Potter, P. A. (2014). *Clinical nursing skills and techniques* (8th ed.). St. Louis, MO: Mosby.)

- In patient-controlled analgesia (PCA), a specialized pump is used to allow patients to self-administer pain medications, usually opiates ([Figure 10.76](#)). These pumps allow the patient to self-administer only as much medication as needed to control the pain, by pushing a button for intravenous bolus doses. Safety features of the pump prevent accidental overdoses. A patient receiving PCA pump infusions should be monitored closely for response to the drug, excessive sedation, hypotension, and changes in mental and respiratory status. Follow the facility's guidelines for set-up and use.
- [Figure 10.77](#) displays a smart pump, a type of intravenous infusion safety system designed to reduce intravenous medication errors. A smart pump contains built-in software that is programmed with facility-specific dosing profiles. The pump is able to “check” the dose-limits and other clinical guidelines, and when the pump is set up for patient use, it can warn the nurse if a potentially unsafe drug dose or therapy is entered.

Intravenous Push Medications

Always begin by performing hand hygiene and maintain standard precautions/routine practices (see [Box 10.1](#)). When administering intravenous push (or bolus) medications, keep in mind the following points:

- Registered nurses are usually the only nursing staff members allowed to give intravenous push medications. This may vary at different facilities.
- Intravenous push injections allow for rapid intravenous administration of a drug. The term *bolus* refers to a dose given all at once. Intravenous push injections may be given through an existing intravenous line, through an intravenous (saline or heparin) lock, or directly into a vein.
- Because the medication may have an immediate effect, monitor the patient closely for therapeutic effects as well as for adverse reactions.
- Follow the pharmacy or manufacturer's instructions carefully when preparing an intravenous push medication. Some drugs require careful dilution. Consult the pharmacist if unsure about the dilution procedure. Improper dilution may increase the risk of phlebitis and other complications. Always follow the agency guidelines or policies for dilution and administration of IV push medications.
- Some drugs are never given by intravenous push. Examples include dopamine, potassium chloride, and antibiotics such as vancomycin. Some medications administered by IV push require specific monitoring and are given only in specialty areas such as the emergency department and Critical Care Unit. Follow agency protocols on the administration of drugs given by IV push.
- Small amounts of medication—less than 1 mL—need to be diluted in 5 to 10 mL of NS or another compatible fluid to ensure that the medication does not collect in a “dead space” of the tubing (such as the Y-site port). Check the facility's policy.
- Most drugs given by intravenous push injection are to be given over a period of 1 to 5 minutes to reduce local or systemic adverse effects. Always time the administration with your watch because it is difficult to estimate the time accurately. Adenosine, however, must be given rapidly, within 2 to 3 seconds, for optimal action. ALWAYS check packaging information for guidelines, because many errors and adverse effects have been associated with too-rapid intravenous drug administration.

Intravenous Push Medications Through a Peripheral Intravenous Lock

- Obtain two syringes of 0.9% NS; both syringes should contain the required amount of fluid or solution according to agency policy. (Facilities may differ in protocol for intravenous lock flushes.) Many facilities provide prefilled syringes. Prepare medication for injection. If ordered, prepare a syringe with heparin sulphate flush solution.
- Follow the guidelines for a needleless system, if used.
- Cleanse the injection port of the intravenous lock with an alcohol or antiseptic swab for 15 seconds or according to agency protocol ([Figure 10.78](#)).
- Insert the syringe of NS into the injection port ([Figure 10.79](#); a needleless system is shown). Open the clamp of the intravenous lock tubing, if present.

Fig. 10.78 Cleanse the port before attaching the syringe. (From Rick Brady, Riva, MD.)

Fig. 10.79 Attaching the syringe to the intravenous lock. (From Rick Brady, Riva, MD.)

- Gently aspirate and observe for blood return. Be sure to follow the agency policy regarding the need to aspirate for blood. Absence of blood return does not mean that the intravenous line is occluded; further assessment may be required.
- Flush gently with saline while assessing for resistance. A push-pause technique is recommended when instilling flush solution (e.g., give 2 mL to 3 mL of flush, pause, give another 3 mL of flush, pause, give another 2 mL to 3 mL of flush, and repeat until completed). The push-pause action creates turbulence within the needleless connector and catheter for more thorough flushing. If you feel resistance, do not apply force. Stop and reassess the intravenous lock.
- Observe for signs of infiltration while injecting saline.
- Reclamp the tubing (if a clamp is present) and remove the NS syringe. Repeat cleansing of the port and attach the medication syringe. Open the clamp again.
- Inject the medication over the prescribed length of time. Measure time with a watch or clock ([Figure 10.80](#)).
- When the medication is infused, clamp the intravenous lock tubing (if a clamp is present), and remove the syringe.
- Repeat cleansing of the port; attach a 2- 3-mL NS syringe and inject the contents into the intravenous lock slowly. If a heparin sodium flush is ordered, attach the syringe containing

Fig. 10.80 Slowly inject the intravenous push medication through the intravenous lock; use a watch to time the injection. (From Rick Brady, Riva, MD.)

Fig. 10.81 When giving an intravenous push medication through an intravenous line, pinch the tubing just above the injection port. (From Rick Brady, Riva, MD.)

the heparin sodium flush solution and inject slowly (per the institution's protocol).

Intravenous Push Medications Through an Existing Infusion

- Prepare the medication for injection. Follow the guidelines for a needleless system, if used.
- Check compatibility of the intravenous medication with the existing intravenous solution.
- Choose the injection port that is closest to the patient.
- Remove the cap, if present, and cleanse the injection port with an alcohol or antiseptic swab.
- Occlude the intravenous line by pinching the tubing just above the injection port (Figure 10.81). Attach the syringe to the injection port.
- Gently aspirate for blood return.
- While keeping the intravenous tubing clamped, slowly inject the medication according to administration guidelines. Be sure to time the injection with a watch or clock.
- After the injection, release the intravenous tubing, remove the syringe, and check the infusion rate of the intravenous fluid.

After Injecting an Intravenous Push Medication

- Monitor the patient closely for adverse effects. Monitor the intravenous infusion site for signs of phlebitis and infiltration.
- Document medication given on the MAR (see Figure 10.5), and monitor the patient for therapeutic response as well as adverse effects.

TOPICAL DRUGS

Administering Eye Medications

Always begin by performing hand hygiene and maintain standard precautions/routine practices (see Box 10.1). Gloves may be worn. When administering eye preparations, keep in mind the following points:

- Assist the patient to a supine or sitting position. The patient's head should be tilted back slightly. Make sure the patient is not wearing contact lenses.

Fig. 10.82 Cleanse the eye, washing from the inner canthus to the outer canthus, before giving eye medications. (From Perry, A. G., & Potter, P. A. (2006). *Clinical nursing skills and techniques* (6th ed.). St. Louis, MO: Mosby.)

- Remove any secretions with a sterile gauze pad; be sure to wipe from the inner to the outer canthus (Figure 10.82).
- Instruct the patient to tilt the head slightly back. With your nondominant hand, gently pull the lower lid open to expose the conjunctival sac.

Eye Drops

- With your dominant hand resting on the patient's forehead, hold the eye medication dropper 1 to 2 cm above the conjunctival sac. Do not touch the tip of the dropper to the eye or with your fingers (Figure 10.83).
- Drop the prescribed number of drops into the conjunctival sac. Never apply eye drops to the cornea.
- If the drops land on the outer lid margins (if the patient moved or blinked), repeat the procedure.
- Age-related considerations: Infants often squeeze the eyes tightly shut to avoid eye drops. To give drops to an uncooperative infant, restrain the head gently and place the drops at the corner where the eyelids meet the nose. When the eye opens, the medication will flow into the eye.

Fig. 10.83 Insert the eye drop into the lower conjunctival sac. (From Elkin, M. K., Perry, A. G., & Potter, P. A. (2004). *Nursing interventions and clinical skills* (3rd ed.). St. Louis, MO: Mosby.)

Fig. 10.85 Applying gentle pressure against the nasolacrimal duct after giving eye medications. (From Rick Brady, Riva, MD.)

Fig. 10.84 Applying eye ointment. (From Rick Brady, Riva, MD.)

Eye Ointment

Gently squeeze the tube of medication to apply an even strip of medication (about 1 to 2 cm) along the border of the conjunctival sac. Start at the inner canthus and move toward the outer canthus (Figure 10.84).

After Instilling Eye Medications

- Ask the patient to close the eye gently. Squeezing the eye shut may force the medication out of the conjunctival sac. A tissue may be used to blot liquid that runs out of the eye, but instruct the patient not to wipe the eye.
- You may apply gentle pressure to the patient's nasolacrimal duct for 30 to 60 seconds, with a gloved finger wrapped in a tissue. This will help reduce systemic absorption of the drug through the nasolacrimal duct and may also help to reduce the taste of the medication in the oropharynx from the nasopharynx (Figure 10.85).
- If multiple eye drops are due at the same time, wait several minutes before administering the second medication. Check the instructions for the specific drug.
- Assist the patient to a comfortable position. Warn the patient that vision may be blurry for a few minutes.
- Document the medication given on the MAR (see Figure 10.5), and check the patient for a therapeutic response as well as for adverse reactions.

Fig. 10.86 With adults, pull the pinna up and back. (From Rick Brady, Riva, MD.)

Administering Eardrops

Always begin by performing hand hygiene and maintain standard precautions/routine practices (see Box 10.1). Gloves may be worn. When administering ear medications, keep in mind the following points:

- After explaining the procedure to the patient, assist the patient to a side-lying position with the affected ear facing up. If drainage is noted in the outer ear canal, remove it carefully without pushing it back into the ear canal.
- Remove excessive amounts of cerumen before instilling medication.
- If refrigerated, warm the ear medication by taking it out of refrigeration for at least 30 minutes before administration. Instillation of cold eardrops can cause nausea, dizziness, and pain.
- Age-related considerations: For an adult or a child 3 years or older, pull the pinna up and back (Figure 10.86). For an infant or a child younger than 3 years of age, pull the pinna down and back (Figure 10.87).
- Administer the prescribed number of drops. Direct the drops along the sides of the ear canal rather than directly onto the eardrum.

Fig. 10.87 With infants and children under 3 years of age, pull the pinna down and back. (From Rick Brady, Riva, MD.)

- Instruct the patient to lie on one side for 5 to 10 minutes. Gently massaging the tragus of the ear with a finger will help distribute the medication down the ear canal.
- If ordered, a loose cotton pledget can be gently inserted into the ear canal to prevent the medication from flowing out. The cotton must remain somewhat loose to allow any discharge to drain out of the ear canal. To prevent the dry cotton from absorbing the eardrops that were instilled, moisten the cotton with a small amount of medication before inserting the pledget. Insertion of cotton too deeply may result in increased pressure within the ear canal and on the eardrum. Remove the cotton after about 15 minutes.
- If medication is needed in the other ear, wait 5 to 10 minutes after instillation of the first eardrops before administering.
- Document the medication given on the MAR (see [Figure 10.5](#)), and monitor the patient for a therapeutic response as well as for adverse reactions.

Administering Nasal Medications

Always begin by performing hand hygiene and maintain standard precautions/routine practices (see [Box 10.1](#)). Patients may self-administer some of these drugs after proper instruction. Gloves must be worn. When administering nasal medications, keep in mind the following points:

- Before giving nasal medications, explain the procedure to the patient and tell the patient that temporary burning or stinging may occur. Instruct the patient that it is important to clear the nasal passages by blowing the nose, unless contraindicated (e.g., with increased intracranial pressure or nasal surgery), before administering the medication. Assess for deviated septum or a history of nasal fractures, because these may impede the patient's ability to inhale through the affected nostril.
- [Figure 10.88](#) illustrates delivery forms for nasal medications: sprays, drops, and dose-measured sprays.
- Assist the patient to the supine position. Support the patient's head as needed.

Fig. 10.88 Nasal medications in various delivery forms. (Flonase® photo reproduced with permission from GlaxoSmithKline Inc., Canada. All rights reserved. Nasonex® photo reproduced with permission from Schering Canada, Inc. All rights reserved.)

Fig. 10.89 Administering nose drops.

- If specific areas are targeted for the medication, position the patient's head as follows:
 - For the posterior pharynx, position the head backward.
 - For the ethmoid or sphenoid sinuses, place the head gently over the top edge of the bed or place a pillow under the shoulders, and tilt the head back.
 - For the frontal or maxillary sinuses, place the head back and turned toward the side that is to receive the medication.

Nasal Drops

- Hold the nose dropper approximately 1 cm above the nostril. Administer the prescribed number of drops toward the midline of the ethmoid bone ([Figure 10.89](#)).
- Repeat the procedure as ordered, instilling the indicated number of drops per nostril.
- Keep the patient in the supine position for 5 minutes.
- Age-related considerations: Infants are nose breathers, and the potential congestion caused by nasal medications may make it difficult for them to suck. If nose drops are ordered, administer them 20 to 30 minutes before a feeding.

Fig. 10.90 Before self-administering the nasal spray, the patient should occlude the other nostril and spray the medication away from the septum.

Nasal Spray

- Have the patient sit upright and occlude one nostril by pressing a finger against the outer naris. After gently shaking the nasal spray container, insert the tip into the nostril. Squeeze the spray bottle into the nostril while the patient inhales through the open nostril (Figure 10.90).
- Repeat the procedure as ordered, instilling the indicated number of sprays per nostril.
- Keep the patient in the supine position for 5 minutes.

After Administration of Nasal Medicines

- Offer the patient tissues for blotting any drainage but instruct the patient to avoid blowing her nose for several minutes after instillation of the drops or spray.
- Assist the patient to a comfortable position.
- Document the medication administration on the MAR (see Figure 10.5), and document drainage, if any. Monitor the patient for a therapeutic response as well as for adverse reactions.

Administering Inhaled Drugs

Always begin by performing hand hygiene and maintain standard precautions/routine practices (see Box 10.1). Gloves may be worn. Patients with asthma need to monitor their peak expiratory flow rates by using a peak flowmeter. A variety of inhalers are available (Figure 10.91). Be sure to check for specific instructions from the manufacturer, as needed. Improper use will result in inadequate dosing and lack of therapeutic effect. When administering inhaled preparations, keep in mind the following points:

Metered-Dose Inhalers

- A spacer is always used with a pressured metered-dose inhaler (MDI) that delivers inhaled corticosteroids. Spacers can make it easier for medication to reach the lungs, and also mean that less medication gets deposited in the mouth and throat, where it can lead to irritation and mild infections.

Fig. 10.91 A, Metered-dose inhaler (MDI). B, Automated MDI. C, "Disk-type" MDI for delivering powdered medication. (From Rick Brady, Riva, MD.)

Fig. 10.92 Using an MDI without a spacer. (From Elkin, M. K., Perry, A. G., & Potter, P. A. (2004). *Nursing interventions and clinical skills* (3rd ed.). St. Louis, MO: Mosby.)

- Shake the MDI gently before using.
- Remove the cap; hold the inhaler upright, and grasp with the thumb and first two fingers.
- Tilt the patient's head back slightly.
- If the MDI is used without a spacer, do the following: Remove the inhaler cap; hold the inhaler upright and grasp with the thumb and first two fingers.
 1. Have the patient open his mouth; position the inhaler 3 to 5 cm away from the mouth (Figure 10.92). For self-administration, some patients may measure this distance as 1 to 2 finger-widths.
 2. Have the patient exhale, then press down once on the inhaler to release the medication; have the patient breathe in slowly and deeply for 5 seconds.
 3. Have the patient hold his breath for approximately 10 seconds and then exhale slowly through pursed lips.
- Age-related consideration: Spacers can be used with children and adults who have difficulty coordinating inhalations with

Fig. 10.93 Using a spacer device with an MDI. (From Rick Brady, Riva, MD.)

activation of metered-dose inhalers (see [Chapter 38](#)). If the inhaler is used with a spacer, do the following:

1. Remove the inhaler cap and then attach the spacer to the mouthpiece of the inhaler.
 2. Place the mouthpiece of the spacer in the patient's mouth.
 3. Have the patient exhale.
 4. Press down on the inhaler to release the medication and have the patient inhale deeply and slowly through the spacer. The patient then breathes in and out slowly for 2 to 3 seconds and then holds her breath for 10 seconds ([Figure 10.93](#)).
 5. Clean the spacer. Take the spacer apart and gently move the parts back and forth in warm, soapy water. Avoid the use of high-pressure or boiling hot water, rubbing alcohol, or disinfectant. Rinse the parts well in clean water. Do not dry the inside of the spacer with a towel as it will create static; rather, air dry.
- If a second puff of the same medication is ordered, wait 1 to 2 minutes between puffs.
 - If a second type of inhaled medication is ordered, wait 2 to 5 minutes between medication inhalations or as prescribed.
 - If both a bronchodilator and a corticosteroid inhaled medication are ordered, the bronchodilator should be administered first so that the air passages will be more open for the second medication.
 - Instruct the patient to rinse the mouth with water after inhaling a steroid medication to prevent the development of an oral fungal infection.
 - Document the medication given on the MAR (see [Figure 10.5](#)), and monitor the patient for a therapeutic response as well as for adverse reactions.
 - It is important to teach the patient how to calculate the number of doses in the inhaler and to keep track of uses. Simply shaking the inhaler to "estimate" whether it is empty is not accurate and may result in its being used when it is empty. Many metered-dose inhalers now come with devices that help to count the remaining doses. If the inhaler does not have a dose-counting device, the patient should be taught to count the number of puffs needed per day (doses) and divide this amount into the actual number of actuations (puffs) in

Fig. 10.94 Adding medication to the nebulizer cup.

the inhaler to estimate the number of days the inhaler will last. Then, a calendar can be marked a few days before this date with a note that it is time to obtain a refill. In addition, the date can be marked on the inhaler with a permanent marker. For example, an inhaler with 200 puffs, ordered to be used 4 times a day (2 puffs per dose, 8 puffs per day), would last for 25 days (200 divided by 8). The patient may experience the sensation of a puff even when the canister is empty. This sensation occurs from the propellant even if there is little or no drug in the puff, and it is, therefore, not effective. Dry powder inhalers have varied instructions, so follow the manufacturer's instructions closely. Instruct patients to cover the mouthpiece completely with their mouths. Capsules that are intended for use with these inhalers should NEVER be taken orally. Some dry powder inhalers also have convenient, built-in dose counters.

Small-Volume Nebulizers

- Check the doctor's order regarding the use of compressed air or oxygen for the administration of the nebulizer treatment.
- In some facilities, the air compressor is located in the wall unit of the room. In other facilities and at home, a small, portable air compressor is used. Be sure to follow the manufacturer's instructions for use.
- In some facilities, nebulizer treatments may be performed by a respiratory therapist. However, closely monitor the patient before, during, and after the drug administration.
- Be sure to take the patient's baseline heart rate, especially if a beta-adrenergic drug is used. Some drugs may increase the heart rate.
- After gathering the equipment, add the prescribed medication to the nebulizer cup ([Figure 10.94](#)). Some medications will require a diluent; others are premixed with a diluent. Be sure to verify before adding a diluent.

Fig. 10.95 Administering a small-volume nebulizer treatment. (From Rick Brady, Riva, MD.)

- Have the patient hold the mouthpiece between the lips ([Figure 10.95](#)).
- Age-related considerations: Use a face mask for a child or an adult who is too fatigued to hold the mouthpiece. Special adaptors are available if the patient has a tracheostomy.
- Before starting the nebulizer treatment, have the patient take a slow, deep breath, hold it briefly, then exhale slowly. Patients who are short of breath should be instructed to hold their breath every fourth or fifth breath.
- Turn on the small-volume nebulizer machine (or turn on the wall unit), and make sure that a sufficient mist is forming.
- Instruct the patient to repeat the breathing pattern mentioned previously during the treatment.
- Occasionally tap the nebulizer cup, during the treatment and toward the end, to move the fluid droplets back to the bottom of the cup.
- Monitor the patient's heart rate during and after the treatment.
- If inhaled steroids are given, instruct the patient to rinse his mouth afterward.
- After the procedure, clean and store the tubing per institution policy.
- Document the medication given on the MAR (see [Figure 10.5](#)), and monitor the patient for a therapeutic response as well as for adverse reactions.
- If the patient will be using a nebulizer at home, instruct the patient to rinse the nebulizer parts daily after each use with warm, clear water and allow to air dry. Soak the nebulizer parts in a vinegar and water solution (four parts water and one part white vinegar) for 30 minutes; rinse thoroughly with clear, warm water; and air dry. Storing nebulizer parts that are still wet will encourage bacterial and mould growth.

Administering Medications to the Skin

Always begin by performing hand hygiene and maintain standard precautions/routine practices (see [Box 10.1](#)). Gloves must be worn. Avoid touching the preparations to your own skin. When administering skin preparations, keep in mind the following points:

Fig. 10.96 Use gloves to apply topical skin preparations. (From Rick Brady, Riva, MD.)

Lotions, Creams, Ointments, and Powders

- Apply powder to clean, dry skin. Have the patient turn her head to the other side during application to avoid inhalation of powder particles.
- Apply lotion to clean, dry skin. Remove residual from previous applications with soap and water.
- Before administering any dose of a topical skin medication, ensure that the site is clean and dry. Thoroughly remove previous applications using soap and water, if appropriate for the patient's condition, and dry the area thoroughly. Be sure to remove any debris, drainage, or pus, if present.
- Age-related considerations: The skin of an older patient may be more fragile and easily bruised or damaged (e.g., skin tears and possible breakdown of skin from use of tape). Be sure to assess for appropriateness of the skin area before applying medication, and handle the skin gently when cleansing to prepare the site for medication and when applying medications.
- With lotion, cream, or gel, obtain the correct amount with your gloved hand ([Figure 10.96](#)). If the medication is in a jar, remove the dose with a sterile tongue depressor and apply to your gloved hand. Do not contaminate the medication in the jar.
- Some ointments and creams may soil the patient's clothes and linens. If these preparations are ordered, cover the affected site with gauze or a transparent dressing.
- Although nitroglycerin ointment is not used as frequently as nitroglycerin transdermal patches, it is still available for use. Nitroglycerin ointment in a tube is measured carefully on clean, ruled application paper before it is applied to the skin. Do not massage nitroglycerin ointment into the skin. Apply the measured amount onto a clean, dry site and then secure the application paper with a transparent dressing or a strip of tape ([Figure 10.97](#)). Always remove the old medication before applying a new dose. Rotate application sites.

Transdermal Patches

- Be sure that the used patch is removed as ordered. Some patches may be removed before the next patch is due—check the order. Clear patches may be difficult to find, and patches

Fig. 10.97 Spread the lotion on the skin with long, smooth, gentle strokes. (From Rick Brady, Riva, MD.)

may be overlooked in obese patients with skin folds. Cleanse the site of the used patch thoroughly. Observe for signs of skin irritation at the old patch site. Rotate sites of application with each dose.

- Transdermal patches that are ordered daily should be applied at the same time each day.
- The used patch can be pressed together and then wrapped in a glove as you remove the glove from your hand. Dispose in the proper container according to the facility's policy. Fentanyl patches are to be disposed of in the sharps container.
- Select a new site for application and ensure that it is clean and without powder or lotion. For best absorption and fewest adverse effects, the site needs to be hairless and free from scratches or irritation. If it is necessary to remove hair, clip the hair instead of shaving to reduce irritation to the skin. Application sites may vary. Follow the drug manufacturer's specific instructions as to where to apply the patch.
- Remove the backing from the new patch (Figure 10.98). Take care not to touch the medication side of the patch with your fingers.
- Place the patch on the skin site and press firmly (Figure 10.99). Press around the edges of the patch with one or two fingers to ensure that the patch is adequately secured to the skin. If an overlay is provided by the drug manufacturer, apply it over the patch.
- Instruct the patient not to cut transdermal patches. Cutting transdermal patches releases all of the medication at once and may result in a dangerous overdose.
- Instruct the patient to safely dispose of the old patch by folding the medicated side facing inward. Using this disposal method prevents contact with the drug-eluting portion of the patch.

Fig. 10.98 Opening a transdermal patch medication. (From Rick Brady, Riva, MD.)

Fig. 10.99 Ensure that the edges of the transdermal patch are secure after applying. (From Rick Brady, Riva, MD.)

After Administering Topical Skin Preparations

- Chart the medication given on the MAR (see Figure 10.5), and monitor the patient for a therapeutic response as well as for adverse reactions.
- Provide instruction on administration to the patient or caregiver.

Analgesic Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Define *acute pain* and *persistent (chronic or long-term) pain*.
2. Contrast the signs, symptoms, and management of acute and persistent pain.
3. Discuss the pathophysiology and characteristics associated with cancer pain and other special pain situations.
4. Describe pharmacological and nonpharmacological approaches for the management and treatment of acute and persistent pain.
5. Discuss the use of nonopioids, nonsteroidal anti-inflammatory drugs (NSAIDs), and opioids (opioid agonists, opioids with mixed actions, opioid agonist-antagonists, and antagonists), and miscellaneous drugs in the management of acute and persistent pain, cancer pain, and special pain situations.
6. Identify examples of drugs classified as nonopioids, nonsteroidal anti-inflammatory drugs, opioids (opioid agonists, opioids with mixed actions, opioid agonist-antagonists, and antagonists), and miscellaneous drugs.
7. Briefly describe the mechanisms of action, indications, dosages, routes of administration, adverse effects, toxicity, cautions, contraindications, and drug interactions of nonopioids, nonsteroidal anti-inflammatory drugs (see [Chapter 49](#)), opioids (opioid agonists, opioids with mixed actions, opioid agonist-antagonists, and antagonists), and miscellaneous drugs.
8. Contrast the pharmacological and nonpharmacological management of acute and persistent pain associated with cancer and pain experienced in terminal conditions.
9. Briefly describe the specific standards of pain management as defined by the World Health Organization and the Canadian Pain Society.
10. Develop a collaborative plan of care based on the nursing process as a result of the use of nonopioid and opioid drug therapy and the nursing process for patients in pain.
11. Identify various resources, agencies, and professional groups that are involved in establishing standards for the management of all types of pain and for promotion of a holistic approach to the care of patients with acute or persistent pain and those in special pain situations.

KEY TERMS

Acute pain Pain that is sudden in onset, usually subsides when treated, and typically occurs over less than a 6-week period. (p. 167)

Addiction Strong psychological or physical dependence on a drug or other psychoactive substance, usually resulting from habitual use, that is beyond normal voluntary control. (p. 171)

Adjuvant analgesic drugs Drugs that are added for combined therapy with a primary drug and may have additive or independent analgesic properties, or both. (p. 166)

Agonists Substances that bind to a receptor and cause a response. (p. 172)

Agonist-antagonists Substances that bind to a receptor and cause a partial response that is not as strong as that caused by agonists (also known as *partial agonists*). (p. 172)

Analgesic ceiling effect The effect that occurs when a particular pain drug no longer effectively controls a patient's pain despite the administration of the highest safe dosages. (p. 172)

Analgesics Medications that relieve pain (sometimes referred to as *painkillers*). (p. 166)

Antagonists Substances that bind to a receptor and prevent (block) a response, resulting in inhibitory or antagonistic drug effects; also called *inhibitors*. (p. 173)

Breakthrough pain Pain that occurs between doses of pain medication. (p. 171)

Cancer pain Pain resulting from any of a variety of causes resulting from cancer or the metastasis of cancer. (p. 168)

Central pain Pain resulting from any disorder that causes central nervous system damage. (p. 169)

Gate control theory A common and well-described theory of pain transmission and pain relief. It uses a gate model to explain how impulses from damaged tissues are sensed in the brain. (p. 169)

Neuropathic pain Pain that results from a disturbance of function or pathological change in a nerve. (p. 168)

Nociception Processing of pain signals in the brain that gives rise to the feeling of pain. (p. 166)

Nociceptive pain Pain that arises from mechanical, chemical, or thermal irritation of peripheral sensory nerves (e.g., after surgery or trauma or associated with degenerative processes). Two subtypes of nociceptive pain are visceral and somatic. (p. 166)

Nociceptors A subclass of sensory nerves (A and C fibres) that transmit pain signals to the central nervous system from other body parts. (p. 166)

Nonopioid analgesics Analgesics that are structurally and functionally different from opioids. (p. 182)

Nonsteroidal anti-inflammatory drugs (NSAIDs) A large, chemically diverse group of drugs that are analgesics and possess anti-inflammatory and antipyretic properties but are not corticosteroids. (p. 169)

Opiate analgesics Synthetic drugs that bind to opiate receptors to relieve pain. (p. 173)

Opioid naive A description of patients who are receiving opioid analgesics for the first time or intermittently for a brief period of time and who therefore are not accustomed to their effects. (p. 176)

Opioid tolerant The opposite of *opioid naive*; a description of patients who have been receiving opioid analgesics (legally or otherwise) for a period of time (1 week or longer) and who are at greater risk of opioid withdrawal syndrome upon sudden discontinuation. (p. 171)

Opioid withdrawal The signs and symptoms associated with abstinence from, withdrawal of, or dose reduction of an

opioid analgesic when the body has become physically dependent on the substance. (p. 176)

Pain An unpleasant sensory and emotional experience associated with actual or potential tissue damage. (p. 166)

Pain threshold The level of stimulus that results in the sensation of pain. (p. 167)

Pain tolerance The amount of pain a patient can endure without its interfering with normal function. (p. 167)

Partial agonist A drug that binds to a receptor and causes a response that is less than that caused by a full agonist (also known as *agonist-antagonist*). (p. 173)

Persistent pain Recurring pain that is often difficult to treat. Includes any pain lasting longer than 3 to 6 months, pain lasting longer than 1 month after healing of an acute injury, or pain that accompanies a nonhealing tissue injury. (Also referred to as *chronic* or *long-term pain*). (p. 167)

Phantom pain Pain experienced in an area of the body part that has been surgically or traumatically removed. (p. 168)

Psychological dependence A pattern of compulsive use of opioids or any other addictive substance characterized by a continuous craving for the substance and the need to use it for effects other than pain relief (also called *addiction*). (p. 171)

Referred pain Pain occurring in an area away from the organ of origin. (p. 168)

Synergistic effects Drug interactions in which the effect of a combination of two or more drugs with similar actions is greater than the sum of the individual effects of the same drugs given alone. (p. 171)

Tolerance A progressively decreased responsiveness to a drug, resulting in a need for a larger dose of the drug to achieve the effect originally obtained by a smaller dose. (p. 167)

Vascular pain Pain that results from pathology of the vascular or perivascular tissues. (p. 168)

Visceral pain Pain that originates from internal organs or smooth muscles. (p. 166)

* Full generic name is given in parentheses. For the purposes of this text, the more common, shortened name is used.

OVERVIEW

The management of pain is an important aspect of nursing care in a variety of settings and across the lifespan. Pain is one of the most common reasons that patients seek health care and is the underlying reason for 78% of emergency department visits annually in Canada. Surgical and diagnostic procedures often require pain management, as do several diseases, including arthritis, diabetes, multiple sclerosis, cancer, and acquired immune deficiency syndrome (AIDS). Pain leads to much suffering and is a tremendous economic burden as a result of lost workplace productivity, workers' compensation payments, and other related health care costs.

To provide quality patient care, it is important to be well informed about both pharmacological and nonpharmacological methods of pain management. This chapter focuses on pharmacological methods of pain management. Some examples of nonpharmacological methods of pain management are listed in [Box 11.1](#).

Medications that relieve pain are classified as **analgesics**. They are also commonly referred to as *painkillers*. There are various classes of analgesics, determined by their chemical structures and mechanisms of action. The focus of this chapter is primarily on the opioid analgesics, which are used to manage moderate to severe pain. Often drugs from other chemical categories are added to the opioid regimen as **adjuvant analgesic drugs** (or adjuvants), and these are described later. **Pain** is most commonly defined as an unpleasant sensory and emotional experience associated with either actual or potential tissue damage. It is a personal and individual experience. Pain can be defined as whatever the patient says it is, and it exists whenever the patient says it does. Although the mechanisms of pain are becoming better understood, a patient's perception of pain is a complex process. Pain involves physical, psychological, and ethnocultural factors (see Ethnocultural Implications box: The Patient Experiencing Pain: Considerations From a Holistic Perspective). Because pain intensity cannot be precisely quantified, health care providers must cultivate relationships of mutual trust with their patients to provide optimal care.

There is no single approach to effective pain management. Instead, it is tailored to each patient's needs. The cause of the pain, the existence of concurrent medical conditions, the characteristics of the pain, and the psychological and ethnocultural characteristics of the patient all need to be considered. It also requires ongoing reassessment of the pain and the effectiveness of treatment. The patient's emotional response to pain depends on the individual psychological experience of pain. Pain results from the stimulation of sensory nerve fibres known as **nociceptors**. These receptors transmit pain signals from various body regions to the spinal cord and brain, which leads to the sensation of pain, or **nociception** (Fig. 11.1). **Nociceptive pain** is transitory in response and serves an important protective role. There are two subtypes of nociceptive pain: **visceral pain** (pain originating from skeletal muscles, ligaments, or joints) and somatic pain (pain originating from internal organs or smooth muscles).

ETHNOCULTURAL IMPLICATIONS

The Patient Experiencing Pain: Considerations From a Holistic Perspective

- Pain is experienced by individuals, not by a culture. Health care providers often interpret pain behaviour through their own cultural lens and often make assumptions about patients by the behaviours they display.
- Know that there are environmental and ethnocultural variations in pain experience and expression and in health care-seeking treatment.
- Recognize the contributions and limitations of the social determinants of health to pain experience, pain expression, and treatment access.
- Know that pain behaviours and reports are best understood in the context of social interactions among the individual, family, employers, and health care providers and in the context of community, governmental, or legal procedures.
- Be aware of communication about cultural and religious variation that health care providers should consider when assessing and managing pain.
- Recognize that social environmental factors, including the individual's beliefs about the origins and nature of pain and how one should access health care, can influence both experiential and expressive features of pain.
- Recognize the internal and exogenous barriers that impact access to the implementation of pain evaluation and treatment (e.g., individual motivation, beliefs, adverse effects, availability of opioids).
- Remain aware of all ethnocultural influences on health-related behaviours and on patients' attitudes toward medication therapy and thus, ultimately, on its effectiveness. A thorough assessment that includes questions about the patient's cultural background and practices is important to the effective and individualized delivery of nursing care.

BOX 11.1 Nonpharmacological Treatment Options for Pain

- Acupressure
- Acupuncture
- Art therapy
- Behavioural therapy
- Biofeedback
- Comfort measures
- Counselling
- Distraction
- Hot or cold packs
- Hypnosis
- Imagery
- Massage
- Meditation
- Music therapy
- Pet therapy
- Physiotherapy
- Reduction of fear
- Relaxation
- Surgery
- Therapeutic baths
- Therapeutic communication
- Therapeutic touch
- Transcutaneous electrical nerve stimulation
- Warming cabinets/warm blankets
- Yoga

Fig. 11.1 Illustration of the four processes of nociception. (Source: Jarvis C., Browne, A. J., MacDonald-Jenkins, J., et al. (2014). *Physical examination and health assessment* (Canadian 2nd ed.) St Louis, MO: Saunders.)

The physical impulses that signal pain activate various nerve pathways from the periphery to the spinal cord and to the brain. The level of stimulus needed to produce a painful sensation is referred to as the **pain threshold**. Because this is a measure of the physiological response of the nervous system, it is similar for most people. However, variations in pain sensitivity may result from genetic factors.

There are three main receptors believed to be involved in pain. The μ (mu) receptors in the dorsal horn of the spinal cord appear to play the most crucial role. Less important but still involved in pain sensations are the κ (kappa) and δ (delta) receptors. Pain receptors are located in both the central nervous system (CNS) and various body tissues. Pain perception—and, conversely, emotional well-being—is closely linked to the number of μ (mu) receptors. This number is controlled by a single gene, the μ (mu) opioid receptor gene. When the number of receptors is high, pain sensitivity is diminished. Conversely, when the receptors are reduced or missing altogether, relatively minor noxious stimuli may be perceived as painful.

The patient's emotional response to the pain is also moulded by the patient's age, gender, culture, previous pain experience, and anxiety level. Whereas pain threshold is the physiological element of pain, the psychological element of pain is called **pain tolerance**. This is the amount of pain a patient can endure without its interfering with normal function. Because it is a subjective response, pain tolerance can vary from patient to patient.

TABLE 11.1 Conditions That Alter Pain Tolerance

Pain Threshold	Conditions
Lowered	Anger, anxiety, depression, discomfort, fear, isolation, persistent pain, sleeplessness, tiredness
Raised	Diversion, empathy, rest, sympathy, medications (analgesics, antianxiety drugs, antidepressants)

Pain tolerance can be modulated by the patient's personality, attitude, environment, culture, and ethnic background. Pain tolerance can even vary within the same person depending on the circumstances involved. **Table 11.1** lists the various conditions that can alter one's pain tolerance.

Pain can also be further classified in terms of its onset and duration as either acute or persistent. **Acute pain** is sudden and usually subsides when treated. One example of acute pain is postoperative pain. **Persistent pain** (also referred to as *chronic* or *long-term pain*) is recurring, lasting 3 to 6 months. It is often more difficult to treat, because changes occur in the nervous system that often require increasing drug dosages (see Evidence in Practice: Student Nurses' Misconceptions of Adults With Chronic Nonmalignant Pain Review box). This situation is known by the general term **tolerance**. Tolerance is the state of progressively decreased responsiveness to a drug as a result of which a larger dose of the drug is needed to achieve the effect.

EVIDENCE IN PRACTICE

Student Nurses' Misconceptions of Adults With Chronic Nonmalignant Pain Review

The purpose of this study was to identify some of the misconceptions that student nurses have, across 3 years of undergraduate education, about adults who are experiencing chronic, nonmalignant pain. The two major questions that this study sought to explore were as follows: (1) Do student nurses hold misconceptions about adults with chronic, nonmalignant pain? and (2) if so, to what extent do these misconceptions develop during their undergraduate education?

Results of Study

Some 435 students were approached to participate in the research study, and 430 completed and returned the surveys, for a total response rate of 99%. A convenience sampling was used because the students were easily accessible; they represented about 75% of students enrolled in the facility in semesters one, four, and six of the undergraduate nursing degree program in the city of Auckland and around 13% of those enrolled in New Zealand. These participants were distributed over a 3-year period of undergraduate studies during six semesters of full-time studies. The majority were female students, although there was no further specific demographic data collected about the participants. A cross-sectional design meant that data gathered came from each participant only once during the study. A research assistant—one who had not taught the students—met with the students and invited them to participate in the study. Sessions were held in the middle of the semester to increase the response rate as well as diminish anxiety during final exam time. More than 38% of the participants demonstrated a misconception about people with chronic pain and that people were tolerant to some degree of pain. More than 60% did not hold this misconception about tolerance to pain. More than one-half of the students' (59%) responses indicated that they held the misconception that psychological impairment results from chronic pain. Approximately 79% of the students suggested that they believed stress was a contributory cause of chronic pain, whereas less than one-fourth indicated that they accurately understood that this was not the case. The misconception of compensation and exaggeration in chronic pain was held by 47.9% of the participants, and 51.7% did not hold this same misconception. About one-third of the students indicated that they held the misconception that patients with chronic pain were manipulative, and the majority indicated that they did not.

Approximately 64% of the participants held the misconception that depression plays a role in the chronic pain experience. About one-half of the participants (54.8%) held the misconception that patients taking opioids were likely to be addicted. Some 58% of the students indicated that they held the misconception that patients with chronic pain were noncompliant and dependent, whereas 41.4% indicated that they did not hold this misconception. Another question posed to the students was about the extent to which they had developed their misconceptions of patients with chronic pain during their undergraduate education. There were significantly positive trends across the semesters, suggesting that students held their misconceptions to a lesser degree as they progressed through their course of study. In summary, analysis of the results indicates that a substantial proportion of students who participated in the study hold misconceptions about patients with chronic pain to some extent.

The analysis of the misconception scores across the semesters indicates that the knowledge and attitudes of students toward adults experiencing chronic, nonmalignant pain developed to some degree because their misconceptions were held to a lesser degree by the end of the program of study.

Link of Evidence to Nursing Practice

It is a known phenomenon that there is a gap between theory and practice across many areas of professional nursing practice. Therefore, it would be ideal for nursing educators and the nursing educational experience to equip students with the knowledge, skills, and attitudes to participate in the discussion, planning, and implementation of care for patients suffering from chronic, nonmalignant pain. Nursing faculty and schools of nursing need to make available experiential learning situations that will enhance the blending of knowledge, skills, and attitudes into professional nursing practice so that these gaps in care are closed. The findings of this study show that students, like many practising nurses, hold misconceptions about adults with chronic, nonmalignant pain, representing a lack of knowledge and inappropriate attitudes. An integrated approach to teaching chronicity and disability needs to be included in the nursing curriculum; however, critical thinking, linking theory to practice, and developing compassion also need to be part of the educational process.

Shaw, S., & Lee, A. (2010). Student nurses' misconceptions of adults with chronic malignant pain. *Pain Management Nursing*, 11(1), 2–14.

originally obtained by a smaller dose (see Chapter 18). Acute and persistent pain differ in their onset and duration, their associated diseases or conditions, and the way they are treated. **Table 11.2** lists the different characteristics of acute and persistent pain and various diseases and conditions associated with each.

Pain can be further classified according to the diseases or conditions that cause it. **Vascular pain** is believed to originate from the vascular or perivascular tissues and is thought to account for a large percentage of migraine headaches. **Referred pain** occurs when visceral nerve fibres synapse at a level in the spinal cord close to fibres that supply specific subcutaneous tissues in the body. An example is the pain associated with cholecystitis, which is often referred to the back and scapular areas. **Neuropathic pain** usually results from damage to peripheral or CNS nerve fibres by disease or injury but may also be idiopathic (unexplained). **Phantom pain** occurs in the area of a body part that has been removed—surgically or traumatically—and is often described as burning, itching, tingling, or stabbing. It can also occur in paralyzed limbs following spinal cord injury.

TABLE 11.2 Acute Versus Persistent Pain

Type of Pain	Onset	Duration	Examples
Acute	Sudden (minutes to hours); usually sharp, localized; physiological response (SNS: tachycardia, sweating, pallor, increased blood pressure)	Limited (has an end)	Myocardial infarction, appendicitis, dental procedures, kidney stones, surgical procedures
Persistent	Slow (days to months); long duration; dull, long-lasting, aching	Long-lasting or recurring (endless)	Arthritis, cancer, lower back pain, peripheral neuropathy

SNS, Sympathetic nervous system.

Cancer pain can be acute or persistent or both. It most often results from pressure of the tumour mass against nerves, organs, or tissues. Other causes of cancer pain include hypoxia from

Fig. 11.2 Gate control theory of pain transmission. **CNS**, central nervous system.

blockage of blood supply to an organ; metastases; pathological fractures; muscle spasms; and adverse effects of radiation, surgery, and chemotherapy. **Central pain** occurs with tumours, trauma, inflammation, or disease (e.g., cancer, diabetes, stroke, multiple sclerosis) affecting CNS tissues.

Over the course of history, the concept of pain has been influenced by the current knowledge at the time. The most common and well described is the **gate control theory**, proposed by Melzack and Wall in 1965. This theory explains the mechanism underlying the alteration of somatosensory afferents that act like a “gate” that is able to adjust pain signals transmitted from the periphery. Four distinct processes, all of which operate simultaneously, are required for nociceptive pain to occur and are widely believed to determine the perception of and response to acute pain.

The first process, *transduction*, corresponds to the transformation of mechanical, chemical, or thermal stimuli into electrochemical energy. At first, tissue injury prompts the release of

numerous chemicals such as prostaglandins, bradykinin, serotonin, substance P, histamine, and potassium from injured cells. Some current pain medications work by altering the actions and levels of these substances (e.g., **nonsteroidal anti-inflammatory drugs [NSAIDs]** target prostaglandins; antidepressants target serotonin). The release of these pain-mediating chemicals initiates action potentials (electrical nerve impulses), at the distal end of sensory nerve fibres, through pain receptors known as *nociceptors*. These nerve impulses are conducted along sensory nerve fibres and activate pain receptors in the dorsal horn of the spinal cord. This is where the so-called gates are located. These gates regulate the flow of sensory nerve impulses. If impulses are stopped by a gate at this junction, no impulses are transmitted to the higher centres of the brain. Conversely, if the gates permit a sufficient number and intensity of action potentials to be conducted from the spinal cord to the cerebral cortex, the sensation of pain is then felt. This is known as *nociception*. **Fig. 11.2** depicts the gate control theory of pain transmission.

TABLE 11.3 A and C Nerve Fibres

Type of Fibre	Myelin Sheath	Fibre Size	Conduction Speed	Type of Pain
A	Yes	Large	Fast	Sharp and well localized
C	No	Small	Slow	Dull and non-localized

The second process, *transmission*, involves the propagation of pain impulses along pain fibres, as well as other sensory nerve fibres, to activate pain receptors in the spinal cord and brain. There are two types of nociceptor pain fibres: large-diameter A-delta fibres and small-diameter C fibres (Table 11.3). The A-delta fibres constitute the majority of myelinated fibres responsible for the first pain sensation. There are two types of A-delta fibres, which are triggered by the specificity of their responses to different stimulation: the *mechanonociceptors* respond to intense and possibly harmful stimulation (flight or fight response) and the polymodal A-delta fibres respond to mechanical, thermal, and chemical stimulation. The C fibres are unmyelinated and transmit poorly localized, dull, and aching pain.

The majority of nociceptive impulses travel through the anterolateral quadrant of the spinal cord. The spinothalamic tract is the most important pathway for transmission. The nociceptive fibres enter the spinal cord through an area known as the *dorsal (posterior) horn*. Here, the neurotransmitters glutamate and substance P continue the pain impulse across the synaptic cleft between nociceptors and dorsal horn neurons. From the dorsal horn, numerous different ascending fibre tracts within the larger spinothalamic tract transmit pain into the thalamus, where the integration of nociceptive information takes place. From the thalamus, the pain impulses are relegated to the cortical structures for pain.

It is at the dorsal horn that the so-called gates are located and where they control pain transmission. Closing of the gate seems to be affected by the activation of A fibres. This causes the inhibition of impulse transmission to the brain and avoidance of pain sensation. Opening of the gate is affected by the stimulation of C fibres. This allows impulses to be transmitted to the brain and pain to be sensed. The gate is innervated by nerve fibres that originate in the brain and modulate the pain sensation by sending impulses to the gate in the spinal cord. These nerve fibres enable the brain to evaluate, identify, and localize the pain. Thus, the brain can control the gate, either by keeping the gate closed or allowing it to open so that the brain is stimulated and pain is sensed. The cells that control the gate have a threshold. Impulses that reach these cells must rise above this threshold before an impulse is permitted to travel up to the brain.

The third process involved in nociceptive pain, *perception*, is less an actual physiological event than a subjective phenomenon of pain (how it feels) that encompasses complex behavioural, psychological, and emotional factors. An identical stimulus can

evoke different types of pain from one individual to another. The μ (mu) receptors in the dorsal horn appear to play a crucial role. Pain perception and, conversely, emotional well-being, are closely linked to the number of μ receptors. Pain sensitivity is diminished when the receptors are present in relative abundance. When the receptors are reduced in number or missing altogether, relatively minor noxious stimuli may be perceived as painful.

Modulation is the fourth process. Modulation is a neural activity that controls pain transmission to neurons in both the peripheral and central nervous systems. The pathways involved are referred to as the *descending pain system* because the neurons originate in the brainstem and descend to the distal horn of the spinal cord. The descending nerve fibres release endogenous neurotransmitters known as *enkephalins* and *endorphins* (e.g., endogenous opioids, serotonin [5-HT], norepinephrine [NE], gamma-aminobutyric acid [GABA], neurotensin). These substances are produced within the body to fight pain and are considered the body's painkillers. Both types of substances are capable of binding with opioid receptors and inhibiting the transmission of pain impulses by closing the spinal cord gates, in a manner similar to that used by opioid analgesic drugs to produce analgesia. Both are capable of bonding with opioid receptors and inhibiting the transmission of pain impulses by closing the spinal cord gates. The term *endorphin* is a condensed version of the term *endogenous morphine*. These endogenous analgesic substances are released whenever the body experiences pain or prolonged exertion. For example, they are responsible for the phenomenon of "runner's high." Fig. 11.1 depicts this entire process.

Another phenomenon of pain relief that may be explained by the gate control theory is the fact that massaging a painful area often reduces the pain. When an area is rubbed or liniment applied, large sensory A nerve fibres from peripheral receptors carry pain-modulating impulses to the spinal cord. Remember, the A fibres cause impulse transmission to be inhibited and the gate to be closed. This action, in turn, reduces the recognition of the pain impulses arriving by means of the small fibres.

TREATMENT OF PAIN IN SPECIAL SITUATIONS

It is estimated that one of every five Canadians experiences persistent pain. Pain is poorly understood and often undertreated. In addition to enduring their baseline persistent pain, patients with illnesses such as cancer, AIDS, and sickle cell anemia may also experience crisis periods of acute pain. Effective management of acute pain is often different from management of persistent pain in terms of medications and dosage used. Routes of drug administration may include oral, intravenous (IV), intramuscular (IM), subcutaneous (subcut), transdermal, and rectal. One IV route commonly used in the hospital setting is patient-controlled analgesia (PCA). In this situation, patients are able to self-medicate by pressing a button on a PCA infusion pump. This method has been shown to be effective and reduces the total opioid dose used. Morphine sulphate and fentanyl are commonly given by PCA.

Patients with complex pain syndromes often benefit from a holistic clinical or multimodal clinical approach that involves pharmacological or nonpharmacological treatment or a combination of both. The goals of pain management include reducing and controlling pain and improving body function and quality of life.

In situations such as pain associated with cancer, the main consideration in pain management is patient comfort and not trying to prevent **addiction** (or **psychological dependence**; see Chapter 18) to the pain medication. Opioid tolerance is a state of adaptation in which exposure to a drug causes changes in drug receptors that result in reduced drug effects over time. This phenomenon can occur in as little as one week. Because of increasing pathology (e.g., tumour burden), patients with cancer usually require increasingly higher opioid doses and thus do become physically dependent on the drugs. Patients with cancer are likely to experience withdrawal symptoms (see Chapter 18) if opioid doses are abruptly reduced or discontinued; however, actual psychological dependence or addiction in such patients is unusual. For long-term pain control, oral, IV, subcut, transdermal, and sometimes even rectal dosing routes are favoured over multiple IM injections due to associated puncture trauma (bruising) and erratic drug absorption.

One controversial issue in pain management is the use of placebos, inert dosage forms that lack medication. Some health care providers feel that this practice may be helpful by taking advantage of the well-documented placebo effect—a psychological therapeutic effect that occurs even in the absence of actual medication. It is believed to arise from activation of the patient's own endorphins. It is also attributed to the patient's belief that any "treatment" is effective, as well as the patient's high level of trust in the health care provider. Critics argue that the use of placebos is unethical, because it requires that the patient be deceived in the process. The use of placebos for pain management has fallen out of favour, and they are rarely used today (see Chapter 3 for further discussion).

The treatment of acute pain in patients who are addicted to opioids is of great concern to clinicians, who may be reluctant to prescribe opioid therapy. However, habitual opioid users are **opioid tolerant** and generally require high dosages. Longer-acting opioids such as methadone or extended-release oxycodone are usually better choices than shorter-acting immediate-release drug products for these patients. Genetic differences in cytochrome P450 enzymes (see Chapters 4 and 5) can impact how effectively different patients, with or without an addiction, respond to a given drug. For this reason, patients must not automatically be viewed with suspicion if they report that a given drug does not work for them.

Health care providers may unfairly use the label of *addict* to justify refusal to prescribe pain medications, resulting in undertreatment of pain, even in patients who do not use street drugs. This is now regarded as an inappropriate and inhumane clinical practice. In these situations, control of the patient's pain takes ethical and clinical priority over concerns regarding drug addiction. Nonetheless, health care providers must contend with the reality of patients' misuse of street or prescription drugs (see Chapter 18). Such patients often request excessive numbers of

prescriptions and may use multiple health care providers or pharmacies. At times, they may also forge prescriptions or call in prescriptions by phone for opioid pain relievers such as those containing oxycodone, hydromorphone, fentanyl, morphine, and codeine. Community pharmacists work collaboratively to detect such abuses and notify law enforcement authorities. Creating a phony prescription for a controlled substance is a felony.

For patients receiving long-acting opioid analgesics, **breakthrough pain** often occurs between doses of pain medications. This is because the analgesic effects wear off as the drug is metabolized and eliminated from the body. Treatment with prn (as needed) doses of immediate-release dosage forms (e.g., oxycodone IR), given between scheduled doses of extended-release dosage forms (e.g., oxycodone ER), is often helpful in these cases. Chewing or crushing of any extended-release opioid drug can cause oversedation, respiratory depression, and even death due to rapid drug absorption. If the patient is requiring larger doses for breakthrough pain, the dose of the scheduled extended-release opioid may need to be increased, administered more frequently, or changed to a more potent opioid.

Drugs from other chemical categories are often added to the opioid regimen as adjuvant drugs. These assist the primary drugs in relieving pain. Such adjuvant drug therapy may include NSAIDs (see Chapter 49), antidepressants (see Chapter 17), antiepileptic drugs (see Chapter 15), and corticosteroids (see Chapter 50), all of which are discussed further in their corresponding chapters. This approach allows the use of smaller dosages of opioids and reduces some of the adverse effects that are seen with higher dosages of opioids, such as respiratory depression, constipation, and urinary retention. It permits drugs with different mechanisms of action to produce **synergistic effects**. Antiemetics (see Chapter 41) and laxatives (see Chapter 40) may also be needed to prevent or relieve associated constipation, nausea, and vomiting (Table 11.4).

One common use of adjuvant drugs is in the treatment of neuropathic pain. Opioids are not completely effective in such cases. Neuropathic pain usually results from nerve damage secondary to disease (e.g., diabetic neuropathy, postherpetic neuralgia secondary to shingles, trigeminal neuralgia, AIDS, or injury, including nerve damage secondary to surgical procedures [e.g., post-thoracotomy pain syndrome occurring after cardiothoracic surgery]). Common symptoms include hypersensitivity or hyperalgesia to mild stimuli such as light touch or a pinprick, or the bed sheets on a person's feet. This phenomenon is also known as *allodynia*. It can also manifest as hyperalgesia to uncomfortable stimuli, such as pressure from an inflated blood pressure cuff on a patient's limb. It may be described as heat, cold, numbness and tingling, burning, or electrical sensations. Examples of adjuvants commonly used in these cases are the antidepressant amitriptyline hydrochloride and the anticonvulsants gabapentin and pregabalin.

The three-step analgesic ladder proposed by the World Health Organization (WHO) (Fig. 11.3) is often applied as the pain management standard for cancer pain and to meet the therapeutic challenges presented by opioid tolerance. In 2019, the WHO developed the *WHO Guidelines for the*

TABLE 11.4 Potential Opioid Adverse Effects and Their Management

Adverse Effect	Preventive Measures
Constipation Opioids decrease gastrointestinal tract peristalsis because of their central nervous system (CNS) depression, with subsequent constipation as an adverse effect. Stool becomes excessively dehydrated because it remains in the gastrointestinal tract longer.	Constipation may be managed with increased intake of fluids; or the use of stimulants such as bisacodyl or senna; and the use of agents such as lactulose, sorbitol, and polyethylene glycol (Clearlax®) solution. Less commonly used are bulk-forming laxatives such as psyllium, for which increased fluid intake is especially important to avoid fecal impactions or bowel obstructions. Ambulation is also a method of promoting bowel movement.
Nausea and Vomiting Opioids decrease gastrointestinal tract peristalsis, and some also stimulate the vomiting centre in the CNS, so nausea and vomiting are often experienced.	Nausea and vomiting may be managed with the use of antiemetics such as phenothiazines.
Sedation and Mental Clouding Any change in mental status should always be evaluated to ensure that causes other than drug-related CNS depression are ruled out.	Persistent drug-related sedation may be managed with a decrease in the dose of opioid or a change in the drug used. The health care provider may also order various CNS stimulants (see Chapter 14).
Respiratory Depression Long-term opioid use is generally associated with tolerance to respiratory depression.	For severe respiratory depression, opioid antagonists (naloxone hydrochloride) may be used to improve respiratory status and, if they are titrated in small amounts, the respiratory depression may be reversed without analgesia reversal.
Subacute Overdose Subacute overdose may be more common than acute respiratory depression and may progress slowly (over hours to days), with somnolence and respiratory depression. Before analgesic dosages are changed or reduced, advancing disease must be considered, especially in patients who are dying.	Often, holding one or two doses of an opioid analgesic is enough to judge if the mental and respiratory depression is associated with the opioid. If there is improvement with this measure, the opioid dosage is often decreased by 25%.
Opioid-Induced Hyperalgesia (OIH) Prolonged use of opioids such as morphine sulphate can cause a paradoxical effect, where the patient develops a heightened sensitivity (hyperalgesia) to noxious stimuli. At times, this may even evolve to a painful response to non-noxious stimuli (allodynia).	Once OIH is diagnosed, the most straightforward intervention is to lower the opioid slowly to minimize withdrawal symptoms. If the patient still requires some amount of analgesia, then titrating to reduce the dose has been found successful.
Other Opioid Adverse Effects Dry mouth, urinary retention, pruritus, myoclonus, dysphoria, euphoria, sleep disturbances, sexual dysfunction, and inappropriate secretion of antidiuretic hormone may occur but are less common than the aforementioned adverse effects.	Ongoing assessment is needed for each adverse effect so that appropriate measures may be implemented (e.g., sucking of sugar-free hard candy or use of artificial saliva drops or gum for dry mouth; use of diphenhydramine hydrochloride for pruritus).

Pharmacological and Radiotherapeutic Management of Cancer Pain in Adults and Adolescents (see <https://www.who.int/ncds/management/palliative-care/cancer-pain-guidelines/en/> for information). Examples of nonopioid analgesic drugs include NSAIDs (see Chapter 49) as well as acetaminophen and tramadol hydrochloride (see Drug Profiles box). Step 1 is the use of nonopioids (with or without adjuvant medications), once the pain has been identified and assessed. If pain persists or increases, treatment moves to step 2, which is defined as the use of opioids with or without nonopioids and with or without adjuvants. Should pain persist or increase, management then rises to step 3, which is the use of opioids indicated for moderate to severe pain, administered with or without nonopioids or adjuvant medications. The goal for patients, as confirmed by the WHO, is freedom from pain.

OPIOID DRUGS

Opioids are classified as both mild **agonists** (e.g., codeine, hydrocodone bitartrate) and strong agonists (e.g., morphine, hydromorphone hydrochloride, oxycodone, meperidine, fentanyl, methadone). Meperidine is not recommended for long-term use because of the accumulation of a neurotoxic metabolite, *normeperidine*. In fact, most hospitals restrict the use of meperidine as a result of adverse events such as neurotoxicity from the normeperidine metabolite, delirium in older adult patients, and serotonin syndrome. Opiate **agonist-antagonists** such as pentazocine are associated with an **analgesic ceiling effect**. This means that the drug reaches a maximum analgesic effect, so that analgesia does not improve even with higher dosages (see Drug Profiles box). Such drugs

Fig. 11.3 Three-step analgesic ladder. Source: World Health Organization. (2008). WHO's pain ladder. Retrieved from <http://www.who.int/cancer/palliative/painladder/en/>.

are useful only in patients who have not been previously exposed to opioids and can be used for non-escalating, moderate to severe pain. Finally, because of associated bruising and bleeding risks, as well as injection discomfort, there is now a strong trend away from IM injections in favour of IV, subcut (e.g., via a subcutaneous butterfly), oral, and transdermal routes of drug administration.

The synthetic pain-relieving drugs currently known as opioid analgesics originated from the opium poppy plant. Natural opioids containing or derived from opium are known as **opiate analgesics**. The word *opium* is a Greek word that means “juice.” More than 20 different alkaloids are obtained from the unripe seed of the poppy plant. The properties of opium and its many alkaloids have been known for centuries. Opium-smoking immigrants brought opium to Canada, where unrestricted availability of opium prevailed until the early twentieth century.

Chemical Structure

Opioid analgesics are strong pain relievers. They can be classified according to their chemical structure or their action at specific receptors. Of the 20 different natural alkaloids available from the opium poppy plant, only three are clinically useful: morphine, codeine, and papaverine. Of these three, only morphine and codeine are pain relievers; papaverine is a smooth muscle relaxant. Relatively simple chemical modifications of these opium alkaloids have produced the three different chemical classes of opioids: morphine-like drugs, meperidine-like drugs, and methadone-like drugs (Table 11.5).

Mechanism of Action and Drug Effects

Opioid analgesics can also be characterized according to their mechanism of action. They are agonists or agonist–antagonists. An agonist binds to an opioid pain receptor in the brain and causes an analgesic response—the reduction of pain sensation.

TABLE 11.5 Chemical Classification of Opioids

Chemical Category	Opioid Drugs
morphine-like drugs	morphine, heroin, hydromorphone, codeine, hydrocodone, oxycodone
meperidine-like drugs	meperidine, fentanyl, remifentanyl, sufentanil, alfentanil
methadone-like drugs	methadone
Other	tramadol, tapentadol

TABLE 11.6 Opioid Receptors and Their Characteristics

Receptor Type	Prototypical Agonist	Effects
μ (mu)	morphine	Supraspinal analgesia, respiratory depression, euphoria, sedation*
κ (kappa)	butorphanol tartrate	Spinal analgesia, sedation, [†] miosis
δ (delta)	enkephalins	Analgesia

*Moderate level of sedation.

[†]Twice as much sedation compared to μ (mu) receptors.

An agonist–antagonist (e.g., pentazocine), also called a **partial agonist**, binds to a pain receptor and causes a weaker pain response than a full agonist does. Different drugs in this class exert their agonist or antagonist effects by binding in different degrees to κ (kappa) and μ (mu) opioid receptors. Although not normally used as first-line analgesics, they are sometimes useful in pain management in patients who are addicted to opioids as well as in obstetrical patients (because they avoid oversedation of the mother and fetus). **Antagonists** (e.g., naloxone) are non-analgesics that bind to pain receptors but do not reduce pain signals. They function as competitive antagonists because they compete with and reverse the effects of agonist and agonist–antagonist drugs at the receptor sites.

The receptors to which opioids bind to relieve pain are listed in Table 11.6. The μ (mu), κ (kappa), and δ (delta) receptors are the most responsive to drug activity, with the μ (mu) being the most important. Many of the characteristics of a particular opioid, such as its ability to sedate, its potency, and its ability to cause hallucinations, can be attributed to relative affinity for these various receptors.

Understanding the relative potencies of various drugs becomes important in clinical settings. *Equianalgesia* refers to the ability to provide equivalent pain relief by calculating dosages of different drugs or routes of administration that provide comparable analgesia. Because fentanyl is most commonly used transdermally, it is discussed separately in its drug profile.

Indications

The main use of opioids is to alleviate moderate to severe pain. The amount of pain control or unwanted adverse

PREVENTING MEDICATION ERRORS

Fentanyl Transdermal Patches

When applying fentanyl (Duragesic Mat®) transdermal patches, the nurse needs to keep in mind several important points to avoid improper administration:

- These patches are recommended to be used only by patients who are considered opioid tolerant. To be considered opioid tolerant, a patient should have been taking, for a week or longer, morphine 60 mg daily, oral oxycodone 30 mg daily, or oral hydromorphone 8 mg daily (or an equianalgesic dose of another opioid). Applying fentanyl transdermal patches to non-opioid-tolerant patients may result in severe respiratory depression. Thorough assessment is important.
- Inform patients that heat, such as a sauna, hot tub, heating pad, or heating pack must never be applied over a fentanyl transdermal patch. The increased circulation from the application of heat may result in increased absorption of medication, causing an overdose.
- Teach patients to avoid the use of soap, alcohol, or other solvents on the skin surface where the patch is to be applied as these products may enhance the drug's ability to penetrate the skin. Recommend the use of plain water to wash the area. After applying or removing the patch, wash hands with water only.

- Teach patients that fentanyl patches should not be cut under any circumstances.
- Teach patients about the proper disposal of transdermal patches. Children have pulled used patches from the trash, which has resulted in deaths because of exposure to the drug. For disposal at home, the product insert recommends that the patch be folded so that the adhesive side of the system adheres to itself and then disposed of by flushing down the toilet. However, disposal practices may vary by area because of concerns for the water systems. Disposal policies in facilities also vary, but some require that used patches be placed in a sharps container rather than be flushed.
- Keep patches, as well as all medications, away from children and pets. Do not store medications in warm, moist places such as medicine cabinets in the bathroom.

The Institute for Safe Medication Practices has described examples of fatal patient incidents resulting from failure to follow the above points. It is essential for patients' safety to read the product labelling and follow instructions precisely. For more information, go to <https://www.ismp-Canada.org>.

effects depends on the specific drug, the receptors to which it binds, and its chemical structure. Strong opioid analgesics such as fentanyl, sufentanil, and alfentanil are commonly used in combination with anaesthetics during surgery. These drugs are used not only to relieve pain but also to maintain a balanced state of anaesthesia. The practice of using combinations of drugs to produce anaesthesia is referred to as *balanced anaesthesia* (see Chapter 12). Use of fentanyl injection for management of postoperative and procedural pain has become popular because of its rapid onset and short duration. Transdermal fentanyl is available in a patch formulation for use in long-term pain management and is not to be used for postoperative pain or any other short-term pain control (see Preventing Medication Errors box: Fentanyl Transdermal Patches).

Strong opioids such as morphine, meperidine, hydromorphone, and oxycodone are often used to control postoperative and other types of pain. Because morphine and hydromorphone are available in injectable forms, they are often first-line analgesics in the immediate postoperative setting. There is a trend away from using meperidine due to its greater potential for toxicity (see Drug Profile). All available oxycodone dosage forms are orally administered. The brand name product OxyContin is a sustained-release form of oxycodone that contains more oxycodone hydrochloride than the immediate-release formulation, with the intent to last up to 12 hours. The "Contin" in the product name stands for "continuous release," a synonym for long action in any drug product. If the tablet is chewed, crushed, or dissolved, however, the medication is released all at once. This may occur accidentally, or it may be done deliberately to achieve a euphoric high. Once crushed, the drug can also be snorted or injected. Due to this abuse and the increase in the number of addicted individuals, this formulation was removed from the

Canadian market. It has been replaced with OxyNeo®, a formulation designed to reduce misuse; when the drug is crushed and combined with water, it becomes gel-like and difficult to inject. The drug product MS Contin® is a long-acting or sustained-release form of morphine that is also designed to provide 8 to 12 hours of pain relief. The "MS" stands for the salt name, morphine sulphate. Morphine is generally available. There are immediate-release dosage forms of oxycodone and morphine in tablet, capsule, and liquid form. Meperidine is available only in immediate-release dosage forms, both oral and injectable. The analgesic effects of immediate-release dosage forms of all three drugs typically last for about 4 hours.

Opioids also suppress the medullary cough centre, which results in cough suppression. The most commonly used opioid for this purpose is codeine (see Chapter 37). Hydrocodone is also used in many cough suppressants, either alone or in combination with other drugs. Sometimes opioid-related cough suppressants have a depressant effect on the CNS and cause sedation. To avoid this problem, dextromethorphan, a nonopioid cough suppressant, is often given instead (see Chapter 37).

Constipation from decreased gastrointestinal (GI) motility is often an unwanted adverse effect of opioids resulting from their anticholinergic effects. However, these effects are sometimes helpful in treating diarrhea. Some of the opioid-containing antidiarrheal preparations are opium/belladonna tincture (paregoric) and diphenoxylate/atropine (Immodium®) tablets.

Contraindications

Contraindications to the use of opioid analgesics include known drug allergy and severe asthma. It is not uncommon for patients to state they are allergic to codeine, when, in most of these patients, nausea was the "allergic" reaction. Many patients

TABLE 11.7 Opioid-Induced Adverse Effects by Body System

Body System	Adverse Effect
Central nervous	Sedation, disorientation, euphoria, lightheadedness, dysphoria, lowered seizure threshold, tremors
Cardiovascular	Hypotension, palpitations, flushing
Respiratory	Respiratory depression and asthma exacerbation
Gastrointestinal	Nausea, vomiting, constipation, biliary tract spasm
Genitourinary	Urinary retention
Integumentary	Itching, rash, wheal formation

will claim to be allergic to morphine because it causes itching. Itching is a pharmacological effect due to histamine release and not an allergic reaction. Thus, it is important to determine the exact nature of a patient's stated allergy. Although not absolute contraindications, extreme caution is to be used in cases of respiratory insufficiency, especially when resuscitative equipment is not available; conditions involving elevated intracranial pressure (e.g., severe head trauma); morbid obesity or sleep apnea; myasthenia gravis; paralytic ileus (bowel paralysis); and pregnancy, especially with long-term use or high doses.

Adverse Effects

Many of the unwanted effects of opioid analgesics result from their pharmacological effects in areas other than the CNS. Some of these unwanted effects can be explained by the drug's selectivity for the receptors listed in Table 11.6. The various body systems that the opioids affect, and the corresponding adverse effects, are summarized in Table 11.7.

Opioids that have an affinity for μ receptors, and that have rapid onset of action, produce marked euphoria. These are the opioids that are most likely to be misused and used recreationally by the lay public as well as by health care providers, who often have relatively easy access. The person taking opioids to deliberately achieve an altered mental status will soon become psychologically dependent (addicted; see Chapter 18).

In addition, opioids cause histamine release. It is thought that this histamine release is responsible for many of the drugs' unwanted adverse effects, such as itching or pruritus, rash, and hemodynamic changes. Histamine release causes peripheral arteries and veins to dilate, which leads to flushing and orthostatic hypotension. The amount of histamine release that an opioid analgesic causes is a result of its chemical class. The naturally occurring opiates (e.g., morphine) elicit the most histamine release; the synthetic opioids (e.g., meperidine) elicit the least histamine release. (See Table 11.5 for a list of the opioids and their respective chemical classes.)

The most serious adverse effect of opioid use is CNS depression, which may lead to respiratory depression. When death occurs from opioid overdose, it is almost always due to respiratory depression. When opioids are given, care must be taken to titrate the dose so that the patient's pain is controlled without

affecting respiratory function. Individual responses to opioids vary, and patients may occasionally experience respiratory compromise despite careful dose titration. Respiratory depression can be prevented in part by using drugs with short duration of action and no active metabolites. Respiratory depression seems to be more common in patients with a pre-existing condition causing respiratory compromise, such as asthma, chronic obstructive pulmonary disease, or sleep apnea. Respiratory depression is also dependent on the degree of sedation (see Toxicity and Management of Overdose, below).

GI tract adverse effects are common in patients receiving opioids due to stimulation of GI opioid receptors. Nausea, vomiting, and constipation are the most common adverse effects. Opioids can irritate the GI tract, stimulating the chemoreceptor trigger zone in the CNS, which, in turn, may cause nausea and vomiting. Opioids slow peristalsis and increase water absorption from intestinal contents. These two actions combine to produce constipation. This problem is more pronounced in hospitalized patients who are nonambulatory. Patients may require laxatives (see Chapter 40) to help maintain normal bowel movements.

Urinary retention, or the inability to void, is another unwanted adverse effect of opioid analgesics caused by increasing the sphincter tone of the bladder by sympathetic overstimulation, resulting in increased bladder outlet resistance. Opioids also decrease the sensation of bladder fullness by partially inhibiting the parasympathetic nerves that innervate the bladder. This is sometimes prevented by giving low dosages of an opioid agonist-antagonist, an opioid antagonist, or a cholinergic agonist (see Chapter 21) such as bethanechol.

Severe hypersensitivity or anaphylactic reaction to opioid analgesics is rare. Many patients will experience GI discomforts or histamine-mediated reactions to opioids and call these "allergic reactions." However, true anaphylaxis is rare, even with intravenously administered opioids. Some patients may report flushing, itching, or wheal formation at the injection site, but this is usually local and histamine mediated and not a true allergy. Refer to Table 11.4 for additional information on opioid adverse effects and their management.

Toxicity and Management of Overdose

Naloxone and naltrexone are opioid antagonists that bind to and occupy all of the receptor sites (μ , κ , and δ). They are competitive antagonists with a strong affinity for these binding sites. Through such binding, they can reverse the adverse effects induced by the opioid drug, such as respiratory depression. These drugs are used in the management of opioid overdose and less commonly for opioid addiction. The commonly used opioid antagonists (reversal drugs) are listed in Table 11.8.

When treating an opioid overdose or toxicity, the symptoms of withdrawal need to be considered. However, regardless of potential withdrawal symptoms, when a patient experiences severe respiratory depression, naloxone must be given. In Canada, take-home naloxone kits are available in most pharmacies and walk-in clinics and come with information about

TABLE 11.8 Opioid Antagonists (Reversal Drugs)

Generic Name	Trade Name	Cautions
naloxone hydrochloride (IV)	Naloxone hydrochloride injection	Raised or lowered blood pressure, dysrhythmias, pulmonary edema, withdrawal
naltrexone (PO)	ReVia	Nervousness, headache, nausea, vomiting, pulmonary edema, withdrawal

signs of overdose (e.g., altered mobility and speech, altered consciousness including confusion/drowsiness, respiratory depression, constricted pupils), as well as how to administer the drug as a nasal spray or injectable ([Health Canada, 2019a](#)). If you suspect an overdose, it is important to stay with the patient or person, call for assistance or 911 if in the community, and administer naloxone. Naloxone kits have been used by first responders (paramedics and firefighters) to successfully reverse thousands of overdoses in Canada. Since take-home kits were made available in the community, this number has continued to increase.

Some degree of physical dependence is expected in opioid-tolerant patients. The extent of opioid tolerance is most visible when an opioid drug is discontinued abruptly or when an opioid antagonist is administered. This situation usually leads to symptoms of **opioid withdrawal**, also known as *abstinence syndrome* (see Chapter 18). This condition can occur after as little as two weeks of opioid therapy in patients who are **opioid naive**. Gradual dosage reduction after chronic opioid use, when possible, helps to minimize the risk and severity of withdrawal symptoms.

Respiratory depression is the most serious adverse effect associated with opioids. Stimulating the patient may be adequate to reverse mild hypoventilation. If this is unsuccessful, ventilatory assistance using a bag and mask or endotracheal intubation may be needed to support respiration. Administration of opioid antagonists (e.g., naloxone) may also be necessary to reverse severe respiratory depression. Careful titration of dose until the patient begins to breathe independently will prevent over-reversal. The effects of naloxone are short lived, usually lasting about one hour. With long-acting opioids, respiratory depressant effects may reappear, and naloxone may need to be re-dosed.

The onset of withdrawal symptoms is a direct result of the half-life of the opioid analgesic being used. Withdrawal symptoms resulting from discontinuing or the reversal of therapy with short-acting opioids (codeine, hydrocodone bitartrate, morphine, and hydromorphone) will appear within 6 to 12 hours and peak at 24 to 72 hours. Withdrawal symptoms usually subside within 7 to 10 days but depend on a variety of factors (e.g., amount taken, length of time taking the drug, severity of

Administration of Naloxone Take-Home Kit

Naloxone 0.4 mg/mL IM	Naloxone 4 mg Nasal Spray
Place person into recovery position and initiate rescue breathing if required.	Place person in supine position and support the neck and initiate rescue breathing if required.
Check expiry date on packaging	Check expiry date on packaging
Remove top from glass vial or remove cap from vial, depending on what is supplied in the kit.	Take nasal spray from packaging and hold the device.
After removing the cap, be sure to clean the top of the vial with an alcohol swab.	
Using syringe supplied, draw up entire 1 mL vial and remove all excess air from syringe.	
Landmark using rectus femoris or vastus lateralis site. Clean landmarked area with alcohol swab and inject contents of the syringe into the muscle tissue at 90° angle.	Position spray into right or left nares and push all contents of spray into the nares.
Note: Most take-home kits suggest exposing thigh as much as possible, divide quadriceps muscle into thirds and inject all contents of the syringe into middle section at 90° angle.	
If not already in recovery position, put person into recovery position and continue rescue breathing if required.	Place person into recovery position and continue rescue breathing if required.
It can take up to 2 to 5 minutes for naloxone to take effect. Repeat injection after 2 minutes if no change is observed or when help arrives.	Repeat spray (with new package) every 5 minutes if person does not become conscious or continues to show signs of respiratory depression, and/or when help arrives.

dependence). Withdrawal symptoms associated with the long half-life drugs (methadone and transdermal fentanyl) may not appear for 24 hours or more after drug discontinuation and may be milder.

Interactions

Potential drug interactions with opioids are significant. Coadministration of opioids with alcohol, antihistamines, barbiturates, benzodiazepines, promethazine, and other CNS depressants can result in additive respiratory depressant effects. The combined use of opioids (such as

meperidine) with monoamine oxidase inhibitors, such as selegiline, can result in respiratory depression, seizures, and hypotension.

Laboratory Test Interactions

Opioids can cause an abnormal increase in the serum levels of amylase, alanine aminotransferase, alkaline phosphatase, bilirubin, lipase, creatinine kinase, and lactate dehydrogenase (see Lab Values Related to Drug Therapy: Analgesics box).

Other abnormal results include a decrease in urinary 17-keto-steroid levels and an increase in urinary alkaloid and glucose concentrations.

Dosages

For the recommended initial dosages of selected analgesic drugs in opioid-naïve patients, see the Dosages table on p. 181. Drug pharmacokinetics for selected drugs are provided in the Drug Profiles box.

LAB VALUES RELATED TO DRUG THERAPY

Analgesics

Laboratory Test	Normal Ranges	Rationale for Assessment
Alkaline phosphatase (ALP)	30–120 units/L	ALP is found in many tissues but is found in highest concentrations in the liver, biliary tract, and bone. Detection of this enzyme is important for determining liver and bone disorders. Enzyme levels of ALP are increased in both extrahepatic and intrahepatic obstructive biliary disease and cirrhosis or other liver abnormalities.
Alanine aminotransferase (ALT)	4–36 units/L Older adults may have slightly higher levels than adults	ALT is found mainly in the liver and, in lesser amounts, in the kidneys, heart, and skeletal muscle. If there is injury or disease to the liver parenchyma (cells), it will cause a release of this liver cellular enzyme into the bloodstream and thus elevate serum ALT levels. Most ALT elevations are from liver disease. Therefore, if medications are then metabolized by the liver, this metabolic process will be altered and possibly lead to toxic levels of drugs.
Gamma-glutamyl transferase (GGT)	Males/females 45 years of age and older: 8–38 units/L	GGT is an enzyme that is present in liver tissue; when there is damage to the liver cells (hepatocytes) that manufacture bile, the enzyme will be released throughout the cell membranes and into the blood. The normal values for individuals of African ancestry are double those of individuals who are White.

Laboratory Test	Normal Ranges	Rationale for Assessment
Aspartate aminotransferase (AST)	0–35 units/L	AST is elevated with hepatocellular diseases. With disease or injury of liver cells, the cells lyse and the AST is released and picked up by the blood; the elevation of AST is a result of the number of cells affected by disease or injury.
Lactic dehydrogenase (LDH)	100–190 units/L	LDH is found in cells of many body tissues including the heart, liver, red blood cells, kidneys, skeletal muscles, brain, and lungs. Because it is in so many tissues, the total LDH level is not a specific indicator of one disease. If there is disease or injury affecting cells containing LDH, the cells lyse and LDH is released from the cells into the bloodstream, thus increasing LDH levels. This enzyme is just part of the total picture of altered liver function which, if present, will then decrease the breakdown and metabolism of drugs and other chemical compounds, resulting in elevated blood levels of drugs.

Note: Usually levels that are 3 to 5 times the upper level of the normal range of the enzyme test are considered significant and are indicative of liver tissue damage. As well, elevation of a single test may not be clinically significant for liver damage.

DRUG PROFILES

Opioid Agonists

! morphine sulphate

Morphine sulphate, a naturally occurring alkaloid derived from the opium poppy, is the drug prototype for all opioid drugs. It is classified as a Schedule I controlled substance. Morphine is indicated for severe pain and has a high abuse potential. It is available in oral, injectable, and rectal dosage forms. Extended-release forms include MS Contin, M-Eslon®, Kadian®, and Avinza®. Morphine also has a potentially toxic metabolite known as morphine-6-glucuronide. Accumulation of this metabolite is more likely to occur in patients with kidney impairment. For this reason, other Schedule I opioids such as hydromorphone (Dilaudid®) and fentanyl (see fentanyl drug profile) may be safer analgesic choices for patients with kidney insufficiency. Drug profile information for hydromorphone is similar to that for morphine and meperidine. However, it is essential that all health care providers realize that hydromorphone is about five to eight times more potent than morphine. One milligram of IV, IM, or subcut hydromorphone hydrochloride is equivalent to 7 mg of IV, IM, or subcut morphine. Often, this difference in potency is not taken into account when prescribing, and deaths have been reported when larger doses of hydromorphone are given. Epidural dosage forms are injected onto the dura mater of the spinal cord. Epidural analgesics have the potential for causing increased intracranial pressure, especially with multiple injections, and increased CNS depression when given with other CNS depressant drugs. Other CNS depressant drugs are not to be given without orders from an anaesthesiologist.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IM	Rapid	30–60 min	1.7–4.5 hr	6–7 hr

! codeine sulphate/phosphate

Codeine sulphate (oral) (codeine phosphate as injection) is a natural opiate alkaloid (Schedule I) obtained from opium. It is similar to morphine sulphate in terms of its pharmacokinetic and pharmacodynamic properties. In fact, about 10% of a codeine dose is metabolized to morphine in the body. However, codeine is less effective as an analgesic and is the only agonist to possess a ceiling effect (meaning that increasing the dose beyond a certain point will not increase the response). Therefore, it is more commonly used as an antitussive drug in an array of cough preparations (see Chapter 37). Codeine combined with acetaminophen (tablets or elixir) is classified as a Schedule I controlled substance and is commonly used for control of mild to moderate pain as well as cough. Codeine causes GI tract upset, and many patients will say they are allergic to codeine, when in fact it just upsets their stomach. Codeine is metabolized in the liver and converted to morphine through the enzyme CYP2D6. Some individuals have a genetic polymorphism to this enzyme, preventing them from metabolizing it appropriately. There has

been a growing concern for individuals who are so-called “ultra-rapid metabolizers” as they convert codeine into morphine more rapidly, leading to dose-related opioid adverse effects. Current practice regarding codeine administration in pediatrics has been linked to serious morbidity and mortality. Two deaths and one resuscitation of North American children who were prescribed appropriate age-weight doses of codeine have occurred. These events prompted Health Canada to issue a recommendation that codeine and codeine-containing products are not to be used in children under the age of 18 ([Health Canada, 2019b](#)).

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	15–30 min	35–45 min	2.5–4 hr	4–6 hr

! fentanyl

Fentanyl is a synthetic opioid (Schedule I) used to treat moderate to severe pain. Like other opioids, it also has a high misuse or abuse potential. It is available as a parenteral injection, transdermal patch, and sublingual tablet. The injectable form of fentanyl is used most commonly in perioperative settings and in Critical Care Unit settings for sedation during mechanical ventilation. The parenteral form can be used subcutaneously or sublingually, depending on the patient's ability to manage sublingual administration. If administered sublingually, the drug must remain there for at least 5 minutes. Oral bioavailability of fentanyl is negligible and therefore this medication cannot be taken orally. Patients are generally unable to keep more than 1.5 mL to 2 mL under the tongue before it dribbles into the mouth, rendering it inactive. The sublingual and transdermal forms are used primarily for long-term control of both malignant and nonmalignant persistent pain. Fentanyl is a potent analgesic. Fentanyl at a dose of 0.1 mg given intravenously is roughly equivalent to 10 mg of morphine given intravenously.

The transdermal delivery system (patch) has been shown to be highly effective in the treatment of various persistent pain syndromes such as cancer-induced pain, especially in patients who cannot tolerate oral medications. This route is not to be used in opiate-naïve patients or for acute pain relief. Fentanyl patches are difficult to titrate and are best used for nonescalating pain. Second, if the opioid is not morphine, convert its dose to the equianalgesic dose of morphine. Finally, calculate the equipotent transdermal fentanyl dosage. These tables are conservative in their dosages for achieving pain relief, and supplemental short-acting opioid analgesics should be added as needed.

Fentanyl patches take 6 to 12 hours to reach steady-state pain control after the first patch is applied, and supplemental short-acting therapy may be required. Most patients will experience adequate pain control for 72 hours with this method of fentanyl delivery. A new patch is to be applied every 72 hours. It is important to remove the old patch when applying a new one. It takes about 20 hours for fentanyl to reduce by 50% once the patch is removed.

Health Canada has issued many safety warnings about the use of fentanyl patches. Fentanyl patches are intended for

management of persistent or cancer pain in opioid-tolerant patients whose pain is not adequately controlled by other types of medications. These patches are not recommended for acute pain situations such as postoperative pain. Deaths have occurred from drug-induced respiratory arrest when these conditions have not been met. Patients who are considered opioid tolerant are those who have been taking at least 60 mg of oral morphine daily or at least 30 mg of oral oxycodone daily or at least 8 mg of oral hydromorphone daily or an equianalgesic dose of another opioid. Other hazards associated with the use of fentanyl patches are cutting the patch and exposing the patch to heat (e.g., via a heating pad or sauna), both of which accelerate the diffusion of the drug into the patient's body. Fentanyl patches should not be cut for use. In the agency setting, fold used patches in half and place in the needle disposal container, or place in a tamperproof container and return to a community pharmacy, to prevent misuse.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Rapid	Minutes	1.5–6 hr	30–60 min
Transdermal	12–24 hr	48–72 hr	Delayed	1–2 hr
IM	7–15 min	20–30 min	1.5–6 hr	13–40 hr

! meperidine hydrochloride

Meperidine hydrochloride (Demerol®) is a synthetic opioid analgesic (Schedule I). Meperidine must be used with caution, if at all, in older adults and in patients who require long-term analgesia or who have kidney dysfunction. Meperidine has poor oral bioavailability, variable IM absorption, and a short half-life of 3 to 4 hours. An active metabolite, normeperidine, can accumulate to toxic levels and predispose patients to normeperidine neurotoxicity, which does not respond to naloxone and makes meperidine overdose particularly dangerous. Recognition of the adverse consequences associated with meperidine use and its overall unfavourable risk–benefit profile in all patient populations has resulted in a progressive movement away from meperidine use, and it has been removed from stock in many agencies. It is not recommended for long-term pain treatment. However, it may still be used for acute pain during postoperative periods, as well as in emergency department settings for acute migraine headaches. Meperidine is available in tablet and injectable form. Although an oral tablet form is still available from one pharmaceutical company in Canada, the Institute for Safe Medication Practices (ISMP) Canada has recommended the removal of oral meperidine from hospital formularies and is also establishing safe practices surrounding the prescribing of parenteral meperidine, including the use of other, safer alternatives for analgesia.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	15–20 min	1–2 hours	3–4 hours	3–5 hours

! methadone hydrochloride

Methadone hydrochloride (Metadol®) is a synthetic opioid analgesic (Schedule I). It is the opioid of choice for the detoxification treatment of persons addicted to opioids in methadone maintenance programs. Use of agonist–antagonist opioids (e.g., pentazocine) in patients addicted to heroin or those in methadone-maintenance programs can induce significant withdrawal symptoms. There has been renewed interest in the use of methadone for severe persistent (e.g., neuropathic) and cancer-related pain that requires daily, continuous, long-term opioid treatment that is opioid-responsive, and for which alternative options are inadequate. Methadone dosing for pain is different from methadone dosing for opioid dependence because of tolerance to the analgesic effects of opioids. The drug is readily absorbed through the GI tract with peak plasma concentrations at 4 hours for single dosing. Methadone is unique in that its half-life of 24 to 36 hours is longer than its duration of activity because it is bound to the tissues of the liver, kidneys, and brain. With repeated doses, the drug accumulates in these tissues and is slowly released, thus allowing for 24-hour dosing. Methadone is eliminated through the liver, which makes it a safer choice than some other opioids for patients with kidney impairment. There has been concern recently that the prolonged half-life of the drug is a cause of unintentional overdoses and deaths. There is also concern that methadone may cause cardiac dysrhythmias. Methadone is available for oral use in liquid form. In 2015, methadone could only be prescribed by health care providers who received an exemption pursuant to section 56 of the *Controlled Drugs and Substances Act* from the Minister of Health (Canada). This regulatory restraint was removed from the *Controlled Drugs and Substances Act* by the Government of Canada on May 19, 2018 (<https://www.canada.ca/en/health-canada/services/health-concerns/controlled-substances-precursor-chemicals/exemptions/methadone-program.html>). As a result, health care providers who have authority to prescribe are no longer required to obtain an exemption and can prescribe methadone in certain cases: if the client/animal is under their direct professional care, and if methadone is required for the condition the client/animal is being treated for.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Rapid	1 hr	3.9–12.9 hr	24–72 hr

Note: The pharmacokinetics of methadone change with repeat dosing (with continuous dosing, peak at 3–5 days, half life increases up to 59 hours)

Opioid Agonist–Antagonists

Opioids with mixed actions are often called *agonist–antagonists* (Schedule I). They bind to the μ receptor and can therefore compete with other substances for these sites. They either exert no action (i.e., they are competitive antagonists) or have only limited action (i.e., they are partial agonists). They are similar to the opioid agonists in terms of their therapeutic indications;

however, they have a lower risk of misuse and addiction. The antagonistic activity of this group can produce withdrawal symptoms in opioid-dependent patients. Their use is contraindicated in patients who have shown hypersensitivity reactions to the drugs.

These drugs have varying degrees of agonist and antagonist effects on the different opioid receptor subtypes. They are used in situations requiring short-term pain control, such as after obstetrical procedures. They are sometimes chosen for patients who have a history of opioid addiction. These medications can both help prevent overmedication and reduce post-treatment addictive cravings in these patients. Combination products of buprenorphine hydrochloride and naloxone dehydrate offer physicians an in-office treatment of addiction (see Chapter 18). These drugs are normally not strong enough for management of longer-term persistent pain (e.g., cancer pain, persistent lower back pain). They are *not* to be given concurrently with full opioid agonists, because they may both reduce analgesic effects and cause withdrawal symptoms in opioid-tolerant patients. Adverse reactions are similar to those with opioids but with a lower incidence of respiratory depression. Four opioid agonist-antagonists are currently available: a buprenorphine transdermal patch (Butrans®), butorphanol tartrate, nalbuphine (Nubain®), and pentazocine (Talwin®). They are available in various dosage forms as indicated in the dosage table. Buprenorphine hydrochloride is also available in combination with the opioid antagonist naloxone (Suboxone) to enhance its opioid antagonistic effect, which is usually weaker than the agonistic effects of the drug.

Opioid Antagonists

Opioid antagonists produce their antagonistic activity by competing with opioids for CNS receptor sites.

naloxone hydrochloride

Naloxone hydrochloride is a pure opioid antagonist. It has no agonist morphine-like properties and works as a blocking drug to the opioid drugs. Accordingly, the drug does not produce analgesia or respiratory depression. Naloxone is the drug of choice for the complete or partial reversal of opioid-induced respiratory depression. It is also indicated in cases of suspected acute opioid overdose. Failure of the drug to significantly reverse the effects of the presumed opioid overdose indicates that the condition may not be a result of an opioid overdose. The primary adverse effect is opioid withdrawal syndrome, which can occur with abrupt over-reversal in opioid-tolerant patients. Naloxone is available in injectable and nasal spray form. Use of the drug is contraindicated in patients with a history of hypersensitivity to it.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	<2 min	Rapid	64 min	Variable depending on dose and route

naltrexone hydrochloride

Naltrexone hydrochloride (ReVia®) is an opioid antagonist used as an adjunct for the maintenance of an opioid-free state in former opioid addicts. It has been recognized as a safe and effective adjunct to psychosocial treatments of alcoholism. It is also indicated for reversal of postoperative opioid-induced respiratory depression. Nausea and tachycardia are the most common adverse effects resulting from a reversal of the opioid effect. Use of naltrexone hydrochloride is contraindicated in cases of known drug allergy and in patients with hepatitis or liver dysfunction or failure.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	30–60 min	1.5–2 hr	25 hr	24–48 hr

oxycodone hydrochloride

Oxycodone hydrochloride is an analgesic drug that is structurally similar to morphine and has comparable analgesic activity (Schedule I). It is also commonly combined in tablets with acetaminophen (Percocet®) and with aspirin (Ratio-Oxycodone®). Oxycodone is also available in immediate-release formulations (Oxy IR) and sustained-release formulations (OxyNeo). Oxycodone and naloxone (Targin®) is a new controlled-release combination offering a dual therapeutic effect. It is indicated for severe pain requiring daily, long-term opioid treatment, and the naloxone blocks and reduces the adverse effects of opioid analgesic-induced constipation. Naloxone blocks the pain-relieving effects of opioids in general, but this formulation of oral naloxone blocks only the bowel adverse effects and is not absorbed through the intestine to block the drug's pain-relieving properties in the body and brain. A somewhat weaker but commonly used opioid is hydrocodone bitartrate (Schedule I), which is available in a tablet and as a syrup. It is available in combination with phenyltoloxamine (Tussinex®) as a controlled-release resin. The addition of phenyltoloxamine potentiates the antitussive effect of hydrocodone bitartrate.

PHARMACOKINETICS (IMMEDIATE RELEASE)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	10–15 min	1 hr	2–3 hr	3–6 hr

NONOPIOID AND MISCELLANEOUS ANALGESICS

Acetaminophen (Tylenol) is the most widely used nonopioid analgesic. Over 4 billion doses of acetaminophen are sold each year in Canada, with approximately 15% of these sales for prescription products ([Health Canada, 2015](#)). Combination products (acetaminophen plus another medication) (see [Table 11.9](#) for a common example of combination products including acetaminophen, codeine, and caffeine), including over-the-counter

Dosages

Selected Analgesic Drugs and Related Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications
Opioids			
codeine sulphate (oral); codeine phosphate injection	Opioid; opiate; opium alkaloid	Adults/Children (18 yr and older) PO: 15–60 mg q4–6 hr IV: 30–60 mg q4–6 hr Adults/Children (18 yr and older) 15–60 mg tid–qid; maximum 120 mg/day	Analgesia Antitussive
fentanyl (Abstral®, Duragesic Mat, Fentanyl Citrate Injection®)	Opioid analgesic	All doses titrated to response, starting with lowest effective dose Children (2–12 yr) IV: 2–3 mcg/kg/dose Adults IV: 2–150 mcg/kg (range from minor to complicated procedures) Adults Epidural: 100 mcg diluted in 8 mL 0.9% sodium chloride on demand; continuous infusion 1 mcg/kg/hr Duragesic (transdermal patch): 12–100 mcg/h q72 hr Buccal/Sublingual tablets (Fentora): Begin with lowest dosage 100 mcg and titrate as necessary	Procedural sedation or adjunct to general anaesthesia Relief of moderate to severe acute pain; relief of persistent pain, including cancer pain
meperidine hydrochloride (Demerol)	Opioid analgesic	Children IM/subcut: 1.1–1.8 mg/kg q2–3 hr prn (max 100 mg/dose) IM/subcut: 1.1–1.2 mg/kg 30–90 min before anaesthesia Adults PO (18 yr and older): 50–150 mg q3–4 hr prn IM/subcut: 50–100 mg 30–90 min before anaesthesia; 50–150 mg q3 hr prn for pain	Meperidine hydrochloride use not recommended because of the unpredictable effects of neurometabolites at analgesic doses and potential for seizures; use for 2 days Obstetric analgesia; preoperative sedation
methadone hydrochloride (Methadose®, Metadol®, Metadose®) (D)	Opioid analgesic	Adults PO for pain 2.5–10 mg q4 hr × 3–5 days; followed by fixed dose q8–12 hr depending on patient needs	Opioid analgesic, relief of persistent pain, opioid detoxification, opioid addiction maintenance
morphine sulphate (M.O.S. Sulphate®, MS IR®, Statex®) morphine hydrochloride (Doloral syrup®)	Opioid; opiate; opium alkaloid	Children PO: 0.1–0.5 mg/kg/dose q3–4 hr subcut: 0.1–0.2 mg/kg q4 hr (maximum 15 mg/single dose) Adults PO: 10–30 mg q4 hr IV/IM/subcut: 2.5–15 mg q2–4 hr	Opioid analgesia Opioid analgesia
morphine sulphate, continuous release (Kadian, M-ESLON, MS Contin)	Opiate analgesic; opium alkaloid	Adults only PO: 10–100 mg q8 hr to 100 mg q12 hr daily	Relief of moderate to severe pain
oxycodone hydrochloride, immediate-release (Oxy-IR®)	Opioid, synthetic	Children PO: 1.25–2.5 mg q6 hr prn Adults PO: 5–20 mg q4–6 hr prn	Relief of moderate to severe pain
oxycodone hydrochloride, continuous-release (ACT Oxycodone SR®, OxyNeo)	Opioid, synthetic	Adults only PO: 10–20 mg q12 hr, titrated to relief	Relief of moderate to severe pain
Opioid Antagonists			
naloxone hydrochloride	Opioid antagonist	Neonates IM/IV/subcut: 0.1 mg/kg at 2–3-min intervals Children IV: 0.01 mg/kg IV followed by 0.1 mg/kg if needed; 0.005–0.01 mg/kg; repeat in 2–3-min intervals Adults IV: 0.4–2 mg; repeat in 2–3 min if needed; 0.1–0.2 mg; repeat in 2–3-min intervals	Opioid-induced depression Treatment of opioid overdose; postoperative anaesthesia reversal Treatment of opioid overdose; postoperative anaesthesia reversal

Dosages—cont'd

Selected Analgesic Drugs and Related Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications
naltrexone hydrochloride (ReVia)	Opioid antagonist	Adults PO: 50 mg daily or 100 mg every other day PO: 50–100 mg q3–4 hr	Maintenance of opioid-free state
Nonopioids			
acetaminophen (Tylenol®, others)	Nonopioid analgesic, antipyretic	Children PO/PR: 15mg/kg/dose Q4-6 hours PRN (with maximum 5 doses per day or 75mg/kg or 4g daily) Adults PO/PR: 325–650 mg q4–6 hr; do not exceed 4 g/day In those with alcohol disorders, do not exceed 2 g/day	Relief of mild to moderate pain Relief of mild to moderate pain
tramadol hydrochloride immediate-release (Apo-Tramadol®) tramadol hydrochloride extended-release (Durela®, Ralivia®, Tridura®)	Nonopioid analgesic (with opioidlike activity)	Adults 18 yr and older PO: 50–100 q4–6 hr; not to exceed 400 mg/day PO: 100–300 mg q24 hr; not to exceed 300 mg/day	Relief of moderate to moderately severe pain

IM, Intramuscular; IV, intravenous; PO, oral; *subcut*, subcutaneous

TABLE 11.9 Acetaminophen–Codeine Tablet Combinations

Combination	Amount of Acetaminophen*	Amount of Codeine	Amount of Caffeine
Tylenol with codeine no-1 TAB®	300 mg	8 mg	15 mg
Tylenol with codeine no-2 TAB®	300 mg	15 mg	15 mg
Tylenol with codeine no-3 TAB®	300 mg	30 mg	15 mg
Tylenol with codeine no-4 TAB®	300 mg	60 mg	None

*Depending on the pharmaceutical company, there are some variations in the amount of acetaminophen.

(OTC) cough and cold remedies and pain relievers containing opioids, make up more than half of all acetaminophen doses sold ([Health Canada, 2015](#)).

All drugs in the NSAID class (which includes aspirin; ibuprofen; naproxen; the cyclo-oxygenase-2 [COX-2] inhibitor, celecoxib [Celebrex®]; and others) are **nonopioid analgesics**. These drugs are discussed in greater detail in [Chapter 49](#). They are used for management of pain, especially pain associated with inflammatory conditions such as arthritis, because they have significant anti-inflammatory effects in addition to their analgesic effects.

Miscellaneous analgesics include tramadol and transdermal lidocaine and are discussed in depth in their respective drug profiles in this chapter. Capsaicin is a topical product made from several different types of peppers. It works by decreasing or interfering with substance P, a pain signal in the brain. Capsaicin is available over the counter. It can be used for muscle pain, joint pain, and nerve pain.

Mechanism of Action and Drug Effects

The mechanism of action of acetaminophen is similar to that of the salicylates. It blocks peripheral pain impulses by inhibition of prostaglandin synthesis. Acetaminophen also lowers febrile body temperature by acting on the hypothalamus, the structure in the brain that regulates body temperature. Heat is dissipated through resulting vasodilation and increased peripheral blood flow. In contrast to NSAIDs, acetaminophen lacks anti-inflammatory effects (although there is some controversy in this area). Although acetaminophen shares the analgesic and antipyretic effects of the salicylates and other NSAIDs, it does not have many of the unwanted effects of these drugs. For example, acetaminophen products are not usually associated with cardiovascular effects (e.g., edema) or platelet effects (e.g., bleeding), as aspirin and other NSAIDs are. They also do not cause the aspirin-related GI tract irritation or bleeding, nor any of the aspirin-related acid–base changes.

Indications

Acetaminophen is indicated for the treatment of mild to moderate pain and fever. It is an appropriate substitute for aspirin because of its analgesic and antipyretic properties. Acetaminophen is a valuable alternative for those patients who cannot tolerate aspirin or for whom aspirin may be contraindicated. Acetaminophen is also the antipyretic (antifever) drug of choice in children and adolescents with flu syndromes because the use of aspirin in such populations is associated with a condition known as Reye's syndrome—a rare yet extremely serious condition that causes swelling in the brain and liver ([Chapman & Arnold, 2019](#)).

Contraindications

Contraindications to acetaminophen use include known drug allergy, severe liver disease, and the genetic disease known as *glucose-6-phosphate dehydrogenase (G6PD) enzyme deficiency*.

Adverse Effects

Acetaminophen is an effective and relatively safe drug. It is therefore available over the counter and in many combination prescription drugs. Acetaminophen is generally well tolerated. Possible adverse effects include rash, nausea, and vomiting. Much less common but more severe are the adverse effects of blood disorders or dyscrasias (e.g., anemias) and kidney function when acetaminophen is taken with light-to-moderate alcohol intake, and, of most concern, hepatotoxicity.

Toxicity and Management of Overdose

Most people do not realize that acetaminophen, despite its OTC status, is a potentially lethal drug when taken in overdose. Patients who are depressed (especially adolescents) may intentionally take an overdose of the drug without realizing the grave danger involved.

The ingestion of large amounts of acetaminophen, as in an acute overdose or even persistent unintentional misuse, can cause liver necrosis. This is the most serious acute toxic effect. Acute ingestion of acetaminophen doses of 150 mg/kg (approximately 7 to 10 grams) or more may result in liver toxicity. Acute hepatotoxicity can usually be reversed with acetylcysteine, whereas long-term toxicity is more likely to be permanent.

The standard maximum daily dose of acetaminophen for healthy adults is 4 000 mg. At the time of writing this book, Health Canada is considering additional steps to minimize the risk of liver damage and improve acetaminophen safety—for example, reducing the maximum daily recommended dose for all oral and rectal forms of acetaminophen-containing products, decreasing the unit dose for some products, or both. As well, product labelling and packaging, such as requiring children's liquid products to be sold with an accurate dosing device in the package, are also being considered.

Limitation of acetaminophen dosages to 2 000 mg or less maximum daily dose may be necessary for patients with risk factors such as advanced age or those with liver dysfunction. Excessive dosing may occur inadvertently with the use of combination products that include a fixed ratio of an opioid drug plus acetaminophen (e.g., hydrocodone plus acetaminophen). Health care providers must be mindful of recommended daily dose limits when prescribing these medications.

The long-term ingestion of large doses of acetaminophen is more likely to result in severe hepatotoxicity, which may be irreversible. Because the reported or estimated quantity of drug ingested is often inaccurate and not a reliable guide to the therapeutic management of the overdose, serum acetaminophen concentration should be determined no sooner than 4 hours after the ingestion. If a serum acetaminophen level cannot be determined, it should be assumed that the overdose is potentially toxic and treatment with acetylcysteine needs to be started. Acetylcysteine is the recommended antidote for acetaminophen toxicity and works by preventing the hepatotoxic metabolites of acetaminophen from forming. It is most effective when given within 10 hours of an overdose. Historically, the usual dosage regimen—140 mg/kg oral loading dose, followed by 70 mg/kg

every 4 hours for 17 additional doses—is usually administered intravenously according to protocol.

The oral drug is notoriously bad tasting, with an odour of rotten eggs, and vomiting of an oral dose is common. It is recommended that the dose be repeated if vomiting occurs within 1 hour of dosing.

Interactions

A variety of substances may interact with acetaminophen. Alcohol is potentially the most dangerous. Persistent heavy alcohol abuse may increase the risk of liver toxicity from excessive acetaminophen use. For this reason, a maximum daily dose of 2 000 mg is generally recommended. Health care providers need to warn patients with regular intake of moderate to large amounts of alcohol not to exceed recommended doses of acetaminophen because of the risk of liver dysfunction and possible liver failure. Ideally, alcohol consumption is not to exceed the recommended guidelines of 15 drinks per week for men and 10 drinks per week for women. Other drugs that can potentially interact with acetaminophen include phenytoin, barbiturates, warfarin sodium, isoniazid, rifampin, beta blockers, and anticholinergic drugs, all of which are discussed in greater detail in later chapters. Drug pharmacokinetics for selected drugs are provided in the Drug Profiles box.

DRUG PROFILES

acetaminophen

Acetaminophen (Tylenol) is an effective and relatively safe nonopioid analgesic used for mild to moderate pain relief. Acetaminophen is provided in oral and rectal dosage formulations. Acetaminophen is also a component of several prescription combination drug products, including with oxycodone (Endocet®, Percocet®).

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	10–30 min	0.5–2 hr	1–4 hr	3–4 hr

! tramadol hydrochloride

Tramadol hydrochloride (Ultram®) is categorized as a miscellaneous analgesic because of its unique properties. It is a centrally acting analgesic with a dual mechanism of action. It creates a weak bond to the μ (mu) opioid receptors and inhibits the reuptake of both norepinephrine and serotonin. Although it does have weak opioid receptor activity, tramadol is not currently classified as a controlled substance. Tramadol is indicated for the treatment of moderate to moderately severe pain. Tramadol is rapidly absorbed, and its absorption is unaffected by food. It is metabolized in the liver to an active metabolite (O-dimethyl tramadol) and eliminated via renal excretion.

Tramadol has a relatively safe profile in comparison to other opiates; however, two potential significant adverse effects of

this drug are seizures and serotonin syndrome. Seizures have been reported in patients taking tramadol and occur in patients taking both normal and excessive dosages. Patients who may be at risk are those receiving tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs), monoamine oxidase inhibitors, neuroleptics, or other drugs that reduce the seizure threshold. There is also an increased risk of developing serotonin syndrome when tramadol is taken concurrently with SSRIs (see Chapter 17). Other adverse effects are similar to those of opioids and include drowsiness, dizziness, headache, nausea, constipation, and respiratory depression.

Use of tramadol is contraindicated in cases of known drug allergy, which may include allergy to opioids due to potential cross-reactivity. It is also contraindicated in cases of acute intoxication with alcohol, hypnotics, centrally acting analgesics, opioids, or psychotropic drugs. The drug is available only in oral dosage forms, including a combination with acetaminophen (Tramacet®), as well as an extended-release formulation (Durela, Ravilia, Zytram XL®). A new drug, tapentadol hydrochloride (Nucynta®) is structurally similar to tramadol, with a dual mechanism of action. It is a μ (mu) agonist and a norepinephrine reuptake inhibitor. It is currently recommended to be a scheduled opioid.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	30 min	2 hr	5–8 hr	Unknown

lidocaine, transdermal

Transdermal lidocaine is a topical anaesthetic and cardiac anti-dysrhythmic (see Chapter 26 discussion) that is formulated into a patch (EMLA®), which is placed onto painful areas of the skin. It is indicated for the treatment of post-herpetic neuralgia, a painful skin condition that remains after a skin outbreak of shingles. Shingles is caused by the herpes zoster virus, also known as the *varicella zoster virus*, which causes chickenpox in children. Lidocaine patches provide local pain relief, and up to three patches may be placed on a large painful area. However, the patches are not to be worn for longer than 12 hours a day to avoid potential systemic drug toxicity (e.g., cardiac dysrhythmias). Because they act topically, there are minimal systemic adverse effects. However, the skin at the site of treatment may develop redness or edema, and unusual skin sensations may occur. These reactions are usually mild and resolve within a few minutes to hours. Patches are applied only to intact skin with no blisters. They can be used either alone or as part of adjunctive treatment with systemic therapies such as antidepressants (see Chapter 17), opioids, or anticonvulsants (see Chapter 15). Used patches must be disposed of securely because they may be dangerous to children or pets. Specific pharmacokinetic data are not listed due to the continuous nature of dosing. Studies have demonstrated that a patch can provide varying degrees of pain relief for 4 to 12 hours.

NURSING PROCESS

Pain may be acute or persistent and occurs in patients in all settings and across the lifespan, thus leading to much distress. Patients experiencing pain pose many challenges to the nurse, prescribers, and other health care providers involved in their care. The challenge is that pain is a complex and multifaceted problem that requires astute assessment skills with appropriate interventions based on the individual, the specific type of pain, related diseases, or health status.

Medical associations, health care organizations, governing bodies, and professional nursing organizations have been involved in defining guidelines and outcomes of care regarding assessment and management of pain. For example, the Canadian Guideline for Safe and Effective Use of Opioids (<http://nationalpaincentre.mcmaster.ca/opioid/>) is a national, evidence-informed guideline to help primary care providers and specialists safely and effectively use opioids to treat patients with persistent non-cancer pain. In addition, the WHO (www.who.int/en) has developed standards related specifically to cancer pain and guidelines for management of acute pain and pain in children. Professional nursing organizations, such as the Registered Nurses Association of Ontario, have also created best-practice guidelines and standards of care, including pain assessment and management (see <https://rnao.ca/bpg/guidelines/assessment-and-management-pain>).

ASSESSMENT

Adequate analgesia requires a holistic, comprehensive, and individualized patient assessment with specific attention to the type, intensity, and characteristics of the pain and of the levels of comfort. *Comfort*, in this situation, is defined as the extent of physical and psychological ease that an individual experiences. Perform a thorough health history, nursing assessment, and medication history as soon as possible or upon the first encounter with the patient, including questions about the following: (1) allergies to nonopioids, opioids, partial or mixed agonists, or opioid antagonists (see previous pharmacological discussion for examples of specific drugs); (2) potential drug–drug or drug–food interactions; (3) presence of diseases or CNS depression; (4) history of the use of alcohol, street drugs, or any illegal drug or substance and history of substance abuse, with information about the substance, dose, and frequency of use; (5) results of laboratory tests ordered, such as levels of serum ALT, ALP, GGT, 5'-nucleotidase, and bilirubin (indicative of liver function), or levels of blood urea nitrogen (BUN) and creatinine (reflective of kidney function); abnormal liver or kidney function that may require lower doses of analgesic to prevent toxicity or overdose (see Lab Values Related to Drug Therapy box: Analgesics on p. 177); (6) character and intensity of the pain, including onset, location, and quality (e.g., stabbing/knifelike, throbbing, dull ache, sharp, diffuse, localized, referred); actual rating of the pain using a pain assessment scale (see later); and any precipitating, aggravating, or relieving factors; (7) duration of the pain (acute versus persistent); and (8) types of pharmacological, nonpharmacological, or adjunctive measures that have been

implemented, with further explanation of the treatment's duration of use and overall effectiveness.

To be thorough and effective, include in the assessment the factors or variables that may impact an individual's pain experience, such as physical factors (e.g., age, gender, pain threshold, overall state of health, disease processes, pathologies) and emotional, spiritual, and cultural variables (e.g., reaction to pain; pain tolerance; fear; anxiety; stressors; sleep patterns; societal influences; family roles; phases of growth and development; religious, racial, or ethnic beliefs or practices). Age-appropriate assessment tools are recommended in assessing pain across the lifespan (see later discussion). For pediatric and older adult patients, nonverbal behaviour or cues and information from family members or caregivers may be helpful in identifying pain levels. In an older adult, physical or cognitive impairment may affect reporting of pain; however, this does not mean that the older adult patient is not experiencing pain—the patient's reporting may just be altered. Persistent pain and pain associated with cancer are both complex and multifactorial problems requiring a holistic approach with attention to other patient reports, such as a decrease in activities of daily living, insomnia, depression, social withdrawal, anxiety, personality changes, and quality of life issues.

Perform a system-focused nursing assessment with collection of both subjective and objective data as follows: neurological status (e.g., level of orientation and alertness, level of sedation, sensory and motor abilities, reflexes); respiratory status (e.g., respiratory rate, rhythm, and depth; breath sounds); GI status (e.g., presence of bowel sounds; bowel patterns; reports of constipation, diarrhea, nausea, vomiting, or abdominal discomfort); genitourinary (GU) status (e.g., urinary output, any burning or discomfort on urination, urinary retention); and cardiac status (e.g., pulse rate and rhythm, blood pressure, any problems with dizziness or syncope). Assess and document vital signs, including blood pressure, pulse rate, respirations, temperature, and level of pain (now considered the fifth vital sign). It is important to pull from one's knowledge base and remember that during the acute pain response, stimulation of the sympathetic nervous system may result in elevated values for vital signs, with an increase in blood pressure (120/80 mm Hg or higher), pulse rate (100 beats/min or higher), and respiratory rate and depth (20 breaths/min or higher and shallow breathing).

A variety of pain assessment tools are available that may be used to gather information about the fifth vital sign. One basic assessment tool is the Numeric Pain Intensity Scale (0 to 10 pain rating scale); patients are asked to rate their pain intensity by picking the number that most closely represents their level of pain. The Verbal Rating Scale, another pain assessment tool, uses verbal descriptors for pain, including words such as *mild*, *moderate*, *severe*, *aching*, *agonizing*, or *discomfort*. The FACES Pain Rating Scale is helpful in assessing pain in patients of all ages and educational levels because it relies on a series of faces ranging from happy to sad to sad with tears. The patient is asked to identify the face that best represents the pain being experienced at that moment. When the patient is in acute pain, when pain intensity is a primary focus for assessment, or when the need is to determine the efficacy of pain management intervention, the simple, one-dimensional scales (e.g., the Numeric Pain

Intensity Scale) work best. Older adult patients, especially those with cognitive impairment, may need more time to respond to the assessment tool and may also require large-print versions of written tools.

There are other assessment tools that are multidimensional scales and are more beneficial in assessing patients who experience persistent pain rather than acute pain. One example is the Brief Pain Inventory assessment tool, which includes a body map so that the patient can identify on the figure the exact area where pain is felt. This tool also helps in obtaining information about the impact of pain on functioning. Assess pain before, during, and after the pain intervention, as well as the level of pain during activity and at rest. The following sections provide assessment information for specific drug classes.

◆ Nonopioids

For patients taking nonopioid analgesics, focus the assessment not only on general data as described earlier but also on the specific drug being given. For example, in those patients taking acetaminophen, begin the assessment determining whether the patient has allergies, is pregnant, or is breastfeeding. As mentioned in the pharmacology section, acetaminophen is contraindicated in those with severe liver disease and in patients with G6PD deficiency. Additionally, due to possible adverse effects of blood disorders (anemias) or kidney or liver toxicity, cautious use is necessary. See pharmacology discussion for more information about acute overdose and persistent unintentional misuse. Also assess for any other medications the patient is taking, because of the risk of excessive doses when taking combination products containing acetaminophen. Inadvertent overdosing is a possible consequence of this situation. Other drug interactions and concerns are addressed in the pharmacology discussion.

Once therapy has been initiated, closely monitor for persistent acetaminophen poisoning, looking for symptoms such as rapid, weak pulse; dyspnea; and cold and clammy extremities. Long-term daily use of acetaminophen may lead to increased risk of permanent liver damage; therefore, frequently monitor the results of liver function studies. Adults who ingest higher-than-recommended dosages may be at higher risk of liver dysfunction as well as other adverse effects such as loss of appetite, jaundice, nausea, and vomiting. Children are also at high risk of liver dysfunction if the recommended dosage ranges are exceeded. With the use of NSAIDs (e.g., ibuprofen, aspirin, and COX-2 inhibitors), assess kidney and liver functioning and gather information about GI disorders such as ulcers (see [Chapter 49](#) for more information on anti-inflammatory drugs). With aspirin, age is important; this drug is not to be given to children and adolescent patients because of the risk of Reye's syndrome. Aspirin may also lead to bleeding and ulcers, so ruling out conditions that represent contraindications and cautions to its use before therapy begins is important to patient safety. With tramadol, assessment of age is important because this drug is not recommended for use in individuals 75 years of age or older.

A miscellaneous nonopioid analgesic, lidocaine transdermal, is another option for managing different types of pain. For lidocaine transdermal patches, understand that this transdermal drug is indicated in those with postherpetic neuralgia, and thus

assess the herpetic lesion(s) and surrounding skin. When these patches are used, they must be kept away from children and pets and are not to be prescribed for young, small, or debilitated patients because they are at higher potential for toxicity. Liver function also needs to be assessed and monitored.

◆ Opioids

When opioid analgesics or any other CNS depressants are prescribed, focus assessment on vital signs; allergies; respiratory disorders; respiratory function (rate, rhythm, depth, and breath sounds); presence of head injury (which will mask signs and symptoms of increasing intracranial pressure); neurological status, with attention to level of consciousness or alertness and level of sedation; sensory and motor functioning; GI tract functioning (bowel sounds and bowel patterns); and GU functioning (intake and output). In addition, all opioids may cause spasms of the sphincter of Oddi. If kidney and liver function studies are ordered, monitor results because the risk of toxicity increases with diminished function of these organs.

An additional concern is any past or present history of neurological disorders such as Alzheimer's disease, dementia, multiple sclerosis, myasthenia gravis, or cerebrovascular accident (stroke)—the use of opioids may alter symptoms of the disorder or disease process, possibly masking symptoms or worsening the clinical presentation when no actual pathological changes have occurred. In these situations, use of another analgesic or pain protocol may be indicated. Attention to age is also important because both older adults and young patients are more sensitive to opioids, as to many other medications. In fact, older or younger age may be a contraindication to opioid use, depending on the specific drug. See the earlier pharmacology discussion regarding cautions, contraindications, and drug interactions. See Special Populations: Children and Special Populations: Older Adults boxes for use of opioids in both age groups.

SPECIAL POPULATIONS: CHILDREN

Opioid Use

- Assessment of children is challenging, and all types of behaviour that may indicate pain, such as muscular rigidity, restlessness, agitation, screaming, fear of moving, and withdrawn behaviour, must be carefully considered.
- Pain management is more difficult to determine in children; depending on age, children are less able or unable to express themselves. Frequently, the reason older children do not verbalize their pain is their fear of the treatment, such as injections. Compassionate and therapeutic communication skills, as well as the use of alternate routes of administration, as ordered, will help the nurse in these situations.
- The "ouch scale" or FACES scale is often used to determine the level of pain in children (Fig. 11.4). This scale is used to obtain the child's rating of the intensity of pain from 0 to 5 by means of simple face diagrams, from a happy face for level 0 (no pain) to a sad, tearful face for level 5 pain. Parents and caregivers play an important role in pain management in the child and in noting any crying or distress.
- Pain assessment is important in children because they are often undermedicated. Always thoroughly assess a child's verbal and nonverbal behaviour, and never underestimate the child's reports. Remember that parents and caregivers can play an important role in this assessment.

- The child's baseline age, weight, and height are important to document because drug calculations are often based on these variables. With children, check and double-check *all* mathematical calculations for accuracy to avoid excessive dosages; this is especially true for opioids.
- Analgesics must be given before pain becomes severe, with oral dosage forms used first, if appropriate.
- If suppositories are used, be careful to administer the exact dose and not to split, halve, or divide an adult dose into a child's dose—this may result in the administration of an unknown amount of medication and possible overdose.
- When subcut, IM, and IV medications are used, the principle of nontraumatic care in the delivery of nursing care must be followed. One method to ensure nontraumatic care is the application of a mixture of local anaesthetics or other prescribed substances to the injection site before the injection is given. EMLA (lidocaine/prilocaine) is a topical cream that anaesthetizes the site of the injection; if ordered, apply 1 to 2-1/2 hours prior to the injection.
- Distraction and creative imagery may be used for younger children such as toddlers or preschool-aged children.
- Children should always be monitored closely for any unusual behaviour while they are receiving opioids.
- The following signs and symptoms should be reported to the physician immediately if they occur: CNS changes such as dizziness, lightheadedness, drowsiness, hallucinations, changes in level of consciousness, or sluggish pupil reaction. Do not administer further medication until receiving further orders from the physician.
- Always monitor and document vital signs before, during, and after the administration of opioid analgesics. An opioid medication is usually withheld if a patient's respiration rate is less than 10 breaths/min or if there are any changes in the level of consciousness. Always follow protocol, and never ignore a patient's status.
- Smaller doses of opioids (with close and frequent monitoring) are indicated for children. Giving oral medications with meals or snacks will help decrease GI tract distress.

SPECIAL POPULATIONS: OLDER ADULTS

Opioid Use

- Record the patient's weight and height before the start of opioid treatment, if appropriate.
- Monitor the patient carefully for any changes in vital signs, level of consciousness, central nervous system (CNS) depression, respiratory rate, as well as any changes indicative of respiratory function. Report and document these changes.
- Many institutionalized or hospitalized older adult patients can be stoic about pain; older adult patients may also have altered presentations of common illnesses so that the pain experience manifests in a different way, or they may simply be unable to state how they feel in a clear manner. The older adult patient may also have complex pain needs such as both persistent and acute pain. Each patient, regardless of age, has the right to a thorough pain assessment and adequate and appropriate pain management. It is a myth that aging increases one's pain threshold. The challenge is that cognitive impairment and dementia are often major barriers to pain assessment. Nevertheless, many older adult patients are still reliable in their reporting of pain, even with moderate to severe cognitive impairment (see Evidence in Practice: Student Nurses' Misconceptions of Adults with Chronic Nonmalignant Pain Review box on p. 168).
- Over time, older adults may lose reliability in recalling and accurately reporting persistent pain. Older adults, especially those 75 years of age or older, are at higher potential for too much or too little pain management, and it is important to remember that these drugs have a higher peak and longer duration of action in these patients than in their younger counterparts.

Fig. 11.4 Wong-Baker 'OUCH' FACES Scale. This pain assessment scale is used in Canada for children 3 years and older. <https://wongbakerfaces.org/>.

- Smaller dosages of opioids are generally indicated for older adults because of their increased sensitivity to the CNS depressant effects of the drugs and diminished kidney and liver function. Paradoxical (opposite) reactions and unexpected reactions may be more likely to occur in patients of this age group.
- In older adult male patients, benign prostatic hypertrophy or obstructive urinary diseases should be considered because of the urinary retention associated with the use of opioids. Urinary outflow can become further diminished in these patients and result in adverse reactions or complications. The physician may need to make dosage adjustments.
- Polypharmacy is often a problem in older adults; therefore, have a complete list of all medications the patient is currently taking, and assess for drug interactions and treatment (drug) duplication.
- Frequent assessments of older adult patients are needed. Pay attention to level of consciousness, alertness, and cognitive ability while ensuring that the environment is safe by keeping a call bell or light at the bedside. Using bed alarms is indicated where available.
- Decreased circulation causes variation in the absorption of IM or IV dosage forms and often results in the slower absorption of parenteral forms of opioids.
- Encourage older adults to ask for medications if needed. They often hesitate to ask for pain medication because they do not want to bother the nurse or give in to pain.
- NSAIDs must be used with caution because of their potential for renal and GI toxicity. Acetaminophen is the drug of choice for relieving mild to moderate pain but with cautious dosing because of liver and kidney concerns. The oral route of administration is preferred for analgesia. The regimen should be as simple as possible to enhance adherence. Be sure to note, report, and document any unusual reactions to the opioid drugs. Hypotension and respiratory depression may occur more frequently in older adults taking opioids; thus, careful vital sign monitoring is needed.

Opioid Antagonists

Remember that opioid antagonists are used mainly in reversing respiratory depression secondary to opioid overdose. Naloxone may be used in patients of all ages, including neonates and children. Assess and document vital signs before, during, and after the use of the antagonist so that the therapeutic effects can be further assessed and documented and the need for further doses determined. In addition, remember that the antagonist drug may not work with just one dosing and that repeated doses are generally needed to reverse the effects of the opioid. See the pharmacology section for information about contraindications, cautions, and drug interactions.

NURSING DIAGNOSES

- Reduced gas exchange resulting from opioid-induced CNS effects and respiratory depression
- Acute pain resulting from specific disease processes or conditions and other pathologies leading to various levels and types of pain
- Persistent pain resulting from various disease processes, conditions, or syndromes causing pain
- Constipation resulting from the CNS-depressant effects on the GI system
- Inadequate knowledge resulting from lack of familiarity with opioids, their use, and their adverse effects

PLANNING

Goals

- Patient will regain or maintain a respiratory rate between 10 and 20 breaths per minute without respiratory depression.
- Patient will state adequate acute pain relief associated with appropriate analgesic drug therapy regimen.
- Patient will experience relief from persistent pain associated with appropriate pharmacological therapy regimen.
- Patient will identify measures to help maintain normal bowel elimination patterns and avoid or minimize opioid-induced constipation.
- Patient will demonstrate adequate knowledge about the analgesic or other drug therapy and nondrug regimen.

Expected Patient Outcomes

- Patient states correct technique for coughing and deep breathing and adequate fluid intake while taking opioids or other analgesics for pain.

Opioid Agonist–Antagonists

In patients taking *opioid agonist–antagonists*, assess vital signs with attention to respiratory rate and breath sounds. Opioid agonist–antagonists still possess opioid agonist effects, and therefore the assessment information regarding opioids is applicable to these drugs as well.

It is also important to remember during assessment that these drugs are still effective analgesics and will have CNS-depressant effects but are subject to the analgesic ceiling effect (see earlier definition). Given the action of these drugs, the assessment may help determine whether the patient misuses opioids. This information is important because the simultaneous administration of agonist–antagonists with another opioid will lead to reversal of analgesia and possible opioid withdrawal. Age is another factor to assess because these drugs are not recommended for use in patients 18 years of age or younger. See previous discussion for a listing of contraindications, cautions, and drug interactions.

- Patient's respiratory rate is within normal depth, rate, and patterns with clearing breath sounds.
- Patient relates increased comfort levels as seen by decreased use of analgesics, increased activity and performance of activities of daily living, decreased reports of acute pain, as well as decreased levels of pain as rated on a scale of 1 to 10.
- Patient uses nonpharmacological measures such as relaxation therapy, distraction, and music therapy to help improve comfort and enhance any drug therapy regimens for persistent pain.
- Patient states various measures to help minimize or avoid the occurrence of constipation with forcing of fluids, increasing fibre in the diet, and improving mobility.
- Patient reports appropriate use of analgesics with minimal complications or adverse effects.
- Patient states rationale for the use, action, and therapeutic effects associated with analgesic drugs for management of acute or persistent pain.
- Patient states rationale for the use of nondrug approaches to pain management.
- Patient states importance of taking medication as prescribed.

◆ IMPLEMENTATION

Once the cause of pain has been diagnosed or other assessment and data gathering have been completed, begin pain management immediately and aggressively, according to the needs of each individual patient and situation. Pain management is varied and multifaceted and needs to incorporate pharmacological and non-pharmacological approaches (see [Box 11.1](#) and *Natural Health Products: Feverfew* box). Negotiate with patients by integrating religious ceremonies and traditional healing practices into pain care, rather than imposing Western cultural approaches. Pain management strategies must also include consideration for the type of pain and pain rating as well as pain quality, duration, and precipitating factors, and interventions that help the pain. Some general principles of pain management are as follows:

1. Individualize a plan of care based on the patient as a holistic and cultural being (see *Ethnocultural Implications: The Patient Experiencing Pain* box, p. 166).
2. Manage mild pain with the use of nonopioid drugs such as acetaminophen, tramadol hydrochloride, and NSAIDs (see [Chapter 49](#)).
3. Manage moderate to severe pain with a stepped approach, using opioids. Other analgesics or types of analgesics may be used in addition to other categories of medication (see pharmacology discussion).
4. Administer analgesics as ordered but before the pain gets out of control.
5. Always consider the use of nonpharmacological comfort measures (see [Box 11.1](#)) such as homeopathic and folk remedies, exercise, distraction, music or pet therapy, massage, and transcutaneous electrical stimulation. Although not always effective, these measures may prove beneficial for some patients. See Patient Teaching Tips for more information regarding analgesics.

◆ Nonopioids

Give nonopioid analgesics as ordered or as indicated for fever or pain. Acetaminophen should be taken as prescribed and within the recommended dosage range over a 24-hour period because of the risk of liver damage and acute toxicity. If a patient is taking other OTC medications with acetaminophen, he or she needs to understand the importance of reading the labels (of other medications) carefully to identify the total amount of acetaminophen taken and any other drug–drug interactions. In educating the patient, emphasize the signs and symptoms of acetaminophen overdose: bleeding, loss of energy, fever, sore throat, and easy bruising (because of hepatotoxicity). These signs and symptoms must be reported immediately by the patient, family member, or caregiver to the nurse or health care provider. Any worsening or change in the nature or characteristic of pain must also be reported.

If the medication is taken by suppository, once the suppository is unwrapped, cold water may be run over it to moisten it for easier insertion. The suppository is inserted into the rectum using a gloved finger and water-soluble lubricating gel if necessary. Acetaminophen tablets may be crushed if needed. Adult patients who take more than 4 000 mg/day are at potential for acute hepatotoxicity. Death may occur after ingestion of more than 15 g. Liver damage from acetaminophen may be minimized by timely dosing with acetylcysteine (see previous discussion). If acetylcysteine is indicated, warn the patient about the drug's foul taste and odour; many patients report that the drug smells and tastes like rotten eggs. Acetylcysteine is better tolerated if it is disguised by mixing with a drink such as cola or flavoured water to increase its palatability. Use of a straw may help minimize contact with mucous membranes of the mouth and is recommended. This antidote may be given through a nasogastric tube or intravenously, if necessary.

Tramadol may cause drowsiness, dizziness, headache, nausea, constipation, and respiratory depression. If dizziness, blurred vision, or drowsiness occurs, be sure to assist the

NATURAL HEALTH PRODUCTS

Feverfew (Chrysanthemum parthenium)

Overview

A member of the marigold family known for its anti-inflammatory properties

Common Uses

Treatment of migraine headaches, menstrual cramps, inflammation, and fever

Adverse Effects

Nausea, vomiting, constipation, diarrhea, altered taste sensations, muscle stiffness, and joint pain

Potential Drug Interactions

Possible increase in bleeding with use of aspirin and other NSAIDs, dipyridamole, and warfarin sodium

Contraindications

Contraindicated in those with allergies to ragweed, chrysanthemums, and marigolds, as well as those about to undergo surgery

patient with ambulation to minimize the risk of fall and injury. Educate the patient about injury prevention, including the need to dangle the feet over the edge of the bed before full ambulation, changing positions slowly, and asking for assistance when ambulating. In addition, while the patient is taking tramadol, as well as any other analgesics, and especially opioids, the patient needs to avoid any tasks that require mental clarity and alertness. Increasing fluids and fibre in the diet may help with constipation. Use of flat cola, ginger ale, or dry crackers may help to minimize nausea.

◆ Opioids

When opioids (and other analgesics) are prescribed, administer the drug as ordered after checking for the “rights” of medication administration (see Chapter 1). After the health care provider’s order has been double-checked, and before administering another dose, closely examine the medication profile and documentation to determine the last time the medication was given. Monitor the patient’s vital signs at frequent intervals, with special attention to respiratory changes. A respiratory rate of 10 breaths/min (some protocols still adhere to the parameter of 12 breaths/min) may indicate respiratory depression and must be reported to the health care provider. The drug dosage, frequency, or route may need to be changed or an antidote (opioid antagonist) given if respiratory depression occurs. Naloxone must always be available, especially with the use of IV or other parenteral dosage forms of opioids, such as PCA (see Chapter 10 and the discussion to follow) or epidural infusions. Naloxone is indicated to reverse CNS depression, specifically respiratory depression, but remember that this antidote also reverses analgesia. Monitor the patient’s urinary output as well; it should be at least 720 mL/24 hr. Monitor bowel sounds during therapy; decreased peristalsis may indicate the need for a dietary change, such as increased fibre, or use of a stool softener or mild laxative. Assess the patient’s pupillary reaction to light. Pinpoint pupils indicate a possible overdose.

Opioids or any analgesic must be given before the pain reaches its peak to help maximize the drug’s effectiveness. Once the drug is administered, return at the appropriate time (taking into consideration the times of onset and peak effect of the drug and the route) to assess the effectiveness of the drug or other interventions as well as observe for the presence of adverse effects (see previous discussion of pain assessment tools). In regard to the route of administration, the recommendation is that oral dosage forms be used first, but only if ordered and if there is no nausea or vomiting. Taking the dose with food may help minimize GI upset. Should nausea or vomiting be problematic, an antiemetic may be ordered for administration before or with the dosing of medication. Crucial safety measures include keeping bed side rails up, turning bed alarms on (depending on facility policies and procedures), and making sure the call bell or alarm is within the patient’s reach. These measures will help to prevent falls or injury resulting from opioid use. Opioids and similar drugs lead to CNS depression with possible confusion, altered sensorium or alertness, hypotension, and altered motor functioning. Because of these drug effects, all

patients are at potential for falls or injury, and older adults are at higher risk (see Special Populations: Older Adults: Use of Opioids box). See Table 11.10 below for more specific information concerning the handling of controlled substances and opioid counts.

When managing pain with morphine sulphate, meperidine hydrochloride, and similar opioid drugs, withhold the dose and contact the health care provider if there is any decline in the patient’s condition or if vital signs are abnormal (see parameters mentioned earlier), and especially if the respiratory rate is less than 10 breaths/min. IM injections of analgesics are rarely used because of the availability of other effective and convenient dosage forms, such as PCA pumps, transdermal patches, constant subcut infusions, and epidural infusions. For transdermal patches (e.g., transdermal fentanyl), two systems are used. The older type of patch contains a reservoir system consisting of four layers, beginning with the adhesive layer and ending with the protective backing. Between these two layers are the permeable rate-controlling membrane and the reservoir layer, which holds the drug in a gel or liquid form. The newer type of patch has a matrix system consisting of two layers—one containing the active drug with the releasing and adhesive mechanisms, and the other a protective, impermeable backing layer. The advantages of the matrix system over the reservoir system are that the patch is slimmer and smaller, it is more comfortable, it is worn for up to 7 days (the older reservoir system patch is worn for up to 3 to 4 days), and it appears to result in more constant serum drug levels. In addition, the matrix system is alcohol free; the alcohol in the reservoir system often irritates the patient’s skin. It is important to know what type of delivery system is being used so that proper guidelines are followed to enhance the system’s and drug’s effectiveness.

Apply transdermal patches to only a clean, nonhairy area. When the patch is changed, place the new patch on a new site, but only after the old patch has been removed and the site cleansed of any residual medication. Rotation of sites helps decrease irritation and enhance drug effects. Transdermal patches require special discarding of old and used patches (see Preventing Medication Errors: Fentanyl Transdermal Patches box on p. 174). Transdermal systems are beneficial for the delivery of many types of medications, especially analgesics, and have the benefits of allowing multiday therapy with a single application, avoiding first-pass metabolism, improving patient adherence, and minimizing frequent dosing. However, the patient should be watched carefully for the development of any type of contact dermatitis caused by the patch (contact the health care provider immediately if this occurs) and maintain a pain journal when at home. Journal entries are a valid source of information for the nurse, other health care providers, the patient, and family members to assess the patient’s pain control and to monitor the effectiveness of not only transdermal analgesia but any medication regimen.

With the IV administration of opioid agonists, follow the manufacturer’s guidelines and institutional policies regarding specific dilution amounts and solution as well as the time period for infusion. When PCA is used, the amounts and times of dosing should be noted in the appropriate records and tracked

TABLE 11.10 Opioid Administration Guidelines

Opioid	Nursing Administration
buprenorphine and butorphanol tartrate codeine phosphate	When giving IV, infuse over the recommended time (usually 3–5 min). Always assess respirations. Give IM as ordered. Give PO doses with food to minimize gastrointestinal tract upset; ceiling effects occur with oral codeine phosphate, resulting in no increase in analgesia with increased dosage.
fentanyl	Administer parenteral doses as ordered and per manufacturer's guidelines in regard to mg/min to prevent CNS depression and possible cardiac or respiratory arrest. Transdermal patches come in a variety of dosages. Be sure to remove residual amounts of the old patch prior to application of a new patch. Dispose of patches properly to avoid inadvertent contact with children or pets. A fentanyl citrate sublingual effervescent tablet (Fentora®) is available for the management of breakthrough pain in patients with cancer that are 18 years of age and older and who are already receiving and are tolerant to continuous opioid therapy for their persistent baseline cancer.
hydromorphone hydrochloride meperidine hydrochloride	May be given subcut, rectally, IV, IM, or PO. Given by a variety of routes: IV, IM, or PO; highly protein bound, so watch for interactions and toxicity. Monitor older adults for increased sensitivity.
morphine sulphate	Available in a variety of forms: subcut, IM, IV, PO, extended, and immediate release, and for epidural infusion. Always monitor respiratory rate.
nalbuphine hydrochloride naloxone hydrochloride oxycodone hydrochloride	IV dosages of 10 mg given undiluted over 5 min Antagonist given for opioid overdose; 0.4 mg usually given IV over 15 sec or less. Reverses analgesia as well. Often mixed with acetaminophen or aspirin; PO and suppository dosage forms. Available in both immediate and sustained-release tabs
pentazocine	PO, subcut, IV, and IM forms; mixed agonist–antagonist; IV dose of 5 mg to be given over 1 min

CNS, Central nervous system; IM, intramuscular; IV, intravenous; PO, oral; subcut, subcutaneous.

by appropriate personnel. The fact that a pump is being used, however, does not mean that it is 100% reliable or safe. Closely monitor and frequently check all equipment. Additionally, frequently monitor pain levels, response to medication, and vital signs with the use of other parenteral opioid administration. Always follow dosage ranges for all opioid agonists and agonist–antagonists and pay special attention to the dosages of morphine and morphine-like drugs. For IV infusions, the nurse is responsible for monitoring the IV needle site and documenting any adverse effects or complications. Another point to remember when administering opioids, as well as other analgesics, is that each medication has a different onset of action, peak, and duration of action, with the IV route producing the most rapid onset (i.e., within minutes) (see Table 11.10).

To reverse an opioid overdose or opioid-induced respiratory depression, an opioid antagonist such as naloxone must be administered. If naloxone is used, 0.4 to 2 mg should be given intravenously in its undiluted form and should be administered over 15 seconds (or as ordered); if reconstitution is needed, 0.9% NaCl or 5% dextrose injection should be used (see Table 11.8). However, the guidelines in the package insert should also be followed. Emergency resuscitative equipment should be nearby in the event of respiratory or cardiac arrest.

◆ Opioid Agonist–Antagonists

When giving agonist–antagonists, remember that they react differently depending on whether they are given by themselves or with other drugs. When administered alone, they are effective analgesics because they bind with opiate receptors and produce an agonist effect (see discussion in pharmacology section). If given at the same time with other opioids, however, they lead to reversal of analgesia and acute withdrawal because of the blocking of opiate receptors. Be careful to check dosages and routes as well as perform the interventions mentioned for opioid agonist drugs, including closely assessing vital signs, especially

respiratory rate. Emphasize with the patient the importance of reporting any dizziness, unresolved constipation, urinary retention, and sedation. See Table 11.7 for additional adverse effects of opioid agonists as they are similar to the opioid agonist–antagonist drugs. Other points to emphasize include that the drug also has the ability to reverse analgesia as well as precipitate withdrawal (if taken with other opioid agonists). A list of other opioid agonists must be shared with the patient as well.

◆ Opioid Antagonists

Opioid antagonists must be given as ordered and be readily available, especially when the patient is receiving PCA with an opioid, is opioid naive, or is receiving continuous doses of opioids. Several doses of these drugs are often required to ensure adequate opioid agonist reversal (see earlier discussion). Encourage patients to report any nausea or tachycardia.

◆ General Considerations

You are always responsible and accountable for maintaining a current, updated knowledge base on all forms of analgesics as well as protocols for pain management, with focus on the specific drug(s) as well as differences in the treatment of mild to moderate pain, severe pain, and pain in special situations (e.g., cancer pain). The WHO's three-step analgesic ladder provides a standard for pain management in patients with cancer and must be reviewed and considered, as needed. Dosing of medications for pain management is important to the treatment regimen. Once a thorough assessment has been performed, it is best to treat the patient's pain before it becomes severe, which is the rationale for considering pain the fifth vital sign. When pain is present for more than 12 hours a day, analgesic doses are individualized and best administered around the clock rather than on an as-needed basis, while always staying within safe practice guidelines for each drug used. Around-the-clock (or scheduled) dosing maintains steady-state levels of the medication and

TABLE 11.11 Drugs Not Recommended for Treatment of Cancer Pain

Class	Drug	Reason for Not Recommending
Opioids with dosing around the clock	meperidine	Short (2–3 hr) duration of analgesia; administration may lead to CNS toxicity (tremor, confusion, or seizures)
Miscellaneous	cannabinoids	Adverse effects of dysphoria, drowsiness, hypotension, and bradycardia, which preclude their routine use as analgesics; may be indicated for use in treating severe chemotherapy-induced nausea and vomiting
Opioid agonist–antagonists	pentazocine butorphanol tartrate nalbuphine buprenorphine	May precipitate withdrawal in opioid-dependent patients; analgesic ceiling effect; possible production of unpleasant psychological adverse effects, including dysphoria, delusions, and hallucinations
Opioid antagonists	naloxone naltrexone	Analgesic ceiling effect; can precipitate withdrawal if given with an opioid Reverses analgesia as well as CNS depressant effects, such as respiratory depression
Anxiolytics (as monotherapy) or sedative–hypnotics (as monotherapy)	Benzodiazepines (e.g., alprazolam) Barbiturates	Analgesic properties not associated with these drugs except in some situations of neuropathic pain; common risk of sedation, which may put some patients at higher potential for neurological complications Analgesic properties not demonstrated; sedation is problematic and limits use

prevents drug troughs and pain escalation. No given dosage of an analgesic will provide the same level of pain relief for every patient; thus, there is a need for a process of titration, upward or downward, to be carried out based on the individual's needs. Aggressive titration may be necessary in difficult pain control cases and in cancer pain situations. Patients with severe pain, metastatic pain, or bone metastasis pain may need increasingly higher doses of analgesic. These special pain situations may require an opiate such as morphine that needs to be titrated until the desired response is achieved or until adverse effects occur. A patient-rated pain level of less than 4 on a scale of 1 to 10 is considered an indication of effective pain relief.

If pain is not managed adequately by monotherapy, other drugs or adjuvants may need to be added to enhance analgesic efficacy. This includes the use of NSAIDs (for analgesic and anti-inflammatory effects), acetaminophen (for analgesic effects), corticosteroids (for mood elevation and anti-inflammatory, antiemetic, and appetite-stimulation effects), anti-convulsants (for treatment of neuropathic pain), tricyclic antidepressants (for treatment of neuropathic pain and opioid-potentiating effects), neuroleptics (for treatment of persistent pain syndromes), local anaesthetics (for treatment of neuropathic pain), hydroxyzine hydrochloride (for mild anti-anxiety properties as well as sedating effects and antihistamine and mild antiemetic actions), or psychostimulants (for reduction of opioid-induced sedation when opioid dosage adjustment is not effective). See [Table 11.11](#) for a listing of drugs that should not be used in patients experiencing cancer pain.

Dosage forms are also important, especially with persistent pain and cancer pain. Oral administration is always preferred but is not always tolerated by the patient and may not even be a viable option for pain control. If oral dosing is not appropriate, less invasive routes of administration include rectal and transdermal routes. Rectal dosage forms are safe, inexpensive, effective, and helpful if the patient is experiencing nausea or vomiting or altered mental status; however, this route is not suitable for those with diarrhea, stomatitis, or low blood cell counts. Transdermal patches (e.g., the buprenorphine transdermal patch) may provide up to 7 days of pain control but are not

for rapid dose titration and are used only when stable analgesia has been previously achieved. Long-acting forms of morphine and fentanyl may be delivered via transdermal patches when a longer duration of action is needed. Intermittent injections or continuous infusions via the IV or subcut routes are often used for opioid delivery and may be administered at home in special pain situations, such as in hospice care and in persistent cancer pain management. Subcut infusions are often used when there is no IV access. PCA pumps may be used to help deliver opioids intravenously, subcutaneously, or even intraspinally and can be managed in home health care or hospice care for the patient at home. Use of the intrathecal or epidural route requires special skill and expertise, and delivery of pain medications using these routes is available only from certain home health care agencies for at-home care. The main reason for long-term intraspinal opioid administration is intractable pain. Transnasal dosage forms are approved only for butorphanol tartrate, an agonist–antagonist drug, and this dosage form is generally not used or recommended. Regardless of the specific drug or dosage form used, a fast-acting rescue drug needs to be ordered and available for patients with cancer pain or other special challenges in pain management. Regardless of the drug(s) used for the pain management regimen, always remember that individualization of treatment is one of the most important considerations for effective and quality pain control. Also consider implementing the following:

- At the initiation of pain therapy, conduct a review of all relevant histories, laboratory test values, nurse-related charting entries, and diagnostic study results in the patient's medical record.
- If there are underlying problems, consider them while never forgetting to treat patients with dignity and respect. Never let compounding variables or any other problems overshadow the fact that there is a patient who is in pain and deserving of safe, quality care.
- Develop goals for pain management in conjunction with the patient, family members, significant others, or caregivers. These goals include improving the level of comfort with increased levels of activities of daily living and ambulation.

- Collaborate with other members of the health care team to select a regimen that will be easy for the patient to follow while in the hospital and, if necessary, at home (e.g., for patients with cancer and other patients experiencing persistent pain).
- Be aware that most regimens for acute pain management include treatment with short-acting opioids plus the addition of other medications such as NSAIDs.
- Be familiar with equianalgesic doses of opioids because lack of knowledge of equivalencies may lead to inadequate analgesia or overdose.
- Use an analgesic appropriate for the situation (e.g., short-acting opioids for severe pain secondary to a myocardial infarction, surgery, or kidney stones). For cancer pain, the regimen usually begins with short-acting opioids with eventual conversion to controlled-release formulations.
- Use preventive measures to manage adverse effects. In addition, switch to another opioid as soon as possible if the patient finds that the medication is not controlling the pain adequately.
- Consider the option of analgesic adjuvants, especially in cases of persistent pain or cancer pain; these might include other prescribed drugs such as NSAIDs, acetaminophen, corticosteroids, anticonvulsants, tricyclic antidepressants, neuroleptics, local anaesthetics, hydroxyzine hydrochloride, or psychostimulants. Over-the-counter drugs and natural health products may also be helpful.
- Be alert to patients with special needs, such as patients with breakthrough pain. Generally, the drug used to manage such pain is a short-acting form of the longer-acting opioid being given (e.g., immediate-release morphine for breakthrough pain while sustained-release morphine is also used).
- Identify community resources that can assist the patient, family members, or significant others. These resources may include various websites for patient education such as <http://www.canadianpainsociety.ca>, <http://www.chronicpaincanada.com>, and <http://www.iasp-pain.org>. Many other pain management sites may be found on the Internet by searching using the terms *pain*, *pain clinic*, or *pain education* and looking for patient-focused materials or sites.
- Conduct frequent online searches to remain current on the topics of pain management, pain education, drug and nondrug therapeutic regimens for pain, and special pain situations.
- Because fall prevention is of utmost importance in patient care (after the ABCs [airway, breathing, circulation] of care are addressed), monitor the patient frequently after an analgesic is given. Frequent measurement of vital signs, inclusion of the patient in a frequent watch program, or use of bed alarms is encouraged.

◆ EVALUATION

Positive therapeutic outcomes of acetaminophen use are decreased symptoms, including decreased fever and pain. Monitor for adverse reactions of anemias and liver problems due to hepatotoxicity, and report patient reports of abdominal pain or vomiting to the health care provider. During and after the administration of nonopioid analgesics such as tramadol, opioids, and mixed opioid agonists, monitor the patient for both

therapeutic effects and adverse effects, frequently and as needed. Therapeutic effects of analgesics include increased comfort periods as well as decreased reports of pain, with improvements in performance of activities of daily living, appetite, and sense of well-being. Monitoring for adverse effects varies with each drug (see earlier discussions), but adverse effects may consist of nausea, vomiting, constipation, dizziness, headache, blurred vision, decreased urinary output, drowsiness, lethargy, sedation, palpitations, bradycardia, bradypnea, dyspnea, and hypotension. If vital signs change, the patient's condition declines, or pain continues, the health provider should be contacted immediately, and the patient closely monitored. Respiratory depression may be manifested by a respiratory rate of less than 10 breaths/min, dyspnea, diminished breath sounds, or shallow breathing. Include a review of the effectiveness of multimodal and nonpharmacological approaches to pain management in your evaluation.

CASE STUDY

Opioid Administration

You are assigned to care for a patient, Daphna, who is in the terminal stage of breast cancer. As a community health care nurse, you have many responsibilities; however, you have not cared for many patients who are in the terminal stages of their illness. In fact, most of your patients are postoperative and have only required assessments, dressing changes, and wound care.

Daphna is 48 years of age and underwent bilateral mastectomy 4 years ago. She had lymph node involvement at the time of surgery and was recently diagnosed with metastasis to the bone. She has been taking sustained-release oxycodone (one 10-mg tab every 12 hours) at home but is not sleeping through the night and is now reporting increasing pain to the point that her quality of life has decreased significantly. She wants to stay at home during the terminal stage of her illness but needs to have adequate and safe pain control. Her husband of 18 years is supportive. They have no children. They are both university graduates and have medical insurance.

1. Daphna's recent increase in pain has been attributed to bone metastasis in the area of the lumbar spine. Currently, oxycodone is not beneficial, and you need to advocate for Daphna to receive adequate pain relief. When discussing her pain medications with her health care provider, what type of medication would you expect to be ordered to relieve the bone pain, and what is the rationale for this recommendation? Provide references from within this chapter for the selection of the specific opioid drug.
2. Daphna's husband confides in you that he is worried that she will become addicted to the new medication. He is not sure he agrees with round-the-clock dosing. How do you address his concerns?
3. What should Daphna's husband do if he thinks that Daphna has had an overdose?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

PATIENT TEACHING TIPS

- Capsaicin is a topical product made from different types of peppers that may help with muscle pain and joint or nerve pain. It may cause local, topical reactions, including burns and blistering, so be sure to share information with the patient about its safe use.
- Opioids are not to be used with alcohol or with other CNS depressants, unless ordered, because of worsening of the depressant effects.
- A holistic approach to pain management may be appropriate, with the use of complementary modalities, including the following: biofeedback, imagery, relaxation, deep breathing, humour, pet therapy, music therapy, massage, use of hot or cold compresses, and use of herbal products.
- Dizziness, difficulty breathing, low blood pressure, excessive sleepiness (sedation), confusion, or loss of memory must be promptly reported to the nurse or other health care provider.
- Opioids may result in constipation, so encouraging fluids (up to 3 L/day unless contraindicated), increased fibre consumption, and exercise as tolerated are recommended. Stool softeners may also be necessary.
- Report any nausea or vomiting. Antiemetic drugs may be prescribed.
- Any activities requiring mental clarity or alertness may need to be avoided if the patient is experiencing drowsiness or sedation. Ambulate with caution or assistance as needed.
- It is important for the patient to share any history of addiction with health care providers, but when such a patient experiences pain and is in need of opioid analgesia, understand that the patient has a right to comfort. Any further issues with addiction may be managed during and after the use of opioids. Keeping an open mind regarding the use of resources, counselling, and other treatment options is important in dealing with addictive behaviours.
- If pain is problematic and not managed by monotherapy, a combination of a variety of medications may be needed. Other drugs that may be used include antianxiety drugs, sedatives, hypnotics, or anticonvulsants.
- For the patient with cancer or special needs, the health care provider will monitor pain control and the need for other options for therapy or for dosing of drugs. For example, the use of transdermal patches, buccal tablets, and continuous infusions while the patient remains mobile or at home is often helpful in pain management. It is also important to understand that if morphine or morphine-like drugs are being used, there is a potential for addiction; however, in specific situations, the concern for quality of life and pain management is more important than the concern for addiction.
- Most hospitals have inpatient and outpatient resources such as pain clinics. Patients need to constantly be informed and aware of all treatment options and remain active participants in their care for as long as possible.
- Tolerance does occur with opioid use, so if the level of pain increases while the patient remains on the prescribed dosage, the prescriber or health care provider must be contacted. Dosages must not be changed, increased, or doubled unless prescribed.

KEY POINTS

- Pain is individual and involves senses and emotions that are unpleasant. It is influenced by age, ethnoculture, spirituality, and all other aspects of the person.
- Pain is associated with actual or potential tissue damage and may be exacerbated or alleviated depending on the treatment and type of pain.
- Types of analgesics include the following:
 - Nonopioids including acetaminophen and aspirin and other NSAIDs
 - Opioids, which are natural or synthetic drugs that either contain or are derived from morphine (opiates) or have opiate-like effects or activities (opioids), and opioid agonist-antagonist drugs
- Child dosages of morphine must be calculated cautiously with close attention to the dose and kilograms of body weight. Cautious titration of dosage upward is usually the standard. Older adult patients may react to analgesics differently from what is expected, especially opioids and opioid agonist-antagonists.
- Remember that older adult patients experience pain the same as the general population, but they may be reluctant to report pain. They also may metabolize opiates at a slower rate and thus are at increased potential for adverse effects such as sedation and respiratory depression. The best rule is to begin with low dosages, re-evaluate often, and go slowly during upward titration.

EXAMINATION REVIEW QUESTIONS

1. For best results when treating severe pain associated with pathological spinal fractures resulting from metastatic bone cancer, the nurse should remember that the best type of dosage schedule is to administer the pain medication in which way?
 - a. As needed
 - b. Around the clock
 - c. On schedule during waking hours only
 - d. Around the clock, with additional doses as needed for breakthrough pain
2. A patient is receiving an opioid via a PCA pump as part of his postoperative pain management program. During rounds, the nurse finds him unresponsive, with respirations of 8 breaths/min and blood pressure of 102/58 mm Hg. After stopping the opioid infusion, what should the nurse do next?
 - a. Notify the charge nurse
 - b. Draw arterial blood gases
 - c. Administer an opiate antagonist per standing orders
 - d. Perform a thorough assessment, including mental status examination

3. A patient with bone pain caused by metastatic cancer will be receiving transdermal fentanyl patches. The patient asks the nurse what benefits these patches have. The nurse's best response includes which of these features?
 - a. More constant drug levels for analgesia
 - b. Less constipation and minimal dry mouth
 - c. Less drowsiness than with oral opioids
 - d. Lower dependency potential and no major adverse effects
4. IV morphine is prescribed for a patient who has had surgery. The nurse informs the patient that which common adverse effects can occur with this medication? (Select all that apply.)
 - a. Diarrhea
 - b. Constipation
 - c. Pruritus
 - d. Urinary frequency
 - e. Nausea
5. Several patients have standard orders for acetaminophen, as needed for pain. When the nurse reviews their histories and assessments, it is discovered that one of the patients has a contraindication to acetaminophen therapy. Which of the following patients should receive an alternate medication?
 - a. A patient with a fever of 39.7°C
 - b. A patient admitted with deep vein thrombosis
 - c. A patient admitted with severe hepatitis
 - d. A patient who had abdominal surgery 1 week earlier
6. The nurse is administering an IV dose of morphine to a 48-year-old postoperative patient. The dose ordered is 3 mg every 3 hours, as needed for pain. The medication is supplied in vials of 4 mg/mL. How much will be drawn into the syringe for this dose?
7. An opioid analgesic is prescribed for a patient. The nurse checks the patient's medical history knowing this medication is contraindicated in which disorder?
 - a. Renal insufficiency
 - b. Severe asthma
 - c. Liver disease
 - d. Diabetes mellitus
8. A patient with renal cancer needs an opiate for pain control. Which opioid medication would be the safest choice for this patient?
 - a. fentanyl
 - b. hydromorphone (Dilaudid)
 - c. morphine sulphate
 - d. methadone (Dolophine)

CRITICAL THINKING ACTIVITIES

1. The nurse is about to administer 5 mg of morphine intravenously to a patient with severe postoperative pain, as ordered. What priority assessment data must be gathered before and after administering this drug? Explain your answer.
 2. A patient reports that the drugs he is receiving for severe pain are not really helping. What is the nurse's priority action at this time?
 3. A young woman is brought by ambulance to the emergency department because she was found unconscious next to an empty bottle of acetaminophen. While the medical team assesses her, the nurse goes to question the family about the situation. What is the most important piece of information to know about this possible overdose?
- For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

General and Local Anaesthetics

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Define *anaesthesia*.
2. Describe the basic differences between general and local anaesthesia.
3. List the most commonly used general and local anaesthetics and associated risks.
4. Discuss the differences between depolarizing neuromuscular blocking drugs and nondepolarizing blocking drugs and their impact on the patient.
5. Compare the mechanisms of action, indications, adverse effects, routes of administration, cautions, contraindications, and drug interactions of general anaesthesia and local anaesthesia, and of drugs used for procedural sedation.
6. Develop a collaborative plan of care for patients before anaesthesia (preanaesthesia), during anaesthesia, and after anaesthesia (postanaesthesia), related to general anaesthesia.
7. Develop a collaborative plan of care for patients undergoing local anaesthesia or procedural sedation.

KEY TERMS

Adjunct anaesthetics Drugs used in combination with anaesthetic drugs to control the adverse effects of anaesthetics or to help maintain the anaesthetic state in the patient (See *balanced anaesthesia*). (p. 196)

Anaesthesia The loss of the ability to feel pain, resulting from the administration of an anaesthetic drug. (p. 196)

Anaesthetics Drugs that depress the central nervous system (CNS) or peripheral nerves to produce decreased sensation, loss of sensation, or muscle relaxation. (p. 196)

Balanced anaesthesia The practice of using combinations of different classes of drugs rather than a single drug to produce anaesthesia. (p. 196)

General anaesthesia A drug-induced state in which CNS nerve impulses are altered to reduce pain and other sensations throughout the entire body. It normally involves complete loss of consciousness and depression of normal respiratory drive. (p. 196)

Local anaesthesia A drug-induced state in which peripheral or spinal nerve impulses are altered to reduce or eliminate

pain and other sensations in tissues innervated by these nerves. (p. 196)

Malignant hyperthermia A genetically linked, major adverse reaction to general anaesthesia characterized by a rapid rise in body temperature as well as tachycardia, tachypnea, and sweating. (p. 198)

Overton–Meyer theory A theory that describes the relationship between the lipid solubility of anaesthetic drugs and their potency. (p. 197)

Procedural sedation A milder form of general anaesthesia that causes partial or complete loss of consciousness but does not generally reduce normal respiratory drive (formerly referred to as *conscious sedation* or *moderate sedation*). (p. 200)

Spinal anaesthesia Local anaesthesia induced by injection of an anaesthetic drug near the spinal cord to anaesthetize nerves that are distal to the site of injection (also called *intraspinous anaesthesia*). (p. 201)

OVERVIEW

Anaesthetics are drugs that reduce or eliminate pain by depressing the central nervous system (CNS) or the peripheral nervous system (PNS). This state of reduced neurological function is called **anaesthesia**. Anaesthesia is further classified as general or local. **General anaesthesia** involves complete loss of consciousness, loss of body reflexes, elimination of pain and other sensations throughout the entire body, and skeletal and smooth muscle paralysis, including paralysis of respiratory muscles. **Local anaesthesia** does not involve paralysis of respiratory function but does involve elimination of pain sensation in the tissues innervated by anaesthetized nerves. Functions of the autonomic nervous system, which includes the sympathetic and parasympathetic nervous system, may also be affected.

GENERAL ANAESTHETICS

General anaesthetics are drugs that induce general anaesthesia and are most commonly used to induce anaesthesia during surgical procedures. General anaesthetics are given only under controlled situations by anaesthesiologists. General anaesthesia is achieved by the use of one or more drugs. Often a synergistic combination of drugs is used, which allows lower doses of each drug and better control of the patient's anaesthetized state. Inhalational anaesthetics are volatile liquids or gases that are vaporized or mixed with oxygen to induce anaesthesia. For a historical perspective on general anaesthesia, see [Box 12.1](#).

Parenteral anaesthetics ([Table 12.1](#)) are given intravenously and are used for induction or maintenance of general anaesthesia, for induction of amnesia, and as adjuncts to inhalation-type anaesthetics ([Table 12.2](#)). The specific goal varies with the drug. Common intravenous (IV) anaesthetic drugs include drugs classified solely as general anaesthetics, such as propofol.

Adjunct anaesthetics, or simply *adjuncts*, are also used. *Adjunct* is a general term for any drug that enhances clinical therapy when used simultaneously with another drug. Adjunct drugs can be thought of as “helper drugs” when their use complements the use of any other drug(s). They are used simultaneously with general anaesthetics for anaesthesia initiation (induction), sedation, reduction of anxiety, and amnesia. Adjuncts include neuromuscular blocking drugs (NMBDs; see Neuromuscular Blocking Drugs later in this chapter), sedative-hypnotics or anxiolytics (see Chapter 13) such as propofol (this chapter), benzodiazepines (e.g., diazepam, midazolam), barbiturates (e.g., thiopental, methohexital; see Chapter 13), opioid analgesics (e.g., morphine sulphate, fentanyl citrate, sufentanil citrate; see Chapter 11), anticholinergics (e.g., atropine sulphate; see Chapter 22), and antiemetics (e.g., ondansetron

BOX 12.1 General Anaesthesia: A Historical Perspective

Until recently, general anaesthesia was described as having several definitive stages. This was especially true with the use of many of the ether-based inhaled anaesthetic drugs. Features of these distinctive stages were easily observable to the trained eye. They included specific physical and physiological changes that progressed gradually and predictably with the depth of the patient's anaesthetized state. Gradual changes in pupil size, progression from thoracic to diaphragmatic breathing, vital sign changes, and several other changes all characterized the various stages. Newer inhalational and IV general anaesthetic drugs, however, often have a much more rapid onset of action and body distribution. As a result, the stages of anaesthesia once observed with older drugs are no longer sufficiently well defined to be observable. Thus, the concept of *stages of anaesthesia* is an outdated one in most modern surgical facilities. Registered nurses who pursue advanced training to become certified registered nurse anaesthesiologists often find this to be a rewarding and interesting area of nursing practice. In Canada, there is currently one program providing training for nurse practitioners in anaesthesia care (NP-A). The role of an anaesthesia assistant is also relatively new in Canada; however, training programs are not limited to registered nurses. Regulations about the role of anaesthesia assistants vary among provinces and territories. In addition, peri-anaesthesia nursing is a recognized specialty at a national level. Nurses who successfully write the certification exam are recognized for their knowledge and expertise by the Canadian Nurses Association.

hydrochloride dihydrate; see Chapter 41). Note that propofol can be used as a general anaesthetic or sedative-hypnotic, depending on the dose. The simultaneous use of both general anaesthetics and adjuncts is called **balanced anaesthesia**. Common adjunct anaesthetic drugs are listed in [Table 12.3](#).

Mechanism of Action and Drug Effects

Many theories have been proposed to explain the actual mechanism of action of general anaesthetics. The drugs vary widely in their chemical structures, and their mechanisms of

TABLE 12.3 Adjunct Anaesthetic Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications/Uses
alfentanil hydrochloride (Alfenta®) fentanyl citrate (Fentanyl Citrate injection®)	Opioid analgesic	Initial loading dose: 130 mcg–245 mcg/kg (with a maintenance infusion of 0.5–1.5 mcg/kg/minute) Anaesthesia as an adjunct agent there is low, moderate and high dose regimens (ranging from 1 mcg/kg to 20 mcg/kg)	Anaesthesia induction
remifentanil hydrochloride sufentanil citrate		0.5 to 1 mcg/kg/min 50–100 mcg/kg IV 0.5–1 mcg/kg IV doses up to 8 mcg/kg/IV	
diazepam (Valium®) midazolam	Benzodiazepine	2–10 mg PO/IV/IM 1–5 mg IV/IM (Note: midazolam is dosed on a mg/kg basis depending on if patient is pre-medicated unmedicated prior to surgery)	Amnesia and anxiety reduction
atropine sulphate glycopyrrolate scopolamine	Anticholinergic	0.02–0.6 mg/kg IM/subcut 4 mcg/kg IM Children: 0.006 mg/kg IV/ IM/subcut Adults: 0.3–0.6 mg IV/IM/subcut	Drying up of excessive secretions
morphine sulphate	Opioid analgesic	5–20 mg IM/subcut	Pain prevention and pain relief
hydroxyzine hydrochloride promethazine hydrochloride	Antihistamine	25–100 mg PO/IM 25–50 mg IV/IM	Sedation, prevention of nausea and vomiting, anxiety reduction
pentobarbital sodium	Sedative-hypnotic	150–200 mg IM	Amnesia and sedation
Dexmedetomidine hydrochloride (Precedex)	α_2 agonist	0.2–1.1 mcg/kg/hour doses up to 1.4 mcg/kg/hr have been shown to be effective) For procedural sedation: Initial load: 0.5–1 mcg/kg Maintenance: 0.2–0.6 mcg/kg/hr Note: dose is different for ICU sedation	Sedation

IM, intramuscular; IV, intravenous; PO, oral; subcut, subcutaneous.

action are not easily explained by a structure–receptor relationship. The concentrations of various anaesthetics required to produce a given state of anaesthesia also differ greatly. The **Overton–Meyer theory** has been used to explain some of the properties of anaesthetic drugs since the early days of anaesthesiology. In general terms, it proposes that, for all anaesthetics, potency varies directly with lipid solubility. In other words, across a continuum of drug potency, fat-soluble drugs are stronger anaesthetics than water-soluble drugs. Nerve cell membranes have a high lipid content, as does the blood–brain barrier (see Chapter 2). Lipid-soluble anaesthetic drugs can therefore easily cross the blood–brain barrier and concentrate in nerve cell membranes.

The overall effect of general anaesthetics is a progressive reduction of sensory and motor CNS functions. The degree and speed of this process varies with the anaesthetics and adjuncts used, along with their dosages and routes of administration. General anaesthesia initially produces a loss of the senses of sight, touch, taste, smell, and hearing, along with loss of consciousness. Cardiac and pulmonary functions are usually the last to be interrupted because they are controlled by the medulla

of the brainstem. These are the classical “stages” of anaesthesia. Mechanical ventilatory support is absolutely necessary. In more extensive surgical procedures, especially those involving the heart, pharmacological cardiac support involving adrenergic drugs (see Chapter 19) and inotropic drugs (see Chapter 25) may also be required.

The reactions of various body systems to general anaesthetics are further described in [Table 12.4](#).

Indications

General anaesthetics are used to produce unconsciousness and relaxation of skeletal and visceral smooth muscles for surgical procedures, as well as in electroconvulsive therapy for severe depression (see Chapter 17).

Contraindications

Contraindications to the use of anaesthetic drugs include known drug allergy. Depending on the drug type, contraindications may also include pregnancy, narrow-angle glaucoma, and known susceptibility to malignant hyperthermia (see Adverse Effects) from prior experience with anaesthetics.

TABLE 12.4 Effects of Inhaled and Intravenous General Anaesthetics

Organ/System	Reaction
Respiratory system	Depressed muscles and patterns of respiration; altered gas exchange and reduced oxygenation; depressed airway-protective mechanisms; airway irritation and possible laryngospasm
Cardiovascular system	Depressed myocardium; hypotension and tachycardia; bradycardia in response to vagal stimulation
Central nervous system	CNS depression; blurred vision; nystagmus; progression of CNS depression to decreased alertness and sensorium as well as decreased level of consciousness
Cerebrovascular system	Increased intracranial blood volume and increased intracranial pressure
Gastrointestinal system	Reduced liver blood flow and thus reduced liver clearance
Renal system	Decreased glomerular filtration
Skeletal muscles	Skeletal muscle relaxation
Cutaneous circulation	Vasodilation

Adverse Effects

Adverse effects of general anaesthetics are dose dependent and vary with the individual drug. The heart, peripheral circulation, liver, kidneys, and respiratory tract are the sites primarily affected. Pulmonary aspiration is a possible complication of general anaesthesia. Patient-related factors such as a full stomach and diabetes may place a patient at higher potential for aspiration; this is why adequate fasting is required prior to elective procedures requiring general anaesthesia. Myocardial depression is a common adverse effect. All halogenated anaesthetics are capable of causing hepatotoxicity.

With the development of newer drugs, many of the unwanted adverse effects characteristic of the older drugs (such as hepatotoxicity and myocardial depression) are now in the past. In addition, many bothersome adverse effects such as nausea, vomiting, and confusion are less common since balanced anaesthesia has been widely used. This practice prevents many of the unwanted, dose-dependent adverse effects and toxicity associated with anaesthetic drugs while also achieving a more balanced general anaesthesia. Substance misuse (e.g., alcohol misuse; see Chapter 18) can predispose a patient to anaesthetic-induced complications (e.g., liver toxicity). A positive history of substance misuse may lead to dosage adjustments in one or more of the drugs used. A patient who misuses drugs and has a high tolerance for street drugs may also require higher doses of anaesthesia-related drugs (e.g., benzodiazepines, opioids) to achieve the desired sedative effects.

Malignant hyperthermia is an uncommon, but potentially fatal, genetically linked adverse metabolic reaction to general anaesthesia. It is classically associated with the use of volatile inhalational anaesthetics as well as the depolarizing NMBD succinylcholine (see Neuromuscular Blocking Drugs, later in this chapter). Signs include rapid rise in body temperature, tachycardia, tachypnea, and muscular rigidity. Patients known to be at greater potential for malignant hyperthermia include children, adolescents, and individuals with muscular or skeletal abnormalities such as hernias, strabismus, ptosis, scoliosis, and muscular dystrophy. Malignant hyperthermia is treated with cardiorespiratory

supportive care as needed to stabilize heart and lung function, along with the skeletal muscle relaxant dantrolene sodium (see Chapter 13). All facilities that provide general anaesthesia must maintain a certain amount of dantrolene sodium on hand in case of malignant hyperthermia.

Toxicity and Management of Overdose

In large doses, anaesthetics are potentially life threatening, with cardiac and respiratory arrest as the ultimate causes of death. However, these drugs are almost exclusively administered in a controlled environment by personnel trained in advanced cardiac life support. These drugs are also quickly metabolized. In addition, the medullary centre, which governs the vital functions, is the last area of the brain to be affected by anaesthetics and the first to regain function. These factors combined make an anaesthetic overdose rare and easily reversible.

Interactions

Some of the common drugs that interact with general anaesthetics are antihypertensives and beta blockers, which have additive effects when given with general anaesthetics (increased hypotensive effects from antihypertensives; increased myocardial depression with beta blockers). Long-term antihypertensives such as beta blockers are usually discontinued prior to the procedure requiring a general anaesthetic. No significant laboratory test interactions have been reported.

DOSAGES

Selected General Anaesthetic Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications
Halothane®	Inhalation general anaesthetic (halogenated hydrocarbon)	0.5–1.5% concentration	General anaesthesia
isoflurane (Forane®)	Inhalation general anaesthetic (enflurane isomer)	Induction: 1.5–3%, Maintenance: 0.5–2.5% depending on concomitant gases	General anaesthesia
nitrous oxide ("laughing gas")	Inorganic inhalation general anaesthetic	20–40% with oxygen (e.g., 70% with 30% oxygen)	Analgesia Anaesthesia

Dosages

For the recommended dosages of selected general anaesthetic drugs, see the Dosages table above.

DRUG PROFILES

The dose of any anaesthetic depends on the complexity of the surgical procedure to be performed and the physical characteristics of the patient. All general anaesthetics have a rapid onset of action along with rapid elimination upon discontinuation. Anaesthesia is maintained intraoperatively by continuous administration of the drug.

SPECIAL POPULATIONS: OLDER ADULTS

Anaesthesia

- Older adult patients are affected more adversely by anaesthesia than young or middle-aged adult patients. With aging comes organ system deterioration. Declining liver function results in decreased metabolism of drugs, and a decline in kidney functioning leads to decreased drug excretion. Either of these can lead to drug toxicity, unsafe levels, or overdose. If both organs are not functioning properly, the risk of drug toxicity or overdose is even greater. In addition, the older adult population is more sensitive to the effects of drugs affecting the central nervous system.
- Presence of cardiac and respiratory diseases places the older adult patient at higher potential for cardiac dysrhythmias, hypotension, respiratory depression, atelectasis, or pneumonia during the postanaesthesia and postoperative phases.
- The practice of polypharmacy is yet another concern in older adults in regard to administration of any type of anaesthetic. Due to the presence of various age-related diseases, older patients are generally taking more than one medication. The more drugs a patient is taking, the higher the risk of adverse reactions and drug–drug interactions, including interactions with anaesthetics.

isoflurane

Isoflurane (Forane) is a fluorinated ether that is a chemical isomer of the older fluorinated ether, enflurane. It has a more rapid onset of action, causes less cardiovascular depression, and has little or no toxicity. This is in contrast to enflurane, which can cause seizures, and halothane, which is associated with liver toxicity.

sevoflurane

Sevoflurane is a fluorinated ether that is now widely used. Its pharmacokinetics, with rapid onset and rapid elimination, make it especially useful in outpatient surgery settings. It is also nonirritating to the airway, which greatly facilitates induction of an unconscious state, especially in pediatric patients.

ketamine hydrochloride

Ketamine hydrochloride (Ketalar®) is a unique drug with multiple properties. Given intravenously, it can be used for both general anaesthesia and procedural sedation. It is commonly

used in the emergency department for setting broken bones. It can also provide procedural sedation when given intravenously. It binds to receptors in both the central and peripheral nervous systems, including opioid receptors. The most important receptors for the therapeutic activity of this drug, however, are the N-methyl-D-aspartate (NMDA) receptors located in the dorsal horn of the spinal cord. The drug is highly lipid soluble and penetrates the blood–brain barrier rapidly, which results in a rapid onset of action. It has a low incidence of reduction of cardiovascular, respiratory, and bowel function. Adverse effects can include disturbing psychomimetic effects, including hallucinations. However, these are less likely to occur when benzodiazepines (see Chapter 13) are coadministered with the drug. Interacting drugs include NMBDs (prolonged paralysis) and halothane (reduced cardiac output and blood pressure). The drug is contraindicated in cases of known drug allergy.

nitrous oxide

Nitrous oxide, also known as *laughing gas*, is the only inhaled gas currently used as a general anaesthetic. It is the weakest of the general anaesthetic drugs and is used primarily for dental procedures or as a useful supplement to other, more potent anaesthetics.

propofol

Propofol (Diprivan®) is a parenteral general anaesthetic used for the induction and maintenance of general anaesthesia and also for sedation for mechanical ventilation in the Critical Care Unit (CCU) and other critical care settings. Because it provides a rapid deep sedation, an anaesthesiologist or sedation team often administers it and monitors its use outside the operating room. It is thought to mediate gamma-aminobutyric acid (GABA) activity. Propofol has no analgesic properties. In lower doses, it can also be used as a sedative–hypnotic for procedural sedation. Propofol is typically well tolerated, producing few undesirable effects. However, it does lead to a dose-dependent reduction in arterial blood pressure and cardiac output; therefore, it must be used with caution in patients who are hemodynamically unstable. Propofol is a lipid-based emulsion, and prolonged use, or

SPECIAL POPULATIONS: CHILDREN

Anaesthesia

- Premature infants, neonates, and pediatric patients are more adversely affected by anaesthesia than young or middle-aged adult patients. The reason for this difference in response is the increased sensitivity of the pediatric patient to anaesthetics and related drugs because of immature functioning of the liver and kidneys, which leads to possible drug accumulation, toxicity, and subsequent complications. The central nervous system of pediatric patients is also more sensitive to the effects of anaesthetics. Because of these risks of toxicity and complications with all forms of anaesthesia, take every precaution to ensure that the patient remains safe and free from harm.
- Cardiac and respiratory systems are not fully developed in the neonate, premature infant, and newborn, which makes this age group more susceptible to problems with the metabolism and excretion of drugs. Some of the more common problems include central nervous system depression with subsequent respiratory and cardiac depression, development of atelectasis, pneumonia, and cardiac abnormalities.
- Neonates (see age group definitions and further discussion in Chapter 4) are at higher risk of upper airway obstruction during general anaesthesia. During the anaesthetic process, the risk of laryngospasm resulting from the intubation process may be increased for neonates because of the specific physical characteristics of the larynx and respiratory structures in this age group. Their higher metabolic rate and small airway diameter also put neonates at greater risk of complications during general anaesthesia.
- Before any medications are given to the pediatric patient, perform a careful check and double-check of mathematical drug calculations. In addition to weight, take into consideration body surface area and laboratory test results that may indicate organ dysfunction when making the actual drug calculation.
- Resuscitative equipment should be readily available on any neonatal or pediatric nursing care unit.

use in conjunction with total parenteral nutrition, requires serum lipids to be monitored.

! dexmedetomidine

Dexmedetomidine (Precedex®) is an α_2 -adrenergic receptor agonist (see Chapter 13). It produces dose-dependent sedation, decreased anxiety, and analgesia without respiratory depression. It is used for procedural sedation and for surgeries of short duration. It has a short half-life, and the patient awakens quickly upon withdrawal of the drug. Dexmedetomidine is also used in the critical care setting for sedation of mechanically ventilated patients. Lower doses may be needed with concurrent anaesthetics, sedatives, or opioids. Adverse effects include hypotension, bradycardia, transient hypertension, and nausea. Doses are listed in Table 12.3. Although the prescribing information states that dexmedetomidine is to be used for only 24 hours, multiple studies have shown it to be safe and effective at longer durations.

DRUGS FOR PROCEDURAL SEDATION

Procedural sedation refers to anaesthesia that does not cause complete loss of consciousness and does not normally cause respiratory arrest. As more minor surgical procedures move from traditional operating room settings to outpatient surgery centres or office-based practices, the use of procedural sedation will continue to increase. Procedural sedation allows patients to relax and have markedly reduced or no anxiety, yet still maintain their own open airway and respond to verbal commands. Standards must be followed when providing procedural sedation. Health care providers who administer procedural sedation are required to have advanced cardiac life support training; one professional must have no duties other than to monitor the patient, and someone with the ability to intubate the patient must be present in case the patient slips into a deeper state of sedation and is unable to maintain an open airway. The Canadian Anesthesiologists' Society (2019a, 2019b) has published guidelines on the practice of anaesthesia as well as on procedural sedation, both of which can be found at <https://www.cas.ca/en/practice-resources/guidelines-to-anesthesia>.

The most commonly used drugs for procedural sedation include a benzodiazepine, usually midazolam (see Chapter 13), with an opioid, usually fentanyl citrate or morphine sulphate. Propofol is also commonly used. Propofol is usually given by an anaesthesiologist. The doses of midazolam used in procedural sedation are 0.02 to 0.1 mg over a 2-minute period, not to exceed 2.5 mg. If needed, a repeat dose of 25% of the initial dose may be used. If midazolam is combined with an opioid such as fentanyl citrate or morphine sulphate, the dose should be reduced by 30 to 50%. The most common dose of fentanyl citrate is 1 to 2 mcg/kg, which may be repeated every 30 minutes. The dose of morphine sulphate for procedural sedation is 2 mg IV. When these drugs are combined with a benzodiazepine, lower doses should be used. The dose of propofol for procedural sedation is 0.5 to 1 mg/kg, followed by 0.25–0.5 mg/kg every 3 to 5 minutes. Mild amnesia is also a common effect, due to the midazolam. This is often desirable for helping patients not to remember painful medical procedures. Procedural sedation is associated with a more rapid recovery time than general anaesthesia is; it is also

SPECIAL POPULATIONS: CHILDREN

Procedural Anaesthesia*

- Procedural sedation (anaesthesia) is used to reduce anxiety, pain, and fear in the pediatric patient. The use of procedural anaesthesia in the pediatric patient allows a procedure to be performed restraint free in most situations while keeping the patient responsive.
- Pediatric dosing often conforms to the following guidelines:
 - Morphine sulphate—pediatric dosing may be at 0.05 to 0.1 mg/kg intravenously (IV) over a 2-minute period and is ideal for long procedures or cases in which pain is anticipated after the procedure.
 - Fentanyl citrate—pediatric dosing may be at 0.5 to 1 mcg/kg with increments over 3 minutes, to a maximum of 3 doses. Too rapid an IV injection may result in chest rigidity, which may need to be treated with muscle relaxants and possibly mechanical ventilation. Fentanyl citrate is used often for short procedures.
- Discharge status of the pediatric patient depends on the types of drugs and drug combinations used. Discharge after procedural sedation is based mainly on whether the following criteria are met:
 - Patient is alert and oriented compared with the baseline neurological assessment.
 - Protective swallowing is intact.
 - Vital signs are stable and consistent with baseline values for at least 30 minutes after the last dosing. Different health care facilities set different criteria that must be met and documented (blood pressure and pulse rate within normal limits or within 20 points of baseline, temperature lower than 38.3°C).
 - Oxygen saturation is at least 95% on room air, 30 minutes after the last dose.
 - Pain rating is at baseline levels or less.
 - Ambulation is at baseline level.
 - An adult is present to take the child home and remain with him or her for a time equal to at least two half-lives of the various drugs used for the anaesthesia.
 - If a reversal drug was administered, there has been time for the drug to be excreted.

* Drugs given as anaesthesia for procedural sedation procedures are given only under controlled situations by anaesthesiologists.

associated with a better safety profile because of lower cardiopulmonary risks.

The oral route of drug administration is commonly used in pediatric patients. This often involves administering an oral syrup form of midazolam with or without concurrent use of injected medications such as opiates. This is especially helpful for pediatric patients who must undergo uncomfortable procedures—such as wound suturing—or diagnostic procedures requiring reduced movement, such as computed tomography and magnetic resonance imaging. See the Special Populations: Children box below for other considerations.

LOCAL ANAESTHETICS

Local anaesthetics are the second major class of anaesthetics. They reduce pain sensations at the level of peripheral nerves, although this can involve intraspinal anaesthesia (see later). They are also called *regional anaesthetics* because they render a specific portion of the body insensitive to pain without major reduction of CNS function and level of consciousness. They act

BOX 12.2 Types of Local Anaesthesia

Central

Spinal or intraspinal anaesthesia: Anaesthetic drugs are injected into the area near the spinal cord within the vertebral column. Intraspinal anaesthesia is commonly accomplished by one of two injection techniques: intrathecal or epidural. Spinal anaesthesia is commonly used for surgery on the lower extremities, perineum (e.g., surgery on the genitalia or anus), or lower body wall (e.g., inguinal herniorrhaphy). Caesarean deliveries are routinely performed under spinal anaesthesia, as are total hip arthroplasty and total knee arthroplasty.

- **Intrathecal anaesthesia:** Anaesthetic drugs are injected into the subarachnoid space. Intrathecal anaesthesia is commonly used for patients undergoing major abdominal or orthopedic surgery or planned Caesarean sections for whom the risks of general anaesthesia are too high or who prefer this technique instead of complete loss of consciousness during their surgical procedure. More recently, intrathecal injection of anaesthetics through implantable drug pumps is being used on an outpatient basis in patients with severe persistent pain syndromes, such as those resulting from occupational injuries.
- **Epidural anaesthesia:** Anaesthetic drugs are injected via a small catheter into the epidural space without puncturing the dura. Epidural anaesthesia is commonly used to reduce maternal discomfort during labour and delivery, for planned Caesarean sections, orthopedic surgery, and to manage postoperative acute pain after major abdominal or pelvic surgery. This route is becoming more popular for the administration of opioids for pain management.

Peripheral

- **Infiltration:** Small amounts of anaesthetic solution are injected into the tissue that surrounds the operative site. This approach to anaesthesia is commonly used for such procedures as wound suturing and dental surgery. Often, drugs that cause constriction of local blood vessels (e.g., epinephrine) are also administered to limit the site of action to the local area.
- **Nerve block:** Anaesthetic solution is injected at the site where a nerve innervates a specific area, such as a tissue. This method allows large amounts of anaesthetic to be delivered to a specific area without affecting the whole body and is often reserved for more difficult-to-treat pain syndromes, such as cancer pain and chronic orthopedic pain.
- **Topical anaesthesia:** The anaesthetic drug is applied directly onto the surface of the skin, eye, or any other mucous membrane to relieve pain or prevent it from being sensed. Topical anaesthesia is commonly used for diagnostic eye examinations and skin suturing.

by interfering with nerve transmission in specific areas of the body, blocking nerve conduction only in the area in which they are applied, without causing loss of consciousness. They are most commonly used in clinical settings in which loss of consciousness is undesirable or unnecessary. These include childbirth and other situations in which **spinal anaesthesia** is desired, dental procedures, suturing of skin lacerations, and diagnostic procedures (e.g., lumbar puncture, thoracentesis, biopsy).

Most local anaesthetics belong to one of two major groups of organic compounds—esters or amides. They are classified as either *parenteral* (injectable) or *topical* anaesthetics. Parenteral anaesthetics are most commonly given intravenously but may also be administered by various spinal injection techniques (Box 12.2). Topical anaesthetics are applied directly to the skin and mucous membranes. They are available in the form of solutions, ointments, gels, creams, powders, suppositories, and ophthalmic drops. Their dosage strengths are listed in Table 12.5.

TABLE 12.5 Selected Topical Anaesthetics

Drug	Route	Dosage Strength
benzocaine (Cetacaine®, Lanacane®, Solarcaine®)	Topical, aerosol, and spray	18% gel
dibucaine hydrochloride (Nupercainal®)	Topical	0.5–1% ointment or cream
dyclonine hydrochloride (Suctrets®)	Topical	Lozenges
lidocaine (Bactine®, Betacaine®)	Topical	Jelly, ointment, cream, spray
prilocaine/lidocaine (EMLA)	Topical	2.5% prilocaine and 2.5% lidocaine cream, patch
tetracaine hydrochloride (Pontocaine®)	Injection, topical, and ophthalmic	0.5–2% solution, gel, ointment, or cream

TABLE 12.6 Selected Parenteral Local Anaesthetic Drugs*

Generic Name	Trade Name	Potency	Onset	Duration
lidocaine hydrochloride	Xylocaine	Moderate	Immediate	60–90 min
mepivacaine hydrochloride	Carbocaine®, Isocaine®	Moderate	Rapid onset with moderate duration, depending on route	120–150 min
tetracaine hydrochloride	Pontocaine	Highest	5–10 min	90–120 min

*Other common parenteral anaesthetic drugs include bupivacaine (Marcaine®, Sensorcaine®), chloroprocaine (Nesacaine®), and ropivacaine (Naropin®).

The injection of parenteral anaesthetic drugs into the area near the spinal cord is known as *spinal* or *intraspinal* anaesthesia. This type of anaesthesia is generally used to block all peripheral nerves that branch out distal to the injection site. The result is elimination of pain and paralysis of the skeletal and smooth muscles of the corresponding innervated tissues. Some of the medications used for spinal anaesthesia include the opioids morphine sulphate, hydromorphone, and fentanyl citrate (see Chapter 11), and the local anaesthetics lidocaine and bupivacaine. Because spinal anaesthesia does not normally depress the CNS at a level that causes loss of consciousness, it can be thought of as a large-scale type of local anaesthesia rather than a general anaesthesia. Common types of local anaesthesia are described in Box 12.2. The parenteral anaesthetic drugs and their pharmacokinetics are summarized in Table 12.6.

Local anaesthesia of specific peripheral nerves is accomplished either by nerve block anaesthesia or infiltration anaesthesia. Nerve block anaesthesia involves relatively deep injections of drugs (e.g., lidocaine) into locations adjacent to major nerve

trunks or ganglia. It focuses on a relatively large body region but not necessarily one as extensive as that affected by spinal anaesthesia. In contrast, infiltration anaesthesia involves multiple small injections (intra-dermal, subcutaneous (subcut), submucosal, or intramuscular [IM]) to produce a more limited or “local” anaesthetic field. Another subtype of local anaesthesia involves topical application of a drug (e.g., lidocaine) onto the surface of the skin, mucous membranes, or eye. A newer method of administering local anaesthetics is via a peripheral nerve catheter attached to a pump containing the local anaesthetic. These pumps are designed to infuse local anaesthetic around the nerves that innervate the surgical site for several days postoperatively. The catheter is implanted during surgery and is normally taken out by the patient at home once the anaesthetic has been infused. A common trade name is the ON-Q® PainBuster pump.

Mechanism of Action and Drug Effects

Local anaesthetics act by rendering a specific portion of the body insensitive to pain by interfering with nerve transmission. Nerve conduction is blocked only in the area in which the anaesthetic is applied, and there is no loss of consciousness. Local anaesthetics block both the generation and conduction of impulses through all types of nerve fibres (sensory, motor, and autonomic), by blocking the movement of certain ions (sodium, potassium, and calcium) important to this process. They do this by making it more difficult for these ions to move in and out of the nerve fibre. For this reason, some of these drugs are also described as *membrane-stabilizing* because they alter the cell membrane of the nerve so that the free movement of ions is inhibited. The membrane-stabilizing effects occur first in the small fibres and then in the large fibres. In terms of paralysis, usually autonomic activity is affected first, and then pain and other sensory functions are lost; motor activity is the last to be lost. When the effects of the local anaesthetic wear off, recovery occurs in reverse order: motor activity returns first, then sensory functions, and finally autonomic activity.

Possible systemic effects of the administration of local anaesthetics include effects on circulatory and respiratory functions. The systemic adverse effects depend on where and how the drug is administered (e.g., injection at a certain level in the spinal cord or topical application of a drug that gains access to the circulatory system). Such adverse effects are unlikely unless large quantities of a drug are injected. Local anaesthetics also produce *sympathetic blockade*; that is, they block the action of the two neurotransmitters of the sympathetic nervous system, norepinephrine and epinephrine (see Chapter 19). The cardiac effects include a decrease in stroke volume, cardiac output, and peripheral resistance. The respiratory effects include reduced respiratory function and altered breathing patterns, but complete paralysis of respiratory function is unlikely.

Indications

Local anaesthetics are used for surgical, dental, and diagnostic procedures, as well as for the treatment of certain types of persistent pain. Spinal anaesthesia is used to control pain during surgical procedures and childbirth. Nerve block anaesthesia is used for surgical, dental, and diagnostic procedures and for the therapeutic management of persistent pain. Infiltration

anaesthesia is used for relatively minor surgical and dental procedures.

Contraindications

Contraindications for local anaesthetics include known drug allergy. Only specially formulated dosage forms are intended for ophthalmic use (see Chapter 57).

Adverse Effects

The adverse effects of the local anaesthetics are limited and of little clinical importance in most circumstances. The undesirable effects usually occur with high plasma concentrations of the drug, which result from inadvertent intravascular injection, an excessive dose or rate of injection, slow metabolic breakdown, or injection into a highly vascular tissue. One notable complication of spinal anaesthesia is spinal headache. Spinal headache occurs in up to 70% of patients who either experience inadvertent dural puncture during epidural anaesthesia or undergo intrathecal anaesthesia. Spinal headache is most often self-limiting and is treated with bedrest and conventional analgesic medications. Oral forms of the CNS stimulant caffeine (see Chapter 14) are also sometimes used. Severe cases of spinal headache may be treated by the anaesthesiologist by injection of a small volume (approximately 15 mL) of venous sample of the patient's own blood into the patient's epidural space. The exact mechanism by which this blood patch provides relief is unknown, but it is effective in treating spinal headache in over 90% of cases. Another complication is catastrophic bleeding during spinal anaesthesia in anticoagulated patients. Bleeding can occur in the area around the spinal cord during the time of placement and removal of the spinal catheter. Coagulation medication, including newer direct oral anticoagulants (DOAC) must be stopped between 12–92 hours prior to spinal anaesthesia, depending on the type of anticoagulant therapy the patient is receiving ([Thrombosis Canada, 2017](#)).

True allergic reactions to local anaesthetics are rare. However, they can occur, ranging from skin lesions, urticaria, and edema, to anaphylactic shock. Such allergic reactions are generally limited to a chemical class of anaesthetics called the *ester type*. [Box 12.3](#) categorizes the local anaesthetic drugs into the ester and amide chemical families. Different enzymes are responsible for the breakdown of these two groups of anaesthetics in the body. Anaesthetics belonging to the ester family are metabolized by cholinesterase in the plasma and liver. They are converted into a para-aminobenzoic acid (PABA) compound, which is responsible for the allergic reactions. In contrast, the amide type of

BOX 12.3 Chemical Groups of Local Anaesthetics

Ester Type	Amide Type
Benzocaine	bupivacaine hydrochloride
chloroprocaine	dibucaine hydrochloride
Procaine	lidocaine
proparacaine	mepivacaine hydrochloride
propoxycaine	prilocaine hydrochloride
tetracaine	

anaesthetics is metabolized uneventfully to active and inactive metabolites in the liver by other enzymes. Often when an individual has an adverse reaction to one of the local anaesthetics, using a drug from the alternate chemical class avoids this problem.

Toxicity and Management of Overdose

Local anaesthetics have little opportunity to cause toxicity under most circumstances. However, systemic reactions are possible if sufficiently large quantities are absorbed into the systemic circulation. To prevent this from occurring, a vasoconstrictor such as epinephrine is often coadministered with the local anaesthetic to maintain localized drug activity (e.g., lidocaine with epinephrine or bupivacaine with epinephrine). This property of epinephrine also serves to reduce local blood loss during minor surgical procedures. If significant amounts of the locally administered anaesthetic are absorbed systemically, cardiovascular and respiratory function may be compromised. In extreme cases, such as inadvertent injection of a drug into a major blood vessel, symptomatic and supportive cardiovascular or respiratory therapy may be required until the drug is metabolized and eliminated.

Interactions

Few clinically significant drug interactions occur with local anaesthetics. When given with enflurane, halothane, or epinephrine, these drugs can lead to dysrhythmias.

DRUG PROFILES

Besides lidocaine, profiled here, local anaesthetics include bupivacaine hydrochloride, mepivacaine hydrochloride, prilocaine hydrochloride, and tetracaine hydrochloride. There are two major types of local anaesthetics as determined by their chemical structure: amides and esters. These designations refer to the type of linkage between the aromatic ring and the amino group of the chemical structures of the drug molecules. These structural components give these drugs their anaesthetic properties.

Lidocaine hydrochloride

Lidocaine belongs to the amide class of local anaesthetics. Some patients may report that they have allergic or anaphylactic reactions to the “caines,” as they may refer to lidocaine and the other amide drugs. In these situations, it may be wise to try a local anaesthetic of the ester type.

Lidocaine hydrochloride (Xylocaine®) is one of the most commonly used local anaesthetics. It is available in several strengths, both alone and in different concentrations with epinephrine, and is used for both infiltration and nerve block anaesthesia. Lidocaine hydrochloride is also available in topical forms, including the unique product, EMLA®. EMLA is a cream mixture of lidocaine hydrochloride and prilocaine hydrochloride that is applied to skin to ease the pain of needle punctures (e.g., when starting an IV line). Parenteral lidocaine is also used to treat certain cardiac dysrhythmias (see Chapter 26). Contraindications include known drug allergy. There are no adequate, well-controlled studies in pregnant women on the effect of lidocaine hydrochloride on the developing fetus.

NEUROMUSCULAR BLOCKING DRUGS

Historically, snakes and plants have played a role in the identification of substances that cause paralysis and in the discovery of related receptor proteins in animals and humans. The beginning steps involved study of the irreversible nerve transmission inhibition in muscles caused by toxins in the venom of the kraits snake and certain varieties of cobra.

Curare, a general term for various South American arrow poisons, has a long and intriguing history. It has been used for centuries by natives of the Amazon River region and other parts of South America to kill wild animals for food. Animals shot with arrows soaked in this plant substance normally die from paralysis of the respiratory muscles. Once the receptor sites of action of venoms and toxins were identified, pharmacological drugs were developed that mimic these substances. Curare can be considered the grandfather of modern NMBDs. Several curarelike drugs are now used in clinical practice. The first drug derived from curare to be used medicinally was d-tubocurarine, which was introduced into anaesthesia practice in 1940; it has now been replaced by newer drugs such as pancuronium. Pancuronium has a pharmacodynamic profile similar to that of curare but produces fewer adverse effects.

NMBDs prevent nerve transmission in skeletal and smooth muscles, leading to paralysis. They are often used as adjuncts with general anaesthetics for surgical procedures. NMBDs also paralyze the skeletal muscles required for breathing: the intercostal muscles and the diaphragm. The patient is rendered unable to breathe independently, and mechanical ventilation is required to prevent brain damage or death by suffocation. Deaths have been reported when an NMBD is accidentally mistaken for a different drug and given to a patient who is not mechanically ventilated. Most hospitals have taken extra precautions to keep NMBDs separated from other drugs, or at least marked with warning stickers. It is essential that the nurse ensure that the patient is ventilated before giving an NMBD and double-check that an NMBD is not inadvertently given. In the event of an error, the patient would experience a horrendous death, because the mind would be alert, but the patient would not be able to speak or move (see Preventing Medication Errors: Neuromuscular Blocking Drugs box).

PREVENTING MEDICATION ERRORS

Neuromuscular Blocking Drugs

Neuromuscular blocking drugs are considered high-alert drugs, because improper use may lead to severe injury or death. The Institute for Safe Medication Practices Canada has reported several cases of patient death or injury as a result of medication errors involving NMBDs. Because these drugs paralyze the respiratory muscles, incorrect administration without sufficient ventilator support has resulted in patient deaths. There have been medication errors due to “sound-alike” drug names as well (e.g., vancomycin and vecuronium). Most facilities have followed recommendations to restrict access to these drugs, provide warning labels and reminders, and increase staff awareness of the dangers of these drugs.

Mechanism of Action and Drug Effects

NMBDs are classified into two groups based on mechanism of action: depolarizing and nondepolarizing. Depolarizing NMBDs work similarly to the neurotransmitter acetylcholine (ACh). They bind in place of ACh to cholinergic receptors at the motor endplates of muscle nerves or neuromuscular junctions. Thus, they are competitive agonists (see Chapter 2). There are two phases of depolarizing block. During phase I (depolarizing phase), the muscles fasciculate (twitch). Eventually, after continued depolarization has occurred, muscles are no longer responsive to the ACh released; thus, muscle tone cannot be maintained and muscles become paralyzed. This is phase II, or the desensitizing phase. Depolarizing NMBDs include d-tubocurarine and succinylcholine (see later in this chapter). The duration of action of succinylcholine after a single dose to facilitate intubation is only about 5 to 9 minutes because of the rapid breakdown of the drug by cholinesterase, the enzyme responsible for metabolizing succinylcholine. Nondepolarizing NMBDs also bind to ACh receptors at the neuromuscular junction, but instead of mimicking ACh, they block its actions. Therefore, these drugs are competitive antagonists (see Chapter 2) of ACh. Consequently, the nerve cell membrane is not depolarized, the muscle fibres are not stimulated, and skeletal muscle contraction does not occur. Nondepolarizing NMBDs include vecuronium and pancuronium and are typically classified into three groups, based on their duration of action: short-acting, intermediate-acting, and long-acting drugs (Table 12.7).

The typical time course of NMBD-induced paralysis during a surgical procedure is as follows. The first sensation typically experienced is muscle weakness. This is usually followed by a total flaccid paralysis. Small, rapidly moving muscles such as those of the fingers and eyes are typically the first to be paralyzed. The next are those of the limbs, neck, and trunk. Finally, the intercostal muscles and the diaphragm are paralyzed; the patient can no longer breathe independently. It must be noted that NMBDs, when used alone, do *not* cause sedation or relieve pain or anxiety. Therefore, the patient needs to also receive appropriate medications to manage pain or anxiety. NMBDs temporarily inactivate the body’s natural drive to control respirations. Recovery of muscular activity after discontinuation of anaesthesia usually occurs in the reverse order to the initiation of paralysis, and thus the diaphragm is ordinarily the first muscle to regain function.

TABLE 12.7 Classification of Neuromuscular Blocking Drugs
Drug
Intermediate-Acting
atracurium besylate
cisatracurium besylate
rocuronium bromide (Zemeron®)
Long-Acting
pancuronium bromide

Indications

The main therapeutic use of NMBDs is for maintaining skeletal muscle paralysis to facilitate controlled ventilation during surgical procedures. Shorter-acting NMBDs are often used to facilitate intubation with an endotracheal tube. This is commonly done for a variety of diagnostic procedures such as laryngoscopy, bronchoscopy, and esophagoscopy. When used for this purpose, NMBDs are frequently combined with anxiolytics or anaesthetics. Additional nonsurgical applications include reduction of laryngeal or general muscle spasms, reduction of spasticity from tetanus and neurological diseases such as multiple sclerosis, and prevention of bone fractures during electroconvulsive therapy (see Chapter 17). These drugs are also used for the diagnosis of myasthenia gravis, a disease characterized by chronic muscular weakness.

Contraindications

Contraindications to NMBDs include known drug allergy and also may include previous history of malignant hyperthermia, penetrating eye injuries, and narrow-angle glaucoma.

Adverse Effects

The key to limiting adverse effects with most NMBDs is to use only enough of the drug to block the neuromuscular receptors. If too much is used, the risk is increased that other ganglionic receptors will be affected. Blockade of these other ganglionic receptors leads to most of the undesirable effects of NMBDs. The effects of ganglionic blockade in various areas of the body are listed in Table 12.8.

The muscle paralysis induced by depolarizing NMBDs (e.g., succinylcholine) is sometimes preceded by muscle spasms, which may damage muscles. These muscle spasms are termed *muscle fasciculations* and are most pronounced in the muscle groups of the hands, feet, and face. Injury to muscle cells may cause postoperative muscle pain and release potassium into the circulation, resulting in hyperkalemia, which is usually self-limiting and reversible. Small doses of nondepolarizing NMBDs are sometimes administered with succinylcholine to minimize these muscle fasciculations. Despite these disadvantages, succinylcholine is still popular due to its rapid onset of action, its depth of neuromuscular blockade, and its short duration of action. For these reasons, it is often preferred to nondepolarizing

TABLE 12.8 Effects of Ganglionic Blockade by Neuromuscular Blocking Drugs		
Site	Part of Nervous System Blocked	Physiological Effect
Arterioles	Sympathetic	Vasodilation and hypotension
Veins	Sympathetic	Dilation
Heart	Parasympathetic	Tachycardia
Gastrointestinal	Parasympathetic	Reduced tone and tract motility; constipation
Urinary bladder	Parasympathetic	Urinary retention

NMBDs for rapid-sequence induction of anaesthesia (e.g., for emergency intubation).

The effects on the cardiovascular system vary depending on the NMBD used and the individual patient. Increases and decreases in blood pressure and heart rate have been seen. Some NMBDs cause a release of histamine, which can result in bronchospasm, hypotension, and excessive bronchial and salivary secretion. The gastrointestinal tract is seldom affected by NMBDs. When it is affected, decreased tone and motility typically result, which can lead to constipation or even ileus. Use of succinylcholine has been associated with hyperkalemia; dysrhythmias; fasciculations; muscle pain; myoglobinuria; increased intraocular, intragastric, and intracranial pressure; and malignant hyperthermia.

Toxicity and Management of Overdose

The primary concern when NMBDs are overdosed is prolonged paralysis requiring prolonged mechanical ventilation (see the Preventing Medication Errors: Neuromuscular Blocking Drugs box on p. 203). Cardiovascular collapse may be seen and is thought to be the result of histamine release. Multiple medical conditions can predispose an individual to toxicity. These conditions increase the sensitivity of the individual to NMBDs and prolong their effects and are listed in Box 12.4. Some conditions make it more difficult for NMBDs to work, and therefore higher doses of NMBDs are required in these cases. Although these conditions do not necessarily lead to toxicity or overdose, they are worthy of mention and are listed in Box 12.5.

Anticholinesterase drugs such as neostigmine methylsulphate, pyridostigmine bromide, and edrophonium chloride are antidotes and are used to reverse muscle paralysis. They work by preventing the enzyme cholinesterase from breaking down ACh. This causes ACh to build up at the motor endplate, and it eventually displaces the nondepolarizing NMBD molecule, returning the nerve to its original state. Dysmetabolic syndrome, known as *malignant hyperthermia* (see General Anaesthetics earlier in the chapter) can also occur with NMBDs, especially succinylcholine.

BOX 12.4 Conditions That Predispose Patients to Toxic Effects From Neuromuscular Blocking Drugs

Acidosis	Myasthenia gravis
Amyotrophic lateral sclerosis	Myasthenic syndrome
Hypermagnesemia	Neonatal status
Hypocalcemia	Neurofibromatosis
Hypokalemia	Paraplegia
Hypothermia	Poliomyelitis

BOX 12.5 Conditions That Oppose the Effects of Neuromuscular Blocking Drugs

Cirrhosis with ascites	Hyperkalemia
Clostridial infections	Peripheral nerve transection
Hemiplegia	Peripheral neuropathies
Hypercalcemia	Thermal burns

INTERACTIONS

Many drugs can interact with NMBDs, which may lead to either synergistic or opposing effects. Aminoglycoside antibiotics, when given with an NMBD, can have additive effects. Tetracycline antibiotics can also produce neuromuscular blockade, possibly by chelation of calcium, and calcium channel blockers have also been shown to enhance neuromuscular blockade. Other notable drugs that interact with NMBDs are listed in Box 12.6.

DOSAGES

For dosage information of selected NMBDs, refer to the Dosages table on p. 206.

DRUG PROFILES

Neuromuscular blocking drugs are one of the most commonly used classes of drugs in the operating room. They are given primarily with general anaesthetics to facilitate endotracheal intubation and to relax skeletal muscles during surgery. In addition to their use in the operating room, they are given in the CCU to paralyze mechanically ventilated patients. There are two basic types of NMBDs: depolarizing and nondepolarizing drugs. Nondepolarizing drugs are generally classified by their duration of action. Table 12.8 lists examples of currently used nondepolarizing drugs.

Depolarizing Neuromuscular Blocking Drugs

succinylcholine

Succinylcholine (Quelcin®) is the only currently available drug in the depolarizing subclass of NMBDs. Succinylcholine has a structure similar to that of the parasympathetic neurotransmitter ACh. It stimulates the same neurons as ACh and produces the same physiological responses, initially. Compared to ACh, however, succinylcholine is metabolized more slowly. Because of this slower metabolism, succinylcholine subjects the motor endplate to ongoing depolarizing stimulation. Repolarization cannot occur. If sufficient succinylcholine concentrations are present, the muscle loses its ability to contract, and flaccid muscle paralysis results. Because of its quick onset of action, succinylcholine is most commonly used to facilitate endotracheal intubation. It is seldom used over long

BOX 12.6 Drugs That Interact With Neuromuscular Blocking Drugs

Additive Effects	Opposing Effects
Aminoglycosides	carbamazepine

periods because of its tendency to cause muscular fasciculations. It is contraindicated in patients with personal or familial history of malignant hyperthermia, skeletal muscle myopathies, and known hypersensitivity to the drug. For dosage information, refer to the Dosages table on p. 206.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Rapid, less than 1 min	Rapid	Less than 1 min	4–6 min

Nondepolarizing Neuromuscular Blocking Drugs

Nondepolarizing NMBDs are commonly used to facilitate endotracheal intubation, reduce muscle contraction, and facilitate a variety of diagnostic procedures. They are often combined with anxiolytics or anaesthetics. They may also be used to induce respiratory arrest in patients on mechanical ventilation. Nondepolarizing NMBDs are typically classified into three groups, based on their duration of action: short-, intermediate-, and long-acting drugs (see Table 12.7).

pancuronium bromide

Pancuronium bromide is a long-acting nondepolarizing NMBD. It is used as an adjunct to general anaesthesia to facilitate endotracheal intubation and to provide skeletal muscle relaxation during surgery or mechanical ventilation. It is most commonly employed for long surgical procedures that require prolonged muscle paralysis. Use of pancuronium is contraindicated in cases of known drug allergy. It is available only in injectable form. For dosage information, refer to the Dosages table below.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	3–5 min	5 min	100 min	60–100 min Note: Adults 22 minutes (prolonged by hypothermia)

vecuronium bromide

Vecuronium bromide is an intermediate-acting nondepolarizing NMBD. It is used as an adjunct to general anaesthesia to facilitate tracheal intubation and to provide skeletal muscle relaxation during surgery or mechanical ventilation, and it is one of the most commonly used NMBDs. Long-term use in the CCU setting has resulted in prolonged paralysis and subsequent difficulty weaning from mechanical ventilation. This is believed to be due to an active metabolite, 3-desacetyl vecuronium, which tends to accumulate with prolonged use. Use of vecuronium bromide is contraindicated in cases of known drug allergy. For dosage information, refer to the Dosages table on p. 206.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	2.5–3 min	3–5 min	65–76 min	25–40 min

Dosages

Selected Neuromuscular Blocking Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications
pancuronium bromide	Nondepolarizing NMBD (long acting)	Adults, children older than 1 month IV: 0.04–0.1 mg/kg Neonates up to 1 month Because neonates are especially sensitive to nondepolarizing NMBDs, give a test dose of 0.02 mg/kg IV	Intubation Adjunct to balanced anaesthesia
 succinylcholine chloride (Quelicin Chloride Injection®)	Depolarizing NMBD (short acting)	IM: 3–4 mg/kg Adults IV: 0.3–1.1 mg/kg over 10–30 sec IM: 2.5–4 mg/kg Children IV: 0.08–0.1 mg/kg	Intubation Mechanical ventilation
 vecuronium bromide (Norcuron®)	Nondepolarizing NMBD (intermediate acting)	Adults IV: 0.08–0.1 mg/kg Continuous infusion: 0.16–1.8 mcg/kg/hr	Intubation Mechanical ventilation

CASE STUDY**Procedural Sedation**

Helen is a 53-year-old woman who is scheduled to have a colonoscopy this morning, and she is extremely anxious. The anaesthesiologist has explained the procedural sedation that is planned (midazolam and morphine sulphate), but after the anaesthesiologist leaves the room, the patient says, "I'm so afraid of feeling it during the test. Why don't they just put me to sleep?"

1. How does procedural sedation differ from general anaesthesia?
 2. What is the nurse's best answer to Helen's question?
 3. What is important for the nurse to assess before this procedure is performed?
 4. Explain the purpose of these two medications during procedural sedation. How are the dosages adjusted when these are given together?
- For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

PHARMACOKINETIC BRIDGE TO NURSING PRACTICE

With procedural sedation or anaesthesia, it is always important to understand the pharmacokinetic properties of the drug(s) used. For example, the IV form of midazolam has an onset of action of 1 to 5 minutes, a peak plasma effect time of 20 to 60 minutes, an elimination half-life (time it takes for 50% of the drug to be excreted) of 1 to 4 hours, and a duration of action of 2 to 6 hours. Therefore, if midazolam is used for procedural sedation, you will begin to see the sedating properties within 1 to 5 minutes and peak effects on the patient between 20 and 60 minutes. Since the drug's action lasts for only 2 to 6 hours, midazolam is an attractive option for use in outpatient procedures because of fast onset and short duration of action. Therefore, as noted with this drug's pharmacokinetic properties, you may then be able to predict the drug's onset of action, peak effect, and duration of action.

❖ NURSING PROCESS

◆ ASSESSMENT

It is important to note that anaesthetics are not typically given by registered nurses or practical nurses. Exceptions to this statement are orders for topical forms, such as oral swish-and-swallow solutions that may be used during chemotherapy and lidocaine patches for pain relief. Associated with each drug used for general and local anaesthesia are some broad as well as specific assessment parameters. First, for any form of anaesthesia, and during any of the phases of anaesthesia, the major parameters to assess are airway, breathing, and circulation (ABCs). Include questions in your assessment regarding allergies and use of prescription as well as over-the-counter drugs, natural health products (NHPs), and social and illegal drugs.

Another important area to consider is the use of alcohol and nicotine. Excessive use of alcohol may alter the patient's response to general anaesthesia, especially if there is liver impairment. Also, if the patient has a history of alcohol misuse, withdrawal symptoms may occur during the recovery from anaesthesia or surgery. Perform a respiratory assessment (e.g., respiratory rate, rhythm, and depth; breath sounds; oxygen saturation level), especially if the patient has a history of smoking or is currently a smoker. The patient's history of smoking is important because nicotine has a paralyzing effect on the cilia within the respiratory system. Once they are malfunctioning, these cilia cannot perform their main function of keeping foreign bodies out of the lungs and allowing mucus and secretions to be coughed up with ease. Malfunctioning of the cilia can potentially lead to atelectasis or pneumonia.

Other objective data to be collected include weight and height because these parameters are often used in determining the dosing of anaesthesia. Other studies that may be ordered by the anaesthesiologist or surgeon include an electrocardiogram, a chest radiograph, and tests of kidney function (e.g., BUN level, creatinine level, urinalysis with specific gravity) and liver function (e.g., total protein and albumin levels; bilirubin level; ALP, AST, ALT levels). Additional laboratory tests may include Hgb, Hct, WBC with differential, and tests that indicate clotting abilities, such as PT-INR, aPTT, and platelet count. Also assess results of tests for serum electrolytes, specifically potassium, sodium, chloride, phosphorus, magnesium, and calcium because abnormalities may lead to further complications from the anaesthesia. You must assess the results of a pregnancy test in females of childbearing age, if ordered, because of the possibility of teratogenic effects (adverse effects on the fetus) resulting from the anaesthetic drug.

Neurological assessment is extremely important and includes performing and documenting a thorough baseline survey. Determine and document level of consciousness, alertness, and orientation to person, place, and time, prior to the anaesthesia. Additional neurological assessment includes motor assessments, with left-right and upper extremity versus lower extremity comparisons of strength, reflexes, grasp, and ability to move on command. Sensory assessment focuses on the same anatomical areas, with comparisons of the response to various types of stimuli such as sharp, dull, soft, and cold versus warm. Swallowing ability is also important to assess and document for baseline status and comparisons. When these motor, sensory, and cognitive parameters are within normal limits, there is proof of an intact neurological system.

One significant reaction to assess for in patients receiving general anaesthesia is that of malignant hyperthermia. This is a rapid progression of hyperthermia that may be fatal if not promptly recognized and aggressively treated. The tendency is inherited, so questions about related signs and symptoms in the patient's and family's medical histories are important to document and report. A familial history of malignant hyperthermia would put the patient at risk. Signs and symptoms of malignant hyperthermia include a rapid rise in body temperature, tachycardia, tachypnea, muscle rigidity, cyanosis, irregular heartbeat, mottling of the skin, diaphoresis (profuse sweating), and an unstable blood pressure. If there is

no documented problem with general anaesthesia or if the patient is undergoing general anaesthesia for the first time, perform an astute and careful examination of all medical and medication histories. With any type of anaesthesia, it is often slight changes in vital signs, other vital parameters, and laboratory test results that may provide nurses and other health care providers with a possible clue to the patient's reaction to anaesthesia. Note that malignant hyperthermia occurs during the anaesthesia process and in the surgical suite; nevertheless, close observation after anaesthesia is still important and much needed. Intravenously administered anaesthetic drugs are usually combined with adjunct drugs (given at the same time) such as sedative-hypnotics, antianxiety drugs, opioid and nonopioid analgesics, antiemetics, and anticholinergics. These drugs are used to decrease some of the undesirable aftereffects of inhaled anaesthetics. If they are used, perform a complete assessment for each of the drugs, including obtaining a medical history and medication profile. Liver and kidney function studies are important in these patients as well, so that any risks of toxicity and complications can be anticipated.

For patients about to undergo anaesthesia with NMBDs, perform a complete head-to-toe assessment with a thorough medical and medication history. Which specific drug is being used and whether it is depolarizing or nondepolarizing will guide your assessment because of the action of NMBDs on the patient's neuromuscular functioning (see previous discussion in this chapter). Assess all cautions, contraindications, and drug interactions. Another concern with the use of these drugs is that they are associated with an increase in intraocular pressure and intracranial pressure. Therefore, these anaesthetic drugs should not be used, or should be used with extreme caution (close monitoring of these pressures), in patients with glaucoma or closed-head injuries.

Paralysis of respiratory muscles allows patient relaxation to the point where the patient will not fight against the breaths delivered by the ventilator. Complete a thorough respiratory assessment in patients receiving NMBDs because of the effect of these drugs on the respiratory system. In particular, these drugs have a paralyzing effect on the muscles used for breathing and—for this reason—are used to facilitate intubation for mechanical ventilation. Also indicated with the use of NMBDs is careful assessment of serum electrolyte levels, specifically potassium and magnesium levels. Imbalances in these electrolytes may lead to increased action of the NMBD with exacerbation of the drug's actions and toxic effects. Allergic reactions to these drugs are most commonly characterized by rash, fever, respiratory distress, and pruritus. Drug interactions with natural health products are outlined in the Natural Health Products box below. For more specific information on the differences between depolarizing and nondepolarizing NMBDs, see the pharmacology section of this chapter.

With the use of procedural sedation, as with any anaesthesia technique, assessment for allergies, cautions, contraindications, and drug interactions is important. Because procedural sedation is commonly used across the lifespan, closely assess organ function and note diseases or conditions that could lead to excessive levels of the drug in the body, such as liver or kidney impairment. See [Chapters 11 and 13](#) for more information about the assessment associated with the use of opioids and sedative-hypnotics and CNS depressants.

NATURAL HEALTH PRODUCTS

Potential Effects of Popular Natural Health Products When Combined With Anaesthetics

Feverfew: Migraine headaches, insomnia, anxiety, joint stiffness, risk of increased bleeding times with increased risk of bleeding

Garlic: Changes in blood pressure, risk of increased bleeding

Ginger: Sedating effects; risk of bleeding, especially if taken with either aspirin or Ginkgo biloba

Ginseng: Irritability and insomnia, risk of cardiac adverse effects

Kava: Sedating effects, potential liver toxicity, risk of additive effects with medications

St. John's wort: Sedation, blood pressure changes, risk of interaction with other medications that prolong the effects of anaesthesia

Use of spinal anaesthesia requires thorough assessment with an emphasis on the ABCs, respiratory function, and vital signs, specifically blood pressure. Baseline respirations with attention to rate, rhythm, depth, and breath sounds are important to note, as are oxygen saturation levels obtained via pulse oximetry. Because of possible problems with vasodilatation from the spinal anaesthetic, document baseline blood pressure levels and pulse rate. Assess platelet count as a hematoma may be an adverse effect, especially for patients with thrombocytopenia. Record history of previous reactions to this form of anaesthesia, allergies, and a listing of all medications, and report any abnormal reactions to the anaesthesiologist and surgeon. Neurological assessment with notation of sensory and motor intactness in the lower extremities, as well as documentation of any abnormalities, is important. The use of epidural anaesthesia requires special attention to overall hemostasis through monitoring of vital signs and oxygen saturation levels. Assess baseline sensory and motor function in the extremities, and document an intact neurological system (see Implementation for more detailed discussion). Spinal headaches may occur with either spinal anaesthesia or epidural injections, and thus baseline assessment for the presence of headaches is important. Many institutions have care-flow assessment monitoring sheets specifically for assessing the patient with an epidural.

Topical local anaesthetics such as lidocaine, used for either infiltration or nerve block anaesthesia, may be administered with or without a vasoconstrictor (e.g., epinephrine). Vasoconstrictors are used to help confine the local anaesthetic to the injected area, prevent systemic absorption of the anaesthetic, and reduce bleeding. If there is systemic absorption of the vasoconstrictor into the bloodstream, the patient's blood pressure could elevate to life-threatening levels, especially in patients who are at high risk (e.g., those with underlying arterial disease). Therefore, review the patient's medical history to assess for any pre-existing illnesses, such as vascular disease, aneurysms, or hypertension, because these may be contraindications to the use of the vasoconstrictor with the anaesthetic. In addition, with these local anaesthetics, assess for allergies to the drug as well as baseline vital signs. Also assess for possible drug interactions, and note prescription medications, natural health products, and over-the-counter medications. In summary, with any type of anaesthesia, it is important to assess the patient's level of homeostasis prior to actual administration of the drug. This assessment may include taking vital signs

as well as checking the ABCs. Other parameters of interest may be oxygen saturation levels measured by pulse oximetry, cardiovascular and respiratory function, and neurological function.

◆ NURSING DIAGNOSES

1. Reduced gas exchange resulting from the general anaesthetic's CNS-depressant effects with altered respiratory rate and effort (decreased rate, decreased depth)
2. Decreased cardiac output resulting from systemic effects of anaesthesia
3. Acute pain resulting from the adverse effect of spinal headache from epidural anaesthesia
4. Inadequate knowledge resulting from lack of information about anaesthesia
5. Potential for injury resulting from the impact of any form of anaesthesia on the CNS (e.g., CNS depression and decreased sensorium)

◆ PLANNING

◆ Goals

- Patient will state the adverse effects of general or local anaesthesia, including decreased sensorium.
- Patient will state potential complications of anaesthesia involving the cardiac system.
- Patient will experience minimal to no respiratory complications resulting from anaesthesia.
- Patient will adhere to postanaesthesia care to help decrease the chance of complications.
- Patient will follow instructions regarding his or her care during the postoperative period.
- Patient will communicate (as needed) anxiety regarding pre-anaesthesia and postanaesthesia care.
- Patient will communicate anxiety, fears, and concerns regarding anaesthesia.
- Patient will understand the purpose, adverse effects, and complications of anaesthesia.

◆ Expected Patient Outcomes

1. Patient states measures to increase respiratory expansion, through coughing, deep breathing, turning, and ambulating (when allowed).
2. Patient remains well hydrated, with increase in fluids, and remains ambulating to help increase circulation and minimize complications, unless contraindicated.
3. Patient states measures to help minimize or prevent acute pain from possible complication of spinal headache, with bedrest, hydration, and following postanaesthesia and postepidural orders for up to 24 to 48 hours after procedure.
4. Patient experiences maximal effects of anaesthesia, as noted, by following preanaesthesia orders, such as remaining NPO (nothing by mouth) and taking medications only as prescribed, and also experiences minimal adverse effects due to adequate knowledge about the postanaesthesia period and ways to minimize problems (see all measures listed in other Expected Patient Outcomes).

5. Patient remains free of injury or falls by asking for assistance while ambulating or having assistance if at home and recovering, as well as by taking medications only as prescribed, sitting up for brief periods prior to ambulating, staying well hydrated, and resuming adequate nutritional intake during the postanaesthesia period.

◆ IMPLEMENTATION

Regardless of the type of anaesthesia used, one of the most important nursing considerations during the preanaesthesia, intra-anaesthesia, and postanaesthesia periods is close and frequent observation of all body systems. Begin with a focus on the ABCs of nursing care, vital signs, and oxygen saturation levels measured by pulse oximetry as well as by the clinical presentation of the patient. Remember that the way a patient looks is very important, at any point in time! Document the observations from these interventions, and repeat the interventions as needed, depending on the patient's status and in keeping with the standard of care for the type of anaesthesia. Monitor vital signs frequently and as needed, and based on the patient's condition, including assessing the fifth vital sign of pain (see discussion later in this section and in Chapter 11).

For patients undergoing general anaesthesia, assessing the patient's temperature is especially important because of the risk of malignant hyperthermia, and close monitoring is required if malignant hyperthermia occurred during the anaesthesia process. A sudden elevation in the patient's body temperature (i.e., higher than 40°C) not only requires critical care during and immediately after anaesthesia but also calls for close monitoring even during regular postoperative care (see earlier discussion).

When IV, inhaled, or other forms of anaesthesia are used, resuscitative equipment and medications, including opioid antidotes, should be readily available in the surgical and postsurgical areas in case of cardiorespiratory distress or arrest. The anaesthesiologist keeps control of the anaesthetic drug and is well prepared for any emergency—as is the entire group of individuals in the surgical suite and postanaesthesia recovery area. Continual monitoring of the status of breath sounds is an important intervention because hypoventilation may be a complication of general and other forms of anaesthesia. Oxygen is administered after a patient has received general or other forms of anaesthesia to compensate for the respiratory depression that may have occurred during the anaesthesia and surgical process. Because oxygen is a drug, a doctor's order is needed for its administration.

Continuous monitoring of oxygen saturation levels is therefore an important intervention. In addition, hypotension and orthostatic hypotension are possible problems after anaesthesia, so postural blood pressure measurements (supine and standing), in addition to regular blood pressure monitoring, may be needed. Additional nursing interventions include monitoring of neurological parameters such as reflexes, response to commands, level of consciousness or sedation, and pupil reaction to light. Monitor for changes in sensation and movement in the extremities, distal pulses, temperature, and colour when nerve blocks and spinal anaesthesia are used because it is important to confirm that areas distal to the anaesthetic site have remained intact.

Should the patient require pain management once the anaesthesia has been terminated, remember that the anaesthetic and any adjunct drugs used continue to have an effect on the patient until the period of the drugs' action has passed. Therefore, administer sedative–hypnotics, opioids, nonopioids, and other CNS depressants for pain relief cautiously and *only* with close monitoring of vital signs. If the patient has received some of these medications during postanaesthesia, document dosages of drugs used, and then pass them on during a report, when the patient is transferred to another unit. Additional orders are usually provided by the physician, surgeon, or anaesthesiologist regarding doses of analgesics to administer once the patient has been transferred or discharged to home. If such orders have not been provided, however, and the patient is experiencing pain, contact the appropriate prescriber. The concern here is that the patient may receive either too much or not enough analgesic.

Patients who receive NMBDs as part of an induction process for mechanical ventilation need to be monitored closely, during and after initiation of mechanical ventilation. Patients receiving NMBDs and who are awake may need to receive other medications for sedation or pain. These patients are in CCUs, and many protocols are provided regarding interventions after the intubation. These protocols include measurement of vital signs and determination of neurological status, including sensation and hand grasp strength. When mechanical ventilation is used, educate patients and family members about the purpose of the drug-induced paralysis during mechanical ventilation (e.g., to prevent the patient from fighting against the ventilation provided by the machine or resisting the effects of the mechanical ventilatory assistance, which could lead to hypoventilation). Inform the family and remember that, during the care of these patients, they can still hear the spoken word. Knowing what to expect is key to helping decrease fears and anxiety—for both the patient and those visiting the patient.

Patients undergoing procedural sedation as the method of anaesthesia should receive patient education before the procedure. As noted earlier in the chapter, recovery from this type of anaesthesia is more rapid, and the safety profile is better, than with general anaesthesia, with its inherent cardiorespiratory risks. As with general anaesthesia, however, monitor the ABCs of care, vital signs, pulse oximetry oxygen saturation levels, and level of consciousness or sedation. See [Box 12.7](#) for more information on procedural sedation.

With spinal anaesthesia, nursing interventions need to include constant monitoring for a return of sensation and motor activity below the anaesthetic insertion site. Because of the risk that the anaesthetic drug may move upward in the spinal cord and breathing may be affected, continually monitor respiratory and breathing status. Remember, though, that this complication is usually identified and treated by the anaesthesiologist, and patients will not return to their rooms on a nursing unit until all respiratory risks are identified and managed appropriately. Another major area of concern with spinal anaesthesia is the potential for a sudden decrease in blood pressure. This drop in blood pressure is secondary to vasodilation caused by the anaesthetic block to the sympathetic vasomotor nerves. Vital signs and oxygen saturation levels should return to normal before the patient is transferred out of postanaesthesia care; however, continue to monitor these vital signs frequently after transfer.

BOX 12.7 Procedural Sedation: What to Expect and Questions to Ask

1. What questions should the patient or caregiver ask about the technique of procedural sedation?
 - Who will be providing this type of anaesthesia?
 - Who will be monitoring me or my loved one?
 - Will there be constant monitoring of blood pressure, pulse rate, respiratory rate, and temperature?
 - Will there be emergency equipment in the room, in case of need?
 - Are the personnel qualified to administer these drugs? To administer advanced cardiac life support, if needed?
 - What do I need to know about care at home? Will I need help? Can I drive after having the procedure?
2. What are the adverse effects of procedural sedation?
 - Brief periods of amnesia (loss of memory)
 - Headache
 - Hangover
 - Nausea and vomiting
3. What should be expected immediately following the procedure?
 - Frequent monitoring
 - Written postoperative instructions and care
 - If the patient is of driving age, no driving for at least 24 hours after undergoing procedural sedation
 - A follow-up contact by phone to check on the patient
4. Who can administer the procedural sedation?
 - Procedural sedation is safe when administered by qualified health care providers. Certified registered nurse anaesthetists, anaesthesiologists, other physicians, dentists, and oral surgeons are qualified to administer procedural sedation.
5. Which procedures generally require procedural sedation?
 - Breast biopsy
 - Vasectomy
 - Minor foot surgery
 - Minor bone fracture repair
 - Plastic or reconstructive surgery
 - Dental prosthetic or reconstructive surgery
 - Endoscopy (such as diagnostic studies and treatment of stomach, colon, and bladder cancer)
6. What are the overall benefits of this type of anaesthesia?
 - It is a safe and effective option for patients undergoing minor surgeries or diagnostic procedures.
 - It allows patients to recover quickly and resume normal activities in a relatively short period of time.
7. Are there any concerns about daily medications or natural health products for patients undergoing procedural sedation?
 - As with any form of anaesthesia, it is important for patient safety that the patient be open and honest with the anaesthesiologist or other attending professional about all medications and natural health products taken.
 - Be sure to follow instructions closely in regard to the intake of all medications, including natural health products, food, or liquids before anaesthesia, as such substances may react negatively with the drugs being administered.
 - Inquire about any brochures or written pamphlets that provide further information on medications, including natural health products, and procedural sedation.

Another adverse reaction to intraspinal anaesthesia is the occurrence of spinal headaches. These may occur with both intrathecal and epidural injections but are actually more frequent with the latter. Because intrathecal spinal needle designs have been technologically improved, the occurrence of spinal

headaches has become rare. Larger-bore needles are used to deliver epidural anaesthetics, however, and these are more likely to give rise to spinal headache.

A spinal headache can occur as a result of penetration into and through the dura mater of the spinal cord (the covering that encloses the spinal cord and cerebrospinal fluid); a leakage of cerebrospinal fluid occurs from the insertion site. Because this is a pressurized system that extends from the intracranial cavity down to the sacrum, any fluctuation in pressure can result in headache—if enough spinal fluid leaks out, a spinal headache results. Patients say that these headaches are worse than any other type! They are more severe when the patient is in an upright position and improve upon lying down. They may occur up to five days after the procedure and may be prevented with bedrest after the epidural procedure. Adequate hydration using IV fluids is often tried, to help increase cerebrospinal fluid pressure. Other recommendations include drinking beverages that are high in caffeine and strict bedrest for 24 to 48 hours. If the headaches are intolerable, however, the anaesthesiologist may create a blood patch to help close or seal the leak. This procedure requires insertion of a needle into the same space or right next to the area that was injected with the anaesthesia. A small amount of blood is then taken from the patient and injected into the epidural space. The blood clots and forms a seal over the hole that caused the leak, and the headache is relieved.

The use of epidural anaesthesia (also called *regional anaesthesia* in some textbooks) does not pose the same risk of respiratory complications as general anaesthesia; however, monitoring is still needed to confirm overall homeostasis. You must measure vital signs and pulse oximetry to determine oxygen saturation levels. In addition, patients undergoing this form of anaesthesia require monitoring for the return of motor function and tactile sensation. Check the patient frequently for the return of sensation bilaterally along the dermatome (area of the skin innervated by a specific segment of the spinal cord); such monitoring is important to ensure patient safety as well as to maximize comfort. Assess touch sensation through hand pressure or a gentle pinch of the skin. You need to know the level at which the epidural anaesthesia was given to monitor properly for return of sensation. This monitoring process generally occurs in a postanaesthesia care unit, and the patient is not returned to a regular nursing unit until all sensation or voluntary movement of the lower extremities is regained.

Solutions of topical or local anaesthetics (e.g., lidocaine with or without epinephrine) that are not clear and appear cloudy or discoloured are not to be used. Some anaesthesiologists mix the solution with sodium bicarbonate to minimize local pain during infiltration, but this also causes a more rapid onset of action and a longer duration of sensory analgesia. If an anaesthetic ointment or cream is used, the nurse thoroughly cleanses and dries the area to be anaesthetized before applying the drug. If a topical or local anaesthetic is being used in the nose or throat, remember that it may cause paralysis or numbness of the structures of the upper respiratory tract, which can lead to aspiration. If the patient receives a solution form of anaesthetic, exact amounts of the drug are used, at exact dosing times or intervals. Local anaesthetics are not to be swallowed unless the physician has so instructed. Should this occur, closely observe the patient and expect to withhold food or drink until the patient's sensation has returned.

Once the patient has recovered from the anaesthesia and procedure and is ready for discharge, complete your patient teaching. Focus the patient education on the patient's needs and how these needs can be met at home. Home health care or rehabilitation services may be indicated, and arrangements should be made before the patient is discharged. If additional resources are needed at home (e.g., for a patient who lives alone), these arrangements should be completed in a timely fashion. Some examples of procedures for which help might be needed are wound care, dressing changes, surgical site care, drawing of blood for laboratory studies, and administration of various medications through the IV, IM, or subcut route. Some patients may also need assistance with taking oral medications at home. Pain management requires thorough and individualized patient teaching and also includes any necessary education for patients who will require home health care. Refer to Chapter 11 for more information on analgesics.

Provide simple instructions, using age-appropriate teaching strategies. Sharing of information about community resources is also important, especially for patients who need transportation, assistance with meals, housekeeping during recovery, or the services of additional health care providers (e.g., physiotherapists, occupational therapists) in the home setting. Some of these community resources may include agencies supported by municipal, provincial, or territorial social service programs; Meals on Wheels; older adult support groups; and faith-based groups, to name just a few. Many of these resources are free or have income-based fees. Additional suggestions regarding patient education are provided in the Patient Teaching Tips.

◆ EVALUATION

The therapeutic effects of any general or local anaesthetic include loss of consciousness (during general anaesthesia) or loss of sensation to a particular area (during local anaesthesia—e.g., loss of sensation to the eye during corneal transplantation). Constantly monitor patients who have undergone general anaesthesia for the occurrence of adverse effects of the anaesthesia. These may include myocardial depression, convulsions, respiratory depression, allergic rhinitis, and decreased kidney or liver function. Constantly monitor patients who have received a local anaesthetic for the occurrence of adverse effects, including bradycardia, myocardial depression, hypotension, and dysrhythmias. In addition, as mentioned earlier in the chapter, significant overdoses of local anaesthetic drugs or direct injection into a blood vessel may result in cardiovascular collapse or cardiac or respiratory depression. For those receiving spinal anaesthesia, therapeutic effects include loss of sensation below the area of administration, while adverse effects include hypotension, hypoventilation, urinary retention, the possibility of a prolonged period of decreased sensation or motor ability, and infection at the site. With epidural anaesthesia, therapeutic effects are similar to those seen with intrathecal anaesthesia; however, adverse effects include possible spinal headache (often severe) and loss of motor function or sensation below the area of administration. Procedural sedation provides the therapeutic effect of a decreased sensorium but without the complications of general anaesthesia; however, there are CNS-depressant effects associated with the drugs used.

PATIENT TEACHING TIPS

- Whenever general anaesthesia is used, emphasize the prescriber's recommendations and orders about whether any medications should be discontinued or tapered before anaesthetic administration.
 - Make sure information about the anaesthetic, route of administration, adverse effects, and special precautions is included in preprocedure and surgical education.
 - Openly discuss with the patient all fears and anxieties about anaesthesia and related procedures or surgery.
 - Share with the patient and family instructions about the postanaesthesia process and the need for close monitoring of vital signs, breath sounds, and neurological intactness. Patients should expect frequent turning, coughing, and deep breathing to prevent atelectasis or pneumonia.
 - Encourage patients to ambulate with assistance as needed and as ordered. Mobility helps increase circulation and improve ventilation to the alveoli of the lungs; consequently, circulation to the legs will be improved (which helps prevent stasis of blood and possible blood clot formation in the leg veins). Assistance is needed to prevent falls or injury until recovery from the anaesthetic.
 - Encourage the patient to request pain medication, if needed, before pain becomes moderate to severe. Inform the patient that, even though anaesthesia has been administered, there may still be discomfort or pain from the procedure or surgery.
- The anaesthesia will wear off, and adequate analgesia will be needed. Ask the patient to rate the pain on a scale of 0 to 10, with 0 being no pain and 10 being the worst possible pain. See Chapter 11 for more information on pain assessment and its management.
- Explain the rationale for any other treatments or procedures resulting from the anaesthesia (e.g., epidural catheter placement; delivery of oxygen; administration of a gas; use of various tubes, catheters, or IV lines). Adequate patient education will help ease fears and anxieties and help prevent adverse effects or complications.
 - For a patient with diminished sensorium, the bed side rails should be up and a call button should be available at the bedside. These precautions are crucial to patient safety. Note that bed alarms may be used instead of side rails. Everyone involved in the postanaesthesia and postsurgical care (e.g., family members) should be educated about these safety measures.
 - With local anaesthesia, the patient should understand the purpose and action of the local anaesthetic, as well as adverse effects.
 - Inform patients receiving spinal anaesthesia about the need for frequent assessments, measurement of vital signs, and system assessments during and after the procedure.

KEY POINTS

- Anaesthesia is the loss of the ability to feel pain resulting from the administration of an anaesthetic drug. General anaesthesia is a drug-induced state in which the nerve impulses of the CNS are altered to reduce pain and other sensations throughout the entire body and normally involves complete loss of consciousness and depression of respiratory drive.
- General anaesthetics are drugs that induce general anaesthesia, including the administration of specific parenteral anaesthetics. Inhalational anaesthetic drugs are also general anaesthetics and include volatile liquids or gases.
- Local anaesthetics are used to induce a state in which peripheral or spinal nerve impulses are altered to reduce or eliminate pain and other sensations. Spinal anaesthesia, or regional anaesthesia, is a form of local anaesthesia.
- Procedural sedation is a form of general anaesthesia resulting in partial or complete loss of consciousness but without reducing normal respiratory drive.
- Adjunct anaesthetics are drugs that assist with the induction of general anaesthesia and include neuromuscular blocking drugs (NMBDs), sedative-hypnotics or anxiolytics, and antiemetics.
- Nondepolarizing NMBDs are used as an adjunct to general anaesthesia to provide skeletal muscle relaxation during surgery or mechanical ventilation.
- Nursing assessment is important to patient safety during and after all forms of anaesthesia. With general anaesthesia, however, one major problem is malignant hyperthermia, which may be fatal if not promptly recognized and aggressively treated. Signs and symptoms include rapid rise in body temperature, increased pulse rate (tachycardia), increased respiratory rate (tachypnea), muscle rigidity, and unstable blood pressure.

EXAMINATION REVIEW QUESTIONS

1. The prescriber has requested "lidocaine with epinephrine." The nurse recognizes that the most accurate rationale for adding epinephrine is that it:
 - a. Helps calm the patient before the procedure
 - b. Minimizes the risk of an allergic reaction
 - c. Enhances the effect of the local lidocaine
 - d. Reduces bleeding in the surgical area
2. The surgical nurse is reviewing operative cases scheduled for the day. Which of these patients is more prone to complications from general anaesthesia?
 - a. A 79-year-old woman who is about to have her gallbladder removed
 - b. A 49-year-old male athlete who quit heavy smoking 12 years ago

- c. A 30-year-old woman who is in perfect health but has never had anaesthesia
- d. A 50-year-old woman scheduled for outpatient laser surgery for vision correction
3. Which nursing diagnosis is possible for a patient who is now recovering after having been under general anaesthesia for 3 to 4 hours during surgery?
 - a. Reduced urinary elimination resulting from the use of vasopressors as anaesthetics
 - b. Increased cardiac output resulting from the effects of general anaesthesia
 - c. Potential for falls resulting from decreased sensorium, for 2 to 4 days postoperatively
 - d. Reduced gas exchange due to the CNS-depressant effect of general anaesthesia
4. A patient is recovering from general anaesthesia. What is the nurse's main concern during the immediate postoperative period?
 - a. Airway
 - b. Pupillary reflexes
 - c. Return of sensations
 - d. Level of consciousness
5. A patient is about to undergo cardioversion, and the nurse is reviewing the procedure and explaining procedural sedation. The patient says, "I am afraid of feeling it when they shock me." What is the nurse's best response?
 - a. "You won't receive enough of a shock to feel anything."
 - b. "You will feel the shock but you won't remember any of the pain."
 - c. "The medications you receive will reduce any pain and help you not to remember the procedure."
 - d. "They will give you enough pain medication to prevent you from feeling it."
6. The nurse is administering an NMBD to a patient during a surgical procedure. Number the following phases of muscle paralysis in the order in which the patient will experience them. (Number 1 is the first step.)
 - a. Paralysis of intercostal muscles and diaphragm
 - b. Muscle weakness
 - c. Paralysis of muscles of the limbs, neck, and trunk
 - d. Paralysis of small, rapidly moving muscles (e.g., fingers, eye)
7. During a patient's recovery from a lengthy surgery, the nurse monitors for signs of malignant hyperthermia. In addition to a rapid rise in body temperature, which assessment findings would indicate the possible presence of this condition? (Select all that apply.)
 - a. Respiratory depression
 - b. Tachypnea
 - c. Tachycardia
 - d. Seizure activity
 - e. Muscle rigidity
8. A patient will be receiving diazepam (Valium), 2 mg, IV push as part of preprocedure sedation. The medication is available in an injectable solution of 5 mg/mL. How many milliliters will the nurse give for this dose?

CRITICAL THINKING ACTIVITIES

1. The nurse is monitoring a patient in the postanesthesia care unit. The patient had a colectomy with formation of a colostomy because of colon cancer. During this time, what is the priority focus of the nurse's assessment of the patient?
 2. The nurse on the orthopedic surgery unit is monitoring the vital signs of a patient who had hip replacement surgery 2 hours earlier. At this time, the nurse reports that the patient's temperature has changed from 37.2°C to 40.4°C. Another nurse comments that the patient must be developing an infection from the hip replacement. What is the nurse's priority action at this time?
 3. The nurse is assessing a patient who is receiving mechanical ventilation because of respiratory problems. The patient's wife is visiting and asks the nurse, "Is he awake? Can he hear me?" What would be the nurse's best answer?
- For answers, see** <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Central Nervous System Depressants and Muscle Relaxants

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Briefly describe the functions of the central nervous system.
2. Contrast the effects of central nervous system depressant drugs and central nervous system stimulant drugs (see Chapter 14) pertaining to their basic actions.
3. Define the terms *hypnotic*, *rapid eye movement*, *rapid eye movement sleep interference*, *rapid eye movement rebound*, *sedative*, *sedative-hypnotic*, *sleep*, and *therapeutic index*.
4. Briefly discuss the problem of sleep disorders.
5. Identify the specific drugs within each of the following categories of central nervous system depressant drugs:
 - benzodiazepines, nonbenzodiazepines, muscle relaxants, and miscellaneous drugs.
6. Contrast the mechanisms of action, indications, adverse effects, toxic effects, cautions, contraindications, dosage forms, routes of administration, and drug interactions of the following medications: benzodiazepines, nonbenzodiazepines, muscle relaxants, and miscellaneous drugs.
7. Discuss the nursing process as it relates to the nursing care of a patient receiving any central nervous system depressants or muscle relaxants.
8. Develop a collaborative plan of care regarding the use of pharmacological and nonpharmacological approaches to the treatment of sleep disorders.

KEY TERMS

Barbiturates A class of drugs that are chemical derivatives of barbituric acid. They are used to induce sedation. (p. 218)

Benzodiazepines A chemical category of drugs most frequently prescribed as anxiolytic drugs and less frequently as sedative-hypnotic agents. (p. 215)

Gamma-aminobutyric acid (GABA) The primary inhibitory neurotransmitter found in the brain. A key compound affected by sedative, anxiolytic, psychotropic, and muscle-relaxing medications. (p. 216)

Hypnotics Drugs that, when given at low to moderate doses, calm or soothe the central nervous system (CNS) without inducing sleep but when given at high doses cause sleep. (p. 215)

Non-rapid eye movement (NREM) sleep The largest portion of the sleep cycle. It has four stages and precedes REM sleep. Most of a normal sleep cycle consists of non-REM sleep. (p. 215)

Rapid eye movement (REM) sleep One of the stages of the sleep cycle. Some of the characteristics of REM sleep are rapid movement of the eyes, vivid dreams, and irregular breathing. (p. 215)

REM interference A drug-induced reduction of REM sleep time. (p. 215)

REM rebound Excessive REM sleep following discontinuation of a sleep-altering drug. (p. 215)

Sedatives Drugs that have an inhibitory effect on the CNS to the degree that they reduce nervousness, excitability, and irritability without causing sleep. (p. 215)

Sedative-hypnotics Drugs that can act in the body either as sedatives or hypnotics. (p. 215)

Sleep A transient, reversible, and periodic state of rest in which there is a decrease in physical activity and consciousness. (p. 215)

Sleep architecture The structure of the various elements involved in the sleep cycle, including normal and abnormal patterns of sleep. (p. 215)

Therapeutic index The ratio between the toxic and therapeutic concentrations of a drug. If the index is low, the difference between the therapeutic and toxic drug concentrations is small, and use of the drug is more hazardous. (p. 218)

OVERVIEW

Sedatives and hypnotics are drugs that have a calming effect or that depress the central nervous system (CNS). A drug is classified as either a sedative or a hypnotic drug, depending on the degree to which it inhibits the transmission of nerve impulses to the CNS. **Sedatives** reduce nervousness, excitability, and irritability without causing sleep, but a sedative can become a hypnotic if it is given in large enough doses. **Hypnotics** cause sleep and have a much more potent effect on the CNS than do sedatives. Many drugs can act as either a sedative or a hypnotic, depending on dose and patient responsiveness, and for this reason are called sedative-hypnotics. **Sedative-hypnotics** can be classified chemically into three main groups: barbiturates, benzodiazepines, and nonbenzodiazepine sedatives.

PHYSIOLOGY OF SLEEP

Sleep is defined as a transient, reversible, and periodic state of rest in which there is a decrease in physical activity and consciousness. Normal sleep is cyclic and repetitive, and a person's responses to stimuli are markedly reduced during sleep. During waking hours, the body is bombarded with stimuli that provoke the senses of sight, hearing, touch, smell, and taste. These stimuli elicit voluntary and involuntary movements or functions. During sleep, a person is no longer aware of the sensory stimuli within the immediate environment.

Sleep research involves study of the patterns of sleep, or what is sometimes referred to as **sleep architecture**. The architecture of sleep consists of two basic stages that occur cyclically: **rapid eye movement (REM) sleep** and **non-rapid eye movement (NREM) sleep**. The normal cyclic progression of the stages of sleep is summarized in Table 13.1. Various sedative-hypnotic drugs affect different stages of the normal sleep pattern. Prolonged sedative-hypnotic use may reduce the cumulative amount of REM sleep; this is known as **REM interference**. This interference can result in daytime fatigue, since REM sleep provides a certain component of the “restfulness” of sleep. Upon discontinuance of a sedative-hypnotic drug, **REM rebound** can occur, during which the patient has an abnormally large amount of REM sleep, often leading to frequent and vivid dreams. Misuse of sedative-hypnotic drugs is common and is discussed in Chapter 18. In the Ethnocultural Implications box, sleep aids used by different ethnocultural groups are listed.

Melatonin, a hormone secreted by the pineal gland in the human brain, is a natural health product (NHP) and a commonly used sleep aid. It helps regulate other hormones and maintains the body's circadian rhythm. The pineal gland is inactive during the day, and during darkness (at around 2100 hours), the pineal gland secretes melatonin, which promotes drowsiness. Nocturnal melatonin levels and the quality of sleep both decline at puberty, while in older adults, periods of sleep tend to become shorter and the quality of sleep becomes poorer. Melatonin is often taken for insomnia, sleep difficulties associated with menopause, and jet lag, and it may promote sleep in children with attention deficit

TABLE 13.1 Stages of Sleep

Stage	Characteristics	Average Percentage of Time in Each Stage (for Young Adults)
NON-REM SLEEP		
1	Dozing or feelings of drifting off to sleep; person can be easily awakened; those with insomnia have longer stage 1 periods than normal	2–5%
2	Relaxed, but person can easily be awakened; person has occasional REMs and also slight eye movements	50%
3	Deep sleep; difficult to wake person; respiratory rates, pulse, and blood pressure may decrease	5%
4	Difficult to wake person; person may be groggy if awakened; dreaming occurs, especially about daily events; sleepwalking or bedwetting may occur	10–15%
REM SLEEP		
	REMs occur; vivid dreams occur; breathing may be irregular	25–33%

Modified from George, N. M., & Davis, J. E. (2013). Assessing sleep in adolescents through a better understanding of sleep physiology. *American Journal of Nursing*, 113(6), 26–32. doi:10.1097/01.

NAJ.0000430921.99915.24; McKenry, L., Tessier, E., & Hogan, M. (2006). *Mosby's pharmacology in nursing* (22nd ed.). St. Louis, MO: Mosby.

hyperactivity disorder or autism spectrum disorder. Adverse effects may include daytime fatigue, drowsiness, headaches, and dizziness. It should not be used in any patients who are using anticoagulants, immunosuppressants, antihyperglycemics, or birth control medications. It is contraindicated in patients with depression, hypertension, reduced liver function, or seizure disorder.

BENZODIAZEPINES AND MISCELLANEOUS HYPNOTIC DRUGS

Historically, **benzodiazepines** were the most commonly prescribed sedative-hypnotic drugs, and they continue to be prescribed; nonbenzodiazepine drugs are also frequently prescribed. Other drugs commonly used for sleep include the antihistamine diphenhydramine hydrochloride (see Chapter 37), and the antidepressants trazodone hydrochloride and amitriptyline hydrochloride (see Chapter 17). The benzodiazepines show favourable adverse effect profiles, efficacy, and safety when used therapeutically in the short term. Benzodiazepines are classified as either sedative-hypnotics or anxiolytics, depending on their primary usage. Anxiolytic drugs are used to reduce the intensity of feelings of anxiety. However, any of these drugs can function along a continuum as a sedative or hypnotic or anxiolytic, depending on the dosage and patient sensitivity. See Chapter 17 for a further discussion

ETHNOCULTURAL IMPLICATIONS

Understanding Your Patients' Sleep Needs

- When working with patients whose ethnocultures are unfamiliar to you, ask them about usual sleep patterns and habits and about their practices to promote sleep.
- Collect a thorough health, medication, and diet history to identify food and natural health practices used to manage common, everyday problems such as insomnia.
- People from Africa and Asia as well as Indigenous peoples have a high incidence of lactose intolerance, so use of warm milk at bedtime to help with sleep may lead to gastrointestinal (GI) distress, abdominal cramping, and bloating. Lactose-free milk may be used.
- Many Canadians practise meditation, herbalism, nutritional interventions, and acupuncture to aid sleep.
- Some Chinese patients have been found to require lower doses of benzodiazepines (e.g., diazepam [Valium®]).
- Some Hispanic people believe that maintaining a balance in diet and physical activity prevents evil or poor health. Nondrug therapies or home remedies of vegetables and herbs may be used for sleep.
- Some people may tend to be less accepting of therapeutic touch, whether because of their culture or religion or for some other reason. Nurses should be sensitive to this and find alternatives to massage.
- There are numerous sleep traditions that Muslim people may follow in accordance with the practice of the Prophet. For example, some Muslims must not be involved in any activity after the darkness prayer (1.5 to 2 hours after sunset) and before the Fajr prayer (1 hour before sunrise).

of the anxiolytic use of benzodiazepines. There are five benzodiazepines commonly used as sedative–hypnotic drugs. In addition, there are several miscellaneous drugs that are used as hypnotics. They function much like benzodiazepines but are chemically distinct from them. All are listed in [Table 13.2](#).

Mechanism of Action and Drug Effects

The sedative and hypnotic action of benzodiazepines is a result of their ability to depress activity in the CNS. The specific areas affected include the hypothalamic, thalamic, and limbic systems of the brain. Although the mechanism of action is not certain, research suggests that there are specific receptors in the brain for benzodiazepines. These receptors are thought to be either **gamma-aminobutyric acid (GABA)** receptors or other adjacent receptors. GABA is the primary inhibitory neurotransmitter in the CNS of the brain, and it serves to modulate CNS activity by inhibiting overstimulation. Like GABA itself, benzodiazepines' activity appears to be a result of their ability to inhibit stimulation of the brain. They have many favourable characteristics compared with the older drug class *barbiturates* (see the next section of this chapter). They do not suppress REM sleep to the same extent, nor do they induce liver microsomal enzyme activity as the barbiturates do. They are safe to administer to patients who are taking medications metabolized by this enzyme system.

Indications

Nonbenzodiazepines are used for the short-term treatment and symptomatic relief of insomnia. Benzodiazepines have a variety of therapeutic applications. They are commonly used for sedation,

zopiclone*	Imovane

*These drugs share many characteristics with the benzodiazepines but are classified as miscellaneous hypnotic drugs.

relief of agitation or anxiety, treatment of anxiety-related depression, sleep induction, skeletal muscle relaxation, and treatment of acute seizure disorders. Benzodiazepines are often combined with anaesthetics, analgesics, and neuromuscular blocking drugs in balanced anaesthesia and also procedural sedation (see [Chapter 12](#)) for their amnesic properties to reduce memory of painful procedures. Finally, benzodiazepine receptors in the CNS are in the same area as those that play a role in alcohol addiction. Therefore, some benzodiazepines (e.g., diazepam, chlordiazepoxide) are used in the treatment and prevention of the symptoms of alcohol withdrawal (see [Chapter 18](#)). When benzodiazepines are used to treat insomnia, it is recommended that they be used short term, if clinically feasible, to avoid dependency.

Contraindications

Contraindications to the use of benzodiazepines include known drug allergy, narrow-angle glaucoma (may increase intraocular pressure), and pregnancy due to association with preterm delivery and low birth weight ([Shyken, Babbar, Babbar, et al., 2019](#)).

Adverse Effects

Adverse effects associated with the use of benzodiazepines usually involve the CNS and include confusion, ataxia, amnesia, and drowsiness. These effects are more pronounced in the older adult population, who are most commonly prescribed with this class of drugs. Other commonly reported undesirable effects are headache, paradoxical excitement or nervousness, dizziness or vertigo, and lethargy. Benzodiazepines can create a significant fall hazard in older adults, and the lowest effective dose must be used in this patient population. Although these drugs have comparatively less intense effects on the normal sleep cycle, a “hangover” effect is sometimes reported (e.g., daytime sleepiness). Withdrawal symptoms such as rebound insomnia (i.e.,

TABLE 13.3 Flumazenil Treatment Regimen

Indication	Recommended Regimen	Duration
Reversal of procedural sedation or general anaesthesia	0.2 mg IV, given over 15 sec; if consciousness does not occur in 60 sec, give 0.1 mg; may be repeated at 60-sec intervals (maximum total dose, 1 mg; usual dose is 0.3–0.6 mg)	1–4 hr
Management of suspected benzodiazepine overdose	0.2 mg IV, given over 30 sec; wait 30 sec, then give 0.3 mg over 30 sec if consciousness does not occur; further doses of 0.5 mg can be given over 30 sec at intervals of 60 sec to a cumulative maximum total dose of 3 mg	1–4 hr

greater insomnia than pretreatment) may occur with abrupt discontinuation. Long-term use of benzodiazepines is associated with tolerance. Physical dependence can occur after a few weeks or months of use.

Toxicity and Management of Overdose

An overdose of benzodiazepines may result in any or all of the following symptoms: somnolence, confusion, coma, or diminished reflexes. Overdose of benzodiazepines alone rarely results in hypotension and respiratory depression. These symptoms are more commonly seen when benzodiazepines are taken with other CNS depressants, such as alcohol or barbiturates. The same holds true for their lethal effects. In the absence of the concurrent ingestion of alcohol or other CNS depressants, benzodiazepine overdose rarely results in death.

Treatment of benzodiazepine intoxication is generally symptomatic and supportive. Flumazenil, a benzodiazepine antidote, can be used to acutely reverse the sedative effects of benzodiazepines. Flumazenil antagonizes the action of benzodiazepines on the CNS by directly competing with them for binding at the receptors. Flumazenil is used in cases of oral overdose or excessive intravenous sedation. Table 13.3 summarizes the dosage regimen to be followed for the reversal of procedural sedation or general anaesthesia induced by benzodiazepines and the management of suspected benzodiazepine overdose.

Interactions

Potential drug interactions with the benzodiazepines are significant because of their intensity, particularly when they involve other CNS depressants (e.g., alcohol, opioids, muscle relaxants). Use of these drugs results in further CNS-depressant effects, including decreased blood pressure, reduced respiratory rate, sedation, confusion, and diminished reflexes. These and other major drug interactions are listed in Table 13.4. NHP interactions include those with kava and valerian, which may also lead to further CNS depression (see Natural Health Products: Kava and Valerian box). Food–drug interactions with grapefruit and grapefruit juice, which alter drug metabolism via inhibition of the cytochrome P450 system, can result in prolonged effect, increased effect, and toxicity.

TABLE 13.4 Benzodiazepines: Drug Interactions

Drug/Food	Mechanism	Result
Azole antifungals, verapamil, diltiazem, protease inhibitors, macrolide antibiotics, grapefruit juice	Decreased benzodiazepine metabolism	Prolonged benzodiazepine action
CNS depressants	Additive effects	Increased CNS depression
olanzapine	Unknown	Increased benzodiazepine effects
rifampin	Increased metabolism	Decreased benzodiazepine effects

NATURAL HEALTH PRODUCTS

Kava (*Piper methysticum*)

Overview

Kava consists of the dried rhizomes of *Piper methysticum*. The drug contains kava pyrones (kawain). Extended continuous intake can cause a temporary yellow discoloration of the skin, hair, and nails.

Common Uses

Relief of anxiety, stress, restlessness; promotion of sleep

Adverse Effects

Skin discoloration, possible accommodative disturbances and papillary enlargement, and scaly skin (with long-term use). In 2002, Health Canada banned the selling of kava supplements because of the risk of severe liver damage and toxicity; however, individuals can import kava for personal use.

Potential Drug Interactions

Alcohol, barbiturates, psychoactive drugs

Contraindications

Contraindicated in patients with Parkinson's disease, liver disease, depression, or alcoholism; in those operating heavy machinery; and in pregnant and breastfeeding women

Valerian (*Valeriana officinalis*)

Overview

Valerian root, consisting of fresh underground plant parts, contains essential oil with monoterpenes and sesquiterpenes (valerianic acids).

Common Uses

Relief of anxiety, restlessness, sleep disorders

Adverse Effects

Central nervous system depression, hepatotoxicity, nausea, vomiting, anorexia, headache, restlessness, insomnia

Potential Drug Interactions

Central nervous system depressants, monoamine oxidase inhibitors, phenytoin, warfarin sodium; may have enhanced relative and adverse effects when taken with other drugs (including other natural health products) that have known sedative properties (including alcohol)

Contraindications

Contraindicated in patients with heart disease, liver disease, or those operating heavy machinery

Dosages

For dosage information, see the table on p. 219.

DRUG PROFILES

The benzodiazepines and miscellaneous sedative-hypnotic drugs are prescription-only drugs and are designated as Schedule IV controlled substances. Uses for benzodiazepines can vary, including treatment of insomnia, moderate sedation (see [Chapter 12](#)), muscle relaxation, anticonvulsant therapy (see [Chapter 15](#)), and anxiety relief (see [Chapter 17](#)). The miscellaneous drugs are normally used only for their hypnotic purposes to treat insomnia. Dosage information appears in the Dosages table on page 219.

Benzodiazepines

diazepam

Diazepam (Valium) was the first clinically available long-acting benzodiazepine drug. It has varied uses, including for treatment of anxiety, procedural sedation (and as an anaesthesia adjunct), anticonvulsant therapy, and skeletal muscle relaxation following orthopedic injury or surgery.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Immediate	8 min	20–50 hr	15–60 min
PO	30 min	1–2 hr	20–60 hr	12–24 hr

lorazepam

Lorazepam (Ativan) is an intermediate-acting benzodiazepine. In addition to treating anxiety (see [Chapter 17](#)), lorazepam has been found effective in the immediate treatment of acute seizure activity (see [Chapter 15](#)).

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	30–60 min	2 hr	11–16 hr	8 hr

! midazolam

Midazolam is most commonly used preoperatively and for procedural sedation (see [Chapter 12](#)). It is useful for this indication due to its ability to cause amnesia and anxiolysis (reduced anxiety) as well as sedation. This helps patients to feel less anxious about, and avoid remembering, uncomfortable medical procedures. Refer to [Chapter 12](#) for dosage information.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	1–5 min	20–60 min	1–4 hr	2–6 hr

Nonbenzodiazepines

zolpidem tartrate

Zolpidem tartrate (Sublinx®, Ambien®), available as a sublingual, orally disintegrating tablet, is a short-acting nonbenzodiazepine hypnotic. Its relatively short half-life and its lack of active metabolites contribute to a lower incidence of daytime sleepiness compared with benzodiazepine hypnotics.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	30 min	1.6 hr	1.4–4.5 hr	6–8 hr

zopiclone

Zopiclone (Imovane®, Rhovane®) is a short-acting benzodiazepine-like drug. It is indicated for the short-term treatment of insomnia and should be limited to 7 to 10 days of treatment.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	30 min	90 min	5 hr	6–8 hr

BARBITURATES

Barbiturates were first introduced into clinical use in 1903 and were the standard drugs for treating insomnia and producing sedation. Chemically, they are derivatives of barbituric acid. There are few in clinical use today due to the favourable safety profile and proven efficacy of the benzodiazepines. Barbiturates can produce many unwanted adverse effects. They are physiologically habit forming and have a low **therapeutic index** (i.e., there is only a narrow dosage range within which the drug is effective, and above that range it is rapidly toxic).

Mechanism of Action and Drug Effects

Barbiturates are CNS depressants that act primarily on the brain stem in an area called the *reticular formation*. Their sedative and hypnotic effects are dose related, and they act by reducing the nerve impulses travelling to the area of the brain called the *cerebral cortex*. Their ability to inhibit nerve impulse transmission is due in part to their ability to potentiate the action of the inhibitory neurotransmitter GABA, which is found in high concentrations in the CNS. Barbiturates also raise the seizure threshold and can be used to treat seizures (see [Chapter 15](#)).

Indications

All barbiturates have the same sedative-hypnotic effects but differ in their potency, time to onset of action, and duration of action. They can be used as hypnotics, sedatives, and anticonvulsants, as well as for anaesthesia during surgical procedures.

Contraindications

Contraindications to barbiturate use include known drug allergy, pregnancy, significant respiratory difficulties, and severe kidney or liver disease. These drugs must be used with caution in older adults due to the drugs' sedative properties and increased fall risk.

Dosages

Benzodiazepines: Selected Hypnotic Drugs

Drug	Onset and Duration	Usual Dosage Range	Indications/Uses
diazepam (Valium)	Long acting	Adults PO: 2–10 mg 3–4 times daily IV: 2–10 mg IV (supplied 5 mg/mL) IM: infrequent use	Muscle relaxation, preprocedure sedation, status epilepticus, acute anxiety or agitation
lorazepam (Ativan)	Intermediate acting	Adults PO: 1–4 mg daily IV/IM: 0.02–0.04 mg/kg	PO: Generalized anxiety disorder IV: Status epilepticus IM: Excessive anxiety prior to surgery
zolpidem tartrate (Sublinox)		Adults Sublingual: 5–10 mg at bedtime	Sleep induction
zopiclone (Imovane, Rhovane)	Short acting	Adults PO: 3.75–7.5 mg at bedtime	Sleep induction

Adverse Effects

Adverse effects of barbiturates relate to the CNS and include drowsiness, lethargy, dizziness, hangover (prolongation of drowsiness, lethargy, and dizziness), and paradoxical restlessness or excitement. Their long-term effects on normal sleep architecture can be detrimental. Common adverse effects of barbiturates are listed in [Table 13.5](#).

Toxicity and Management of Overdose

An overdose of barbiturates produces CNS depression, ranging from sleep to profound coma and death. Respiratory depression progresses to Cheyne-Stokes respirations, hypoventilation, and cyanosis. Patients often have cold, clammy skin or are hypothermic, and later they can exhibit fever, areflexia, tachycardia, and hypotension. Because phenobarbital is also used to treat status epilepticus (prolonged uncontrolled seizures), in extreme cases, patients may be intentionally overdosed to cause therapeutic phenobarbital or pentobarbital coma. Because of the inhibitory effects on nerve transmission in the brain (possibly GABA mediated), uncontrollable seizures can be stopped until enough serum levels of anticonvulsant drugs are achieved.

Treatment of an overdose is mainly symptomatic and supportive. The mainstays of therapy are maintenance of an adequate airway, assisted ventilation, and oxygen administration if needed, along with fluid and pressor support as indicated. Barbiturates are highly metabolized by the liver, where they also induce enzyme activity. In an overdose, however, the amount of barbiturate may overwhelm the liver's ability to metabolize it. This is a situation in which administration of activated charcoal may be helpful. Activated charcoal adsorbs (binds to) drug molecules in the stomach. It also has the effect of drawing the drug from the circulation into the GI tract for elimination. Multiple-dose (every 4 hours) nasogastric administration of activated charcoal is a common regimen. Phenobarbital is relatively acidic and can be eliminated more quickly by the kidneys when the urine is alkalinized (pH is raised). This keeps the drug in the urine and prevents it from being resorbed back into the circulation. Alkalinization, along with forced diuresis using diuretics (e.g., furosemide [see [Chapter 29](#)]), can hasten elimination of the barbiturate.

Interactions

Barbiturates as a class are notorious enzyme inducers. They stimulate the action of enzymes in the liver that are responsible

TABLE 13.5 Barbiturates: Adverse Effects

Body System	Adverse Effects
Cardiovascular	Vasodilation and hypotension, especially if given too rapidly
Gastrointestinal	Nausea, vomiting, diarrhea, constipation
Hematological	Agranulocytosis, thrombocytopenia
Nervous	Drowsiness, lethargy, vertigo
Respiratory	Respiratory depression, cough
Other	Hypersensitivity reactions: urticaria, angioedema, rash, fever, Stevens-Johnson syndrome

for the metabolism or breakdown of many drugs. By stimulating the action of these enzymes, they cause many drugs to be metabolized more quickly, which usually shortens their duration of action. Other drugs that are enzyme inducers are warfarin sodium, rifampin, and phenytoin.

Additive CNS depression occurs with the coadministration of barbiturates with alcohol, antihistamines, benzodiazepines, opioids, and tranquilizers. Most of the drug–drug interactions are secondary to the effects of barbiturates on the hepatic enzyme system. Barbiturates increase the activity of hepatic microsomal or cytochrome P450 enzymes (see [Chapter 2](#)). This process is called *enzyme induction*. Induction of this enzyme system results in increased drug metabolism and breakdown. However, if two drugs are competing for the same enzyme system, the result can be inhibited drug metabolism and possibly increased toxicity for the wide variety of drugs that are metabolized by these enzymes. Drugs most likely to have marked interactions with the barbiturates include monoamine oxidase inhibitors (MAOIs), tricyclic antidepressants (see [Chapter 17](#)), anticoagulants (see [Chapter 27](#)), glucocorticoids (see [Chapter 49](#)), and oral contraceptives (see [Chapter 35](#)) with barbiturates. Coadministration of MAOIs and barbiturates can result in prolonged barbiturate effects. Coadministration of anticoagulants with barbiturates can result in decreased anticoagulation response and possible clot formation. Coadministration of barbiturates with oral contraceptives can result in accelerated metabolism of the contraceptive drug and possible unintended pregnancy. Women taking both types of medication concurrently need to be advised to consider an additional method of contraception as a backup.

DOSAGES

Selected Barbiturates

Drug	Onset and Duration	Usual Dosage Range	Indications/Uses
phenobarbital	Long acting	Pediatric PO: 2 mg/kg in 3 divided doses IM/IV: 1–3 mg/kg 1–2 hr before surgery	seizures Load: IV 20 mg/kg (1000 mg max/10 mins) may repeat after 10 mins maintenance 3–6 mg/kg/day Sedative Preoperative sedative
		Adults PO: 15–30 mg bid or tid IM/IV: 130–200 mg 1–2 hr before surgery	Status epilepticus load: IV 15 mg/kg maintenance: 60–200 mg/day (usually divided) Sedative Preoperative sedative

Dosages

Barbiturates can act as either sedatives or hypnotics, depending on the dosage. For information on selected barbiturates and their recommended sedative and hypnotic dosages, see the table above.

DRUG PROFILES

Like benzodiazepines, barbiturates can also have varied uses, including preoperative sedation, anaesthesia adjunct, and anticonvulsant therapy. All barbiturates are controlled substances. Dosage information appears in the Dosages table for barbiturates.

phenobarbital

Phenobarbital is the most commonly prescribed barbiturate, either alone or in combination with other drugs. It is considered the prototypical barbiturate and is classified as a long-acting drug. Phenobarbital is used for the prevention of generalized tonic-clonic seizures and fever-induced convulsions. In addition, it has been useful in the treatment of hyperbilirubinemia in neonates. It is only rarely used today as a sedative and is no longer recommended as a hypnotic drug. It is available in oral and injectable forms.

PHARMACOKINETICS

Route	Onset	Peak	Half-Life	Duration
IV	5 min	30 min	50–120 hr	6–12 hr
PO	30 min	1–6 hr	50–120 hr	6–12 hr

OVER-THE-COUNTER HYPNOTICS

Nonprescription sleep aids often contain antihistamines (see [Chapter 37](#)), which have a CNS-depressant effect. The most common antihistamines contained in over-the-counter sleep aids are doxylamine succinate (Unisom-2®) and diphenhydramine hydrochloride (Sleep-Eze®, Unisom®). Analgesics (e.g., acetaminophen [see [Chapter 11](#)]) are sometimes added to offer some pain relief if pain is a component of the sleep disturbance (e.g.,

acetaminophen/diphenhydramine hydrochloride [Extra Strength Tylenol® Nighttime]). As with other CNS depressants, concurrent use of alcohol can cause respiratory depression or arrest.

MUSCLE RELAXANTS

A variety of conditions, such as trauma, inflammation, anxiety, and pain, can be associated with acute muscle spasms. Although there is no perfect therapy available for relief of skeletal muscle spasticity, muscle relaxant drugs can provide some relief. Muscle relaxants are a group of compounds that act predominantly within the CNS to relieve pain associated with skeletal muscle spasms. Most muscle relaxants are known as *centrally acting* skeletal muscle relaxants because their site of action is the CNS. These compounds are similar in structure and action to other CNS depressants such as diazepam. It is believed that the muscle relaxant effects are a result of this CNS depressant activity. Only one of these compounds, dantrolene, acts directly on skeletal muscle. It belongs to a group of relaxants known as *direct acting* skeletal muscle relaxants and closely resembles GABA. Muscle relaxants are most effective when used in conjunction with rest and physiotherapy. When taken with alcohol, other CNS depressants, or opioid analgesics, enhanced CNS depressant effects are seen. In such cases, close monitoring and dosage reduction of one or both drugs need to be considered.

Mechanism of Action and Drug Effects

The majority of muscle relaxants work within the CNS. Their beneficial effects are believed to come from their sedative effects, rather than from direct muscle relaxation. Dantrolene acts directly on the excitation-contraction coupling of muscle fibres and not at the level of the CNS. It directly affects skeletal muscles by decreasing the response of the muscle to stimuli. It appears to exert its action by decreasing the amount of calcium released from storage sites in the sarcoplasmic reticulum of muscle fibres. All other muscle relaxants have no direct effects on muscles, nerve conduction, or muscle-nerve junctions and have a depressant effect on the CNS. Their effects are the result of CNS depression in the brain, primarily at the level of the brain-stem, thalamus, and basal ganglia, as well as in the spinal cord.

The effects of muscle relaxants are relaxation of striated muscles, mild weakness of skeletal muscles, decreased force of muscle contraction, and muscle stiffness. Other effects include generalized CNS depression manifested as sedation, somnolence, ataxia, and respiratory and cardiovascular depression. Baclofen is one of the more effective drugs in this class and is a derivative of GABA. It is believed to work by depressing nerve transmission in the spinal cord. The other drugs in this class are not derivatives of GABA but act by enhancing GABA's central inhibitory effects at the level of the spinal cord.

Indications

Muscle relaxants are used primarily for the relief of painful musculoskeletal conditions, such as muscle spasms, often following injuries such as low back strain. They are most effective when used in conjunction with physiotherapy. They may also be used in the management of spasticity associated with severe chronic disorders, such as multiple sclerosis and other types of cerebral lesions, cerebral palsy, and rheumatic disorders. Some relaxants are used to reduce choreiform movement in patients with Huntington's disease, to reduce rigidity in patients with parkinsonian syndromes, or to relieve the pain associated with trigeminal neuralgia. Intravenous dantrolene is used for the management of the hypermetabolic muscle spasms that accompany the crisis condition of malignant hyperthermia (see Chapter 12).

Contraindications

The only usual contraindication to the use of muscle relaxants is known drug allergy, but contraindications for some of these drugs may include severe renal impairment.

Adverse Effects

The primary adverse effects of muscle relaxants are an extension of their effects on the CNS and skeletal muscles. Euphoria, lightheadedness, dizziness, drowsiness, fatigue, confusion, and muscle weakness are often experienced early in treatment. These adverse effects are generally short-lived, as patients grow tolerant of them over time. Less common adverse effects seen with muscle relaxants include diarrhea, GI upset, headache, slurred speech, muscle stiffness, constipation, sexual difficulties in males, hypotension, tachycardia, and weight gain.

Toxicity and Management of Overdose

The toxicities and consequences of an overdose of muscle relaxants primarily involve the CNS. There is no specific antidote (or reversal drug) for muscle relaxant overdoses. They are best treated with conservative supportive measures. More aggressive therapies are generally needed when muscle relaxants are taken along with other CNS-depressant drugs as an overdose. Gastric lavage and close observation of the patient are recommended. An adequate airway must be maintained and means of artificial respiration should be readily available. Electrocardiographic monitoring needs to be instituted and large quantities of intravenous fluids are administered to avoid crystalluria.

Interactions

When muscle relaxants are administered along with other depressant drugs, such as alcohol and benzodiazepines, caution needs to be used to avoid overdose. The combination of propoxyphene and orphenadrine has resulted in additive CNS effects. Mental confusion, anxiety, tremors, and additive hypoglycemic activity have been reported with this combination as well. A dosage reduction or discontinuance of one or both drugs is recommended.

Dosages

For dosage information for commonly used muscle relaxants, refer to the table on p. 222.

DRUG PROFILES

Apart from dantrolene (Dantrium®), which acts directly on skeletal muscle tissues, muscle relaxants are classified as centrally acting relaxants because of their site of action in the CNS. These include baclofen (Lioresal®), chlorzoxazone (Acetazone Forte C8®), cyclobenzaprine, methocarbamol (Robaxacet®, Robaxacin®), orphenadrine citrate (Norflex®), and tizanidine hydrochloride. Muscle relaxants are not controlled substances. Use of all muscle relaxants is contraindicated in patients who have shown a hypersensitivity reaction to them or have compromised pulmonary function, active liver disease, or reduced myocardial function. Dosage information appears in the Dosages table for muscle relaxants.

▶ baclofen

Baclofen (Lioresal) is available in both oral and injectable dosage forms. The injectable form is for use with an implantable baclofen pump device. This method is sometimes used to treat chronic spastic muscular conditions. With this route, a test dose needs to be administered initially to test for a positive response. The injection is diluted before infusion. Both oral and injectable doses are titrated to desired response.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	0.5–1 hr	2–3 hr	2.5–4 hr	8 hr or longer

▶ cyclobenzaprine hydrochloride

Cyclobenzaprine hydrochloride is available in a 10-mg dose. Cyclobenzaprine is a centrally acting muscle relaxant that is structurally and pharmacologically related to the tricyclic anti-depressants. It is the most commonly used drug in this class to reduce spasms following musculoskeletal injuries. It is very common for patients to exhibit marked sedation from its use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1 hr	3–8 hr	8–37 hr	12–24 hr

Dosages

Selected Muscle Relaxants

Drug	Pharmacological Class	Usual Dosage Range	Indications
baclofen (Lioresal)	Central acting	Adults PO: 5 mg tid daily ×3 days, then 10 mg daily tid ×3 days, then 15 mg daily tid ×3 days, then 20 mg tid daily ×3 days, then titrated to response to max of 80 mg daily	Spasticity
cyclobenzaprine hydrochloride (Novo-Cycloprine, Riva-Cycloprine)	Central acting	Adults PO: 10 mg tid	Spasticity
dantrolene sodium (Dantrene)	Direct-acting	Children PO: 0.5 mg/kg/bid up to 3 mg/kg/day given in divided doses bid–qid	Chronic spasticity and malignant hyperthermia
		Adults PO: 25 mg/day; may increase to 25–100 mg bid–qid Children/Adults IV: 1 mg/kg; may repeat to total dose of 10 mg/kg	Malignant hyperthermia
tizanidine hydrochloride	Direct-acting	Adults PO: 2 mg increased by 2–4 mg to optimum effect up to 36 mg/day divided tid	Spasticity

NURSING PROCESS

ASSESSMENT

Before administering any CNS-depressant drug, such as a benzodiazepine, nonbenzodiazepine, miscellaneous drug, muscle relaxant, or barbiturate, perform an assessment focusing on some of the more common parameters and data, including the following: (1) reports of any insomnia, with attention to onset, duration, frequency, and pharmacological as well as nonpharmacological measures used (see [Box 13.1](#)); (2) any concerns of the patient or family about sleep disorders, sleep patterns, difficulty in sleeping, or frequent awakenings; (3) the time it typically takes to fall asleep and energy level upon awakening; (4) vital signs with attention to blood pressure (both supine and standing measurements); pulse rate and rhythm; respiratory rate, rhythm, and depth; body temperature; and presence of pain; (5) thorough physical assessment or examination for baseline comparisons; (6) neurological findings with a focus on any changes in mental status, memory, cognitive abilities, alertness, level of orientation (to person, place, and time), level of sedation, mood changes, depression or other mental health disorder, sensation, anxiety, or panic attacks; and (7) miscellaneous information about medical history; allergies; use of alcohol; smoking history; caffeine intake; past and current medication profile, with notation of use of any prescription drugs, over-the-counter drugs, and NHPs; alternative or folk practices; and any changes in health status, weight, nutrition, exercise, life stressors (including loss and grief), or lifestyle.

For patients taking benzodiazepines and benzodiazepinelike drugs, assessment needs to also include the identification of disorders or conditions that represent cautions or contraindications to the use of these drugs, as well as drugs the patient is taking that might interact with benzodiazepines or benzodiazepinelike drugs. Closely monitor those who are anemic, are suicidal, or

have a history of misusing drugs, alcohol or other substances. Other significant cautions pertain to use of these drugs in older adults and very young children because of their increased sensitivity to these drugs, as well as in women who are pregnant or are lactating. Older adults and very young children may require lower dosages due to potential ataxia and excessive sedation. In addition, before initiating drug therapy with benzodiazepines or other sedative-hypnotic drugs, including barbiturates, the prescriber may order blood studies, such as a complete blood count (CBC). Kidney function studies (blood urea nitrogen [BUN] or creatinine levels) or liver function studies (alkaline phosphatase isoenzyme level) may be ordered to rule out organ impairment and prevent potential toxicity or complications resulting from decreased excretion or metabolism. Potential drug interactions are presented in [Table 13.4](#). Pay attention to the concurrent use of other CNS depressants (e.g., opioids), because this may lead to severe decreases in blood pressure, respiratory rate, reflexes, and level of consciousness.

With the nonbenzodiazepines such as zaleplon, zopiclone, and zolpidem tartrate, include a head-to-toe physical assessment and a thorough medication history with measurement of vital signs and other parameters (see above discussion). Assess and document for allergies to these drugs and to aspirin. If the patient is allergic to aspirin, there is an associated risk of allergies to nonbenzodiazepines. Other considerations include the need for assessment of any confusion and lightheadedness, especially in older adults, because of their increased sensitivity. Do not use zaleplon or zopiclone in those younger than 18 years of age and use extreme caution if there is a history of compromised respiratory status or drug, alcohol, or other substance abuse. Drug interactions include other CNS depressants.

For muscle relaxants, always note drug allergies before use, and perform a complete head-to-toe assessment with focus on the neurological system. In older adults, there is increased risk of CNS toxicity with possible hallucinations, confusion, and excessive

BOX 13.1 Sleep Diaries and Nonpharmacological Treatment of Sleep Disorders

Information for a Sleep Diary

- What time do you usually go to bed and wake up?
- How long and how well do you sleep?
- When were you awake during the night, and for how long?
- How easy was it to go to sleep?
- How easy was it to wake up in the morning?
- How much caffeine do you consume?
- What time did you last eat or drink (if after dinner)?
- Did you have a bedtime snack?
- What emotions or stressors do you have?
- What medications do you take daily?
- Do you smoke? If so, how many cigarettes do you smoke a day, and how long have you been smoking?
- Do you consume alcohol? If so, how often do you have a drink and how long have you been drinking that amount?
- Do you take any over-the-counter drugs? If so, what drugs do you take and for what reason? How often do you take these drugs and in what dosages? How long have you been taking them?
- Do you take any natural health products? If so, which ones? What do you take them for and how long have you been taking them?

Nonpharmacological Sleep Interventions

- Establish a set sleep pattern, with a time to go to bed at night and a regular time to get up in the morning, and stick to it. This will help to reset your internal clock.
- Sleep only as much as you need to feel refreshed and renewed. Too much sleep may lead to fragmented sleep patterns and shallow sleep.
- Keep the temperature in the bedroom moderate, if possible.
- Avoid caffeine-containing beverages and food within 6 hours of bedtime.
- Decrease exposure to loud noises while you sleep.
- Avoid daytime napping.
- Avoid exercise late in the evening (i.e., not past 1900 hours).
- Avoid alcohol in the evening. Rather than putting you to sleep, it actually causes fragmented sleep.
- Avoid tobacco at bedtime because it disturbs sleep.
- Try to relax before bedtime with soft music, yoga, relaxation therapy, deep breathing, or light reading on a topic that is not intense or anxiety provoking.
- Drink a warm, noncaffeinated beverage, such as warm milk or chamomile tea, 30 minutes to 1 hour before bedtime.
- If you are still awake 20 minutes after going to bed, get up and engage in a relaxing activity (as noted previously) and go back to bed once you feel drowsy. Repeat as necessary.

sedation. Assessment includes taking a thorough health and medication history and examining the complete patient profile with results of associated laboratory studies. See pharmacology discussion about cautions, contraindications, and drug interactions.

Barbiturates are discussed further in [Chapter 15](#) along with other antiepileptic drugs. However, a brief description is needed to emphasize the importance of conducting a thorough patient assessment as well as evaluating for cautions, contraindications, and drug interactions. Barbiturates are not to be used by pregnant or lactating women. These drugs cross the placenta and breast-blood barriers, posing a risk of respiratory depression in the fetus and neonate. Withdrawal symptoms may appear in neonates born

to women who have taken barbiturates during their last trimester of pregnancy. Barbiturates may also produce paradoxical excitement in children and confusion and mental depression in older adults, so baseline neurological assessment is needed. Assessment of kidney and liver function is also important in those with compromised organ function and in older adults to help avoid toxicity.

◆ NURSING DIAGNOSES

- Reduced gas exchange resulting from respiratory depression associated with CNS depressants
- Inadequate knowledge resulting from inadequate information about the various CNS drugs and their first-time use
- Disturbed sleep pattern resulting from the drug's interference with REM sleep
- Potential for injury and falls as a result of the adverse effect of decreased sensorium
- Potential for injury resulting from possible drug overdose or adverse reactions regarding drug-drug interactions (e.g., combined use of the drug with alcohol, tranquilizers, or analgesics) and decreased level of alertness and unsteady gait
- Potential for injury and addiction resulting from physical or psychological dependency on CNS drugs

◆ PLANNING

◆ Goals

- Patient will maintain normal gas exchange and be free of respiratory depression.
- Patient will demonstrate adequate knowledge about the drugs, how they work, and their adverse effects and interactions.
- Patient will remain free of further disturbed sleep patterns.
- Patient will remain free of self-injury and falls due to safety measures for decreased sensorium.
- Patient will remain free of injury due to adequate information about drug interactions that lead to further CNS depression.
- Patient will remain free of injury to self, with no drug dependence.

◆ Expected Patient Outcomes

- Patient states measures to maintain normal gas exchange, such as coughing, deep breathing, taking only the prescribed amount of medication, and reporting any difficulty breathing to prescriber.
- Patient demonstrates adequate knowledge about the medication(s) used, including their sedating or hypnotic properties, CNS-depressant effects, and adverse effects of altered respirations, decreased depth and rate of respirations, altered cough, confusion, drowsiness, and interactions with other CNS depressants.
- Patient states potential for REM interference from sedative-hypnotic drugs with associated sleep interference with most of these drugs, as well as known hangover effects.
- Patient states importance of trying nonpharmacological measures for enhancing sleep, as appropriate, prior to drug

therapy—such as massage, relaxation therapy, music, or bio-feedback.

- Patient demonstrates understanding of safety measures to decrease risk of injury or falls while taking sedatives or hypnotics, such as taking medication only as prescribed, removing all throw rugs from walking areas (especially at night), moving and changing positions slowly, ambulating with caution, and reporting any excessive drowsiness or sedation to prescriber.
- Patient states common drug interactions associated with, and to avoid with, sedatives or hypnotics (i.e., other CNS depressants, opioids, NHPs [e.g., kava, valerian], alcohol, and sedating products found over the counter [e.g., diphenhydramine hydrochloride]).
- Patient remains free of risk of drug dependence issues through appropriate use of sedatives or hypnotics, taking medication only as prescribed, reporting any problems with increased resistance to the drug's effects, as well as excessive sedation and the feeling that more medication is needed to get the same drug effect.
- Patient tries nonpharmacological measures to promote sleep, as needed.

◆ IMPLEMENTATION

Patients taking benzodiazepines and other CNS depressants experience sedation and possible ataxia; thus, patient safety measures are needed. Hospital or facility policies mandate the type of safety precautions to be taken, such as the use of side rails or bed alarms. Ambulation needs to occur safely and with assistance when patients are sedated or are experiencing the adverse effects of these drugs. In addition, dependence may be a problem with benzodiazepines. While taking these drugs, patients need to avoid driving or participating in any activities that require mental alertness. It is recommended that these drugs be taken on an empty stomach for faster onset of action; however, this often results in GI upset. So, practically speaking, these drugs need to be taken with food—a light snack or meal. Orally administered benzodiazepines have an onset of action of 30 minutes to 6 hours, depending on the drug (see the Pharmacokinetics tables in the Drug Profiles box), and the appropriate timing and intervals of dosing will be determined by these characteristics. For example, if a patient takes a benzodiazepine or other CNS drug to induce sleep and the drug's onset of action is 30 to 60 minutes, the drug needs to be dosed 60 minutes prior to bedtime. In addition, it is crucial to patient adherence and safety to understand that the patient may develop drug tolerance to many of these drugs and so may require larger dosages to produce the same therapeutic effect at some point. Interrupting therapy helps to decrease drug tolerance.

Among the benzodiazepines, REM interference is less problematic with flurazepam, primarily because it produces fewer active metabolites. Educate patients about the REM interference and rebound insomnia that may occur with just a 3- to 4-week regimen of drug therapy. To minimize REM interference, benzodiazepines and other drugs are used only when nonpharmacological methods fail and must be used with caution and for short periods of time in all patients with sleep disorders. Gradual

weaning-off periods are recommended with benzodiazepines and all CNS depressants. Hangover effects are also associated with many of the CNS depressants but occur less frequently with benzodiazepines and nonbenzodiazepines than with barbiturates.

It is recommended that nonbenzodiazepines be taken for the prescribed time. Zolpidem tartrate sublingual, orally disintegrating tablets, have optimal absorption if taken at bedtime on an empty stomach with no crushing or chewing, and they are not to be taken with water. Place the tablet under the tongue, where it will disintegrate. This drug may infrequently lead to temporary memory loss. To help avoid this adverse effect, it is important to encourage the patient to not take a dose of the drug without having had a full night's sleep (i.e., at least 7 to 8 hours) the previous night. As with any CNS-depressant drug, the patient should avoid tasks requiring mental alertness until response to the drug is known. Tolerance and dependence are possible with prolonged use, and this drug is to be gradually weaned before discontinuation.

Muscle relaxants have different indications from those of barbiturates and benzodiazepines and are not used to treat insomnia. They are generally indicated for some forms of spasticity (e.g., from upper motor neuron syndromes or muscular pain or spasms from peripheral musculoskeletal conditions). However, they may lead to adverse effects and toxicities, so frequently monitor airway, breathing, and circulation. Early identification of toxicity is critical to provide prompt treatment and prevent respiratory and other CNS-depressant effects. Closely monitor all vital parameters, level of consciousness, and presence of sedation when these muscle relaxants are used. Encourage cautious ambulation. Recommend that the patient change positions purposefully and slowly to prevent syncope or dizziness. The greatest potential for hypotension associated with these drugs is usually within 1 hour of dosing, so the patient must be more cautious about activity during this time.

Barbiturates are to be used with close monitoring and extreme caution. Observe and document the patient's level of consciousness or sedation; orientation to person, place, and time; respiratory rate; oxygen saturation; and other vital signs. Advise the patient to take oral doses with food or a light snack and not to alter dosage forms. Use a bed alarm system or side rails and provide assistance with ambulation, as needed or indicated, to help prevent injury. Barbiturates also produce a hangover effect; this residual drowsiness occurs upon awakening and results in reduced reaction times. Intermediate- and long-acting hypnotics are often the culprits of this adverse effect. Abrupt withdrawal of barbiturates after prolonged therapy may produce adverse effects ranging from nightmares, hallucinations, and delirium to seizures. In addition, while the patient is taking barbiturates, monitor red blood cell (RBC) count and hemoglobin and hematocrit levels because of the possible adverse effect of anemia. Long-term use of barbiturates also requires monitoring of therapeutic blood levels of the drug. For example, the therapeutic level of phenobarbital must range between 10 and 40 mcg/mL. Patients with serum levels above 40 mcg/mL may experience toxicity, manifested by cold and clammy skin, a respiratory rate of less than 10 breaths per minute, and other signs of severe CNS depression.

Intravenous use of barbiturates, as with some benzodiazepines (e.g., diazepam), requires dilution of the drug with normal saline or other recommended solutions. Recommendations regarding diluents and rates of intravenous administration must be strictly followed for safe use. Most of the drugs are not to be given any faster than 1 mg/kg per minute, and a maximum amount per minute may be specified. Consult authoritative drug sources (e.g., the agency parenteral administration policy, a current drug handbook or reference, or the manufacturer's insert) for the recommended rate of infusion before giving any of these drugs. Too rapid an infusion of a barbiturate may produce profound hypotension and marked respiratory depression. If intravenous infiltration is present, the site may become swollen, erythematous, and tender. Tissue necrosis may occur with this infiltration, depending on the irritating qualities of the particular drug. There are antidote protocols for some of the intravenous barbiturates. For example, with phenobarbital intravenous infiltration, the solution must be discontinued, a 0.5% procaine solution injected into the affected area, and moist heat applied, as per institutional policy or procedure. Always check protocol for management of infiltration of an intravenous drug before intervening because, in certain situations, the intravenous catheter may be left in place until antidotes are administered. Another area of concern with intravenous drugs is incompatibilities with other intravenously administered medications, and barbiturates have several. Some intravenous drugs that are incompatible with barbiturates include amphotericin B, hydrocortisone, and hydromorphone. Give these drugs only after the intravenous line has been adequately flushed with normal saline. With intramuscular injection, give the solution deep into a large muscle mass to prevent tissue sloughing; however, avoid this route and use only when necessary.

In summary, before giving any CNS depressant, it is always important to try nonpharmacological measures to induce sleep. However, if medication therapy is indicated, preventing respiratory depression and other problems associated with CNS depression is of prime importance, as is maintaining patient safety and preventing injury. Documentation must be timely, clear, and concise and reflect follow-up of the patient's response to the drug. After each dose is given, it is also important to document the dose, route, time of administration, and safety measures taken.

EVALUATION

Some of the criteria by which to confirm a patient's therapeutic response to a CNS depressant include the following: an increased ability to sleep at night, fewer awakenings, shorter sleep induction time, few adverse effects such as hangover effects, and an improved sense of well-being because of improved sleep. Therapeutic effects regarding muscle relaxants include decreased spasticity, reduction of choreiform movements in patients with Huntington's disease, decreased rigidity in parkinsonian syndromes, and relief of pain from trigeminal neuralgia. Constantly watch for and document the occurrence of any of the adverse effects of benzodiazepines, barbiturates, and muscle relaxants. See the previous discussion on adverse effects for each type of drug. Evaluation for CNS-depressant toxic effects includes monitoring for severe CNS depression of all body systems, especially respiratory and circulatory collapse, with decrease in respiratory rate or depth (or both) and decrease in blood pressure.

CASE STUDY

Drugs for Sleep

Pamela, a 68-year-old retired administrative assistant, comes to the office stating that she feels "so tired" during the day. She has had trouble sleeping, off and on for years, and a few weeks ago she received a prescription for the benzodiazepine alprazolam (Xanax®) to take "as needed for nerves." Upon closer questioning, the nurse discovers that Pamela has been using alprazolam almost every night for 3 weeks to help her get to sleep. She says, "I just could not fall asleep before! I am sleeping very well, but

I'm so tired during the day. I don't understand how I can get such good sleep and still feel tired!"

1. Can you explain the reason for her tiredness?
2. Pamela's nurse practitioner prescribes a period of decreasing doses of the alprazolam each evening, then every other evening, until the medication is stopped. Explain the rationale behind the tapering dosage schedule.
3. Pamela receives a prescription for zolpidem tartrate (Sublinx). How is this drug different from alprazolam?
4. What nonpharmacological measures can Pamela try to improve her sleep?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

PATIENT TEACHING TIPS

- Encourage patients to keep a journal where they record sleep habits and their response to both drug and nondrug therapy (Box 13.1).
- To enhance sleep, implement nonpharmacological measures first. This is important because the use of CNS depressants for treatment of sleep deficit or insomnia often leads to interference with the REM stage of sleep, hangover effects, and tolerance, as well as other adverse effects.
- Advise the patient to always check with the prescriber or pharmacist before taking any over-the-counter medications because of the many drug interactions with CNS depressants.
- Instruct the patient to keep these drugs and all medications out of the reach of children.
- Emphasize that medications are to be taken only as prescribed. The patient is usually told that if one dose does not work, not to double up on the dosage unless otherwise prescribed or directed.

- Educate the patient about any time constraints while taking these medications, when driving, when operating heavy machinery or equipment, and during participation in activities requiring mental alertness.
- Instruct the patient not to abruptly discontinue or withdraw these medications, if possible, to avoid rebound insomnia.
- Sedative-hypnotic drugs (for sleep promotion) are not intended for long-term use because of their adverse effects, interference with REM sleep, and addictive properties.
- Advise the patient that hangover effects may occur with most of these drugs and that this effect is more problematic in older adults and patients with altered kidney and liver function.
- Provide the patient with thorough instructions about safety with these drugs, such as avoiding smoking in bed and when lounging.
- Educate the patient about significant drug-drug and drug-food interactions with all these medications.
- Educate patients about the effect of grapefruit and grapefruit juice on benzodiazepines—the grapefruit causes decreased drug metabolism via inhibition of the cytochrome P450 system and may lead to a prolonged effect and possible toxicity (of the benzodiazepine).

KEY POINTS

- Nonpharmacological measures to improve sleep should be tried before resorting to treatment with medications.
- Recognize and understand the classification and pharmacokinetic properties of barbiturates. The short-acting barbiturate is pentobarbital sodium but there are no short-acting or intermediate-acting barbiturates available in Canada. The long-acting barbiturate is phenobarbital.
- The pharmacokinetics of each group of barbiturates lends specific characteristics to the drugs in that group. The nurse needs to understand how these drugs are absorbed orally and used parenterally, as well as their onset, peak, and duration of action. In addition, the nurse must understand the life-threatening potential of these drugs because too rapid an infusion may precipitate respiratory or cardiac arrest.
- Benzodiazepines are commonly used for sedation, relief of anxiety, skeletal muscle relaxation, and treatment of acute seizure disorders; they are for short-term use.
- Most sedative-hypnotic drugs suppress REM sleep and should be used only for the recommended period. This time frame varies, depending on the specific drug used.
- Long-acting benzodiazepines include clonazepam, diazepam, and flurazepam. Intermediate-acting benzodiazepines include alprazolam, lorazepam, and temazepam. Short-acting benzodiazepines include midazolam and triazolam.
- Zolpidem and zopiclone are nonbenzodiazepine hypnotics and are for short-term use.

EXAMINATION REVIEW QUESTIONS

1. A patient has been admitted to the emergency department because of an overdose of an oral benzodiazepine. He is extremely drowsy but still responsive. The nurse will prepare for which immediate intervention?
 - a. Hemodialysis to remove the medication
 - b. Administration of flumazenil
 - c. Administration of naloxone
 - d. Intubation and mechanical ventilation
2. An older adult had been given a barbiturate for sleep induction, but the night nurse noted that the patient was awake most of the night, watching television, and reading in bed. The nurse documents that the patient has had which type of reaction to the medication?
 - a. Allergic
 - b. Teratogenic
 - c. Paradoxical
 - d. Idiopathic
3. The nurse is preparing to administer a medication for sleep. Which intervention applies to the administration of a non-benzodiazepine, such as zolpidem tartrate (Sublinox)?
 - a. These drugs need to be taken about 1 hour before bedtime.
 - b. Because of their rapid onset, these drugs need to be taken just before bedtime.
 - c. The patient needs to be cautioned about the high incidence of morning drowsiness that may occur after taking these drugs.
 - d. These drugs are less likely to interact with alcohol.
4. For a patient taking a muscle relaxant, the nurse will monitor for which adverse effect?
 - a. CNS depression
 - b. Hypertension
 - c. Peripheral edema
 - d. Blurred vision
5. A hospitalized patient is reporting having difficulty sleeping. Which action will the nurse take first to address this problem?
 - a. Administer a sedative-hypnotic drug, if ordered.
 - b. Offer tea made with the herbal preparation valerian.
 - c. Encourage the patient to exercise by walking up and down the halls a few times, if tolerated.
 - d. Provide a restful environment and reduce loud noises.
6. Which considerations are important for the nurse to remember when administering a benzodiazepine as a sedative-hypnotic drug? (Select all that apply.)
 - a. These drugs are intended for long-term management of insomnia.
 - b. The drugs can be administered safely with other CNS depressants for insomnia.

- c. The dose needs to be given about 1 hour before the patient's bedtime.
 - d. The drug is used as a first choice for treatment of sleeplessness.
 - e. The patient needs to be evaluated for the drowsiness that may occur the morning after a benzodiazepine is taken.
7. A child is to receive phenobarbital 2 mg/kg IV on call as a pre-operative sedative. The child weighs 29 kilograms (64 pounds). How many milligrams will the child receive for this dose?
8. The nurse is reviewing the prescriptions for a patient who will be discharged to home after being hospitalized for a

hysterectomy. The patient asked for a sleeping pill, and the surgeon wrote a prescription for Ambien, 10 mg at bedtime as needed for sleep. What is the nurse's priority action at this time?

- a. Review the potential adverse effects with the patient.
- b. Suggest that the patient try drinking a glass of wine at bedtime.
- c. Contact the prescriber to question the dose of the Ambien.
- d. Assist the patient to find a pharmacy to fill the prescription on her way home.

CRITICAL THINKING ACTIVITIES

1. A patient has a prescription for zopiclone (Imovane) because he has had trouble sleeping. The nurse is reviewing the use of this medication, and the patient says, "I've been drinking a glass of wine before bedtime to help me sleep. Can I still do that? This medication is not like Valium, right?" What is the nurse's best response?
2. During rounds on the night shift, the nurse finds a patient lying in bed, wide awake, at 0400 hours. The patient reports, "I can't sleep. I need my sleeping pill. Can I have it now?" The patient's medication administration record has a prn (as

needed) order for temazepam (Restoril). What is the nurse's priority action at this time?

3. The nurse is talking to a patient about the adverse effects to expect when taking a muscle relaxant for injuries the patient received in an automobile accident. What is the priority adverse effect the nurse needs to discuss with the patient? Explain your answer.

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Central Nervous System Stimulants and Related Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Briefly review the anatomy, physiology, and functions of the central nervous system (CNS) with attention to the stimulant effects on its function.
2. Understand the key terms as they relate to the CNS and stimulant drugs.
3. Identify the CNS stimulant drugs.
4. Discuss the mechanisms of action, indications, dosages, routes of administration, contraindications, cautions, drug interactions, adverse effects, and any related toxicities of the various CNS stimulants and related drugs.
5. Develop a collaborative plan of care based on the nursing process for patients using CNS stimulants and related drugs.

KEY TERMS

Amphetamines A class of stimulant drugs that includes amphetamine sulphate and all of its drug derivatives. (p. 231)

Analeptics CNS stimulants that have generalized effects on the brainstem and spinal cord, which produce an increase in responsiveness to external stimuli and stimulate respiration. (p. 236)

Anorexiants Drugs used to control or suppress appetite. (p. 236)

Attention deficit hyperactivity disorder (ADHD) A syndrome characterized by difficulty in maintaining concentration on a given task or hyperactive behaviour; may affect children, adolescents, and adults. The term *attention deficit disorder* (ADD) has been absorbed under this broader term. (p. 229)

Cataplexy A condition characterized by abrupt attacks of muscular weakness and hypotonia triggered by an emotional stimulus, such as joy, laughter, anger, fear, or surprise. It is often associated with narcolepsy. (p. 230)

Central nervous system (CNS) stimulants Drugs that stimulate specific areas of the brain or spinal cord. (p. 228)

Ergot alkaloids Drugs that narrow or constrict blood vessels in the brain and provide relief of pain for certain migraine headaches. (p. 235)

Migraine A common type of recurring, painful headache characterized by a pulsatile or throbbing quality, incapacitating pain, and photophobia. (p. 230)

Narcolepsy A syndrome characterized by sudden sleep attacks, cataplexy, sleep paralysis, and visual or auditory hallucinations at the onset of sleep. (p. 229)

Serotonin receptor agonists A class of CNS stimulants used to treat migraines; work by stimulating 5-hydroxytryptamine 1 receptors in the brain and are sometimes referred to as *selective serotonin receptor agonists* or *triptans*. (p. 235)

Sympathomimetic drugs CNS stimulants such as noradrenergic drugs (and, to a lesser degree, dopaminergic drugs) whose actions resemble or mimic those of the sympathetic nervous system. (p. 229)

OVERVIEW

The central nervous system (CNS) is a complex system in the human body. Many therapeutic drugs either work in the CNS or cause adverse effects in the CNS. Activity of the CNS is regulated by a checks-and-balances system that consists of excitatory and inhibitory neurotransmitters and their corresponding receptors in the brain and spinal cord tissues. CNS stimulation results from either excessive stimulation of the excitatory neurons or blockade of the inhibitory neurons.

Central nervous system (CNS) stimulants are a broad class of drugs that stimulate specific areas of the brain or spinal cord. Most CNS stimulants act by stimulating the excitatory neurons

TABLE 14.1 Structurally Related CNS Stimulants

Chemical Category	CNS Stimulant
Amphetamines and related stimulants	amphetamine aspartate monohydrate, dextroamphetamine sulphate, lisdexanfetamine dimesylate, methylphenidate
Serotonin agonists	almotriptan malate, eletriptan hydrobromide, frovatriptan succinate, naratriptan hydrochloride, rizatriptan benzoate, sumatriptan succinate, zolmitriptan
Sympathomimetics	methamphetamine, phentermine (not available in Canada)
Xanthines	caffeine, theophylline, aminophylline
Miscellaneous	modafinil, sodium oxybate (CNS depressant), orlistat (lipase inhibitor)

TABLE 14.2 CNS Stimulants: Site of Action

CNS Stimulant	Site of Action
Serotonin agonists	Cerebrovascular system, 5-HT _{1D/1B} receptors
Amphetamines, phenidates, modafinil	Cerebral cortex
Anorexiants	Hypothalamic and limbic regions
Analeptics	Medulla and brainstem

in the brain. These neurons contain receptors for excitatory neurotransmitters, including dopamine (dopaminergic drugs), norepinephrine (adrenergic drugs), and serotonin (serotonergic drugs). Dopamine is a metabolic precursor of norepinephrine, which is also a neurotransmitter in the sympathetic nervous system. The actions of adrenergic drugs often resemble or mimic those of the sympathetic nervous system. For this reason, adrenergic drugs (and, to a lesser degree, dopaminergic drugs) are also called **sympathomimetic drugs**. Other sympathomimetic drugs are discussed further in [Chapter 19](#).

CNS stimulant drugs are classified in three ways. The first is based on chemical structural similarities. Major chemical classes of CNS stimulants include amphetamines, serotonin agonists, sympathomimetics, and xanthines ([Table 14.1](#)). Second, these drugs can be classified according to their site of therapeutic action in the CNS ([Table 14.2](#)). Finally, they can be categorized according to five major therapeutic usage categories for CNS stimulant drugs ([Table 14.3](#)). These include anti-attention deficit, antinarcotic, anorexiatic, antimigraine, and analeptic drugs. There is some therapeutic overlap among these drug categories.

ATTENTION DEFICIT HYPERACTIVITY DISORDER

Attention deficit hyperactivity disorder (ADHD), formerly known as *attention deficit disorder* (ADD), is the most commonly diagnosed neurodevelopmental disorder in children, affecting 3 to 10% of school-aged children. Boys are estimated to be affected from two to nine times as often as girls, although the disorder may be underdiagnosed in girls. Primary symptoms of

TABLE 14.3 CNS Stimulants and Related Drugs: Therapeutic Categories

Category	Drugs
Anti-ADHD	amphetamine aspartate monohydrate, dextroamphetamine sulphate, methamphetamine hydrochloride, methylphenidate, atomoxetine (norepinephrine reuptake inhibitor), lisdexamphetamine
Antinarcotic	dextroamphetamine (adjunct), methamphetamine hydrochloride, methylphenidate, sodium oxybate (CNS depressant used for cataplexy)
Anorexiatic	methamphetamine hydrochloride, orlistat (lipase inhibitor)
Antimigraine (serotonin agonists)	almotriptan malate, eletriptan hydrobromide, frovatriptan succinate, naratriptan hydrochloride, rizatriptan benzoate, sumatriptan succinate, zolmitriptan
Analeptic	caffeine, aminophylline, theophylline, modafinil (antinarcotic)

ADHD, Attention deficit hyperactivity disorder; CNS, central nervous system.

ADHD centre on a developmentally inappropriate inability to maintain attention span, along with the presence of hyperactivity and impulsivity. The disorder may involve predominantly attention deficit, predominantly hyperactivity or impulsivity, or a combination of both. It often begins before 7 years of age, sometimes earlier than 3 years. Previously, a diagnosis of ADHD required at least some symptoms of ADHD to have been present by age 7 years. This age criterion has been raised to the age of 12 years. Symptoms must be present for at least 6 months and occur in at least two different settings (e.g., home and school). For diagnosis in adults 17 years or older, five symptoms of either inattention or either hyperactivity or impulsivity are required. According to the *Diagnostic and Statistical Manual of Mental Disorders-5* (DSM-5), an individual with ADHD can have mild, moderate, or severe ADHD, based on the number of symptoms an individual has and how difficult those symptoms make daily life. Many children outgrow ADHD, but adult ADHD is also common. New to the DSM-5 is that an individual can be diagnosed with ADHD and autism spectrum disorder. Drug therapy for both childhood and adult ADHD is essentially the same. There is some social controversy regarding the possible overdiagnosis of, and overmedication for, this disorder. Studies in twins indicate a degree of genetic predisposition and familial heritability. The disorder is commonly associated with other forms of mental health disorders, including depression, bipolar disorder, anxiety, and learning difficulties. Sleep and alertness difficulties have also been identified in children and adults with ADHD. It is unclear if ADHD stimulants directly affect sleep onset or if insomnia is a result of reduced blood concentrations of the drug at night, or if insomnia is a symptom of mental health comorbidities.

NARCOLEPSY

Narcolepsy is a common, disabling, incurable sleep disorder in which patients experience excessive daytime sleepiness (EDS) and may unexpectedly fall asleep in the middle of normal daily

activities. As a consequence of sleepiness, patients may report inattention, poor memory, blurry vision, diplopia, and automatic behaviours such as driving without awareness. Another major symptom of the disease is dysfunctional rapid eye movement (REM) sleep. REM sleep manifestations that intrude into wakefulness include **cataplexy** (sudden loss of muscle tone triggered by strong emotions; commonly the knees buckle and the individual falls to the floor while still awake), sleep paralysis, *hypnagogic/hypnopompic hallucinations* (sensory events that occur at the transition from wakefulness to sleep), and sleep-onset REM periods. Men and women are equally affected. The prevalence of narcolepsy in Canada is approximately 1 in 2 000 individuals. Often, symptoms begin during adolescence. Some genetic markers have been identified. Approximately one half of patients with narcolepsy experience migraine headaches as well.

OBESITY

Currently, there are approximately 7 million obese adults and 600 000 obese school-aged children in Canada. Prevalence estimates based on waist circumference indicate that 37% of adults and 13% of youth are abdominally obese (Janssen, 2013). Between 2016 and 2017, 34% of Canadians were considered overweight and 27% were considered morbidly obese (Statistics Canada, 2018). The prevalence of obesity is expected to continue to rise at a predicted rate of 4 to 5% per year. Obesity was formerly defined as being 20% or more above one's ideal body weight, based on population statistics for height, body frame, and gender. More recent data are based on a measurement known as the body mass index (BMI), defined as weight in kilograms divided by height in metres squared (i.e., $BMI = \text{weight [kg]} \div [\text{height (m)}]^2$). *Overweight* is now defined as a BMI of 25 to 29.9, whereas *obesity* is now defined as a BMI of 30 or higher. Waist circumference is also a gauge of health risk associated with excess fat or central obesity around the waist. It provides an independent estimate of health risk beyond the BMI. A waist circumference of 102 cm or more in men or 88 cm or more in women is associated with increased health risks. Waist circumferences for each gender for ethnicity-specific populations are associated with increased risks as follows: for people of European, Sub-Saharan African, Eastern Mediterranean, and Middle Eastern (Arab) descent, greater than 94 cm for men and 80 cm for women respectively; for people of South Asian, Chinese, Japanese, and South and Central American descent, greater than 90 cm for men and 80 cm for women, respectively. Moreover, the incidence of obesity in young people aged 6 to 19 years has more than doubled since 1980. Almost one in three children and adolescents is overweight (19.8%) or obese (11.8%). Most adolescents do not outgrow this problem, and in fact, many continue to gain excess weight. The pathophysiology of obesity is not fully understood, but calorie excess, disordered metabolism, inadequate sleep, and other factors are hypothesized. Obesity increases the potential for hypertension; dyslipidemia; coronary artery disease; stroke; type 2 diabetes mellitus; gallbladder disease; gout; osteoarthritis; sleep apnea; nonalcoholic fatty liver disease; and certain types of cancer, including breast and colon cancer. An estimated 80% of diabetes risk in Canada can be attributed to excess weight. The

burden of obesity is estimated at \$4.6 billion. Yet, many people who attempt weight loss do so for cosmetic reasons rather than health reasons. Obese people are often stigmatized, at times even by the health care providers treating them.

MIGRAINE

A **migraine** is a common type of recurring headache, usually lasting from 4 to 72 hours. Typical features include a pulsatile quality with pain that worsens with each pulse. The pain is most commonly unilateral but may occur on both sides of the head. Associated symptoms include nausea, vomiting, photophobia (avoidance of light), and phonophobia (avoidance of sounds). In addition, some migraines are accompanied by an aura, which is a predictive set of altered visual or other senses (formerly termed *classic migraine*). However, most migraines are without an aura (formerly termed *common migraine*). Migraines affect about 8% of Canadians over the age of 12, with a reported incidence in females three times that in males. Migraines are most commonly experienced by both men and women between the ages of 35 and 45 (WHO, 2016), although approximately 8% of children and adolescents suffer from migraines. Migraine headaches have been classified by the World Health Organization (WHO) as one of the 19 most disabling diseases worldwide. Migraines commonly begin after 10 years of age and peak between the mid-twenties and early forties. Often, they fade after 50 years of age. Familial inheritance of migraine is well recognized, and environmental factors, stress, and psychological factors also play a role in the development of migraines. There are several conditions that coexist commonly with migraine headaches, including depression and anxiety, with risk increasing in those with daily headaches. Individuals who experienced adverse childhood events such as abuse and unfavourable family conditions, and whose symptoms are complicated by anxiety and depression, are more likely to experience disabling pain; it is also more challenging to treat them.

Historically, there have been several theories regarding the cause of migraines, including the “vascular hypothesis” and the “neurovascular hypothesis”—most recent evidence points to decreased serotonin levels. Thus, most current investigations involve drugs that can increase serotonin levels.

It is believed that repeated migraine attacks cause neuroplastic changes in the brain's structure and function over time, resulting in chronic daily headaches rather than episodic ones. These chronic migraines alter brain metabolism, cause atrophy of grey matter, and result in generalized hyperexcitability of the CNS and central sensitization. Sensitization tends to progress from isolated trigeminal nerve throbbing pain to more centralized allodynia (i.e., resulting from a stimulus that does not normally cause pain). More severe allodynia may not respond to serotonin receptor agonists.

DRUGS FOR ATTENTION DEFICIT HYPERACTIVITY DISORDER AND NARCOLEPSY

CNS stimulants are the first-line drugs of choice for both ADHD and narcolepsy. They are potent drugs with a strong potential for tolerance and psychological dependence

(addiction; see [Chapter 18](#)). They are classified as Schedule III drugs under the *Controlled Drugs and Substances Act*. Although there has been some public controversy regarding their use in ADHD, these drugs have led to a 65 to 75% improvement in symptoms in treated patients, compared with a placebo. In general, CNS stimulants elevate mood, produce a sense of increased energy and alertness, decrease appetite, and enhance task performance reduced by fatigue or boredom. Two of the oldest known stimulants are cocaine and amphetamine, which are prototypical drugs for this class. Caffeine, contained in coffee and tea, is another plant-derived CNS stimulant.

Amphetamine sulphate was first synthesized in the late 1800s. It was subsequently used to treat narcolepsy and then to prolong the alertness of soldiers during World War II. Later derivatives of this drug, which are still used clinically, include its D-isomer dextroamphetamine sulphate, methamphetamine hydrochloride, and mixed amphetamine salts—salts of both amphetamine and dextroamphetamine. They are often collectively referred to simply as *amphetamines*. Methylphenidate, a synthetic amphetamine derivative, was first introduced for the treatment of hyperactivity in children in 1958. Its D-isomer is the drug dexamethylphenidate. The phenidates are also Schedule III drugs. All these amphetamine-related drugs are used to treat ADHD or narcolepsy. The sole nonamphetamine stimulant is modafinil.

Atomoxetine is a nonstimulant drug that is also used to treat ADHD. Atomoxetine is a norepinephrine reuptake inhibitor. Because it is not an amphetamine, it is associated with a low incidence of insomnia and has low misuse potential. Another advantage is that phone-in refills are allowed for this drug (as opposed to Schedule III drugs, which require a written prescription). One of the newest drugs in the ADHD arsenal is lisdexamfetamine dimesylate (Vyvanse®), recommended for use in children aged 6 to 12 years, at a dosage of 30 mg once daily in the morning. It is a prodrug for dextroamphetamine, meaning it is converted in the body to dextroamphetamine.

Mechanism of Action and Drug Effects

Amphetamines stimulate areas of the brain associated with mental alertness, such as the cerebral cortex and the thalamus. Pharmacological actions of CNS stimulants are similar to the actions of the sympathetic nervous system, in that the CNS and respiratory systems are the primary body systems affected. CNS effects include mood elevation or euphoria, increased mental alertness and capacity for work, decreased fatigue and drowsiness, and prolonged wakefulness. The respiratory effects most commonly seen are relaxation of bronchial smooth muscle, increased respiration, and dilation of pulmonary arteries. Stringent controls have greatly reduced their medical use in Canada, as CNS stimulants are potent drugs with a strong potential for tolerance and psychological dependence. They are therefore classified as Schedule III drugs under the *Controlled Drugs and Substances Act* (see [Legal & Ethical Principles](#) box on the proper handling of prescription drugs).

LEGAL & ETHICAL PRINCIPLES

Handling of Prescription Drugs

It is important for nurses to understand the federal laws that apply to the handling of all prescription drugs by the registered nurse. (Note: This is a summary and does not reflect the laws in their entirety. Currently, nurse practitioners can prescribe in Canada. As well, in some provinces and territories, registered nurses who work in specialty areas can also prescribe and dispense [see [Chapter 3](#)]).

The registered nurse is prohibited from doing the following:

- Compounding or dispensing the designated drugs for legal distribution and administration
- Distributing the drugs to any individuals who are not licensed or authorized by federal or provincial or territorial law to receive the drugs (e.g., those individuals outside the health care provider–patient relationship); the penalties for such actions are generally severe.
- Making, selling, keeping, or concealing any counterfeit drug equipment
- Possessing any type of stimulant or depressant drug unless authorized to do so by a legal prescription (as a patient); any unauthorized possession is illegal
- It is important to adhere to these legal guidelines in the practice of drug administration to avoid legal penalties, including possible loss of licensure or other severe penalties.

The amphetamines and phenidates increase the effects of norepinephrine and dopamine in CNS synapses by increasing their release and blocking their reuptake. As a result, both neurotransmitters are in contact with their receptors longer, which lengthens their duration of action. The sole nonamphetamine stimulant available in Canada is modafinil (Alertec®). Modafinil is also classified as an analeptic. It promotes wakefulness like the amphetamines and phenidates. It lacks sympathomimetic properties, however, and appears to work primarily by reducing gamma-aminobutyric acid (GABA)–mediated neurotransmission in the brain. (GABA is the principal inhibitory neurotransmitter in the brain.) The nonstimulant drug atomoxetine is also being used to treat ADHD. It works in the CNS by selective inhibition of norepinephrine reuptake.

Indications

Various amphetamine derivatives, including methylphenidate, are currently used to treat both ADHD and narcolepsy. The newer nonstimulant drug atomoxetine is also now used to treat ADHD. Amphetamine sulphate was also used to treat obesity in the early to mid-twentieth century. In Canada, amphetamines are not currently approved for this indication due to safety concerns. The nonamphetamine stimulant modafinil is indicated for narcolepsy. Specialists sometimes recommend periodic “drug holidays” (e.g., 1 day per week) without medication to diminish the addictive tendencies of the stimulant drugs. Often, school-aged children taking these drugs do not take them on weekends or during school vacations.

Contraindications

Contraindications to the use of amphetamine and nonamphetamine stimulants include known drug allergy and cardiac structural abnormalities. These drugs can also exacerbate the following conditions: marked anxiety or agitation, Tourette’s syndrome and other tic disorders (hyperstimulation), hypertension, and

glaucoma (can increase intraocular pressure; see [Chapter 57](#)). The drugs must not be used in patients who have received therapy with any monoamine oxidase inhibitor (MAOI) in the preceding 14 days (see [Chapter 16](#)). Contraindications specific to atomoxetine include drug allergy, glaucoma, and recent MAOI use.

ADVERSE EFFECTS

Both amphetamine and nonamphetamine stimulants have a wide range of adverse effects that most often arise when these drugs are administered at high doses. These drugs tend to “speed up” body systems. For example, effects on the cardiovascular system include increased heart rate and blood pressure. Other adverse effects include angina, anxiety, insomnia, headache, tremor, blurred vision, increased metabolic rate, gastrointestinal distress, dry mouth, and worsening of or new onset of psychiatric disorders, including mania, psychoses, or aggression. Common adverse effects associated with atomoxetine include headache, abdominal pain, vomiting, anorexia, and cough.

In 2015, Health Canada issued a safety communication with strong warnings on the risk of suicidal thoughts and behaviours regarding all drugs used in the treatment of ADHD. Health Canada (2015) opinion is that the benefits of these drugs in the effective management of ADHD continue to outweigh their risks. The product monographs will now contain information in a warning section about the possible occurrence of psychiatric adverse effects with ADHD drugs. The need for focus on monitoring moods, behaviours, thoughts, and feelings in adults and children taking these medications is highlighted, as is the significance of taking psychiatric disorders into account when prescribing these drugs.

Interactions

Drug interactions associated with these drugs vary greatly from class to class. Refer to [Table 14.4](#) for a summary of some of the more common interactions for all drug classes in this chapter.

Dosages

For dosage information, refer to the table on p. 233.

DRUG PROFILES

Amphetamines and Related Stimulants

The principal drugs used to treat ADHD and narcolepsy are the amphetamines and nonamphetamine stimulants. Atomoxetine, a nonstimulant drug, is also used for ADHD.

amphetamines

The various amphetamine salts are the prototypical CNS stimulants used to treat ADHD and narcolepsy. Amphetamine is available in prescription form only for oral use, as dextroamphetamine sulphate (Dexedrine®) and amphetamine aspartate monohydrate (Adderall®).

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	30–60 min	90–120 min	7–14 hr	10 hr

methylphenidate hydrochloride

Methylphenidate hydrochloride (Ritalin®) was the first prescription drug indicated for ADHD and continues to be the most widely prescribed drug for its treatment. It is also used to treat narcolepsy. Extended-release (XR) dosage forms include Ritalin SR®, Concerta®, and Biphentin® and are often preferred over the immediate-release (IR) stimulants. Short-acting stimulants peak after several hours and must be taken two to three times a day, compared with the longer-acting or extended-release stimulants which last for 8 to 12 hours and are usually taken once a day. Children with ADHD taking XR stimulant medication are less likely to visit an emergency room and less likely to be hospitalized (and when they are, they are hospitalized for a shorter period of time) than those initially prescribed IR stimulants. This may be due to improved adherence and the resulting effectiveness or as a result of the prolonged therapeutic effect of the XR medications, leading to fewer inattentive or impulsive behaviours in the evening. However, the XR drugs may not be covered by public or private drug plans.

There is some controversy regarding drug therapy for ADHD. Some parents may be understandably apprehensive regarding this type of drug therapy. However, with proper diagnosis of the disorder, proper dosing of the drug, and regular medical monitoring, many children can achieve significant improvement in school performance and social skills. Psychosocial problems within a child's family need to be ruled out or addressed if they are contributing to the child's problems, regardless of whether the medication is prescribed.

PHARMACOKINETICS (EXTENDED RELEASE)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	20–60 min	6–8 hr	3.5 hr	12 hr

atomoxetine hydrochloride

Atomoxetine hydrochloride (Strattera®) is approved for treating ADHD in children older than 6 years of age and in adults. This medication is not a controlled substance because it lacks addictive properties, unlike amphetamines and phenidates. For this reason, it has rapidly gained popularity as a therapeutic option for treating ADHD. However, Health Canada and the drug manufacturer did issue a warning describing cases of suicidal thinking and behaviour in a small number of adolescent patients receiving this medication, similar to its previous warnings regarding adolescent use of antidepressant medications ([Chapter 17](#)). With each prescription or refill of Strattera, pharmacists are to provide the medicine guide to patients, families, or caregivers. Health care providers are advised to work with parents in providing prudent monitoring of any young patients taking this medication and to promptly re-evaluate patients showing any behavioural symptoms of concern.

Dosages

Selected CNS Stimulants and Related Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications/Uses
amphetamine aspartate monohydrate (mixed salts) (Adderall XR®)	CNS stimulant	<i>Children 6–12 yr</i> PO: 5–10 mg once daily in morning, increased weekly until desired effect to a daily max of 30 mg <i>Adolescents 13–17 yr, adults</i> PO: 10 mg once daily in morning, increased weekly to a daily max of 20 mg (not to exceed 30 mg/day)	ADHD, narcolepsy
atomoxetine hydrochloride (Strattera)	Selective norepinephrine reuptake inhibitor	<i>Children 6 yr and older, adolescents (less than 70 kg)</i> PO: 0.5–1.4 mg/kg/day divided once or twice daily <i>Children/Adolescents/Adults (70 kg or more)</i> PO: 40–100 mg/day divided once or twice daily	ADHD
methylphenidate hydrochloride, extended-release (Concerta)	CNS stimulant	<i>Children 6–12/adolescents 13–18</i> PO: 18–54 mg/day, single dose <i>Adults over 18</i> PO: 18–72 mg/day, single dose	ADHD
methylphenidate hydrochloride (Ritalin, Ritalin SR)	CNS stimulant	<i>Children/adolescents, 6 yr and older</i> PO: Start at 20 mg am daily (titrate, max 60 mg/day) <i>Adults</i> PO: Start at 20 mg daily (titrate, max dose 100 mg daily)	ADHD ADHD
modafinil (Alertec)	CNS stimulant	<i>Adults over 18</i> PO: 200 mg qAM; if second dose is needed, give at noon	Narcolepsy
orlistat (Xenical®)	Lipase inhibitor	<i>Adults</i> PO: 120 mg tid with each meal	Obesity
sumatriptan (Imitrex®, Imitrex DF®)	Serotonin receptor agonist	<i>Adults</i> PO: 50 mg, repeat after 2 hr to max 200 mg/day Subcut: 6 mg, repeat in 1 hr; max 12 mg/day Nasal spray: 5–20 mg, repeat after 2 hr; max 40 mg/day	Acute migraine with or without aura

ADHD, Attention deficit hyperactivity disorder; CNS, central nervous system.

EVIDENCE IN PRACTICE

Ibuprofen May Help Relieve Acute Migraine Headaches

Review

Migraine headache is a common, disabling condition that has a major impact on individuals, health care services, and society. Many migraine sufferers do not seek proper medical attention and often rely on the use of over-the-counter (OTC) medications. The goal of this Cochrane review of literature is to assess the effectiveness and tolerability of ibuprofen on migraine headaches in adults. Additionally, this review is to assess ibuprofen when given as monotherapy or together with an antiemetic, as compared to placebo treatment or other drug treatment for the relief of acute migraines in adults.

Type of Evidence

The investigators searched the databases of Cochrane CENTRAL, MEDLINE, and EMBASE, as well as the Oxford Pain Relief Database. These sources were used to identify studies published through April 2010 about ibuprofen and migraines. Criteria used to determine inclusion included randomized, double-blind trials of self-given ibuprofen versus active comparators to treat a migraine episode with outcome data for at least 10 participants per treatment group. Once data were collected, two independent investigators performed a methodological trial from which nine studies comparing ibuprofen and placebo or other active drugs were

identified. Over 4 300 participants were studied for a total of over 5 220 migraine attacks. Of these studies, none were representative of the protocol of using ibuprofen and an antiemetic. Single doses of medications were used to treat all the attacks. Relative risk and number needed to treat (NNT) or harm versus placebo or other active drug were calculated from the participants.

Results of Study

When comparing ibuprofen 400 mg with use of the placebo, the NNTs were 7.2 for 2 hours pain-free (26% versus 12%), 3.2 for 2 hours of headache relief (57% versus 25%), and 4.0 for 24-hour sustained headache relief (45% versus 19%). Ibuprofen 200 mg versus the placebo showed that the NNTs were 9.7 for 2 hours pain-free (20% versus 10%) and 6.3 for 2 hours of headache relief (52% versus 37%). The ibuprofen dose of 400 mg offered significantly better 2-hour headache relief than the 200-mg dose, and the soluble dosage forms of ibuprofen offered better 1-hour relief but not the 2-hour headache relief, as compared to standard tablet dosage forms. Another set of symptoms that was looked at included nausea, vomiting, photophobia, phonophobia, and functional disability. These symptoms were reduced within 2 hours with the ibuprofen versus placebo. Additionally, fewer participants used rescue medication. Side effects were

EVIDENCE IN PRACTICE—Cont'd

Ibuprofen May Help Relieve Acute Migraine Headaches

mostly mild and temporary and occurred similarly in participants across treatment groups. The major limitation of this review includes weaknesses inherent in the reviewed studies, as well as the fact that a small number of events were used to calculate some of the results.

Link of Evidence to Nursing Practice

About 8% of the Canadian population over the age of 12 experience migraines with significant impacts on quality of life. Migraine management remains a huge challenge for health care providers and has a subsequent negative impact on health care costs. As migraines have been classified as one of the 19 most disabling diseases worldwide, adequate management or treatment is crucial to patient quality of life and to helping trim the costs of health care. Ibuprofen has been identified as an effective treatment for acute migraine headaches, leading to pain relief in about 50% of sufferers but only complete relief from pain (and other symptoms) in a minority of participants. This review is just one example of the need for more effective studies with larger sample sizes. Additionally, there

is a need for further studies on migraines, looking at a variety of outcomes for pain relief, types of management, and multisymptom management. Dosage formulations and their advantages and effectiveness also need to be studied. Nurse researchers need to continue to take the lead in identifying patient problems as well as help to identify a variety of medical, holistic, and alternative approaches to their short- and long-term treatment.

In another Cochrane review, Derry, Wiffen, Moore, and colleagues (2017) concluded that 400 mg of ibuprofen can provide pain relief in episodic tension-type headaches at 2 hours. The authors found that a small proportion of participants suffering this type of headache and who have acute, moderate to severe initial pain had complete pain relief from 400 mg ibuprofen. This finding was similar to that of Rabbie, Derry, Moore, et al. (2010) but cannot be directly compared due to the differences in types of headache. Although not considered a migraine, episodic tension-type headaches can be debilitating, and one in every five people experience this type of headache, worldwide.

Rabbie, R., Derry, S., Moore, R. A., et al. (2010). Ibuprofen with or without an antiemetic for acute migraine headaches in adults. *Cochrane Database of Systematic Reviews*, 2010(10). <https://doi.org/10.1002/14651858.CD008039.pub2>; Derry, S., Wiffen, P. J., Moore, R. A., et al. (2017). Ibuprofen for acute treatment of episodic tension-type headache in adults. *Cochrane Database of Systematic Reviews*, 2017(7). <https://doi.org/10.1002/14651858.CD011474.pub2>

TABLE 14.4 CNS Stimulants: Common Drug Interactions

Drug	Interacting Drugs	Mechanism	Result
Amphetamine and Nonamphetamine Stimulants			
Amphetamines (various salts), methylphenidate	CNS stimulants	Additive toxicities	Cardiovascular adverse effects, nervousness, insomnia
	MAOIs	Increased release of catecholamines	Headaches, dysrhythmias, severe hypertension
Atomoxetine	Sympathomimetic drugs	Enhanced SNS effects	Cardiovascular adverse effects (dysrhythmias, tachycardia, hypertension)
	CYP2D6 inhibitors (MAOIs, paroxetine)	Reduced metabolism of atomoxetine	Enhanced atomoxetine toxicity
Anorexiants and Analeptics			
phentermine	CNS stimulants	Additive toxicities	Nervousness, insomnia, seizures
	MAOIs	Increased release of catecholamines	Headaches, dysrhythmias, severe hypertension
	Serotonergic drugs	Additive toxicity	Cardiovascular adverse effects, nervousness, insomnia, convulsions
Serotonin Agonists			
sumatriptan and others	Ergot alkaloids, MAOIs	Additive toxicity	Cardiovascular adverse effects, nervousness, insomnia, convulsions
Ergot Alkaloids			
dihydroergotamine mesylate (DHT®)	Protease inhibitors, azole antifungals, macrolide antibiotics	Increased ergot levels	Acute ergot toxicity, nausea, vomiting, hypotension or hypertension, seizures, coma, death; use with ergot alkaloids is contraindicated

CNS, Central nervous system; CYP2D6, cytochrome P450 enzyme 2D6; MAOIs, monoamine oxidase inhibitors; SNS, sympathetic nervous system; SSRIs, selective serotonin reuptake inhibitors.

modafinil

Modafinil (Alertec) is indicated for improvement of wakefulness in patients with excessive daytime sleepiness associated with narcolepsy and with shift work sleep disorder. It has less misuse potential than amphetamines and methylphenidate and is available by prescription.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1–2 months for therapeutic effect	2–4 hr	8–15 hr	Unknown

ANOREXIANTS

An anorexiant is any substance that suppresses appetite. **Anorexiants** are CNS stimulant drugs used to promote weight loss in obesity; however, their effectiveness has not been proven. Stringent regulations have greatly reduced their medical use in Canada, and none are currently approved for treating obesity. Orlistat (Xenical) is a related nonstimulant drug used to treat obesity. It works locally in the small and large intestines where it inhibits absorption of caloric intake from fatty foods.

Mechanism of Action and Drug Effects

Orlistat differs from other antiobesity drugs in that it is not a CNS stimulant. It works by irreversibly inhibiting the enzyme lipase. This results in reduced absorption of dietary fat from the intestinal tract and increased fat elimination in the feces.

Indications

Orlistat is to be used in conjunction with a mildly hypocaloric diet; it is indicated for obesity management, including weight loss, weight maintenance, and reduction of the risk of weight regain after prior weight loss. Orlistat is for obese patients with a BMI of 30 or higher, or patients with a BMI of 27 or higher who are also hypertensive or have high cholesterol or type 2 diabetes.

Contraindications

Orlistat is contraindicated in patients with known drug allergy, chronic malabsorption syndrome (e.g. Crohn's disease, colitis, short bowel syndrome) or cholestasis.

Adverse Effects

The most common adverse effects of orlistat include headache, upper respiratory tract infection (mechanism uncertain), and gastrointestinal distress, including fecal incontinence.

DRUG PROFILES

Anorexiants

Amphetamine salts are no longer used for treatment of obesity because of their high misuse potential. The nonstimulant drug orlistat, a lipase inhibitor, is available by prescription.

orlistat

Orlistat (Xenical) works by binding to gastric and pancreatic enzymes called *lipases*. Blocking these enzymes reduces fat absorption by approximately 30%. Restricting dietary intake of fat to less than 30% of total calories can help reduce some of the gastrointestinal adverse effects, which include oily spotting, flatulence, and fecal incontinence in 20 to 40% of patients. Decreases in serum concentrations of vitamins A, D, and E and beta carotene are seen as a result of the blocking of fat absorption. Supplementation with fat-soluble vitamins corrects this deficiency.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	3 mo for therapeutic effect	6–8 hr	1–2 hr	Unknown

Interactions

Drug interactions for orlistat are listed in [Table 14.4](#).

Dosages

For dosage information, refer to the table on p. 233.

ANTIMIGRAINE DRUGS

Serotonin receptor agonists, first introduced in the 1990s, have revolutionized the treatment of migraine headache. They work by stimulating serotonin receptors in the brain. They include sumatriptan succinate (Imitrex), almotriptan malate (Axert®), eletriptan hydrobromide (Relpax®), naratriptan hydrochloride (Amerge®), rizatriptan benzoate (Maxalt®), zolmitriptan (Zomig®), and frovatriptan succinate (Frova®). Collectively, these drugs are referred to as *triptans*. They are to be used cautiously in patients with severe cardiovascular disease (especially angina pectoris). Historically, **ergot alkaloids** were the mainstay of migraine headache treatment, but these have been replaced by the triptans for first-line therapy. The ergot alkaloids are obtained from a fungus and cause vasoconstriction of dilated blood vessels in the brain and the carotid arteries. They are contraindicated in patients with peripheral vascular disease, coronary artery disease, sepsis, reduced renal or hepatic function, or severe hypertension.

Mechanism of Action and Drug Effects

The chemical name for serotonin is 5-hydroxytryptamine, or 5-HT. Physiologists have further identified two 5-HT receptor subtypes on which these drugs have their greatest effect: 5-HT_{1B} and 5-HT_{1D}. Triptans stimulate these receptors in cerebral arteries, causing vasoconstriction and normally reducing or eliminating headache symptoms. They also reduce the production of inflammatory neuropeptides. This is known as *abortive* drug therapy because it treats a headache that has already started. Ergot alkaloids also narrow or constrict blood vessels in the brain. Although the cause of migraines is not fully understood, they are thought to be a result of abnormal dilation of the blood vessels within the brain.

Indications

The triptan antimigraine drugs, also referred to as *selective serotonin receptor agonists* (SSRAs), are indicated for abortive therapy of an acute migraine headache. Although they may be taken during aura symptoms in patients who have auras with their headaches, these drugs are not indicated for preventive migraine therapy. Preventive therapy is indicated if migraine attacks occur one or more days per week. A variety of drugs are used for preventive therapy; most of them are discussed in more detail in other chapters. First-line drugs for preventive therapy include propranolol (see [Chapter 20](#)), amitriptyline (see [Chapter 17](#)), valproic acid, and topiramate (see [Chapter 15](#)). Second-line therapies include the ergot alkaloid dihydroergotamine mesylate (DHE®); nonsteroidal anti-inflammatory drugs, including naproxen (see [Chapter 49](#)); calcium channel blockers; and angiotensin receptor blockers (see [Chapter 23](#)). In addition, BOTOX® (onabotulinumtoxin A) is used in Canada for chronic migraines as a preventive therapy. Injections are made in key muscles around the head and neck for a total of 155–195 U per treatment session, with effects that can last up to three months (see <https://allergan-web-cdn-prod.azureedge.net/allergancanadaspecialty/allergancanadaspecialty/media/actavis-canada-specialty/en/products/pms/9060x-2018-10-16-en-botox.pdf>). Patients can visit specialized medical clinics for this therapy, and it can reduce monthly chronic migraine days, leading to an increase in quality of life ([Escher, Paracka, Dressler, et al., 2017](#)). In many cases, preventive drug therapy is enough to prevent a full-blown migraine. However, when prevention fails, treatment is needed, and the triptans are the most commonly prescribed drug class. Another frequently used product for abortive therapy is Fiorinal®, which is a combination of either acetaminophen or aspirin plus the barbiturate butalbital, plus the analeptic caffeine. In addition to potentiating the effects of the analgesics, caffeine can also enhance intestinal absorption of the ergot alkaloids and has a vasoconstricting effect, which can reduce cerebral blood flow to ease headache pain. Caffeine also has a diuretic effect, which may ultimately also reduce cerebral blood flow, owing to reduced vascular volume secondary to enhanced urinary output.

Contraindications

Contraindications to triptans include known drug allergy and the presence of serious cardiovascular disease because of the vasoconstrictive potential of these medications. Contraindications to the use of ergot alkaloids include uncontrolled hypertension; cerebral, cardiac, or peripheral vascular disease; dysrhythmias; glaucoma; and coronary artery disease.

DRUG PROFILES

Serotonin Receptor Agonists

Serotonin receptor agonists are used to treat migraine headache. They can produce relief from moderate to severe migraines within 2 hours, in 70 to 80% of patients. They work by stimulating 5-HT₁ receptors in the brain. They are available in a variety of formulations, including oral tablets, sublingual tablets, subcutaneous self-injections, and nasal sprays. A common effect of migraines is nausea and vomiting. Orally administered medications are therefore not tolerated by some patients. Non-oral (including sublingual) forms are advantageous for this reason.

They also often have a more rapid onset of action, producing relief in some patients in 10 to 15 minutes, compared with 1 to 2 hours for tablets taken orally. For dosage information, refer to the table on p. 233.

sumatriptan

Sumatriptan (Imitrex) was the original prototype drug for this class. There are now seven triptans. Slight pharmacokinetic differences exist between some of these products, but their effects are comparable overall.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	0.5–1 hr	2.5 hr	2.5 hr	4 hr

Ergot alkaloids, such as ergotamine, are still used in the treatment and prevention of migraines but are rapidly being replaced by the triptans. Dihydroergotamine mesylate (DHE) is available in injectable form and as a nasal spray (Migranal®).

ERGOT ALKALOIDS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Nasal spray	rapid	30–60 mins	9–10 hours	unknown

Adverse Effects

Triptans have potential vasoconstrictor effects, including effects on coronary circulation. Injectable dosage forms may cause local irritation at the site of injection. Other adverse effects include tingling, flushing (skin warmth and redness), or a congested feeling in the head or chest. Ergot alkaloids are associated with the adverse effects of nausea, vomiting, cold or clammy hands and feet, muscle pain, dizziness, numbness, a vague feeling of anxiety, a bitter or foul taste in the mouth or throat, and irritation of the nose (with the nasal spray dosage form). Overuse of abortive therapy may result in rebound headaches.

Interactions

Drug interactions for antimigraine drugs are presented in [Table 14.4](#).

Dosages

For dosage information, refer to the table on p. 233.

ANALEPTICS

Analeptics include the methylxanthines aminophylline, theophylline, and caffeine. The drugs are mentioned here, although they are used to treat neonatal and postoperative respiratory depression. Postoperative respiratory depression is a less common problem today due to the design of newer anaesthetic drugs with shorter durations of action.

Mechanism of Action and Drug Effects

Analeptics work by stimulating areas of the CNS that control respiration, mainly the medulla and spinal cord. Methylxanthine

analeptics (caffeine, aminophylline, and theophylline) also inhibit the enzyme phosphodiesterase. This enzyme breaks down a substance called cyclic adenosine monophosphate (cAMP). When analeptics block this enzyme, cAMP accumulates. This results in relaxation of smooth muscle in the respiratory tract, dilation of pulmonary arterioles, and stimulation of the CNS in general. Aminophylline is a prodrug (a drug that is formulated for greater solubility to facilitate administration but must be metabolized to an active form); it is hydrolyzed to theophylline in the body. Theophylline, in turn, is metabolized to caffeine. Caffeine is inherently a stronger CNS stimulant, hence its popularity in coffee, tea, and soft drinks. It also helps to potentiate the effects of analgesics used for migraine therapy and has a diuretic effect. The stimulant effects of caffeine are attributed to its antagonism (blocking) of adenosine receptors in the brain. Adenosine is associated with sleep promotion.

Indications

Analeptics are used primarily to stimulate respirations.

Contraindications

Contraindications to the use of analeptics include drug allergy, peptic ulcer disease (especially for caffeine), and serious cardiovascular conditions. Concurrent use of other phosphodiesterase-inhibiting drugs, such as sildenafil and similar drugs, is also not recommended.

DRUG PROFILES

Analeptic drugs include the methylxanthines aminophylline, theophylline, and caffeine. The profiles for aminophylline and theophylline can be found in [Chapter 38](#). The antinarcotic drug modafinil is discussed in the Narcolepsy section of this chapter.

► caffeine

Caffeine is a CNS stimulant that can be found in OTC drugs and combination prescription drugs. It is also contained in many beverages and foods. A few of the many foods and drugs that contain caffeine are listed in [Table 14.5](#). Caffeine is contraindicated in patients with a known hypersensitivity to it and should be used with caution in patients who have recently suffered a myocardial infarction or who have a history of peptic ulcers or cardiac dysrhythmias. In Canada, pure caffeine is regulated as a food additive. It may be added only to carbonated soft drinks and it must be declared in the ingredients list on the product label. Caffeine may not be added to any other food. It is available in oral forms.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	15–45 min	1 hr	3–4 hr	6 hr

Adverse Effects

At higher dosages, analeptics stimulate the vagal, vasomotor, and respiratory centres of the medulla in the brainstem, as well as skeletal muscles. Vagal effects include stimulation of

gastric secretions, diarrhea, and reflex tachycardia. Vasomotor effects are flushing (warmth, redness) and sweating of the skin. Respiratory effects include elevated respiratory rate (which is normally desired). Skeletal muscle effects are muscular tension and tremors. Neurological effects include reduced deep tendon reflexes.

Interactions

Drug interactions for the analeptics are presented in [Table 14.4](#).

Dosages

For dosage information, refer to the table on p. 233.

NURSING PROCESS

ASSESSMENT

CNS stimulants are used for a variety of conditions and disorders. They have addictive potential, and so the following assessment data need to be collected before CNS stimulant use, regardless of indication: (1) a thorough medical history with attention to pre-existing diseases or conditions, especially those of the cardiovascular, cerebrovascular, neurological, renal, and hepatic systems; (2) past and current history of addictive or substance misuse behaviours; (3) complete medication profile with a listing of prescription and OTC drugs, natural health products, and any use of alcohol, nicotine, or social or illegal drugs; and (4) a complete nutritional and dietary history. Assess all these areas because of the mechanism of action of CNS stimulants, which increases pulse rate and blood pressure and can lead to seizures, intracerebral bleeding, and toxicity (due to decreased drug metabolism and excretion). Stimulation of the respiratory system is desirable, and this action is beneficial in those patients suffering from CNS depression, such as postoperatively. Improvement of attention span is beneficial for those in need of the medication, but the possibility of adverse effects requires a thorough assessment to obtain baseline information. The anorexiant action may cause complications if the drugs are used or ordered inappropriately. When these drugs are taken for appetite suppression, assess and document baseline height, weight, and dietary intake. Measure vital signs with specific attention to blood pressure and pulse rate whenever these drugs are used.

To add to the thoroughness of the assessment, include in your nursing history the following information: inquiry about lifestyle, exercise, nutritional habits and patterns (e.g., a reduction in fat-soluble vitamins, history of any type of eating disorder), educational level, previous teaching and learning successes and failures, available support structures (e.g., family and friends), self-esteem, stress levels, mental status and mental health problems (drugs may exacerbate psychosis), presence of diabetes (patients with diabetes need closer monitoring and tighter glucose control when taking stimulant medications due to increased glycogenolysis), and information regarding contraindications, cautions, and drug interactions (see [Table 14.4](#)).

NATURAL HEALTH PRODUCTS

Selected Herbal Compounds Used for Nervous System Stimulation

Common Name(s)	Uses	Possible Drug Interactions (Avoid Concurrent Use)
Ginkgo biloba, ginkgo	To enhance mental alertness; to improve memory or reduce symptoms in people with dementia	Warfarin sodium, aspirin
Ginseng	To improve mental function and concentration	Drugs for diabetes that lower blood sugar (e.g., insulin, oral hypoglycemic drugs), monoamine oxidase inhibitors
Guarana	To stimulate nervous system, suppress appetite	Adenosine, quinolones, oral contraceptives, β -blockers, iron, lithium carbonate, phenylephrine maleate (e.g., nasal spray), cimetidine, theophylline, tobacco

With drugs used for the management of ADHD, cautiously and continuously assess the patient. For pediatric patients, gather the following information during assessment: baseline weight, height, growth and development patterns, and vital signs. Complete blood counts may be ordered. Thoroughly document any changes in emotional status as well. Adults also require thorough assessment of baseline weight, height, and vital signs. Assess and document usual sleep habits and patterns so that sleep disturbances may be anticipated and managed appropriately. Atypical behaviour, loss of attention span, and history of social problems or problems in school are also important to assess and document before and during therapy for baseline comparison. For children with ADHD, parental support is important to the success of treatment; therefore, a home assessment may be needed. It is important to pay attention to and document daily dietary intake before drug therapy is initiated because of the risk of drug-related weight loss. It is also important that the pediatric patient not lose weight too rapidly or lose too much weight; a thorough nutritional and dietary assessment is needed. Cardiac assessment is important because of CNS stimulation. Blood pressure, pulse rate, heart sounds, and any history of chest pain or palpitations must be noted. Other data to gather during assessment include possible contraindications, cautions, and drug interactions (see previous discussion). Document findings and note the patient's use of any prescription drugs, OTC drugs (e.g., nasal decongestants, which are also stimulants), and natural health products, specifically ginseng and caffeine (see [Natural Health Products: Selected Herbal Compounds Used for Nervous System Stimulation](#) box, above).

The serotonin receptor agonists commonly used in the treatment of migraines are not without adverse reactions, contraindications, cautions, and drug interactions (see previous discussion). Include in the assessment a thorough cardiac history as well as measurement of blood pressure, pulse rate, and rhythm. If a patient has a history of hypertension, there is risk of further

increases in blood pressure to dangerous levels with use of these drugs—hence, the need for careful assessment and documentation. In fact, generally, these drugs are not prescribed for patients with migraines who also have coronary artery disease unless a thorough heart evaluation has been performed. Conduct a careful assessment to identify other drugs the patient is taking that might lead to significant drug interactions, such as ergot alkaloids, selective serotonin receptor inhibitors, and MAOIs. If serotonin agonists are taken within 2 weeks of the use of these drugs, there is high potential for an additive toxicity. Such toxicity would be manifested by nervousness, insomnia, cardiovascular complications, and convulsions (serotonin syndrome).

Ergot alkaloids also have cautions, contraindications, and drug interactions (see previous discussion), which you need to assess for and document. Obtain a history of the migraines and their pattern, exacerbating factors, measures that provide relief, and previous treatments.

Analeptics are used as central respiratory stimulants. This drug has the same concerns regarding contraindications, cautions, and drug interactions as all CNS stimulants do, and with analeptics, you must pay even closer attention to vital signs, especially heart rate, rhythm, and blood pressure. Any elevations in blood pressure and pulse rate may put the patient at a higher risk of complications. Perform a thorough neurological assessment with specific attention to any possibility of seizures. Assess baseline deep tendon reflexes, and document for comparative purposes.

◆ NURSING DIAGNOSES

- Decreased cardiac output resulting from the adverse effects of CNS stimulants (e.g., palpitations and tachycardia)
- Imbalanced nutrition, less than body requirements, resulting from adverse effects of CNS stimulants (e.g., amphetamines and anorexiant)
- Chronic pain resulting from the experience of or a history of migraine headaches
- Disturbed sleep patterns resulting from the action and adverse effects of CNS stimulants

◆ PLANNING

◆ Goals

- Patient will remain free of cardiac symptoms and adverse effects.
- Patient's nutritional status will remain intact and without excess weight loss.
- Patient will regain adequate comfort level with adequate and efficient management of migraines.
- Patient will experience minimal disturbed sleep patterns.

◆ Expected Patient Outcomes

- Patient vital signs, especially blood pressure (120/80) and pulse rate (60 to 100) remain within normal limits and without major fluctuations or changes.
- Patient states symptoms (e.g., palpitations, chest pain) that need to be reported to the prescriber immediately.

TABLE 14.5 Caffeine-Containing Drugs and Beverages

Medication or Beverage	Amount of Caffeine
Selected Nonprescription Medications	
Analgesics	
acetaminophen compound caplets or tablets with 8 mg codeine (Atasol®, Extrol-8®)	15–30 mg/caplet or tab
acetylsalicylic acid 325 mg with caffeine 32 mg (Anacin); acetylsalicylic acid 500 mg with caffeine 32 mg (Anacin Extra-Strength®)	32 mg/tab
acetylsalicylic acid compound tablets with 8 mg codeine (A.C. & C. Tablets)	15–30 mg/tab
acetaminophen 500 mg with caffeine 65 mg (Excedrin Extra-Strength®)	65 mg/tab
Prescription Medications (For Migraine)	
acetylsalicylic acid 330 mg, butalbital 50 mg, caffeine 40 mg, codeine phosphate 30 mg (Fiorinal C1/2®)	40 mg/tab
Beverages	
Cocoa	5–40 mg/237 mL (1 cup)
Coffee (brewed)	135 mg/237 mL (1 cup)
Coffee (decaffeinated)	3 mg/237 mL (1 cup)
Coffee (instant)	76–106 mg/237 mL (1 cup)
Cola beverage (regular)	36–46 mg/355 mL (1 can)
Cola beverage (diet)	39–50 mg/355 mL (1 can)
Tea (brewed, average blend)	43 mg/237 mL (1 cup)
Energy drinks (Red Bull®, Amp Energy®, Rockstar®, Monster Energy®)	80–100 mg/250 mL (1 can)

- Patient maintains appropriate weight, and weight loss is not too rapid, during drug therapy regimen.
- Patient regains or maintains near-normal body weight and BMI during therapy.
- Patient continues to undergo close-to-normal growth and development while taking medications.
- Patient reports a decrease in headaches, improved well-being, and participation in activities of daily living while taking medications as prescribed.
- Patient reports minimal adverse effects from antimigraine medications.
- Patient states improved quality of life with efficient and adequate self-administration of medication.
- Patient experiences more restful sleep while experiencing efficient drug therapy.
- Patient uses nonpharmacological measures to enhance sleep, such as massage, biofeedback, music therapy, relaxation breathing, and keeping the room quiet and at a comfortable temperature.

◆ IMPLEMENTATION

With drugs used for the treatment of ADHD, some pediatric patients may respond better to certain dosage forms, such as immediate release. However, dosing needs to be individualized and based on the patient's needs at different times during the school day (e.g., a noon dose to help with music lessons later in the afternoon). Well-planned scheduling of these medications and close communication among the school, teachers, school nurse, and the family and patient is very important to successful treatment. It is also important to time the dosing of medications—as ordered—for periods in which symptom control is most needed

but without causing alterations in sleep patterns. In general, once-a-day dosing is used with extended-release or long-acting preparations. Adequate and proper dosing will be manifested by good control of inattentive or impulsive behaviour during school time. If extended-release dosage forms lead to acceptable outcomes for the pediatric patient, taking medications at school may not be necessary. Often, a stigma is associated with taking medications at school. The need to do so may be avoided with the use of long-acting preparations or other scheduling. To help decrease the occurrence of insomnia, it is recommended that the last daily dose be taken 4 to 6 hours before bedtime, as ordered. During therapy, monitor the patient for continued physical growth, with specific attention to weight and height. The prescriber may order medication-free times on weekends, holidays, or vacations; that is, the drug may be discontinued periodically so that the need for the medication can be reassessed and sensitivity increased.

Because anorexiant are generally used for a short period, emphasize to the patient and all members of the patient's support system that a suitable diet, appropriate independent or supervised exercise program, and behavioural modifications are necessary to support a favourable outcome and to help the patient cease overeating and experience healthy weight loss. With a drug regimen, usually, medications are taken first thing in the morning, as ordered, to minimize interference with sleep. Therefore, it is recommended that these drugs not be taken within 4 to 6 hours of sleep. If the patient has been taking anorexiant for a prolonged period, an interval period of weaning upon discontinuation is needed to avoid withdrawal symptoms and any chance of a rebound increase in appetite. Weight must be assessed weekly or as ordered. Encourage the patient to keep a journal with a record of food intake as well as responses to the drug regimen, any adverse effects, socialization, exercise, and

mood. Dry mouth may be managed with frequent mouth care and the use of sugar-free gum or hard candy. Sucking ice chips, as well as keeping a bottle of fresh water on hand at all times, may also be helpful. If headaches occur, acetaminophen will most likely be suggested. Caffeine in any form needs to be avoided, including coffee, tea, sodas, caffeinated energy drinks, and chocolate. Other products that may contain caffeine include some OTC analgesics; OTC compounds to treat menstrual symptoms; OTC products for cough, cold, flu, or congestion; and prescription drugs such as analgesics with ergotamine and caffeine, and butalbital with aspirin and caffeine. Supplementation with fat-soluble vitamins may be indicated with use of these drugs. It is also important to watch for tolerance to the anorexiant during treatment. Other nursing considerations include emphasis on a holistic approach to the treatment of obesity, including the possible use of hypnosis, biofeedback, and guided imagery, as ordered. Encourage patients to keep follow-up visits with all those involved in their care.

SSRAs are available in a variety of dosage forms. Rizatriptan is available in a disintegrating tablet or a wafer that dissolves on the tongue. The latter dosage form leads to more rapid absorption. Use of the nasal spray or self-injectable forms of the serotonin agonists is especially desirable in patients experiencing the nausea and vomiting that may occur with migraine headaches. Self-injectable forms and nasal sprays also have the benefit of a quick onset of action—10 to 15 minutes compared with 1 to 2 hours with tablet forms. Administration of a test dose of the injectable and all other dosage forms is usually recommended. If the injectable form is prescribed, provide instructions and demonstrations of the technique. Refer to [Patient Teaching Tips](#) for more information.

Ergot alkaloids should be taken exactly as prescribed—for example, tablets need to be taken with 180 to 240 mL (6 to 8 ounces) of water or other fluid and work best when taken at the first sign of the migraine; these steps allow for more successful treatment. With ergotamine tartrate and related drugs, the maximum dose is usually 6 tablets for a single headache and 10 tablets in any 7-day period. Dependence may occur with the ergots, and if they are withdrawn suddenly, rebound headaches may occur. Encourage the patient to report to the prescriber any headaches that are uncharacteristic or unusual, as well as any persistent headache; worsening of headaches; or severe nausea, vomiting, dizziness, or restlessness. Any of the following also need to be reported immediately to the prescriber: slow, fast, or irregular heartbeat; tingling, pain, or coldness in the fingers or toes; loss of feeling in the fingers or toes; muscle pain or weakness; chest pain; severe stomach or abdominal pain; lower back pain; or little or no urine. Emphasize that the patient must seek immediate medical attention if there is any chest pain, change in vision, confusion, or slurred speech. As mentioned previously, these medications are not to be taken with triptans.

◆ EVALUATION

Therapeutic responses to drugs for ADHD include decreased hyperactivity, increased attention span and concentration, improved behaviour, and, for adults, increased effectiveness at work. Adverse effects range from loss of appetite to increased

irritability, insomnia, palpitations, nausea, and headaches. Therapeutic effects of anorexiant include appetite control and weight loss for the treatment of obesity. Adverse effects of these drugs include dry mouth, headache, insomnia, constipation, cardiac irregularities, hypertension, changes in mental status or sensorium, changes in mood or affect, alteration of sleep patterns, and seizures (all due to excessive CNS stimulation). Evaluating for any increased irritability and withdrawal symptoms (e.g., nausea and vomiting) is also important. If the anorexiant affects fat metabolism, then there may be adverse effects such as flatulence with an oily discharge, spotting, and fecal urgency. The patient also needs to be closely evaluated for decreased levels of fat-soluble vitamins (A, D, E, and K) because their levels may be affected by the decrease in absorption of fats. For drugs used to treat narcolepsy, therapeutic responses include a decrease in sleepiness. Adverse effects for which to monitor include headache, nausea, nervousness, and anxiety.

Therapeutic responses to the serotonin agonists include the aborting of migraine headache with improved daily functioning and performance because of the reduction in headaches. Adverse effects for which to monitor include pain at the injection site (if a self-injectable form is used, such pain should be temporary), flushing, chest tightness or pressure, weakness, sedation, dizziness, sweating, increase in blood pressure and pulse rate, and bad taste with the nasal spray formulation (which may precipitate nausea).

CASE STUDY

Methylphenidate for Attention Deficit Hyperactivity Disorder

Nina, a 13-year-old girl, has been diagnosed with attention deficit hyperactivity disorder. She is in Grade 7 at a local middle school and plays the clarinet in the school's after-school band. Her parents have noticed that she has had trouble focusing on assignments and music practice for the last year and have discussed her problems with Nina's pediatrician. The physician has prescribed methylphenidate

(Ritalin), 5 mg, twice a day for 2 weeks, then increasing the dose to 10 mg twice a day if no improvement is noted.

1. What are the therapeutic effects of methylphenidate?
2. After 3 weeks, Nina's mother calls the physician's office to say that Nina has been doing better at school, as reported by her morning teacher, but the band teacher has reported that Nina gets restless during after-school rehearsals. Nina's mother also reports that Nina seems unable to get to sleep at night and has been staying up too late. What should the nurse suggest?
3. At the 2-month checkup, the physician suggests that Nina's mother hold the medication on weekends, giving the drug only during the weekdays, while Nina is at school. In addition, careful height and weight measurements are taken. What is the reason for this "drug holiday," as described by the physician? What is the purpose of the height and weight measurements?
4. When it is time for a refill, Nina's mother calls the pharmacy. The pharmacist tells her, "I can't refill this medication by phone. You will need to bring in a new prescription." What is the reason for this?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

PATIENT TEACHING TIPS**General Information**

- Medications need to be taken exactly as prescribed, without skipping, omitting, or adding doses.
- Alcohol, nicotine, OTC cold products, cough syrups that contain alcohol, and caffeine-containing food items or beverages must be avoided when taking CNS stimulants.
- Keep a journal of daily activities, response to drug therapy, and any adverse effects.
- Avoid any abrupt or sudden withdrawal of medications.

Drugs Used to Treat Attention Deficit Hyperactivity Disorder

- For maximal drug effects, medications are to be taken on an empty stomach, 30 to 45 minutes before eating.
- Keeping all follow-up appointments is important to monitoring drug therapy.
- If the prescriber decides to discontinue the medication, a weaning process with careful supervision is recommended.
- Extended-release or long-acting preparations are to be taken in their original dosage form and only as directed. They are not to be crushed, chewed, broken, or altered in any way.
- Dosage amounts are not to be increased or decreased by the patient or family because this may lead to drug-related complications. If there is any concern about the drug and its dosage amount or adverse effects, encourage parents or caregivers to contact the prescriber.

Anorexiants

- The patient must follow all prescriber instructions regarding medications, diet, and exercise.
- Some of these medications may impair alertness and the ability to think, so patients need to remain cautious if engaging in activities in which their performance may be adversely affected by these impairments.
- An unpleasant taste from the medication and dry mouth may be minimized by use of mouth rinses, ice chips, sugar-free chewing gum, and hard candies.

Antimigraine Drugs

- Encourage patients who experience migraines to avoid foods or beverages that are known triggers to such headaches.
- Other triggers for some individuals may include food additives, preservatives (including monosodium glutamate, nitrates, and nitrites), artificial sweeteners (especially aspartame when consumed for extended periods of time), and chocolate.
- Before using a nasal spray dosage form of an antimigraine drug, instruct the patient to first gently blow the nose to clear the nasal passages. With the head upright, the patient then closes one nostril and inserts the nozzle into the open nostril. While a breath is taken through the nose, the spray is released. The nozzle is removed, and then the patient gently breathes in through the nose and out through the mouth for 10 to 20 seconds. The patient may experience a bad taste.

- Until a migraine is resolved, the patient may find comfort by avoiding doing things that require alertness and rapid skilled movements. It may be helpful to keep the room darkened and noise to a minimum. If the headache is not resolved or vomiting occurs, the patient may need further medical attention to help avoid additional problems, such as dehydration.
- Encourage the patient to keep a journal about the experience of all headaches, including precipitators, relievers, and the rating of each headache on a scale of 0 to 10 (where 0 is no pain and 10 is the worst pain ever). The patient should also record other symptoms (e.g., photophobia, nausea, and vomiting) as well as their frequency and duration.
- When taking SSRAs, the patient must understand the importance of contacting the physician immediately if there are any problems with palpitations, chest pain, or pain or weakness in the extremities.
- Injectable forms of sumatriptan succinate are to be given subcutaneously and as ordered. Have the patient practise administering injections (without the medication) at the prescriber's office so that proper technique is learned and a moderate comfort level is achieved.
- Autoinjectors with prefilled syringes may be used. The syringe needs to be discarded in an appropriate container or receptacle after use and kept out of the reach of children.
- Administer no more than two injections of sumatriptan succinate during a 24-hour period; at least 1 hour should be allowed between injections.
- When using injectable sumatriptan succinate, contact the prescriber or emergency services immediately if there is swelling around the eyes, pain or tightness in the chest or throat, wheezing, or heart throbbing.
- Treatment for migraine headaches may relieve the pain and symptoms of a migraine attack as well as prevent further migraine attacks. Some abortive therapies, such as sumatriptan succinate, may offer rapid relief if drugs are given as ordered and before the headache worsens. Drugs may be given orally, sublingually, or by subcutaneous injection in the thigh. When a triptan does not work, an ergot alkaloid (e.g., dihydroergotamine mesylate or ergotamine tartrate) may be ordered but is not to be used concurrently. Other drugs that may also be used for prevention of migraine headaches include antidepressants, antiseizure medications, and beta blockers.
- Serotonin agonists are to be taken as prescribed on a prn (as needed) basis at the onset of the migraine but within the frequency and dosage amount prescribed.
- Medications or foods and beverages identified as triggers to a migraine may vary from person to person. Encourage the patient to track food and beverage intake as well as sleep habits and other practices or factors that may be identified as precipitators of migraines.

KEY POINTS

- CNS stimulants are drugs that stimulate the brain and spinal cord.
- The actions of these stimulants mimic those of the neurotransmitters of the sympathetic nervous system (e.g., norepinephrine, dopamine, and serotonin).
- Sympathomimetic drugs mimic the sympathetic division of the autonomic nervous system.
- Included in the family of CNS stimulants are amphetamines, analeptics, and anorexiant, with therapeutic uses for ADHD, narcolepsy, and appetite control.
- Adverse effects associated with CNS stimulants include changes in mental status or sensorium, changes in mood or affect, tachycardia, loss of appetite, nausea, altered sleep patterns (e.g., insomnia), physical dependency, irritability, and seizures.
- Serotonin agonists may be administered as a subcutaneous injection, as a nasal spray, and as oral tablets. Any chest pain or tightness, tremors, vomiting, or worsening symptoms need to be reported to the prescriber immediately.
- Anorexiant control or suppress appetite. They are used to stimulate the CNS, and they result in the suppression of appetite control centres in the brain.
- Contraindications to the use of anorexiant, as well as other CNS stimulants, include hypersensitivity, seizure activity, convulsive disorders, and liver dysfunction.
- The SSRAs are a newer class of CNS stimulants and are used to treat migraine headaches. They are not to be given to patients with coronary artery disease.
- Amphetamines elevate mood or produce euphoria, increase mental alertness and capacity for work, decrease fatigue and drowsiness, and prolong wakefulness.
- Journals are helpful in evaluating the effects of all drugs used to treat ADHD, obesity, migraines, and narcolepsy.

EXAMINATION REVIEW QUESTIONS

1. A patient with narcolepsy will begin treatment with a CNS stimulant. The nurse expects to see which adverse effect?
 - a. Bradycardia
 - b. Nervousness
 - c. Mental clouding
 - d. Drowsiness at night
2. A patient at a weight management clinic who was given a prescription for orlistat (Xenical) calls the clinic hotline because of a “terrible adverse effect.” The nurse suspects the patient is referring to which problem?
 - a. Nausea
 - b. Sexual dysfunction
 - c. Urinary incontinence
 - d. Fecal incontinence
3. The nurse is developing a plan of care for a patient receiving an anorexiant. Which nursing diagnosis is the most appropriate?
 - a. Inadequate fluid volume
 - b. Sleep deprivation
 - c. Reduced memory
 - d. Imbalanced nutrition, more than body requirements
4. A patient has a new prescription for sumatriptan succinate (Imitrex). The nurse providing patient teaching on self-administration will include which information?
 - a. Correct technique for intramuscular injections
 - b. Take the medication before the headache worsens
 - c. Allow at least 30 minutes between injections
 - d. Take no more than 4 doses in a 24-hour period
5. The nurse is reviewing the history of a patient who will be starting the triptan sumatriptan succinate (Imitrex) as part of treatment for migraine headaches. Which condition, if present, may be a contraindication to triptan therapy?
 - a. Cardiovascular disease
 - b. Chronic bronchitis
 - c. History of renal calculi
 - d. Diabetes mellitus type 2
6. The nurse is reviewing medication therapy with the parents of an adolescent with ADHD. Which statement(s) is/are correct? (Select all that apply.)
 - a. “Be sure to have your child blow his nose before administering the nasal spray.”
 - b. “This medication is used only when symptoms of ADHD are severe.”
 - c. “The last dose should be taken 4 to 6 hours before bedtime to avoid interference with sleep.”
 - d. “Be sure to contact the physician right away if you notice expression of suicidal thoughts.”
 - e. “We will need to check your child’s height and weight periodically to monitor physical growth.”
 - f. “If adverse effects become severe, stop the medication for 3 to 4 days.”
7. The medication order reads: “Atomoxetine (Strattera) 1.2 mg/kg/day in 2 divided doses.” The child weighs 30 kg. How much will be given with each dose?
8. A patient with narcolepsy is having problems with excessive daytime sleepiness. The nurse expects which drug to be prescribed to improve the patient’s wakefulness?
 - a. phentermine (Ionamin)
 - b. almotriptan (Axert)
 - c. modafinil (Provigil)
 - d. methylphenidate (Ritalin)

CRITICAL THINKING ACTIVITIES

1. The parents of a 10-year-old boy are concerned about the effects of the medication their son is taking for ADHD. They ask, “What should we be looking for when he starts this medicine?” What is the nurse’s best response?
 2. A patient calls the headache clinic because she is unhappy about her medication. She says, “I’ve been taking zolmitriptan (Zomig) to prevent headaches, but I am still having them.” What is the nurse’s priority action?
 3. A patient who is obese is discussing options for appetite suppressant therapy and says, “I want to lose weight, but I can’t help myself—I’m hungry all the time! The doctor wants me to take a pill to stop my appetite, but I’m afraid there will be bad effects.” What is the priority action by the nurse at this time?

Antiepileptic Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Briefly describe the pathophysiology of epilepsy.
2. Discuss the rationale for the use of the various classes of antiepileptic drugs in the management of the different forms of epilepsy.
3. Identify the various drugs in each of the following drug classes: iminostilbenes, benzodiazepines, barbiturates, hydantoins, and miscellaneous drugs.
4. Identify the mechanisms of action, indications, cautions, contraindications, dosages, routes of administration, adverse effects, toxic effects, therapeutic blood levels, and drug interactions for each antiepileptic drug.
5. Develop a collaborative plan of care, including patient education, based on the nursing process for patients receiving antiepileptic drugs.

KEY TERMS

Anticonvulsants Substances or procedures that prevent or reduce the severity of epileptic or other convulsive seizures. (p. 246)

Antiepileptic drugs (AEDs) Prescription drugs that prevent or reduce the severity of epilepsy and different types of epileptic seizures, not just convulsive seizures. (p. 246)

Autoinduction A metabolic process in which a drug stimulates the production of enzymes that enhance its own metabolism over time, which leads to a reduction in therapeutic drug concentrations. (p. 252)

Convulsion A type of seizure involving excessive stimulation of neurons in the brain and characterized by the spasmodic contraction of voluntary muscles. (See also *seizure*.) (p. 245)

Electroencephalogram (EEG) A recording of the electrical activity that arises from spontaneous currents in nerve cells in the brain, derived from electrodes placed on the outer skull. (p. 245)

Epilepsy Any of a group of neurological disorders characterized by recurrent episodes of convulsive seizures, sensory disturbances, abnormal behaviour, loss of consciousness, or any combination of these. (p. 245)

Focal onset seizures originating in a more localized region of the brain. Formerly known as *partial* seizures. (p. 246)

Generalized onset seizures Seizures originating simultaneously in both cerebral hemispheres. (p. 245)

Gingival hyperplasia Overgrowth of gum tissue; often an adverse effect of phenytoin. (p. 251)

Primary epilepsy Epilepsy in which there is no identifiable cause. Also known as *idiopathic* seizures. (p. 245)

Seizure Excessive stimulation of neurons in the brain, leading to a sudden burst of abnormal neuron activity that results in temporary changes in brain function, primarily affecting sensory and motor activity. (p. 245)

Status epilepticus A medical emergency of prolonged seizure activity, that lasts for 5 minutes or longer, of continuous clinical or electrographic seizure activity or recurrent seizure activity without recovery (returning to baseline) between seizures. (p. 246)

Tonic-clonic seizures Seizures involving initial muscular contraction throughout the body (tonic phase), progressing to alternating contraction and relaxation (clonic phase). (p. 245)

DRUG PROFILES

carbamazepine, p. 252

gabapentin, p. 252

ethosuximide, p. 252

lamotrigine, p. 253

levetiracetam, p. 253

oxcarbazepine, p. 252

perampanel, p. 252

phenobarbital (phenobarbital sodium)*, p. 251

phenytoin (phenytoin sodium)*, p. 251

pregabalin, p. 253

topiramate, p. 253

valproic acid, p. 254

Key drug

* Full generic name is given in parentheses. For the purposes of this text, the more common, shortened name is used.

! HIGH-ALERT DRUG

phenytoin, p. 251

EPILEPSY

Epilepsy is a syndrome of central nervous system (CNS) dysfunction that can cause symptoms ranging from momentary sensory disturbances to convulsive seizures. It is the most common chronic neurological illness, affecting 0.6% of the Canadian population and 50 million people worldwide, approximately 60% of whom experience focal seizures (Epilepsy Canada, 2019). It results from excessive electrical activity from neurons (nerve cells) located in the superficial area of the brain known as the *cerebral cortex* or *grey matter*. The terms *seizure*, *convulsion*, and *epilepsy* are often used interchangeably, but they do not have the same meaning. A **seizure** is the excessive stimulation of the neurons in the brain, leading to a brief episode of abnormal neuron activity that results in temporary changes in brain function, primarily affecting sensory and motor activity. A seizure may lead to a convulsion. A **convulsion** is a more severe seizure characterized by involuntary spasmodic contractions of any or all voluntary muscles throughout the body, including skeletal, facial, and ocular muscles. Commonly reported symptoms include abnormal motor function, loss of consciousness, altered sensory awareness, and psychic changes. In contrast, **epilepsy** is a chronic, recurrent pattern of seizures. Often, excessive electrical discharges can be detected by an **electroencephalogram (EEG)**, which is obtained to help diagnose epilepsy. Fluctuations in the brain's electrical potential are seen in the form of waves. These waves correlate well with different neurological conditions and are used as diagnostic indicators. In the case of epilepsy, they are used to identify specific seizure subtypes.

Up to 50% of the cases of epilepsy have normal EEGs; therefore, a careful history is very important for accurate diagnosis. Other applicable diagnostic tests include skull radiography, computed tomography, and magnetic resonance imaging. These procedures help to rule out structural causes of epilepsy, such as brain tumours. In particularly severe cases, patients may be observed in a hospital setting or sleep study laboratory. This allows for continuous EEG and video monitoring to identify detailed patterns of seizure activity and to allow tailoring of an effective treatment.

Epilepsy occurs most commonly in children and older adults. Epilepsy without an identifiable cause is known as **primary epilepsy** or idiopathic epilepsy. Primary epilepsy accounts for roughly 50% of cases. Evidence indicates genetic predispositions, but these have yet to be clearly defined. Studies in the field of pharmacogenomics (see Chapter 5) are beginning to clarify genetic factors that can help optimize AED therapy. In other cases, epilepsy has a distinct cause, such as trauma, infection, cerebrovascular disorder, or other illness. This type is known as secondary or symptomatic epilepsy. The chief causes of secondary epilepsy in children and infants are developmental defects, metabolic disease, and injury at birth. Febrile seizures occur in children 6 months to 5 years of age and are caused by fever. Children usually outgrow the tendency to have such seizures, and thus they do not constitute a chronic illness. Antipyretic

Fig. 15.1 The new definition and classification of seizures and epilepsy. (Figure from Falco-Walter, J. J., Scheffer, I. E., & Fisher, R. S. (2018). The new definition and classification of seizures and epilepsy. *Epilepsy Research*, 139, 73–79. <https://doi.org/10.1016/j.epilepsyres.2017.11.015>)

drugs (e.g., acetaminophen [see Chapter 11]) are normally adequate for acute treatment.

In adults, acquired brain disorder is the major cause of secondary epilepsy. Examples include head injury, disease or infection of the brain and spinal cord, stroke, metabolic disorders, adverse drug reactions (e.g., meperidine hydrochloride [see Chapter 11], theophylline [see Chapter 38]), primary or metastatic brain tumour, or other nonspecific neurological diseases. Older adults have the highest incidence of new-onset epilepsy. Fortunately, seizures in older adults are often well controlled with drug therapy.

Seizures are classified into different categories based on their presenting features. The International League Against Epilepsy (ILAE) classifications were changed in 2017. Historically, seizures were described as *grand mal* and *petit mal*; then the terms *partial seizures* and *generalized seizures* were used to describe the types of seizures. The new classification is based on three key features: where the seizures begin in the brain, the level of awareness during the seizure, and other features of seizures. The three major classifications of seizures are generalized onset, focal onset, and unknown onset (see Figure 15.1).

Generalized onset seizures are characterized by neuronal activity that originates simultaneously in the grey matter of both hemispheres. There are several subtypes of generalized seizures. **Tonic-clonic seizures** begin with muscular contraction throughout the body (tonic phase) and progress to alternating contraction and relaxation (clonic phase). Tonic seizures involve spasms of the upper trunk, with flexion of the arms.

TABLE 15.1 Antiepileptic Drugs Used to Treat Status Epilepticus

Drug	IV Dose	Onset	Duration	Half-Life	Adverse Effects
diazepam*	5–10 mg (repeat in 2–4 hr if necessary)	3–10 min	Minutes	35 hr	Apnea, hypotension, somnolence
fosphenytoin	15–20 phenytoin equivalents/kg	15–30 min	12–24 hr	10–60 hr	Comparable to those for phenytoin (see below)
lorazepam	0.05–1 mg/kg up to a maximum of 4 mg	1–20 min	Hours	12–15 hr	Apnea, hypotension, somnolence
phenytoin	Adults: 150–200 mg Children: 250 mg/m ²	1–2 hr	12–24 hr	7–42 hr	Cardiac dysrhythmias, hypotension

*Rectal products are also available for emergency use for both adults and children of all ages.

Clonic seizures are the same as tonic–clonic seizures but without the tonic phase. Atonic seizures, also known as *drop attacks*, involve sudden global muscle weakness and syncope. Myoclonic seizures are characterized by brief muscular jerks, but that are not as extreme as in other subtypes. Finally, absence seizures involve a brief loss of awareness that commonly occurs with repetitive spasmodic eye blinking for up to 30 seconds; this type occurs primarily in childhood and rarely after 14 years of age.

Focal onset seizures originate in a localized or focal region (e.g., one lobe) of the brain. There are three types of focal onset seizures. (1) Simple focal onset seizure is characterized by brief loss of awareness (e.g., blank stare) but without loss of consciousness or spasmodic eye blinking as in absence seizures. (2) In complex focal onset seizure, the level of consciousness is reduced but is not completely lost. (3) Focal onset seizures can progress to generalized tonic–clonic seizures in up to 40% of patients. This third type is known as a secondary generalized tonic–clonic seizure. The latter two types are also associated with postictal confusion, a term for the confused mental state that follows seizure activity. Unclassified seizures are those that do not clearly fit into any of the other categories.

Seizure episodes can sometimes start off as focal and then become generalized. If the focal component is not noticed, the patient may be misdiagnosed and receive suboptimal drug therapy. Another important seizure condition is **status epilepticus**. In status epilepticus, multiple seizures occur that last for 5 minutes or longer of continuous clinical or electrographic (or both) seizure activity or recurrent seizure activity without recovery (returning to baseline) between seizures (Brophy, Bell, Classen, et al., 2012; Trinka, Cock, Hesdorffer, et al., 2015).

Status epilepticus may be precipitated by an exacerbation of a pre-existing seizure disorder, the initial manifestation of a seizure disorder, or an insult other than a seizure disorder. In patients with known epilepsy, the most common cause of status epilepticus is a change in medication. Numerous physiological changes occur with a generalized convulsive status epilepticus, due to the release of catecholamines—for example, tachycardia, cardiac arrhythmias, and hyperglycemia. This status epilepticus episode is followed by hypotension, elevated body temperature from the robust muscle activity, followed by metabolic acidosis, hypoxia, brain damage, and possibly death. Thus, status epilepticus is considered a true medical emergency and must be treated promptly and aggressively. Initially, ABCs must be maintained, followed by intravenous administration of drugs (see Table 15.1 for drugs used to treat status epilepticus).

Once status epilepticus is controlled, long-term drug therapy is started with other drugs for the prevention of future seizures.

Febrile seizures can also sometimes progress to status epilepticus. In addition to the website of the International League Against Epilepsy, other helpful websites include those of The National Institute of Neurological Disorders and Stroke <http://www.ninds.nih.gov/disorders/epilepsy/epilepsy.htm> and Epilepsy Canada www.epilepsy.ca.

ANTIEPILEPTIC DRUGS

Antiepileptic drugs (AEDs) are also called *anticonvulsants*. *Antiepileptic drugs* is a more appropriate term because many of these medications are indicated for the management of all types of epilepsy and not necessarily just for convulsions. **Anticonvulsants**, on the other hand, are medications that are used to prevent the convulsive seizures typically associated with epilepsy.

The goal of AED therapy is to control or prevent seizures while maintaining a reasonable quality of life. Approximately 70% of patients with a seizure disorder can expect to become seizure free while taking only one drug (monotherapy). The remaining 30% of cases are more complicated and often require multiple medications. Single-drug therapy must fail before multidrug therapy is attempted. Patients are normally started on a single AED, and the dosage is slowly increased until the seizures are controlled or until clinical toxicity occurs. If the first AED is not effective, the drug is tapered slowly while a second drug is introduced. AEDs are never to be stopped abruptly unless a severe adverse effect occurs.

AEDs have many adverse effects, and it is often difficult to achieve seizure control while avoiding adverse effects. In many cases, the therapeutic goal is not to eliminate seizure activity but rather to maximally reduce the incidence of seizures while minimizing drug-induced toxicity. Many patients must take these drugs for their entire lives. Treatment may eventually be stopped in some, but others will experience repeated seizures if constant levels of AEDs are not maintained in the blood. Abrupt discontinuation of these drugs can result in withdrawal seizures. In both children and adults, there is only a 40% chance of recurrence after the first focal or generalized seizure. Therefore, AED therapy is *not* recommended after a single isolated seizure event.

There are numerous AEDs available. To optimize drug selection, neurologists must consider the known efficacy of the drug for a certain type of seizure, adverse effects and drug interaction profile, cost, ease of use, and availability of pediatric dosage

forms. Many AEDs are also used to treat other types of illnesses, including migraine headaches (see Chapter 14), neuropathic pain syndromes (see Chapter 11), and mental health disorders such as depression and bipolar disorder (see Chapter 17).

Therapeutic drug monitoring (see Chapter 2) of serum drug concentrations provides a useful guideline in assessing the effectiveness of and adherence to therapy. For example, if the serum level is low, it may mean the patient is not taking the medication as prescribed. This gives the nurse an opportunity to ask about why the patient may not be taking the medication. If the level is above normal, the nurse needs to contact the prescriber before giving the next dose.

Maintaining serum drug levels within therapeutic ranges helps not only to control seizures but also to reduce adverse effects. Drugs that are routinely monitored in this way have a narrow therapeutic index (see Chapter 2). There are established normal therapeutic ranges for many AEDs, but these are only guidelines. The serum concentrations of phenytoin, phenobarbital, carbamazepine, and primidone correlate better with seizure control and toxicity than those of valproic acid, ethosuximide, and clonazepam. Each patient must be monitored and dosed individually. It may be possible to achieve maintenance at levels below or above the usual therapeutic range. The goal is to slowly titrate to the lowest effective serum drug level that controls the seizure disorder. This approach reduces the potential for adverse drug effects and drug interactions. Successful control of a seizure disorder hinges on selection of the appropriate drug class and drug dosage, avoidance of drug toxicity, and patient adherence with the treatment regimen.

The AEDs traditionally used to manage seizure disorders include barbiturates, hydantoins, and iminostilbenes, plus valproic acid. Second- and third-generation antiepileptics are also available (Table 15.2). The latter drugs may have fewer adverse effects and drug interactions than the more traditional drugs. This may benefit older adults, who are more likely to be taking multiple medications, and are therefore more prone to drug interactions. However, there is current debate in the neurological literature as to whether patients benefit more from newer than from older drugs. It is now believed that most pediatric and adult patients with epilepsy who have been seizure free for 1 to 2 years while taking AEDs can eventually stop taking them with medical supervision.

Mechanism of Action and Drug Effects

As with many classes of drugs, the exact mechanism of action of the AEDs is not known with certainty. However, evidence indicates that they alter the movement of sodium, potassium, calcium, and magnesium ions. The changes in the movement of these ions result in more stabilized and less responsive cell membranes.

The major pharmacological effects of AEDs are threefold. First, they increase the threshold of activity in the area of the brain called the *motor cortex*. In other words, they make it more difficult for a nerve to be excited, or they reduce the nerve's response to incoming electrical or chemical stimulation. Second, they act to limit the spread of a seizure discharge from its origin. They do this by suppressing the transmission of impulses from one nerve to the next. Third, they can decrease the speed of nerve impulse conduction within a given neuron.

TABLE 15.2 Currently Available Antiepileptic Drugs

Generic Name	Trade Name	Route
Traditional Antiepileptic Drugs		
Barbiturates		
phenobarbital	Generic	PO
	Generic	IV
primidone	Generic	PO
Hydantoins		
phenytoin	Dilantin, Tremytoine INJ®	PO IV
fosphenytoin	Cerebyx	IV, IM
Iminostilbenes		
Eslicarvazepine	Aptiom	PO
carbamazepine	Tegretol, Mazepine	PO
oxcarbazepine	Trileptal	PO
Miscellaneous Antiepileptic Drugs		
ethosuximide	Zarontin	PO
Brivaracetam	Brivlera	PO, IV
Perampanel	Fycompa	PO
Rufinamide	Banzel	PO
Stipwntol	Diacomit	PO
Vigabatrin	Sabril	PO
Zonisamide	Zonegran	PO
gabapentin	Neurontin	PO
lacosamide	Vimpat®	PO, IV
lamotrigine	Lamictal	PO
levetiracetam	Keppra	PO
pregabalin	Lyrica	PO
topiramate	Topamax	PO
valproic acid (divalproex sodium)	Depakene, Diprovaletx, Epival ECT	PO

Less well understood are mechanisms that involve drug effects outside the neuron. For example, some drugs may indirectly affect seizure foci (locations) in the brain by altering the blood supply to these areas. Some drugs work by enhancing the effects of the inhibitory neurotransmitter gamma-aminobutyric acid (GABA). GABA plays a role in regulating neuron excitability in the brain. Low levels of GABA are associated with seizures. Many AEDs increase GABA levels to the normal range, and thus reduce the potential for seizures. Regardless of the mechanism, the overall effect is that antiepileptics stabilize neurons and keep them from becoming hyperexcited and generating excessive nerve impulses to adjacent neurons.

Indications

AEDs are used to prevent or control seizure activity. As evidenced by the wide range of seizure disorders discussed earlier in this chapter, epilepsy is a diverse disorder. As a result, specific indications

TABLE 15.3 Common Seizure Indications for Antiepileptic Drugs

	Focal	Secondary General	Generalized Tonic–Clonic	Absence	Myoclonic
First-Line Drugs	carbamazepine	carbamazepine	carbamazepine	valproic acid	
	phenobarbital	phenobarbital	phenobarbital	ethosuximide	valproic acid
	primidone	primidone	primidone		
	phenytoin	phenytoin	phenytoin		
	fosphenytoin	fosphenytoin	fosphenytoin		
		lamotrigine	lamotrigine		
Adjunct Drugs			valproic acid		
	clonazepam	clonazepam	clonazepam	acetazolamide	clonazepam
	clorazepate	oxcarbazepine			
	oxcarbazepine	gabapentin	topiramate		
	gabapentin		zonisamide		
	perampanel				
	pregabalin	levetiracetam			
	lamotrigine	topiramate			
	levetiracetam				
	topiramate				

vary among drugs. The most recent indications are noted, drug by drug, in [Table 15.3](#), the Dosages table on p. 254, and in specific drug profiles. It is important to have an accurate diagnosis of the seizure type because some drugs may not be ideal for specific seizures. For example, it is known that carbamazepine may worsen myoclonic or absence seizures. Other evidence supports the following generalizations: Phenobarbital, phenytoin, primidone, carbamazepine, and valproic acid are equally effective for focal onset seizures. Lamotrigine, topiramate, gabapentin, and levetiracetam are all effective as adjunct therapy for refractory (not responsive to other therapy) focal onset seizures. Specific AEDs and the seizure disorders they are used to treat are listed in [Table 15.3](#).

Patients who undergo brain surgery or who have suffered severe head injuries may receive prophylactic AED therapy. These patients are at high potential for acquiring a seizure disorder, and often severe complications will arise if seizures are not controlled.

Contraindications

The only usual contraindication to antiepileptics is known drug allergy. Pregnancy is also a common contraindication; however, the prescriber must consider the risks of untreated maternal epilepsy to the mother and fetus and the increased risks for seizure activity. Many women take antiepileptics throughout their pregnancy. The newer-generation AEDs appear to be safer in pregnancy than the traditional drugs.

Adverse Effects

Antiepileptics have numerous adverse effects that often limit their usefulness. Many patients cannot tolerate the adverse

effects, and therapy must be withdrawn. Skin rashes and immune reactions (e.g., Stevens-Johnson syndrome) are extremely common in patients taking AEDs. Birth defects in the infants of mothers who have epilepsy are higher than normal, regardless of whether the mother was receiving drug therapy. Women with epilepsy need to be monitored closely during pregnancy by both an obstetrician and a neurologist. Each AED is associated with its own diverse set of adverse effects. The various AEDs and their most common adverse effects are listed in [Table 15.4](#).

Interactions

Drug interactions that can occur with AEDs are numerous and are summarized in [Table 15.5](#). Many of the AEDs can interact with each other, requiring close monitoring of the patient. Since many of these drugs induce hepatic metabolism, the effects of other drugs may be reduced, including oral contraceptives. There is a prime opportunity to counsel the patient about the need for alternative birth control methods due to reduced efficacy. Carbamazepine is not to be given with grapefruit because this leads to increased toxicity of the AED.

Dosages

For certain AEDs, the therapeutic range is narrow. Drugs that have a narrow difference between safe and toxic levels are called *narrow therapeutic index (NTI) drugs*. [Table 15.6](#) lists the various drugs for which monitoring of therapeutic plasma levels is required as well as their corresponding therapeutic levels. For dosage information, refer to the table on p. 255.

TABLE 15.4 Adverse Effects of Selected Antiepileptic Drugs

Drug or Drug Class	Adverse Effects
Barbiturates: phenobarbital, primidone	Dizziness, drowsiness, lethargy, paradoxical restlessness
Hydantoin: phenytoin, fosphenytoin	Nystagmus, ataxia, drowsiness, rash, gingival hyperplasia, thrombocytopenia, agranulocytosis, hepatitis
Iminostilbenes: carbamazepine, oxcarbazepine	Nausea, headache, dizziness, unusual eye movements, visual change, behavioural changes, rash, abdominal pain, abnormal gait
valproic acid and derivatives, including valproate sodium and divalproex sodium	Dizziness, drowsiness, gastrointestinal upset, weight gain, hepatotoxicity, pancreatitis
gabapentin	Dizziness, drowsiness, nausea, visual and speech changes, edema
perampanel	Dizziness, drowsiness
pregabalin	Dizziness, drowsiness, peripheral edema, blurred vision
lamotrigine	Drowsiness, ataxia, headache, benign skin rashes, nausea, blurred or double vision
levetiracetam	Dizziness; drowsiness; hyperactivity; behaviour changes such as anxiety, hostility, agitation, or suicidal ideation; incoordination
Succinimides: ethosuximide	Nausea, abdominal pain, dizziness, drowsiness
topiramate	Dizziness, drowsiness, GI upset, ataxia

TABLE 15.5 Significant Drug Interactions of Antiepileptic Drugs

AED Drug or Drug Class	Interacting Drug	Mechanism	Results
Barbiturates			
	β -blockers, corticosteroids (e.g., prednisone), oral contraceptives, dihydropyridine, calcium channel blockers, metronidazole, quinidine, theophylline	Altered CYP450 enzyme metabolism	Reduced effects of listed drugs
	ethanol (alcohol)	Enhanced CNS depression	Can be fatal
Hydantoins			
phenytoin	amiodarone, benzodiazepines, azole antifungals, isoniazid, proton pump inhibitors, sulfonamide antibiotics, SSRIs	Altered CYP450 enzyme metabolism	Reduced hydantoin clearance and increased effects
	carbamazepine	Altered CYP450 enzyme metabolism	Increased hydantoin clearance and reduced effects
	cyclosporine, loop diuretics, meperidine, methadone, rifampin, quinidine, quetiapine, theophylline	Increased metabolism	Reduced effects of listed drugs
	warfarin sodium	Displacement of warfarin from plasma protein binding sites	Increased free warfarin levels and bleeding risk
Iminostilbenes			
carbamazepine	Azole antifungals, diltiazem, isoniazid, macrolides, protease inhibitor antiretrovirals, SSRIs, valproic acid, verapamil	Altered CYP450 enzyme metabolism	Increased carbamazepine levels and toxicity risk
	Barbiturates, hydantoins, rifampin, succinimides, theophylline	Altered CYP450 enzyme metabolism	Reduced carbamazepine levels and efficacy
	acetaminophen	Altered CYP450 enzyme metabolism	Increased hepatic metabolism of acetaminophen and toxicity risk, and reduced efficacy
	Antipsychotics, antidepressants, benzodiazepines, cyclosporine, oral contraceptives	Altered CYP450 enzyme metabolism	Reduced efficacy; patient response must be monitored
	Monoamine oxidase inhibitors (MAOIs)	Altered CYP450 metabolism	Increased MAOI toxicity risk

TABLE 15.5 Significant Drug Interactions of Antiepileptic Drugs—cont'd

AED Drug or Drug Class	Interacting Drug	Mechanism	Results
oxcarbazepine	Barbiturates, hydantoins	Altered CYP450 enzyme metabolism	Increased barbiturate and hydantoin levels and reduced oxcarbazepine levels
	valproic acid, verapamil	Altered CYP450 enzyme metabolism	Reduced oxcarbazepine levels
	lamotrigine	Altered CYP450 enzyme metabolism	Reduced lamotrigine levels
	Oral contraceptives	Altered CYP450 enzyme metabolism	Reduced oral contraceptive levels and increased likelihood of pregnancy
Valproic Acid and Derivatives			
valproic acid and divalproex sodium	aspirin	Displacement of valproic acid from plasma protein binding sites	Increased free valproic acid levels and toxicity risk
	carbamazepine, oxcarbazepine, lamotrigine	Altered CYP450 enzyme metabolism	Reduced valproic acid efficacy; increased lamotrigine levels; increased or decreased carbamazepine levels
	lorazepam	Altered hepatic metabolism	Increased lorazepam toxicity risk
	rifampin	Altered CYP450 enzyme metabolism	Reduced valproic acid efficacy
	Tricyclic antidepressants	Altered CYP450 enzyme metabolism	Increased tricyclic antidepressant toxicity risk
Succinimides			
ethosuximide	Hydantoins, barbiturates, valproic acid	Altered CYP450 enzyme metabolism	Increased or reduced involved drug clearance
Miscellaneous AEDs			
gabapentin	Alcohol	Additive CNS depression	Increased CNS depression
perampanel	Carbamazepine, phenytoin, oxcarbazepine	Altered CYP450 enzyme metabolism	Reduced perampanel levels by up to 67%
pregabalin	None listed		
lamotrigine	Hydantoins, oral contraceptives, oxcarbazepine, rifampin	Altered CYP450 enzyme metabolism	Reduced lamotrigine levels and efficacy; may need dosage increase
lamotrigine	CNS depressants	Additive effects	Increased CNS depression
lamotrigine	valproic acid	Altered CYP450 enzyme metabolism	Increased lamotrigine levels and toxicity risk; may need dosage reduction
levetiracetam	None listed		
topiramate	carbamazepine, hydantoins, valproic acid, oral contraceptives	Altered CYP450 enzyme metabolism	Reduced object drug activity

TABLE 15.6 Therapeutic Plasma Levels of Antiepileptic Drugs With a Narrow Therapeutic Range

Antiepileptic Drug	Therapeutic Plasma Level (mcg/mL)
carbamazepine	4–12
phenobarbital	15–30
phenytoin	10–20
primidone	5–12
valproic acid	50–100

DRUG PROFILES

In most children and adults, epilepsy can be controlled with a first-line AED such as carbamazepine (Tegretol®), phenobarbital, phenytoin (Dilantin®), or valproic acid (Depakene®, Diproval®). For patients who do not respond to these first-line

AEDs, there are a number of second-line or adjunct AEDs that are used occasionally, such as ethosuximide (Zarontin®); primidone; the benzodiazepines diazepam (Valium®), clonazepam (Clonapam®, Rivotril®), and clonazepam dipotassium (see Chapter 17); and the diuretic acetazolamide (see Chapter 29).

After valproic acid was introduced in 1978, no major new drugs for the treatment of epilepsy were introduced in Canada until the 1990s. Gabapentin (Neurontin®) and lamotrigine were approved during this decade. These two drugs are used primarily as add-on drugs in adults who have focal seizures alone or with secondary generalized seizures. AEDs most recently approved include levetiracetam (Keppra®), topiramate (Topamax®), and pregabalin (Lyrica®). These drugs fall under the miscellaneous category of antiepileptics and have greatly expanded the options currently available to patients with seizure disorders. Common adverse effects and drug interactions are listed in the individual drug profiles and in Tables 15.3 and 15.4. For dosage information, see the table on p. 255.

Barbiturates

phenobarbital sodium and primidone

Historically, two of the most commonly used AEDs were the barbiturates phenobarbital and primidone. Primidone is metabolized in the liver to phenobarbital and phenylethylmalonamide, both of which have anticonvulsant properties. Use of primidone can provide anticonvulsant activity with a lower serum level of phenobarbital than that attained with phenobarbital alone. This combination can reduce the likelihood of sedation and fatigue associated with phenobarbital. Phenobarbital is a Schedule IV controlled substance, whereas primidone is not controlled. Phenobarbital has been used since 1912, principally for controlling tonic-clonic and focal seizures. Phenobarbital is used for the management of status epilepticus and is an effective prophylactic drug for the control of febrile seizures. Although phenobarbital is still used to treat seizure emergencies, the use of oral phenobarbital for seizure prevention is much less common. In developing countries, oral phenobarbital is often the drug of choice for routine seizure prophylaxis because of its low cost. The most common adverse effect of phenobarbital is sedation, although tolerance to this effect usually develops with continued therapy. Therapeutic effects are generally seen at serum drug levels of 15 to 40 mcg/mL (in children, 15 to 30 mcg/mL). A major advantage of this drug is its long half-life, which allows once-a-day dosing. This can be a substantial advantage for patients who have a difficult time remembering to take their medication or for those who have erratic schedules. Even if a patient takes a dose 12 or even 24 hours late, therapeutic blood levels may still be maintained. Contraindications include known drug allergy, porphyria (a disorder of the synthesis of heme, a component of hemoglobin), liver or kidney impairment, and respiratory illness. Adverse effects include cardiovascular, CNS, gastrointestinal (GI), and dermatological reactions (see Table 15.4). Phenobarbital interacts with many drugs because it is a major inducer of hepatic microsomal enzymes, including the cytochrome P450 system enzymes (see Chapter 2), which causes more rapid clearance of some drugs (see Table 15.5). Phenobarbital is available in oral and injectable forms, whereas primidone is available only for oral use.

PHARMACOKINETICS (Phenobarbital Sodium)

PO	Unknown	3–4 hr	10–12 hr*	Unknown

*Longer for active metabolites, including phenobarbital.

Hydantoins

phenytoin sodium and fosphenytoin

Phenytoin sodium (Dilantin) has been used as a first-line drug for seizures for many years and is the prototypical drug. It is indicated for the management of tonic-clonic and focal seizures. Contraindications include known drug allergy and heart conditions that involve bradycardia or blockage of electrocardiac function. Adverse effects and drug interactions are both numerous and are listed in Tables 15.4 and 15.5, respectively. The most common adverse effects are lethargy, abnormal movements, mental confusion, and cognitive changes. **Gingival hyperplasia** is a well-known adverse effect of long-term oral phenytoin therapy. Scrupulous dental care can help prevent gingival hypertrophy. In addition to gingival hyperplasia, long-term phenytoin therapy can cause acne, hirsutism, and hypertrophy of subcutaneous facial tissue, resulting in an appearance known as *Dilantin facies*. Another long-term consequence of phenytoin therapy is osteoporosis. Vitamin D therapy may help to prevent this condition, particularly in women. Therapeutic drug levels are usually 10 to 20 mcg/mL. At toxic levels, phenytoin can cause nystagmus, ataxia, dysarthria, and encephalopathy. Phenytoin can interact with other medications, for two main reasons. First, it is highly bound to plasma proteins and competes with other highly protein-bound medications for binding sites. Second, it induces liver microsomal enzymes, mainly the cytochrome P450 enzymes (see Chapter 2). This increases the metabolism of other drugs that are metabolized by these enzymes and reduces their blood levels.

Exaggerated phenytoin effects can be seen in patients with extremely low serum albumin concentrations. This effect most commonly occurs in patients who are malnourished or have chronic kidney failure. In these patients, it may be necessary to maintain phenytoin levels well below 80 $\mu\text{mol/L}$. With lower levels of albumin in a patient's body, more of the free, unbound, pharmacologically active phenytoin molecules will be present in the blood.

Phenytoin has many advantages for long-term therapy. It is highly effective, relatively inexpensive, and usually well tolerated. It can also be given intravenously if needed. Most often, however, phenytoin is taken orally. The long half-life allows twice- or even once-daily drug therapy. If a patient has to remember to take medication only once or twice a day, adherence will be increased and thus the likelihood of therapeutic drug levels being reached is increased, leading to better seizure control.

Parenteral phenytoin is adjusted chemically to a pH of 12 for reasons of drug stability. It is extremely irritating to veins when injected and must be given by a slow intravenous (IV) push (not exceeding 50 mg/min in adults), directly into a large vein through a large-gauge needle (20-gauge or higher) venous catheter. Phenytoin is only to be diluted in normal saline (NS) for IV infusion, and a filter must be used. Follow each dose with an injection of saline flush to avoid local venous irritation. Soft-tissue irritation and inflammation can occur at the site of injection, with or without extravasation. This can vary from slight tenderness to extensive necrosis and sloughing, and, in rare

instances, can require amputation. Avoid improper administration, including subcutaneous or perivascular injection, to help prevent the possibility of such occurrences.

Fosphenytoin (Cerebyx®) is an injectable prodrug of phenytoin that was developed to overcome some of the chemical disadvantages of phenytoin injectable. Fosphenytoin is a water-soluble phenytoin derivative that can be given intramuscularly or intravenously—by IV push or continuous infusion—without causing the burning on injection associated with phenytoin. Fosphenytoin is dosed in phenytoin equivalents (PE), as indicated in Table 15.7. Fosphenytoin is given at a rate of 150 mg/min or less to avoid hypotension or cardiorespiratory depression. If dysrhythmias or hypotension occurs, discontinue the infusion. Implement fall prevention measures after infusion of either phenytoin or fosphenytoin because of possible ataxia and dizziness. Take vital signs up to 2 hours after infusion. Check available references or consult with a pharmacist before administering because there are numerous IV incompatibilities with both drugs.

PHARMACOKINETICS (Phenytoin Sodium)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action

IV	1–2 hr	2–3 hr	7–42 hr	12–24 hr

Iminostilbenes

carbamazepine

Carbamazepine (Mazepine®, Tegretol) is the second-most commonly prescribed AED in Canada, after phenytoin. It was marketed in the late 1960s for the treatment of epilepsy after its efficacy and safety were proven for the treatment of trigeminal neuralgia (a painful facial nerve condition). It is chemically similar to the tricyclic antidepressants (see Chapter 17) and is considered a first-line treatment for focal seizures and generalized tonic-clonic seizures. It may worsen myoclonic or absence seizures. Therefore, its use is contraindicated in both of these conditions as well as in cases of known drug allergy and bone marrow depression. Carbamazepine is associated with **autoinduction** of hepatic enzymes. Autoinduction is a process in which, over time, a drug stimulates the production of enzymes that enhance its own metabolism, which leads to lower-than-expected drug concentrations. With carbamazepine, this process usually occurs within the first 2 months after the start of therapy. Carbamazepine has numerous adverse reactions and drug interactions; examples are given in Tables 15.4 and 15.5. It is available for oral use only.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Slow	4–8 hr	25–65 hr	12–24 hr

oxcarbazepine

Oxcarbazepine (Trileptal®) is a chemical analogue of carbamazepine. Its precise mechanism of action has not been

identified, although it is known to block voltage-sensitive sodium channels, which aids in stabilizing excited neuronal membranes. It is indicated for focal seizures and secondary generalized seizures. Contraindications include known drug allergy. Common adverse reactions include headache, dizziness, and nausea (see also Table 15.4). Unlike carbamazepine, this drug is not a hepatic enzyme inducer. As a result, it is associated with far fewer common drug interactions than carbamazepine is (see Table 15.5). Oxcarbazepine is available for oral use only.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	2–4 hr	2–3 days	2–9 hr	Unknown

Succinimide

ethosuximide

Ethosuximide (Zarontin) is used in the treatment of uncomplicated absence seizures. It is not effective for secondary generalized tonic-clonic seizures. The only listed contraindication for either use is known allergy to succinimides. Adverse effects include GI and CNS effects (see Table 15.4). Drug interactions most commonly involve hepatic enzyme-inducing drugs (see Table 15.5). Succinimides are available for oral use only.

PO	Unknown	4 hr	60 hr	Unknown

Miscellaneous Drugs

gabapentin

Gabapentin (Neurontin) is a chemical analogue of GABA, a neurotransmitter that inhibits brain activity. The exact mechanism of action of gabapentin is unknown. Many believe that it works by increasing the synthesis and accumulation of GABA between neurons; hence, the drug name. It is indicated as an adjunct drug for the treatment of focal seizures and for prophylaxis of focal seizures. Evidence also shows gabapentin to be effective as single-drug therapy for new-onset epilepsy. It is most commonly used to treat neuropathic pain (see Chapter 11). Contraindications include known drug allergy. Adverse effects include CNS and GI symptoms (see Table 15.4). Drug interactions are listed in Table 15.5. Gabapentin is available for oral use only.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Unknown	Unknown	5–7 hr	Unknown

perampanel

Perampanel (Fycompa®) is a selective, noncompetitive antagonist of the ionotropic alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) glutamate receptor on postsynaptic neurons, although its precise mechanism is still unknown. Glutamate is the excitatory neurotransmitter in the brain; elevated levels of glutamate have been suspected to trigger seizure activity. Perampanel reduces the neuronal hyperexcitation associated with seizures by targeting glutamate activity. As it binds to the postsynaptic AMPA receptors, perampanel does not directly block glutamate from binding but inhibits activation of the receptor. The drug is indicated as adjunct therapy for focal seizures. Adverse drug reactions are primarily CNS related (see Table 15.4). No clinically significant drug interactions are listed to date; however, as with all AEDs, the potential for additive CNS depression exists when other sedating drugs are used. It is contraindicated in individuals with severe liver or kidney disease. Perampanel is available for oral use only.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Unknown	1 hr	105 hr	Unknown

pregabalin

Pregabalin (Lyrica), like gabapentin, is structurally similar to the inhibitory neurotransmitter GABA. However, it does not bind to GABA receptors but rather to the α_2 -delta receptor sites, which affect calcium channels in CNS tissues. Its mechanism of action is still not fully understood. The drug is indicated as adjunct therapy for focal seizures, although it is most commonly used for neuropathic pain (see Chapter 11) and postherpetic neuralgia (see Chapter 45). Contraindications include known drug allergy. Adverse drug reactions are primarily CNS related (see Table 15.5). No clinically significant drug interactions are listed to date; however, as with all AEDs, the potential for additive CNS depression exists when other sedating drugs are used. Pregabalin is available for oral use only.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Unknown	1.5 hr	6 hr	Unknown

lamotrigine

Lamotrigine (Lamictal®) is indicated for simple or complex focal seizures, for generalized seizures similar to Lennox-Gastaut syndrome (an atypical form of absence epilepsy that may persist into adulthood), and, most recently, for primary generalized tonic-clonic seizures. It is also used for the treatment of bipolar disorder. It has no known contraindications other than drug allergy. Common adverse effects include relatively minor CNS and GI symptoms (see Table 15.4) and dermatological emergencies such as Drug Reaction with Eosinophilia and Systemic

Symptoms (DRESS). DRESS is a drug reaction that has a long latency period between when the drug was started and onset of symptoms (>2 weeks). Patients have a fever and rash and usually have one internal organ involvement, most often the liver. Another potentially serious adverse effect is a rash that can progress to the major dermatological reaction known as Stevens-Johnson syndrome. This condition involves inflammation and sloughing of skin, potentially over the entire body, in a manner that resembles a third-degree burn. It is often reversible but can also be fatal. To avoid this condition, doses are slowly titrated over several weeks. Drug interactions chiefly involve other AEDs as well as other CNS depressants and oral contraceptives (see Table 15.5). Lamotrigine is available for oral use only.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Unknown	1.4–2.3 hr	24 hr	Unknown

levetiracetam

Levetiracetam (Keppra) is indicated as adjunct therapy for focal seizures with and without secondary generalization. It is contraindicated in cases of known drug allergy. Its mechanism of action is unknown. It is generally well tolerated, with the most common adverse effects being CNS related (see Table 15.4). No drug interactions are currently listed; however, like all AEDs, the potential for excessive CNS depression exists when it is used in combination with other sedating drugs. Levetiracetam is available in both oral and injectable forms.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Rapid	1 hr	6–8 hr	Unknown

topiramate

Topiramate (Topamax) is a structurally unique drug that's chemically similar to fructose. It is indicated as adjunct therapy for focal and secondary generalized seizures, for generalized tonic-clonic seizures, and for drop attacks in Lennox-Gastaut syndrome. Contraindications include known drug allergy. Its exact mechanism of action is unknown. Common adverse effects are primarily CNS related (see Table 15.4). Angle-closure glaucoma can also occur, and the patient must immediately report any visual changes. Common drug interactions involve chiefly other AEDs and oral contraceptives (see Table 15.5). Topiramate is available for oral use only. There is an increased risk of cleft palate in infants born to mothers who were taking topiramate during pregnancy.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Unknown	2–4 hr	21 hr	Unknown

valproic acid

Valproic acid (Epival®) is used primarily in the treatment of generalized seizures (absence, myoclonic, and tonic-clonic). It is also used for bipolar disorder (see [Chapter 17](#)) and has been shown to be effective in controlling focal seizures. Contraindications include known drug allergy, liver impairment, and urea cycle disorders (genetic disorders of urea metabolism). Common adverse effects include drowsiness; nausea, vomiting, and other GI disturbances; tremor; weight gain; and transient hair loss (see [Table 15.4](#)). The most serious adverse effects are hepatotoxicity and pancreatitis. Valproic acid can interact with many medications (see [Table 15.5](#)). The main reasons for these interactions are protein binding and liver metabolism. It is highly bound to plasma proteins and competes with other highly protein-bound medications for binding sites. It also is metabolized by hepatic microsomal enzymes and competes for metabolism with other drugs. In contrast to phenobarbital and phenytoin, it is not a hepatic enzyme inducer. It is available in both oral and injectable forms. Valproic acid is chemically the simplest dosage form and is available as an oral syrup and tablet.

NURSING PROCESS

ASSESSMENT

With the use of any of the AEDs, perform a thorough physical assessment and obtain a comprehensive health and medication history, so that any possible allergies, drug interactions, adverse reactions, cautions, and contraindications can be indicated. Include an assessment for Steven-Johnson syndrome, a serious immune reaction that occurs about 1 to 3 weeks after a drug is started. It produces mucosal lesions and usually multiple blisters and is often preceded by fever, sore throat, chills, and malaise. Thoroughly review the patient's medical history and note any type of seizure disorder; precipitating events; and the duration, frequency, and intensity of the seizure activity. Also assess for the occurrence of any other problems or signs and symptoms occurring before, during, or after the seizure. Question the patient about the occurrence of panic attacks because of the possible association between high levels of anxiety or stress and the precipitation of seizures in those at risk. Assess the patient for signs and symptoms of autonomic nervous system responses associated with anxiety or stress, such as cold, clammy hands, excessive sweating (diaphoresis), agitation, and trembling of the extremities. Additional assessment about other problems or symptoms is important because some antiepileptic medications may be indicated for other medical diagnoses, such as prevention of migraines or treatment of postherpetic neuralgia and neuropathic pain. A complete neurological assessment with documentation of baseline CNS functioning is also important before administering AEDs. This may

include testing and grading the response of deep tendon reflexes; bilateral and upper and lower extremity sensory and motor testing; and questioning about the presence of any headaches, photosensitivity, auras, or visual changes.

Before giving these drugs, review the laboratory test results, which may include the results of red blood cell and white blood cell counts, clotting studies, and kidney or liver function studies. Knowing baseline levels of these laboratory values is important to help identify any initial abnormalities as well as to provide a comparison value when assessing for possible adverse effects, cautions, contraindications, and interactions. Assess urinary output (expected output is at least 30 mL/hr) and urine specific gravity to gain baseline kidney function as these drugs are contraindicated in patients with a potential for, or who are in, kidney failure. Conditions other than epilepsy or seizure disorders may also cause loss of, or alterations in, consciousness and are worthy of consideration during assessment. These conditions include syncope, breath-holding practices, transient ischemic attacks, drug use, metabolic disorders, infections, head trauma, tumours, and psychogenic problems. Therefore, an attempt will most likely be made to rule out or eliminate many of these disorders or conditions during the diagnosing of epilepsy, and therein lies the importance of analyzing all available points of data. An EEG may also be ordered to provide more information regarding the diagnosis of epilepsy. Another diagnostic procedure, magnetic resonance imaging, may be performed for neuroimaging and further data gathering.

The use of a succinimide, such as ethosuximide, requires assessment for the specific indication for this medication, that is, generalized absence seizures. In addition to performing a baseline neurological assessment, ask the patient about any problems with nausea, abdominal pain, or dizziness. Always assess for any allergies to this drug.

The miscellaneous drug topiramate is a more recently approved AED and has significant contraindications, cautions, and drug interactions (previously discussed in the pharmacology section in this chapter and summarized in [Tables 15.4](#) and [15.5](#)). Assess vital signs and mental status with attention to the patient's sensorium; level of alertness or consciousness; and any mental depression before, during, and after drug therapy and seizure activity. Document any of the following baseline problems if administering tiagabine or topiramate: dizziness, drowsiness, GI upset, ataxia, or agitation.

If barbiturates have been ordered, carefully assess not only the patient's neurological system but also vital signs because of the CNS depression associated with this class of drugs. Obtain and document all of the aforementioned general assessment data when barbiturates are prescribed. For safety concerns, identify patients at high potential for excessive sedation, such as older adults and those with renal, neurological, and hepatic dysfunction. In both acute care facilities and community settings, assess the room and environment to ensure that safety measures are in place (e.g., side rails up or use of a bed alarm system, depending on facility policy). Also ensure that noise level is controlled, and seizure precautions are available (oxygen, suctioning equipment, and airway devices nearby;

Dosages

Selected Antiepileptic Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications
 carbamazepine (Mazepine, Tegetrol)	Iminostilbene	<i>Children (6–12 yr)</i> PO: 35mg/kg/day in divided doses; 100–1000 mg/day (to best response) <i>Adults/Children over 12 yr</i> PO: 800–1200 mg/day	Focal, secondary generalized, generalized tonic–clonic seizures
ethosuximide (Zarontin)	Succinimide	<i>Children</i> PO: 20–40mg/kg/day; 3–6 yr, 250 mg/day then adjust; older than 6 yr, 500 mg/day then adjust <i>Adults</i> PO: 500 mg/day then adjust	Absence seizures
 fosphenytoin (Cerebyx)	Hydantoin	<i>Children</i> IV: 15–20 PE*/kg loading dose; may begin maintenance dosing 8–12 hr later using child phenytoin dosing guidelines (see below) <i>Adults</i> IV: 15–20 PE*/kg loading dose; maintenance dose 4–6 PE/kg/day	Control of generalized convulsive status epilepticus
 gabapentin (Neurontin)	GABA analogue	<i>Children</i> Not recommended <i>Adults</i> PO: over 18 yr, 900–1800 mg/day	Adjunctive therapy for focal seizures
lamotrigine (Lamictal)	Miscellaneous	<i>Children</i> PO: 2–12 yr, 1–5 mg/kg/day depending on other AEDs used <i>Adults</i> PO: 100–200 mg/day	Focal, secondary generalized, generalized tonic–clonic seizures; seizures associated with Lennox-Gastaut syndrome
levetiracetam (Keppra)	Miscellaneous	<i>Adults</i> PO: 500 mg bid–3000 mg/day	Focal, secondary generalized seizures
oxcarbazepine (Trileptal)	Iminostilbene	<i>Children (6–16 yr)</i> PO: 8–10 mg/kg/day divided bid; max 600 mg/day <i>Adults</i> 300–600 mg bid	Adjunctive therapy, monotherapy of focal seizures
 phenobarbital (oral, injectable)	Barbiturate	<i>Children</i> PO: Initial dosing (Oral/IV) for seizures Infants/children under 5: 3–5 mg/kg/day in 1–2 divided doses Children 5 and up: 2–3 mg/kg/day in 1–2 divided doses Adolescents: 1–3 mg/kg/day in 1–2 divided doses IV: 20 mg/kg over 20 min <i>Adults</i> PO: 50–100 mg bid or tid/day IV: 20 mg/kg at 50–75 mg/min	Focal, secondary generalized, generalized tonic–clonic seizures, prophylaxis for febrile seizures Status epilepticus Focal, secondary generalized, generalized tonic–clonic seizures Status epilepticus

*150 mg fosphenytoin sodium = 100 mg phenytoin sodium.

padded side rails being used; and IV access per facility policy). Note the patient's age because extremely young patients and older adults react with more sensitivity to these drugs, with paradoxical reactions, irritability, and hyperactivity (as

compared to CNS depressant effects). Cautions, contraindications, and drug interactions were previously discussed earlier in the chapter.

With hydantoins like phenytoin, the previously mentioned assessment data are also appropriate. Perform a skin assessment and document intactness and the presence or absence of any rashes because of the possibility of a measles-like rash. In addition, baseline dental hygiene habits and an oral assessment, including the status of the patient's gums and teeth, are important because of the adverse effects of gingival hyperplasia. Assessment of baseline neurological functioning is crucial with the use of these CNS-altering medications and needs to include the following: (1) a focus on vision with attention to any abnormalities, especially in regard to eye movement; (2) baseline neuromuscular stability with attention to coordinated movements, gait, and reflexes; and (3) assessment of speech for clarity and ability to form

and express words appropriately. In addition, when phenytoins are taken, baseline liver function studies and complete blood cell counts (CBCs) are needed. Attention must also be given to specific drug-related cautions, contraindications, and drug interactions.

Before administering carbamazepine, an iminostilbene, a CBC is often ordered. Document these laboratory findings for baseline comparisons because of the possible adverse effect of drug-related anemias (e.g., aplastic anemia). Measure baseline vision and any abnormalities because of the potential visual changes. Significant contraindications include conditions involving bone marrow suppression because it is an adverse effect (though rare).

Gabapentin requires a thorough neurological assessment with attention to baseline energy levels, visual intactness, sensory and motor functioning, and any changes in speech. It is also important to understand the rationale for gabapentin's use so that appropriate education and instructions can be shared with the patient and family. For example, gabapentin may be used for seizure therapy, but it is also used to treat postherpetic neuralgia and neuropathic pain and to prevent migraines. Thus, an individualized plan of care with proper education needs to be developed from the appropriate assessment data. Pregabalin is similar to gabapentin and requires the same assessment.

Valproic acid requires a careful assessment as well. Gather and document information about the patient's medical history, medication profile, and neurological system, with information about seizure activity (see previous discussion). Assessment for drug allergies, cautions, contraindications, and drug interactions has been previously discussed. Other assessment areas include baseline weight, liver function studies, and notation of a history of pancreatitis.

Lamotrigine use requires a thorough neurological assessment and documentation of baseline energy levels, vision acuity, and history of headaches for comparative purposes due to the common adverse effects of headaches, vision changes, and drowsiness. Several newer miscellaneous AEDs are available, such as levetiracetam, topiramate, and pregabalin. These miscellaneous drugs require the same thorough, general assessment as other AEDs do. A few additional points must be kept in mind. For example, in patients taking levetiracetam, you must document the presence of any neuropsychiatric symptoms because of the potential for drug-related agitation, depression, anxiety, and other mood or behavioural changes. Although these adverse effects are rare, the assessment data must still be thorough. One interesting fact, as noted in the pharmacology section, is the lack of drug interactions with levetiracetam; however, because all AEDs depress the CNS in some manner, assessment for the use of other CNS-depressant drugs is important to note. In addition, assess liver and kidney functioning before therapy is initiated. Topiramate is used not only for management of seizures but also for other indications such as cluster headaches and neuropathic pain. Therefore, include a thorough review of the medical and medication history in the assessment to understand the reason for the drug's use. Document energy levels as well.

CASE STUDY

Medications for Seizures

Nahla, a 21-year-old patient, has been brought to the emergency department in status epilepticus. Measures are taken to ensure her safety and prevent injury, and an intravenous (IV) line is started. The emergency department physician has ordered lorazepam (Ativan) 2 mg IV q 2 minutes until seizure resolution (0.1 mg/kg 4 mg max), STAT.

1. Lorazepam is given as a first-line drug for status epilepticus for both pediatric and adult patients with a patent IV line. What other medications can also be given for patients experiencing status epilepticus?
2. In addition to giving lorazepam, Nahla is also given oxygen. Provide the rationale for why oxygen therapy is important during this phase of status epilepticus.
3. Soon after IV lorazepam is given, Nahla's seizures stop, she regains consciousness, and she is admitted to a medical-surgical unit. What seizure precautions should the nurse follow?
4. After 4 months postdischarge, the patient's mother calls to report that Nahla has seemed "very sad lately" and has not wanted to join her friends for evenings out. "Nahla just goes to work, then comes home and stays in her room." What is the priority in this situation?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

NURSING DIAGNOSES

- Inadequate knowledge about and minimal experience with the use of AEDs
- Nonadherence with the therapeutic regimen resulting from patient's misuse of drugs or lack of understanding about the seizure disorder and its treatment
- Chronic low self-esteem regarding diagnosis of a lifelong disease and the adverse effects associated with AEDs
- Potential for injury resulting from decreased sensorium and CNS depression associated with the actions and adverse effects of AEDs

PLANNING

Goals

- Patient will demonstrate adequate knowledge about diagnosis and associated drug therapy.
- Patient will remain compliant with the therapy regimen, avoid adverse effects as much as possible, and experience minimal problems with either overtreatment or undertreatment.
- Patient will maintain positive self-esteem and body image.
- Patient will remain free from injury during drug therapy.

Expected Patient Outcomes

- Patient states the therapeutic drug effects (e.g., minimal to no seizure activity) as well as adverse effects of AEDs and measures to decrease drug-related sedation, confusion, ataxia, and drowsiness.
- Patient or family states the importance of taking the medication exactly as prescribed, such as at the same time every day,

to help maximize therapeutic effectiveness and minimize adverse effects.

- Patient states the dangers associated with sudden withdrawal of the medication, such as rebound seizure activity.
- Patient communicates openly and frequently about diagnosis-related and drug-related changes in self-esteem as well as increase in feelings of anxiety, stress, or altered body image.
- Patient experiences a safe and protective environment while at home and work while implementing safety measures to minimize injury to self, such as keeping throw rugs off the floor and changing positions slowly and purposely.
- Patient reports any symptoms of excessive sedation, confusion, lethargy, and dizziness to prescriber.

◆ IMPLEMENTATION

For patients taking AEDs, interventions are aimed at monitoring the patient while providing safety measures (see previous discussion) and securing the airway, breathing, and circulation. Airway maintenance is of critical importance for patients with epilepsy because the tongue relaxes during seizure activity, falling backward and subsequently blocking the airway. Maintain the patient's airway in the same way as during cardiopulmonary resuscitation, using the chin lift or jaw thrust method. If the patient is not breathing, provide rescue breathing at a rate of 1 breath every 5 seconds. If the patient is breathing, keep the airway open through proper positioning (as just described). In addition to performing these critical components of care, maintain seizure precautions according

to hospital policy. This may include making sure the patient is gently kept in bed or kept from falling, putting the side rails up, or placing the patient in a side-lying position if needed. Avoid use of a tongue blade or other instrument to pry open the patient's mouth or clenched teeth and ensure quick access to oxygen and suctioning equipment at all times. See Special Populations: Antiepileptic Drugs.

With AED administration, adhere closely to the drug dose and frequency of dosing, as ordered. Close monitoring of dosing is important to attain therapeutic blood levels. For example, if an AED is ordered to be administered every 6 hours, it is crucial to dose the drug so that it is given around the clock, to maintain blood levels. Administering the AED at the same time every day is also important to maintain blood levels. Educate patients on the importance of adhering to the medication regimen due to the impact one dose may have on maintaining steady states and therapeutic blood levels (see Chapter 2). If one or more doses of the AED is missed, the prescriber needs to be contacted immediately due to the increased risk of seizure activity. See Patient Teaching Tips for more information.

With oral dosing, it is recommended that these drugs be taken with at least 180 to 240 mL of fluid—preferably water—and with food (a meal or snack) to help decrease the risk of GI upset, a frequently encountered adverse effect. Juices, milk, and carbonated beverages are best avoided because of possible interactions with the drug. Oral suspensions are to be shaken and the solution mixed thoroughly. Capsules are *not* to be crushed, opened, or chewed—especially if extended- or long-release forms. Chewing or altering these long-release formulations would allow for the entire dosage to be released at once versus over a period of time. Usually, extended-release dosage forms are ordered once a day, so checking and double-checking the dosage and frequency is critical to patient safety. These actions will help to prevent the patient from experiencing either too high or too low drug serum levels.

If there are any questions regarding the type of capsule, pill, or tablet, or questions about other dosage forms and recommended administration guidelines, use appropriate authoritative sources to find the answers. These sources include a licensed pharmacist, manufacturer package insert, or a current (within last 3 years) nursing drug handbook or pharmacology book. If there are any questions about the medication order or the medication prescribed, contact the prescriber immediately for clarification. Topiramate and valproic acid tablets and delayed- or extended-release dosage forms are not to be altered in any way and must be given as prescribed.

The following interventions are specific to drugs or drug classes:

- Carbamazepine: This drug is not to be given with grapefruit or grapefruit juice because this leads to increased toxicity of the AED. Grapefruit is a potent inhibitor of the intestinal cytochrome P450 CYP3A4 system, which is responsible for the first-pass effect of many medications. This interaction can lead to increases in bioavailability and result in elevated serum drug levels. If the drug is to be replaced with another AED, a plan must be in place to decrease the dosages of the

SPECIAL POPULATIONS: CHILDREN

Antiepileptic Drugs

- If a skin rash develops in a child or infant taking phenytoin, carbamazepine, lamotrigine, phenobarbital, and valproate, discontinue the drug immediately and notify the prescriber.
- Chewable dosage forms of AEDs are not recommended for once-a-day administration. Intramuscular injections of barbiturates or phenytoin must never be used.
- Encourage family members, parents, significant others, or caregivers to keep a journal with a record of the signs and symptoms before, during, and after a seizure, and before, during, and after treatment with an AED.
- Always encourage the child to wear a MedicAlert bracelet or necklace with information about the diagnosis, drug therapy, and any drug allergies.
- Shake suspension dosage forms thoroughly before use. A graduated device or oral syringe may be used for more accurate dosing of this liquid.
- Pediatric patients are more sensitive to barbiturates and may respond to lower-than-expected dosages. They may also experience more profound CNS depressive effects resulting from the AED or show depression, confusion, or excitement (a paradoxical reaction).
- Any excessive sedation, confusion, lethargy, hypotension, bradypnea, tachycardia, or decreased movement in pediatric patients taking any AED must be reported to the prescriber immediately.
- Carbamazepine may be given with meals to reduce risk of GI distress.
- Oral forms of valproic acid are not to be given with milk because this may cause the drug to dissolve early and irritate the mucosa. Carbonated beverages must also be avoided.

GI, gastrointestinal.

older drug before beginning low doses (at first) of the newer drug. Serum therapeutic levels are given in [Table 15.6](#).

- Hydantoins: As a point of reference, 150 mg of fosphenytoin is the equivalent of 100 mg of phenytoin, and the dose, concentration solution, and infusion rate of fosphenytoin is expressed as a phenytoin equivalent (PE). With parenteral forms, the only dilutional fluid to use with these drugs is normal saline (NS). A filter must also be used. Rates of infusion must follow manufacturer's guidelines and are usually 150 mg PE/min or less to avoid hypotension and cardiorespiratory depression. If dysrhythmias or hypotension occur, discontinue the infusion immediately, monitor patient vital signs, and contact the prescriber immediately. Implement safety measures, such as assisting the patient with ambulation and having the patient move slowly and purposefully, when this drug (or any other AED) is given because of the adverse effects of ataxia and dizziness.
- IV dose administration requires even more cautious use because of the rapid onset of action. CNS depression is always a concern; thus, there is a need to frequently monitor the patient's vital signs. If existing intravenous lines contain D5W or other solutions, the line must be flushed with normal saline before and after dosing to avoid precipitate formation. If infiltration of the IV site leads to subcutaneous tissue access, ischemia and sloughing may occur because of the high alkalinity of the drug. Review hospital or facility policy as well as manufacturer's guidelines regarding use of possible antidotes. If infiltration occurs, discontinue infusion of the solution immediately, but leave the IV catheter and needle in place until all orders from the prescriber have been received. This practice allows any antidote medication to be administered through the IV catheter, if ordered.
- Gingival hyperplasia is an adverse effect and requires that the patient receive daily oral care as well as frequent dental visits. Often, complete blood cell counts are monitored very closely within the first year of therapy (e.g., measured monthly for 1 year, then every 3 months). Sustained or extended release drugs should never be opened, punctured, chewed, or broken in pieces. Other regular forms of the drug may be crushed, as needed.
- Barbiturates (e.g., phenobarbital): Abrupt withdrawal of these drugs or any AED must be avoided due to possible rebound seizure activity. Most of the oral dosage forms of this class of drugs are to be taken with water. Elixir dosage forms may safely be mixed with fruit juice, milk, or water. If IV infusions are indicated, calculate the dose carefully and use an IV infusion pump to administer the drug. Too-rapid infusion of IV dosage forms may lead to cardiovascular collapse and respiratory depression. In addition, frequently monitor vital signs and IV infusion rates and document in the patient's chart. If any signs or symptoms of cardiovascular or respiratory depression are noted, withhold the drug and contact the prescriber immediately, while providing supportive care through maintenance of the airway, breathing, and circulation.
- Gabapentin: This is one of the AEDs that can be taken without regard to meals. If discontinuation of the drug is indicated, taper the dosage, as ordered, over at least 1 week to avoid rebound seizures.
- Lamotrigine: The dosing regimen for this drug must be followed, as ordered. Checking for possible drug interactions is important for patient safety. If the patient shares any suicidal thoughts or actions, contact the prescriber immediately.
- Levetiracetam: The most common adverse effect for this drug is sleepiness. Contact the prescriber if any extreme adverse effects or any problems with moving, walking, or changes in mood or behaviour occur. Any suicidal thoughts or psychotic symptoms must also be reported immediately. With the beginning of antiepileptic therapy, due to the sedation and CNS depression, encourage the patient not to drive, operate heavy machinery, or make any major decisions.
- Oxcarbazepine: This drug is to be taken as prescribed and is usually given in two divided doses. Always check for any potential drug interactions before administering (see previous discussion). The drug must be taken with food or snacks. Rash, abnormal walking or moving, or abdominal pain must also be reported, if present.
- Pregabalin: Usually, the daily dosage of this drug is given in two or three divided doses. Sudden or abrupt withdrawal is to be avoided. Monitor the patient for any excessive dizziness, ocular or visual changes, or edema. If these are present, report this information immediately.
- Valproic acid: Oral dosage forms of this drug are not to be taken with carbonated beverages. It is recommended that this drug be taken with food or at least 180–240 mL of water to minimize GI upset.

EVALUATION

The occurrence of a therapeutic response to AEDs does not mean that the patient has been cured of the seizures, but that seizure activity is decreased or absent. Thoroughly document any response to the medication in the nurses' notes. Because these classes of medications have other indications, such as management of chronic pain, neuropathic pain, fibromyalgia, migraines, and aggressive behaviours in children, the existing problem or disorder should show improvement with minimal adverse effects. In addition, when monitoring and evaluating the effects of AEDs, constantly assess the patient for changes in mental status and level of consciousness, affect, eye problems, or visual disorders. Monitoring CBC is also important because of the occurrence of blood dyscrasias. Measurements of serum levels of the specific AED are ordered at baseline or at the start of therapy and frequently thereafter to determine if subsequent serum levels are subtherapeutic, therapeutic, or toxic. Subtherapeutic levels indicate that the dosage may need to be increased (by the prescriber), and toxic levels require withholding or decreasing the dose—but only if prescribed! Serum therapeutic levels are found in [Table 15.6](#).

PATIENT TEACHING TIPS

- Educate the patient about the sedating effects of drug therapy so that appropriate steps can be taken to ensure patient safety until a steady state is achieved (usually after four or five drug half-lives). The patient is not to drive, operate heavy machinery, or make major decisions until a steady state is achieved.
- The patient needs to understand the importance of reporting any suicidal thoughts or ideas immediately. Alcohol, caffeine intake, and smoking are common and modifiable risk factors that may influence the risk of seizures or epilepsy and are to be avoided.
- AEDs must never be abruptly discontinued as this may precipitate rebound seizure activity.
- Advise female patients contemplating pregnancy to seek education and medical advice from the prescriber due to the teratogenic effects of some of the medications.
- Educate the patient about drug interactions between AEDs and beta blockers, corticosteroids, calcium channel blockers, ethanol (alcohol), and other CNS depressants.
- The adverse effects most commonly associated with these drugs are drowsiness, GI upset, and CNS-depressing effects. Remind the patient that these adverse effects often decrease after the drug has been taken for several weeks. Taking the AED with food or 180–240 mL of fluids, unless otherwise noted, will help to minimize GI upset.
- Inform the patient that a recurrence of seizure activity is usually due to a lack of adherence with the drug regimen. If a dose or doses of medication are missed, the prescriber needs to be contacted for further instructions. Adherence to the medication regimen is critical to the prevention of seizure activity.
- Emphasize to the patient that treatment of epilepsy is lifelong and that adherence with the treatment regimen is important for effective therapy. Share information with the patient and family about community and other appropriate resources (e.g., national and local support groups).
- Discuss with the patient important ways to improve safety in day-to-day activities while taking AEDs. *In the kitchen:* Use an electric stove with no open flame, wear oven mitts, and cook only on rear burners. Cook in the microwave—it is the safest option. Have a plumber install a heat-control device on faucets to avoid burns. Cover floors in carpet to help cushion falls and use plastic dishes and containers instead of glass when possible. *In the bathroom:* Use heat-control devices on faucets. Cover floors in carpet instead of using tile. Do not put a lock on the bathroom door so that help can be obtained if needed. Bathe with only a few inches of water in the tub, and if seizure activity has not been fully controlled, bathe while someone else is present in the home. *During activities:* Always have someone along when engaging in sports, and make sure the person is knowledgeable about the management of airway and seizures. Bike riding with a helmet, swimming, and water sports are okay if an accompanying adult is present who knows how to manage seizure activity and its consequences.
- Each province and territory has different driving regulations for individuals with epilepsy and provides specific requirements and guidelines. In all these jurisdictions, the individual driver is required by law to report to the authorities any health problems, such as epilepsy, that could interfere with driving. In general, a person is legally able to drive when seizures appear to be controlled by medication, the person has been free from seizures for 6 months, and medications do not cause drowsiness or poor coordination. Other restrictions may apply. Contact each provincial or territorial Ministry of Transportation for current and relevant information.
- Many people with epilepsy work at steady jobs and have successful careers. Some are unable to work, but epilepsy should not prevent people from getting a job. The Canadian Human Rights Act prohibits discrimination against persons with disabilities, while the Equality Rights section of the Canadian Charter of Rights and Freedoms guarantees people with disabilities equal benefit and protection before and under the law.
- Always encourage the patient to wear a MedicAlert bracelet or necklace and to carry a medical alert card.
- Keeping a daily diary or journal is important and is a helpful tool for the patient, prescriber, or caregivers. Entries need to include the date and time of any seizure as well as any details such as omitted drug doses, illnesses, and so on.

KEY POINTS

- Epilepsy is a disorder of the brain manifested as a chronic, recurrent pattern of seizures. A seizure is abnormal electrical activity in the brain.
- Seizures are classified as follows: focal onset seizures or those originating in a more localized region of the brain; status epilepticus, a life-threatening emergency characterized by generalized tonic-clonic convulsions that occur repeatedly in succession; and tonic-clonic seizures, involving initial muscular contraction throughout the body (tonic) and progressing to alternating contraction and relaxation (clonic phase).
- It is important to distinguish between the different types of seizure and assess and document all symptoms, events, and problems that occur before, during, and after any seizure activity. This information may aid in the diagnosis of the type of seizure the patient is experiencing.
- Nonadherence with the drug regimen is the most important factor leading to treatment failure.
- Always monitor therapeutic blood levels. Avoid abrupt withdrawal of the AED to prevent rebound seizure activity.
- IV infusions of AEDs are dangerous and must be managed cautiously, with adherence to hospital or facility policy and manufacturer's guidelines. Avoid rapid infusions because of the potential for cardiac or respiratory arrest.
- Older adult patients may experience paradoxical reactions to AEDs, resulting in hyperactivity and irritability versus sedation.

EXAMINATION REVIEW QUESTIONS

- The nurse is preparing to give medications. Which of the following is the most appropriate nursing action for intravenous (IV) phenytoin (Dilantin)?
 - Give IV doses via rapid IV push.
 - Administer in normal saline solutions.
 - Administer in dextrose solutions.
 - Ensure continuous infusion of drug.
- The nurse is reviewing the drugs currently taken by a patient who will be starting drug therapy with carbamazepine (Tegretol). Which drug may raise a concern for interactions?
 - digoxin (Lanoxin®)
 - acetaminophen (Tylenol®)
 - diazepam (Valium)
 - warfarin sodium (Coumadin®)
- Which response would the nurse expect to find in a patient with a phenytoin (Dilantin) level of 35 mcg/L?
 - Ataxia
 - Hypertension
 - Seizures
 - No unusual response; this level is therapeutic
- A patient is taking pregabalin (Lyrica) but does not have a history of seizures. The nurse recognizes that this drug is also indicated for which of the following?
 - Postherpetic neuralgia
 - Viral infections
 - Parkinson's disease
 - Depression
- The nurse is assessing a newly admitted patient who has a history of seizures. During the assessment, the patient has a generalized seizure that does not stop for several minutes. The nurse expects that which drug will be ordered for this condition?
 - valproic acid (Depakote®)
 - gabapentin (Neurontin)
 - carbamazepine (Tegretol)
 - lorazepam (Ativan)
- The nurse is administering an AED and will follow which guidelines? (Select all that apply.)
 - Monitor the patient for drowsiness.
 - Stop medications if seizure activity disappears.
 - Give the medication at the same time every day.
 - Give the medication on an empty stomach.
 - Notify the prescriber if the patient is unable to take the medication.
- The nurse is preparing to administer valproic acid to a child. The order reads: "Give valproic acid, 15 mg/kg/day PO in three divided doses." The child weighs 15 kg. How many milligrams will the child receive with each dose?
- The nurse is providing education for a patient who will be taking an AED for the first time. Which statement by the patient indicates that further teaching is indicated?
 - "I will take the medicine at the same time every day."
 - "I will check with my doctor before taking any over-the-counter drugs."
 - "I will keep the appointments to check my bloodwork."
 - "I can drive to work again once my drug levels are normal."

CRITICAL THINKING ACTIVITIES

- The nurse is about to administer the morning dose of phenobarbital to Paul, a patient with a history of seizures. Before the dose is given, the laboratory calls to report that Paul's phenobarbital blood level is 8 mcg/mL. What is the priority action at this time?
- The laboratory results indicate that Paul's valproic acid level is at toxic levels, but Paul insists that he has not taken extra doses of medication. "I take it the same way at the same time every morning," he states emphatically. Upon further questioning, the patient mentions that he also takes aspirin two or three times a day for muscle aches. "Could that have any effect on my drug level?" he asks. What is the nurse's best response?
- A patient is starting an AED and has many questions about it. The patient states, "I can't wait to be able to drive to work." What is the priority issue for the nurse to consider when replying?

Antiparkinsonian Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Briefly discuss the impact of acetylcholine and dopamine on the brain.
2. Describe the pathophysiology of Parkinson's disease (PD).
3. Identify the different classes of medications used to manage PD and list the drugs in each class.
4. Discuss the mechanisms of action, dosages, indications, routes of administration, contraindications, cautions, drug interactions, adverse effects, and toxic effects of antiparkinsonian drugs.
5. Develop a collaborative plan of care that includes all phases of the nursing process for patients taking antiparkinsonian drugs.

KEY TERMS

Adjunctive drugs Drugs added as a second drug for combined therapy with a primary drug and that may have additive or independent properties. (p. 268)

Akinesia Classically defined as “without movement”; absence or poverty of movement that results in a masklike facial expression and reduced postural reflexes. (p. 264)

Bradykinesia Slowness of movement; a classic symptom of Parkinson's disease. (p. 264)

Chorea A condition characterized by involuntary, purposeless, rapid motions, such as flexing and extending the fingers, raising and lowering the shoulders, or grimacing. (p. 264)

Dyskinesia Abnormal, often distressing involuntary movements; involves inability to control movements, which often occurs as an adverse effect of levodopa therapy. (p. 264)

Dystonia Reduced or distorted voluntary movement, often involving the head, neck, or feet. (p. 264)

Exogenous Any substance produced outside of the body that may be taken into the body (e.g., a medication, food, or environmental toxin). (p. 266)

On-off phenomenon A condition common patients taking medication for Parkinson's disease, which the person experiences periods of greater symptomatic control (“on” time) alternating with periods of lesser symptomatic control (“off” time). (p. 264)

Parkinson's disease (PD) A slowly progressive, degenerative neurological disorder characterized by resting tremor, pill-rolling of the fingers, masklike facies, shuffling gait, forward flexion of the trunk, loss of postural reflexes, and muscle rigidity and weakness. (p. 263)

Postural instability A decrease or change in motor and muscle movements that leads to unsteadiness and hesitation in movement and gait when the individual starts or stops walking or that causes leaning to one side when sitting; occurs in Parkinson's disease. (p. 264)

Presynaptic In reference to drugs, those that exert their antiparkinsonian effects before the nerve synapse. (p. 269)

Rigidity Resistance of the muscles to passive movement; leads to the “cogwheel” rigidity seen in Parkinson's disease. (p. 264)

TRAP An acronym for symptoms of Parkinson's disease; stands for **T**remor, **R**igidity, **A**kinesia, **P**ostural instability. (p. 264)

Tremors In Parkinson's disease, shakiness of the extremities, seen mostly at rest. (p. 264)

Wearing-off phenomenon A gradual worsening of parkinsonian symptoms as a patient's medications begin to lose their effectiveness, despite maximal dosing with a variety of medications. (p. 264)

DRUG PROFILES

amantadine (amantadine hydrochloride)*, p. 270

benzotropine (benztropine mesylate)*, p. 271

bromocriptine (bromocriptine mesylate)*, p. 266

* Full generic name is given in parentheses. For the purposes of this text, the more common, shortened name is used.

PARKINSON'S DISEASE

Parkinson's disease (PD) is a chronic, progressive, neurodegenerative disorder affecting the dopamine-producing neurons in the brain. It is the second-most common neurodegenerative disorder after Alzheimer's disease. PD was initially recognized in 1817, at which time it was called *shaking palsy*. James Parkinson later described in more detail the symptoms of both the early and advanced stages of the disease. The underlying pathological defect was not discovered until the 1960s, when it was recognized that PD involves a dopamine deficit. This deficit occurs in the area of the cerebrum called the substantia nigra, which is contained within another brain structure known as the basal ganglia. Also relevant is the adjacent structure called the globus pallidus. All three structures make up the extrapyramidal system, which is involved in the coordination of movement and the regulation of motor function, including posture, muscle tone, and smooth-muscle activity. In addition, the thalamus serves as a relay station for brain impulses, whereas the cerebellum regulates muscle coordination (Figure 16.1).

Dopamine is an inhibitory neurotransmitter and acetylcholine is an excitatory neurotransmitter in this area of the brain. A correct balance between these two neurotransmitters is needed for the proper regulation of posture, muscle tone, and voluntary movement. PD results from an imbalance in these two neurotransmitters in the basal ganglia. This imbalance is caused by failure of the nerve terminals in the substantia nigra to produce dopamine. Dopamine acts in the basal ganglia to control movements. Destruction of the substantia nigra by PD leads to dopamine depletion. This often results in excessive, unopposed acetylcholine (cholinergic) activity due to the lack of a normal dopaminergic balancing effect. Figure 16.2 illustrates the difference in neurotransmitter concentrations in persons with normal balance and in those with PD.

Fig. 16.1 Basal ganglia and related structures of the brain. (From Copstead-Kirkhorn, L. C., & Banasik, J. L. (2014). *Pathophysiology* (5th ed.). St. Louis, MO: Elsevier Saunders.)

Some experts theorize that PD is the result of a previous head injury or of excess iron in the substantia nigra, which undergoes oxidation and causes the generation of toxic free radicals. Another theory postulates that because dopamine levels naturally decrease with age, PD represents a premature aging of the nigrostriatal cells of the substantia nigra, resulting from environmental or intrinsic biochemical factors, or both. Evidence from animal studies suggests that environmental toxins, such as pesticides and metals, may also contribute to the development of PD.

PD affects over 100 000 Canadians and 4.1 million people worldwide. Approximately 6 600 new cases are diagnosed each year in Canada. The average age of diagnosis is 60 years, although 10% of cases develop symptoms prior to 50 years of age. The number of patients with PD is expected to rise dramatically due to the aging of the baby boomer population, with a 2 to 4% risk among individuals over the age of 60 (UCB Canada, 2019). Between 2011 and 2031, the prevalence of Canadians diagnosed with PD is expected to increase to more than 163 700 (Public Health Agency of Canada, 2014), while the estimated number of patients with PD will increase to 8.7 million in 2030. Young-onset PD can occur in individuals under the age of 40, especially after acute encephalitis or carbon monoxide or metallic poisoning. However, the disease etiology is usually idiopathic. Overall, there is a 2% lifetime chance of developing the disease. Men are affected more often than women, in a ratio of 3:2. Evidence now suggests a possible genetic link, with up to 20% of patients having a family history of the disease.

- A.** Normal balance of acetylcholine and dopamine in the CNS.
B. In Parkinson's disease, a decrease in dopamine results in an imbalance.
C. Drug therapy in Parkinson's disease is aimed at correcting the imbalance between acetylcholine and dopamine. This can be accomplished by either
 1. increasing the supply of dopamine or
 2. blocking or lowering acetylcholine levels.

Fig. 16.2 The neurotransmitter abnormality of Parkinson's disease.

TABLE 16.1 Classic Parkinsonian Symptoms

Symptom	Description
Akinesia	Absence of psychomotor activity, resulting in masklike facial expression
Bradykinesia	Slowness of movement
Rigidity	Cogwheel rigidity, resistance to passive movement
Tremor	Pill-rolling—tremor of the thumb against the forefinger, seen mostly at rest, is less severe during voluntary activity; usually begins on one side and progresses to the other; is a presenting sign in 70% of cases; also seen as tremor of the hand and extremities
Postural instability	Unsteadiness (associated with bradykinesia and rigidity) that leads to danger of falling; leaning to one side, even when sitting

There are no readily available laboratory tests that can detect or confirm PD. The diagnosis is usually made based on the classic symptoms and physical findings. The classic symptoms of PD include **bradykinesia**, **postural instability**, **rigidity**, and **tremors** (TRAP [tremor, rigidity, akinesia, postural instability]), with **akinesia** really manifesting as bradykinesia; refer to [Table 16.1](#). Computed tomography (CT), magnetic resonance imaging (MRI), cerebrospinal fluid analysis, and electroencephalography (EEG) are usually normal and of little diagnostic value. Positron emission tomography (PET) may offer some additional information. CT, MRI, and PET may be useful tools for ruling out other possible diseases as causes of the symptoms, as well as for follow-up imaging after drug and surgical treatments.

PD is a progressive condition. As the disease advances, there is substantial degeneration of surviving dopaminergic terminals that can take up pharmacologically administered levodopa and convert it into dopamine. Various types of motor complications may occur: (1) end-of-dose wearing off (diminishing dopamine effect towards end of dose associated with increasing loss of neuronal storage capability); (2) delayed or no “on response” (due to delayed gastric emptying); (3) start hesitation “freezing of gait” (difficulty initiating movement); and (4) peak-dose dyskinesia. Swings in the response to levodopa—called the **on-off phenomenon**—can occur. Plasma levels may fluctuate erratically because of the 90-minute half-life of levodopa and the frequently unpredictable intestinal absorption of this medication. The result is worsening of the symptoms when too little dopamine is present or dyskinesias when too much is present. In contrast, the **wearing-off phenomenon** occurs when antiparkinsonian medications begin to lose their effectiveness, despite maximal dosing, as the disease progresses. **Dyskinesia** is the difficulty in performing voluntary movements that is commonly seen in PD. The two types of dyskinesias most frequently associated with antiparkinsonian therapy are chorea and dystonia. **Chorea** is irregular, spasmodic, involuntary movements of the limbs or facial muscles. **Dystonia** is a movement disorder that commonly involves the head, neck, and tongue and is a symptom common to patients with PD. These motor complications make PD a prominent cause of disability. Dementia may

also be a result of the disease and is referred to as *Parkinson’s disease–associated dementia*.

Symptoms of PD do not appear until approximately 80% of the dopamine store in the substantia nigra has been depleted. This means that by the time the disease is diagnosed, only approximately 20% of the patient’s original dopaminergic terminals are functioning normally.

TREATMENT OF PARKINSON’S DISEASE

The first step in the treatment of PD is a full explanation of the disease to the patient, family members, and significant others. Physiotherapy, speech-language therapy, and occupational therapy are almost always needed in the later stages of the disease.

Treatment of the disease is primarily drug therapy, which relieves symptoms. Physical activity is also a priority for patients with PD. Many experts believe that physical activity is as important as any drug therapy, and together they greatly improve mobility. For severe cases, the surgical technique of deep brain stimulation may be used. This involves electrical stimulation of dopamine-lacking brain tissues in a way that helps to reduce Parkinson-associated dyskinesias. Surgical treatments are for more severe cases, and patients must still respond well to drug therapy. Stem cell research is ongoing, using embryonic stem cells, induced pluripotent stem cells, and adult stem cells to find ways to regenerate, repair, or replace dopamine-producing cells to restore functioning.

DRUG THERAPY

Because PD is thought to be due to an imbalance of dopamine and acetylcholine, drug therapy is aimed at increasing the levels of dopamine or antagonizing the effects of acetylcholine. Current drug therapy is used not to slow the progression of the disease, but of the symptoms. Drugs available for the treatment of PD are listed in [Table 16.2](#).

Antiparkinsonian drug therapy is based upon the fact that nerve terminals can take up substances, store them, and release them for use when needed. If there are functioning nerve terminals that can take up dopamine, the symptoms of PD can be at least partially controlled. Since PD is essentially a deficiency of dopamine in certain areas of the brain, it seems logical that drug therapies focus primarily on restoring and enhancing dopaminergic activity in these neurons. A variety of both direct-acting and indirect-acting drugs are available for this purpose.

Direct-Acting Dopaminergic Drugs

Direct-acting dopamine receptor agonists are drugs used to treat PD, often as first-line agents used upon diagnosis. These drugs include two subclasses: 1) nondopamine dopamine receptor agonists and 2) dopamine replacement drugs. Nondopamine dopamine receptor agonists are further subdivided into the ergot derivative bromocriptine and the nonergot drugs pramipexole dihydrochloride monohydrate (Mirapex®) and ropinirole (Requip®).

TABLE 16.2 Review of Pharmacological Therapy for Parkinson's Disease

Generic Name	Trade Name	Route	Indications	
Indirect-Acting Dopamine Receptor Agonists (MAO-B Inhibitors)				
selegiline		PO	Used in conjunction with levodopa–carbidopa in early stages of disease; helpful with symptom fluctuations	
rasagiline mesylate	Azilect	PO		
Dopamine Modulator				
amantadine hydrochloride		PO	Used in early stages; can be effective in moderate or advanced stages; reduces tremor or muscle rigidity	
COMT Inhibitors				
entacapone	Comtan	PO	Usually added to levodopa–carbidopa to treat symptom fluctuations; delays “off” periods; has levodopa dose-sparing effect	
Direct-Acting Dopamine Receptor Agonists				
Ergot:				
bromocriptine		PO	Usually used as drug of choice for young patients; first- or second-line therapy of choice for older adults; can be used as adjunct to levodopa for “off” periods; can be used to reduce dyskinesia associated with later stages	
Nonergot:				
levodopa/carbidopa/entacapone combination	Stalevo	PO		
pramipexole dihydrochloride monohydrate	Mirapex	PO		
ropinirole hydrochloride	Requip	PO		
Dopamine Replacement Drugs				
levodopa–carbidopa	Duodopa®, Sinemet	PO	Usually started as soon as patients are unable to function; drug of choice for most older adult patients	
Anticholinergic Drugs*				
benztropine mesylate		PO	Combination of levodopa and benztropine that diminishes the incidence of the levodopa-induced peripheral adverse effects of nausea, vomiting, and possibly cardiac arrhythmias; used as secondary drug for tremors and muscle rigidity	
ethopropazine hydrochloride	Parsitan®	PO		
procyclidine hydrochloride		PO		
trihexyphenidyl hydrochloride		PO		
Antihistamines†				
diphenhydramine hydrochloride	Benadryl	PO, IV	Used as secondary drug for tremors and muscle rigidity	

PO, Oral; IV, intravenous.

*See Chapter 22.

†See Chapter 37.

Nondopamine Dopamine Receptor Agonists

Mechanism of Action and Drug Effects

All the nondopamine dopamine receptor agonists work by direct stimulation of presynaptic or postsynaptic dopamine receptors in the brain. They may be used in early or late stages of the disease. These drugs are preferred in younger patients.

Chemically, bromocriptine is an ergot alkaloid similar to ergotamine (see Chapter 14). (*Ergot* is the name of a pathological fungal growth on plants.) Bromocriptine works by activating presynaptic dopamine receptors to stimulate the production of more dopamine. Its chief site of activity is the D₂ subclass of dopamine receptors. Pramipexole dihydrochloride monohydrate and ropinirole are two newer, nonergot nondopamine dopamine receptor agonists. Both are effective in early and late stages of PD.

Indications

Both ergot and nonergot nondopamine dopamine receptor agonists are used to treat various stages of PD, either alone or in combination with other drugs. There is less risk of motor complications with ergot/nonergot nondopamine receptor agonists monotherapy. This approach is preferred in younger patients.

Bromocriptine also inhibits the production of the hormone prolactin, which stimulates normal lactation. For this reason, it is used to treat women with excessive or undesired breast milk production (galactorrhea) and for the treatment of prolactin-secreting tumours.

Contraindications

Known allergy is a contraindication to dopaminergic drug therapy. These drugs are not to be used concurrently with adrenergic drugs (see Chapter 19) due to the cardiovascular risks of excessive catecholamine activity.

Adverse Effects

Many potential adverse effects are associated with dopaminergic drugs. These effects are listed in Table 16.3.

Interactions

Interactions vary among drugs and are listed in Table 16.4.

Dosages

For dosage information, refer to the table on p. 269.

DRUG PROFILES

The traditional role of the nondopamine dopamine receptor agonists bromocriptine, pramipexole dihydrochloride monohydrate, and ropinirole has been as adjuncts to levodopa for management of motor fluctuations; however, they are now often used as first-line therapy. These drugs differ from levodopa in that they do not replace dopamine itself but act by stimulating dopaminergic receptors in the brain. They have been used as initial monotherapy and as combination therapy with low-dose levodopa to either delay levodopa therapy or reduce the dosage of levodopa and its associated motor complications (see drug profile for levodopa).

bromocriptine mesylate

Bromocriptine mesylate stimulates only the D_2 receptors and antagonizes the D_1 receptors. Eventually, levodopa–carbidopa is needed to control the patient's symptoms. Using amantadine or a nondopamine agonist until it fails may postpone the need for levodopa therapy for up to 3 years. Bromocriptine may also be given with levodopa–carbidopa so that lower dosages of the levodopa are needed. This often results in prolonging the “on” periods and minimizing the “off” periods of the symptoms. Bromocriptine is indicated for PD as well as for hyperprolactinemia. Bromocriptine is contraindicated in cases of known drug allergy to any ergot alkaloids. It is also contraindicated in patients with severe ischemic disease of any kind (e.g., peripheral vascular disease) due to the ability of bromocriptine to stimulate dopamine receptors in the peripheral tissues outside of the brain. This stimulation can result in vasoconstriction, which can worsen peripheral vascular disease. Adverse reactions are listed in Table 16.3. Drug interactions occur with erythromycin (see Chapter 43) and adrenergic drugs (see Chapter 19). Drug interactions are listed in Table 16.4. Bromocriptine is available only for oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	0.5–1.5 hr	1–3 hr	3–5 hr	4–8 hr

ropinirole hydrochloride

Ropinirole hydrochloride (Requip) is a nonergot nondopamine dopamine receptor agonist. A similar drug is pramipexole dihydrochloride monohydrate (Mirapex). These nonergot drugs have a better adverse effects profile (e.g., fewer dyskinesias) than bromocriptine. Ropinirole is more specific than bromocriptine for the D_2 subfamily of dopamine receptors (D_2 , D_3 , D_4). This in turn results in more specific antiparkinsonian effects with fewer of the adverse effects associated with more generalized dopaminergic stimulation. Ropinirole can be effective in both early- and late-stage PD and appears to delay the need for levodopa therapy. Ropinirole is indicated for both monotherapy and adjunctive therapy with levodopa. The drug is contraindicated in patients with known drug allergy. Adverse effects are listed in Table 16.3. Drug interactions occur with any drug metabolized by cytochrome P450 enzyme 1A2 (e.g., warfarin sodium, ciprofloxacin; refer to Table 16.4). Ropinirole is available only for oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	30 min	1–2 hr	3–5 hr	6–10 hr

DOPAMINE REPLACEMENT DRUGS

The drug levodopa has been the traditional cornerstone of therapy for PD. It is a biological precursor of dopamine, required by the brain for dopamine synthesis. However, levodopa cannot be used by itself in the brain and must be combined with another substance, carbidopa. The combination product levodopa–carbidopa provides **exogenous** sources of dopamine that directly replace dopamine in the substantia nigra. These drugs are thus classified as *dopamine replacement* drugs and are drugs of choice in the later stages of PD.

Mechanism of Action and Drug Effects

Dopamine replacement drugs stimulate presynaptic dopamine receptors to increase brain levels of dopamine. Dopamine must be administered orally as levodopa, because exogenously administered dopamine cannot pass through the blood–brain barrier. Levodopa is the biological precursor of dopamine and can penetrate the central nervous system (CNS).

Levodopa is given in combination with carbidopa. Large oral doses of levodopa are required to obtain adequate dopamine replacement because much of the levodopa administered is broken down outside the CNS by the enzyme dopa decarboxylase. Large doses result in high peripheral levels of dopamine and lead to many unwanted adverse effects (see Table 16.3), including confusion, involuntary movements, gastrointestinal (GI) distress, hypotension, and even cardiac dysrhythmias. These problems may be avoided when levodopa is given with carbidopa. Carbidopa is a peripheral decarboxylase inhibitor with little or no pharmacological activity when given alone. When given in combination with levodopa, carbidopa inhibits the breakdown of levodopa in the periphery and thus allows smaller doses of levodopa to be used. Lesser amounts of levodopa result in fewer unwanted adverse effects.

Indications

Dopamine replacement drugs are used to directly restore dopaminergic activity in PD. Dopamine is also given by injection in critical care settings (see Chapter 19) as a pressor drug to raise blood pressure and enhance kidney perfusion.

Contraindications

Levodopa and carbidopa are both contraindicated in cases of primary angle-closure glaucoma because they can raise intraocular pressure. However, they may be used cautiously in patients with open-angle glaucoma (see Chapter 57). Neither drug is to be used in patients with any undiagnosed skin condition because both drugs can activate malignant melanoma.

Adverse Effects

Adverse effects of dopamine replacement drugs include cardiac dysrhythmias, hypotension, chorea, muscle cramps, and GI distress (see Table 16.3).

TABLE 16.3 Adverse Effects of Selected Antiparkinsonian Drugs

Drug or Drug Class	Adverse Effects
MAO-B inhibitor: selegiline	Dizziness, insomnia, hallucinations, ataxia, agitation, depression, paresthesia, somnolence, headache, dyskinesia, nausea, diarrhea, hypotension or hypertension, chest pain, weight loss, dermatological reactions, rhinitis, pharyngitis
Dopamine modulator: amantadine	Dizziness, insomnia, agitation, anxiety, headache, hallucinations, nausea, orthostatic hypotension, peripheral edema, dry mouth
COMT inhibitor: entacapone	GI upset, dyskinesia, urine discoloration, orthostatic hypotension, syncope, dizziness, fatigue, hallucinations, anxiety, somnolence, rash, dyspnea, worsening of dyskinesia
Anticholinergic agent: benztropine	Tachycardia; confusion; memory impairment; rash; hyperthermia; constipation; dry throat, nose, or mouth; nausea; vomiting; urinary retention; blurred vision; fever
Ergot derivative: bromocriptine mesylate	Ataxia, dizziness, headache, depression, drowsiness, GI upset, visual changes
Nonergot derivatives: pramipexole dihydrochloride monohydrate, ropinirole hydrochloride	Edema, fatigue, syncope, dizziness, drowsiness, GI upset
Dopamine replacement drug: levodopa–carbidopa combination	Palpitations, hypotension, urinary retention, depression, dyskinesia

COMT, Catechol ortho-methyltransferase; GI, gastrointestinal; MAO-B, monoamine oxidase type B.

Interactions

A possible drug interaction can occur with pyridoxine (vitamin B₆). Other interactions are listed in Table 16.4.

Dosages

For the recommended dosages of dopaminergic drugs, refer to the table on p. 269.

DRUG PROFILES

levodopa–carbidopa

Levodopa–carbidopa (Sinemet®), available orally, is one of the most commonly used drugs for PD. Carbidopa alone is not used as therapy but rather as an adjunct to treat nausea associated with Sinemet. A variety of studies have shown that the controlled-release product Sinemet CR® (or generic) increases “on” time and decreases “off” time. As with all controlled-release products, Sinemet CR must not be crushed or chewed. Drug interactions occur with tricyclic antidepressants and other drugs (see Table 16.4). A possible drug interaction may occur with pyridoxine hydrochloride (vitamin B₆). Pyridoxine hydrochloride reduces the effectiveness of levodopa–carbidopa; however, the dose can usually be adjusted to overcome this interaction. See the nursing implementation section for discussion of the possible interaction of levodopa–carbidopa with dietary protein. Levodopa–carbidopa is best taken on an empty stomach; however, to minimize GI adverse effects, it can be taken with food.

Levodopa–carbidopa dosage is individualized, and drug administration is continuously matched to the needs and tolerance of the patient. Because the therapeutic range of Sinemet is narrow compared to that of levodopa alone, due to its greater milligram potency, titration and adjustment of dosage should be made incrementally. Recommended dosage ranges should usually not be exceeded. The goal of treatment is maximal benefit without dyskinesias, which are a sign of toxicity. Dosage is usually started at one tablet of Sinemet 100/25 (levodopa 100 mg/carbidopa 25 mg) three times a day, increased by one tablet every

3 days until the optimal dosage has been achieved without dyskinesias. During titration, dosing is usually four times a day.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	2–3 wk for therapeutic effect	0.5–2 hr	1.5 hr	5 hr

INDIRECT-ACTING DOPAMINERGIC DRUGS

Monoamine Oxidase Inhibitors

The enzyme monoamine oxidase (MAO) causes the breakdown of the catecholamines dopamine, norepinephrine, and epinephrine in the body. There are two subclasses of MAO in the body: MAO-A and MAO-B. As early as 1965, nonselective monoamine oxidase inhibitors (MAOIs), which inhibit both MAO-A and MAO-B, were being used to improve the therapeutic effect of levodopa by preventing its metabolic breakdown. They were also among the first medications used to treat depression, but their use for this purpose has been widely replaced by newer drug categories (see Chapter 17). A major adverse effect of the nonselective MAOIs is that they interact with tyramine-containing foods and beverages (e.g., cheese, red wine, beer, yogurt) because of their inhibitory activity against MAO-A. This has been called the *cheese effect*, and it can result in severe hypertension. Selegiline, a selective MAO-B inhibitor, is much less likely to elicit the classic cheese effect. It is approved for use in conjunction with levodopa therapy in the treatment of PD. There was earlier speculation that selegiline, as well as possibly vitamins E and C, might have antiparkinsonian effects due to neuroprotective activity at the neuronal (nerve cell) level. The results of some animal studies suggested this as a possibility; however, no studies to date have conclusively demonstrated this to be true. Nonetheless, this theoretical neuroprotective effect is still debated in the literature.

TABLE 16.4 Selected Drug Interactions of Antiparkinsonian Drugs

Drug or Drug Class	Interacting Drug	Mechanism	Result
MAO-B inhibitor: selegiline hydrochloride	meperidine hydrochloride and other opioids, tramadol hydrochloride, cyclobenzaprine hydrochloride, dextromethorphan hydrobromide, other MAOIs, serotonergic antidepressants, oxcarbazepine	Additive CNS stimulation	Serotonin syndrome
	carbamazepine, oral contraceptives	Reduced selegiline hydrochloride clearance	Potential selegiline hydrochloride toxicity
	buspirone hydrochloride	Uncertain	Hypertension
Dopamine modulator: amantadine	Anticholinergics	Additive effects	Increased anticholinergic adverse effects
COMT inhibitor: entacapone	MAOIs, catecholamines	Reduced catecholamine metabolism	Tachycardia, cardiac dysrhythmias, hypertension
Ergot derivative: bromocriptine	erythromycin	Cytochrome P450 interactions	Increased bromocriptine effects with risk of toxicity
	Sympathomimetics	Additive effects	Hypertension, cardiac dysrhythmias
	Antihypertensives	Additive effects	Hypotension
Nonergot: ropinirole	warfarin sodium, ciprofloxacin	Cytochrome P450 interactions	Reduced ropinirole clearance with risk of toxicity
	Antipsychotics	Antidopaminergic activity	Reduced efficacy of ropinirole
Dopamine replacement: levodopa, carbidopa	Nonselective MAOIs	Additive toxicity	Hypertensive reactions
	Benzodiazepines, antipsychotics, anti-hypertensives	Reduced levodopa effects, additive anti-hypertensive effects	Reduced therapeutic effects, hypotension

CNS, Central nervous system; COMT, catechol ortho-methyltransferase; MAO-B, monoamine oxidase type B; MAOI, monoamine oxidase inhibitor.

Rasagiline is the newest antiparkinsonian drug. Like selegiline, rasagiline is a selective MAO-B inhibitor. It is approved to be given once a day as monotherapy in the early stages of the disease and as adjunctive therapy, in combination with other drugs, in advanced cases. Drug interactions and adverse effects are similar to those of selegiline.

Mechanism of Action and Drug Effects

The MAO enzymes are widely distributed throughout the body, with the highest concentrations found in the liver, kidney, stomach, intestinal wall, and brain. Most MAO-B occurs in the CNS, primarily in the brain. The primary role of MAO enzymes is the breakdown of catecholamines such as dopamine, norepinephrine, and epinephrine, as well as serotonin. Giving a MAO-B inhibitor such as selegiline or rasagiline causes an increase in the levels of dopaminergic stimulation in the CNS. This helps to counter the dopaminergic deficiency seen in PD. Administration of selegiline can also allow the dose of levodopa (discussed previously in this chapter) to be reduced. Improvement in functional ability and decrease in severity of symptoms can occur; however, only approximately 50 to 60% of patients show a positive response.

Indications

Selegiline and rasagiline are currently approved for use in combination with levodopa-carbidopa. They are **adjunctive drugs** used when a patient's response to levodopa is fluctuating. As adjunctive drugs, selegiline and rasagiline can prolong the effects of levodopa and reduce fluctuations in motor control. These benefits decline within 12 to 24 months. Both drugs may also

delay the need for taking levodopa when used as monotherapy in the early stages of the disease. As PD progresses, it becomes more difficult to manage it with levodopa. Ultimately, levodopa no longer controls the disease, and the patient becomes seriously debilitated. This generally occurs between 5 and 10 years after the start of levodopa therapy.

Contraindications

Selegiline and rasagiline are contraindicated in cases of known drug allergy. Concurrent use of the opioid drug meperidine hydrochloride (see [Chapter 11](#)) is contraindicated due to well-documented drug interactions between MAOIs and meperidine hydrochloride.

Adverse Effects

The most common adverse effects associated with the use of selegiline and rasagiline are mild and are listed in [Table 16.3](#). At recommended dosages of 10 mg/day, the drugs maintain their

BOX 16.1 Foods Containing Tyramine

Food	Examples
Aged cheeses	Cheddar, stilton, blue, camembert, gorgonzola
Other dairy	Yogurt
Alcoholic beverages	Draft beer, vermouth
Beef, pork, poultry, fish	Dry sausages, salami, smoked or pickled fish, caviar, soups or casseroles containing meat extracts (e.g., bouillon, beef broth)
Other	Soy products, sauerkraut

Dosages

Selegiline and Selected Dopaminergic Drugs for Parkinson's Disease

Drug	Pharmacological Class	Usual Dosage Range
amantadine hydrochloride	Dopamine modulator	<i>Adults</i> PO: 100–300 mg/day divided q12h
Benztropine	Anticholinergic	PO: 0.5–6 mg/day
Bromocriptine	Direct-acting dopamine agonist; ergot derivative	<i>Adults</i> PO: 2.5–30 mg (TID is max dose)/day divided
entacapone (Comtan®), Stalevo®—levodopa/carbidopa/entacapone)	COMT inhibitor	<i>Adults</i> PO: 100 mg–200 mg (maximum 1600 mg/day) with each dosage of levodopa; Re: Stalevo—Based on L-dopa dose 50–150 mg TID. Max dose 8 tabs/day (all strengths)
levodopa—benserazide hydrochloride (Prolopa®)	Combination direct-acting dopamine agonist/replacement and decarboxylase inhibitor	<i>Adults</i> PO: 100–125, 400–800 mg/day based on levodopa, divided into 4–6 doses
 levodopa—carbidopa (Sinemet, Sinemet CR, Parcopa®)	Antiparkinsonian agent	<i>Adults</i> PO: 100/10, 100/25, 250/25; titrated to optimum dosage (1500 mg levodopa max/day; 70–100 mg carbidopa max/day) CR: 200–50, 1–2 tab bid; up to 8 tabs/day; 100–25: 1–4 tab bid
 ropinirole (ReQuip)	Direct-acting dopamine agonist	<i>Adults</i> PO: 0.25 mg tid slowly titrating to max dose of 24 mg/day
pramipexole (Mirapex)	Direct-acting dopamine agonist	Dose: initial 0.125 mg TID Maximum: 1.5 mg TID
 selegiline (Anipril®)	Selective MAO-B inhibitor	<i>Adults</i> PO: 5 mg bid with breakfast and lunch

COMT, catechol ortho-methyltransferase; CR, controlled release; MAO-B, monoamine oxidase type B; PO, oral.

selective MAO-B inhibition. However, at dosages that exceed 10 mg/day, selegiline becomes a nonselective MAOI, which contributes to the development of the cheese effect described earlier.

Interactions

Selegiline interacts with meperidine hydrochloride and has been associated with delirium, muscle rigidity, hyperpyrexia (high fever), and hyperirritability. Other reported reactions are listed in Table 16.4. Selegiline may safely be taken concurrently with catechol ortho-methyltransferase (COMT) inhibitors (see later drug section). Patients taking higher doses of selegiline

need to avoid tyramine-containing foods (see Box 16.1 for a list of tyramine-containing foods).

Dosage

For the recommended dosage of selegiline see the table in the left column.

DRUG PROFILES

selegiline hydrochloride and rasagiline mesylate

Selegiline hydrochloride is a selective MAO-B inhibitor indicated for PD. It is used as an adjunct drug along with levodopa to reduce the dosage of levodopa needed for symptom control. Adverse effects that are increased with doses greater than 10 mg—when it loses its selectivity for MAO-B—are listed in Table 16.3. Drug interactions are listed in Table 16.4. Rasagiline mesylate (Azilect®) is a newer selective MAO-B inhibitor comparable to selegiline. Its advantage is that it is approved as monotherapy for PD, whereas selegiline is normally used adjunctively with the dopamine replacement drug levodopa.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1 hr	0.5–2 hr	2 hr	1–3 days

DOPAMINE MODULATOR

Only one drug is currently known to function as a dopamine modulator. Amantadine was first recognized as an antiviral drug and was used for treating influenza virus infections. It is still used for this purpose (see Chapter 45) as well as for management of PD.

Mechanism of Action and Drug Effects

Amantadine appears to work by causing the release of dopamine and other catecholamines from their storage sites, or vesicles, in the **presynaptic** fibres of nerve cells within the basal ganglia that have not yet been destroyed by the disease process. Amantadine also blocks the reuptake of dopamine into the nerve fibres. This results in higher levels of dopamine in the synapses between nerves and improved dopamine neurotransmission between neurons. Because amantadine does not directly stimulate dopaminergic receptors, it is considered indirect acting. Amantadine also has some anticholinergic properties (see Chapter 22). This may help further control dyskinesias.

Indications

Amantadine is generally indicated in the early stages of PD, while there are still some intact neurons in the basal ganglia. However, it can be used in the moderate to advanced stages. It is usually effective for only 6 to 12 months, after which it often fails to relieve hypokinesia and rigidity. Once it becomes inadequate, a dopamine agonist

such as bromocriptine is usually tried (see later drug section). It is often used to treat dyskinesia associated with levodopa-carbidopa.

Contraindications

Amantadine is contraindicated in cases of known drug allergy.

Adverse Drug Effects

Common adverse effects associated with amantadine are relatively mild and include dizziness, insomnia, and nausea.

Drug Interactions

When given with anticholinergic drugs, amantadine causes increased anticholinergic adverse effects.

Dosage

For dosage information, refer to the table on p. 269.

DRUG PROFILE

amantadine hydrochloride

Amantadine—an antiviral drug—is indicated for treatment of moderate PD, for which it helps to control symptoms of tremor, including motor rigidity, by virtue of both its dopaminergic and anticholinergic effects. Interacting drugs include anticholinergics (due to additive effects; see Table 16.4). Amantadine is available only for oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	48 hr	2–4 hr	11–15 hr	6–12 wk

CATECHOL ORTHO-METHYLTRANSFERASE INHIBITORS

The third category of indirect-acting dopaminergic drugs is COMT inhibitors. The sole drug in this category is entacapone (Comtan).

Mechanism of Action and Drug Effects

Entacapone, like amantadine, works presynaptically. This drug blocks COMT, the enzyme that catalyzes the breakdown of the body's catecholamines. Entacapone cannot cross the blood-brain barrier and therefore can act only peripherally. The positive effect of this drug is that it prolongs the duration of action of levodopa. This is especially true when levodopa is given with carbidopa (see section on dopamine replacement drugs earlier in the chapter). This results in reduction of the wearing-off phenomenon.

Indications

COMT inhibitors are indicated for the treatment of PD.

Contraindications

Entacapone is contraindicated in cases of known drug allergy.

Adverse Effects

Commonly reported adverse effects with entacapone include GI upset and urine discoloration. In addition, it also can worsen dyskinesia that may already be present (see Table 16.3).

Interactions

Entacapone is to be taken with nonselective MAOIs because of cardiovascular risk due to reduced catecholamine metabolism. However, the selective MAO-B inhibitor selegiline may be safely taken concurrently with COMT inhibitors.

Dosages

For dosage information, see the table on p. 269.

DRUG PROFILE

Inhibition of the enzyme in the body known as COMT is a strategy for prolonging the duration of action of levodopa. Entacapone (Comtan) is a reversible inhibitor of COMT.

entacapone

Entacapone (Comtan) is a COMT inhibitor indicated for the adjunctive treatment of PD. It is taken with levodopa and is effective from the first dose; a patient can feel the benefit of entacapone within a few days. Entacapone benefits patients who are experiencing wearing-off effects. When used with levodopa, it can also reduce on-off effects; the levodopa dosage can often be reduced. Entacapone is contraindicated in patients who have shown a hypersensitivity reaction to it and should be used with caution in patients with pre-existing liver disease. Entacapone is available only for oral use. It is also available in combination tablets that contain various doses of entacapone, carbidopa, and levodopa (Stalevo).

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1 hr	0.5–1.5 hr	1.5–3.5 hr	6 hr

ANTICHOLINERGIC THERAPY

Anticholinergic drugs—drugs that block the effects of acetylcholine—are sometimes useful in treating the muscle tremors and muscle rigidity associated with PD. These two symptoms are caused by excessive cholinergic activity, which occurs because of a lack of normal dopamine balance. Anticholinergics do little, however, to relieve the bradykinesia associated with PD. The rationale for the use of anticholinergics is to reduce excessive cholinergic activity in the brain. The first drugs in this category to be used were the belladonna alkaloids—atropine and scopolamine. However, the anticholinergic adverse effects of dry mouth, urinary retention, and blurred vision can be excessive; therefore, new synthetic anticholinergics and antihistamines with better adverse effect profiles (e.g., benztropine, trihexypenidyl) were developed.

Mechanism of Action and Drug Effects

Anticholinergic drugs block the effects of the neurotransmitter acetylcholine at cholinergic receptors in the brain as well as in the rest of the body. They are discussed in greater detail in [Chapter 22](#). Anticholinergics are used as adjunct drug therapy in PD due to their antitremor properties. The purpose of their use is to reduce excessive cholinergic activity in the brain. Accumulation of acetylcholine in PD causes an overstimulation of the cholinergic excitatory pathways, which results in tremors and muscle rigidity. Rigidity tends to be prominent in the flexor muscles of the trunk and limbs, which results in the stooped posture characteristic of PD. It is often associated with pain, which can be relieved with adjustment of PD drugs and analgesics such as non-steroidal anti-inflammatory drugs (NSAIDs) and opiate receptor agonists (see [Chapter 11](#)) (Skogar & Lokk, 2016). As of the writing of this textbook, there is research under way, led by Dr. Susan Fox, to examine the use of cannabinoids for muscle and joint pain caused by rigidity and stiffness (Parkinson Canada, 2019). *Lead-pipe rigidity* refers to a constant resistance to motion throughout the range of motion; it is the result of an increase in muscle tone. Cogwheel rigidity is a combination of lead-pipe rigidity and tremors. It occurs as jerky resistance that starts and stops as the limb is moved through its range of motion (the muscles contract and relax). Muscle tremors are usually worse when the patient is at rest and consist of a pill-rolling movement and bobbing of the head. Anticholinergic drugs help to alleviate these bothersome and often disabling symptoms. However, anticholinergics do little to relieve the bradykinesia that is also associated with PD.

Acetylcholine is responsible for causing increased salivation, lacrimation (tearing of the eyes), urination, diarrhea, increased gastrointestinal motility, and possible emesis (vomiting). The acronym SLUDGE is often used to describe these cholinergic effects. Anticholinergics have the opposite effects—they can cause dry mouth or decreased salivation, urinary retention, decreased GI motility (constipation), dilated pupils (mydriasis), and smooth-muscle relaxation. Anticholinergic drugs readily cross the blood–brain barrier and therefore can get to the site of PD pathology in the brain, the substantia nigra.

Historically, the anticholinergic drugs atropine sulphate and scopolamine hydrobromide were used. However, the anticholinergic adverse effects of dry mouth, urinary retention, and blurred vision associated with these original anticholinergics can be excessive. Therefore, synthetic anticholinergics were developed that have better adverse effect profiles. The anticholinergics most commonly used include benztropine and trihexyphenidyl hydrochloride. Antihistamines (see [Chapter 37](#)) also have significant anticholinergic properties; they can also be used to manage cholinergic symptoms in PD. The most common choice of antihistamine is diphenhydramine hydrochloride (Benadryl®). Anticholinergics must be used cautiously in older adults because of significant potential adverse effects such as confusion, urinary retention, visual blurring, palpitations, and increased intraocular pressure.

drugs (see [Chapter 17](#)). Benztropine is to be used with caution in hot weather or during exercise because it may cause hyperthermia. Other adverse (anticholinergic syndrome) effects include tachycardia, confusion, disorientation, toxic psychosis, urinary retention, dry throat, constipation, nausea, and vomiting. Anticholinergic syndrome can occur when this drug is given with other drugs, such as amantadine or tricyclic antidepressants, that are associated with a high incidence of anticholinergic effects. Alcohol is to be avoided as it can increase drowsiness and dizziness. Benztropine is available as tablets and in injectable form. The normal dosage is 0.5 to 6 mg/day in one or two divided doses.

NURSING PROCESS

ASSESSMENT

After patients are diagnosed with PD, they soon experience the impact of the disease with every movement and activity of daily living. Not only will their lives never be the same, they soon learn that their quality of life depends on drug therapy and non-drug measures. Before medications for PD are given, assess and document vital signs (e.g., blood pressure, pulse, respirations, temperature, pain) and ABCs (airway, breathing, and circulation). In addition, obtain a complete nursing history with a thorough physical assessment, including compilation of a comprehensive medication profile. Because it may take several weeks to see a therapeutic response to medication regimens, a keen assessment and careful patient monitoring are critical to quality nursing care. Also assess the symptoms of PD (e.g., akinesia, tremors, pill-rolling, shuffling gait, masklike facies, twisting motions, drooling) during drug therapy. The on–off phenomenon may cause symptoms to appear or improve suddenly. A thorough assessment includes a health history, a review of systems, and determination of sensory and motor abilities. Also gather the following information: report(s) upon admission or the symptom(s) or event that led the patient to obtain medical treatment; past and current medical history with a focus on the presence or absence of head injury, seizures, diabetes, hypertension, heart disease, or cancer; family history of any neuromuscular or neurological disorders, heart disease, diabetes, cancer, seizures, cerebrovascular accident (stroke), or PD. Additionally, complete a thorough systems assessment, including gathering subjective and objective information in the following areas, regarding the possible impact of PD:

- *Central nervous system*—Inquire about any headaches, fatigue, weakness, paralysis, dizziness, or syncope. Note any changes in walking or mobility, increases in rigidity or muscle movements, or changes in the ability to carry out activities of daily living. Also important are any changes in sensation in the extremities, changes in vision or hearing,

DRUG PROFILES

benztropine mesylate

Benztropine mesylate is an anticholinergic drug used for PD and also for extrapyramidal symptoms from antipsychotic

loss of or changes in coordination, changes in gait and balance, or changes in energy level. Also include questions about any changes in baseline levels of alertness; changes in memory (short term or long term); blackouts or seizures; numbness, tingling, or abnormal sensations in the extremities; changes in mood; changes in muscle movement or strength (e.g., paralysis) or motor control; and any muscle rigidity or tremors. Assess response to stimuli, and assess pupils with attention to size, shape, response to light, and symmetry (in reactions). Assess deep tendon reflexes with attention to strength bilaterally. Observe and document the patient's ability to walk and the person's gait and extremity strength. Also assess and document the ability to carry out activities of daily living, including self-care.

- *Gastrointestinal and genitourinary (GU) systems*—Perform a general survey of the abdominal area with inspection, auscultation of bowel sounds, and palpation for any distention or tenderness. Determine daily baseline urinary and bowel patterns with attention to any changes in or loss of control of bladder or bowel functioning, as well as the patient's ability to engage in toileting activities. Inquire about the need for assistance with these daily functions. Ask the patient about any difficulty in swallowing (dysphagia) and any problems in self-feeding or preparing meals. Also ask if the patient has any difficulties swallowing medications. If such difficulties are identified, assess further for any subsequent nutrition imbalance.
- *Skin and oral mucous membranes*—Assess the skin colour, texture, turgor, and fragility, and note any breaks in the skin, bruises, lesions, masses, or swelling. Also, document colour and moisture of the oral cavity and mucous membranes.
- *Respiratory system*—Focus attention on respiratory rate, rhythm, depth, effort, and breath sounds.
- *Psychological and emotional status*—Assess the patient for any recent or past changes in mood, affect, or personality. Also note any other disease-related concerns such as depression, emotional ups and downs, increase in irritability, social withdrawal, or changes in sexual functioning or intimacy.
- *Functional abilities*—Inquire about any changes in everyday function in the patient's personal and professional life. Note any changes in daily task performance at work or any sick leave or sick days taken, as well as the patient's ability to exercise, drive, or shop for groceries and other necessities.

With indirect-acting dopamine receptor agonists—such as amantadine—and direct-acting dopamine receptor agonists—such as levodopa-carbidopa and ropinirole—include in your assessment vital signs with supine and standing blood pressures (because of drug-related orthostatic hypotension), height, weight, medication and medical history, and nursing history. Include family, significant others, and caregivers in the assessment and data collection process. Note contraindications, cautions, and drug interactions prior to administering these drugs (see previous pharmacology discussion). Assess motor skills, including abilities and deficiencies, and assess for the presence of akinesia, bradykinesia, postural instability, rigidity, tremors, staggering gait, or drooling (see Key Terms and [Table 16.1](#)).

Assessment of urinary patterns is also important because of the possibility of drug-induced urinary retention. If blood urea nitrogen (BUN) and creatinine measurements are ordered, the results need to be routinely examined because these values are indicators of kidney function. Alkaline phosphatase levels are indicators of liver function and need to be assessed, if ordered. It is important to determine these laboratory values in patients with decreased kidney or liver function so that dosages of antiparkinsonian drugs may be altered by the health care provider.

Regarding lifespan considerations, it is important to understand the gynecological history of the patient and to know if the patient is pregnant or lactating. Some of the dopamine replacement drugs cross into the placenta and into breast milk and have unknown actions in fetuses. Interactions among these drugs are presented in [Table 16.4](#). Refer to [Table 16.3](#) for a listing of selected antiparkinsonian drugs and their related classifications and subclassifications.

When anticholinergic drugs are prescribed, assess the patient carefully to determine gross level of organ functioning—especially in those systems most affected by PD, including the GI, GU, visual, cardiac, and neurological systems. Assess mental status and pay close attention to any present or past changes as well as to any presence of confusion, disorientation, or psychotic-like behaviour. It is important to consider this aspect in older adults because of decline in liver function and a subsequent higher potential for adverse effects and possible toxicity (with antiparkinsonian drugs and drugs in general) and an overall increased sensitivity to the effects of drugs (see [Chapter 4](#)). Cautions, contraindications, and drug interactions have been previously discussed.

For the indirect-acting dopamine receptor agonist drugs (a subclass of presynaptic dopamine release enhancers) that are also antiviral (e.g., amantadine), the previously discussed baseline and general assessment information is also applicable. It is important to confirm the patient's knowledge of the drug's use for PD (versus its use as an antiviral) and awareness that its onset of action will be delayed for several days or longer. Continuous assessment of the patient's status and improvement in disease-related symptoms is important because a decline in this drug's effectiveness (specifically a failure in the ability to control hypokinesia and rigidity) may occur within 6 to 12 months after initiation of therapy. If amantadine (also a prolactin inhibitor) is prescribed, the nurse must understand that this drug is also used for suppression of lactation and must assess for the appropriateness of its use. Patients taking these drugs also require additional CNS assessment because of the possible adverse effects of dizziness, headache, insomnia, and anxiety. Also, if the patient is taking this medication long term, assessment for orthostatic hypotension and dizziness is crucial to patient safety.

The antiparkinsonian drugs classified as indirect-acting dopamine receptor agonists (a subclass of MAO-B inhibitors), such as selegiline, require assessment of many of the same parameters discussed earlier. In addition, however, cardiac status is important to assess and document because of the possible adverse effects of hypotension or hypertension and chest pain. Assessment of dosing is also important because, as with other

CASE STUDY

Drugs for Parkinson's Disease

Boris, a 62-year-old retired contractor, is undergoing surgery to repair an umbilical hernia. He has had Parkinson's disease for 5 years and is currently taking levodopa-carbidopa (Sinemet CR) and selegiline. He has enjoyed good control up until this week but is now experiencing more "bad times," as he calls them. His physician has changed his therapy to include entacapone.

1. Patients who are taking long-term levodopa treatment often experience an "on-off" phenomenon in symptoms. Explain the physiology behind this phenomenon.

2. Explain the reason for giving selegiline along with the levodopa-carbidopa.

3. Are there any concerns regarding drug interactions? Explain your answer.

4. What is the purpose of the entacapone?

5. Before administering the entacapone, the nurse reviews Boris's history for any potential contraindications. What condition(s) would be a potential contraindication to entacapone?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

antiparkinsonian drugs, a low dose is used initially, with gradual increases over an approximately 3- to 4-week period. The lowest possible dose is recommended for initiation of therapy so that there is plenty of room for further increases in dosing as the disease progresses. These drugs also require careful neurological assessment due to the adverse effects of depression, hallucinations, ataxia, and agitation (see Table 16.3).

For the indirect-acting dopamine receptor agonist COMT inhibitors (e.g., entacapone), assessment of baseline vital signs is also required, with a focus on standing and supine blood pressure because of the adverse effects of orthostatic hypotension and syncope. These adverse effects occur with more frequency with the COMT inhibitors than with the other antiparkinsonian drugs, and thus increased caution and concern are needed. Assessment of dosing time is also important because if these drugs are not given 1 hour before or 2 hours after levodopa, the bioavailability of the drug may be adversely affected. Assess serum transaminase levels before and during drug therapy. If the patient's alanine aminotransferase level is elevated to the upper range of normal or higher, the health care provider will most likely discontinue the drug because of the increased risk of liver failure.

◆ NURSING DIAGNOSES

- Reduced urinary retention resulting from the pathophysiological effects of the disease process on the bladder with incomplete emptying
- Constipation resulting from decreased GI peristalsis associated with the disease process
- Imbalanced nutrition, less than body requirements, resulting from the disease process as well as adverse effects of drug therapy
- Reduced physical mobility resulting from the disease process and adverse effects of the various antiparkinsonian medications

- Disturbed body image resulting from changes in appearance and mobility due to the disease process
- Inadequate knowledge resulting from lack of exposure to and experience with a complex and long-term treatment regimen
- Potential for injury resulting from the physical limitations and changes in mobility, gait, balance, and coordination produced by the disease process
- Muscle and joint pain resulting from rigidity, stiffness, and postural instability associated with the disease process

◆ PLANNING

◆ Goals

- Patient will regain as normal as possible bladder elimination patterns.
- Patient will maintain as normal as possible bowel elimination patterns.
- Patient will maintain adequate and balanced nutritional status.
- Patient will be able to maintain safe mobility and activities of daily living.
- Patient will maintain a positive self-image and body image.
- Patient will demonstrate adequate knowledge and comprehension about the illness, medication therapy, and drug-related adverse and toxic effects.
- Patient will remain free from injury and self-harm.

◆ Outcome Criteria

- Patient discusses ways to minimize problems associated with drug-induced alterations in bladder elimination patterns (retention), such as consuming plenty of fluids, taking medications as prescribed, attempting to empty the bladder at regular intervals, and reporting any unresolved urinary problems.
- Patient implements various measures to decrease constipation, such as increasing bulk and fibre in the diet with fruits and vegetables, consuming plenty of fluids, and remaining as active as possible.
- Patient states the importance of maintaining proper nutrition, including the use of nutritional supplements and vitamins, and gives examples of daily menus designed to increase dietary protein and intake from the major food groups (divided into six small, frequent meals).
- Patient participates in ambulation and daily care with the use of assistive devices, as appropriate.
- Patient removes any barriers to safe mobility in the home environment and uses handrails throughout the home.
- Patient maintains mobility and activity participation through involvement in physiotherapy and occupational therapy interventions, as well as doing active and passive range of motion exercises.
- Patient openly verbalizes fears, anxieties, and changes in self-image with family, members of the health care team, support staff, and support groups.
- Patient, family, significant others, and caregivers openly discuss the effects of the disease process on relationships,

daily activities, and future plans, as well as the impact of any drug-related adverse effects (e.g., dizziness, nausea, vomiting, GI upset, palpitations) and the lifelong need for daily medication and monitoring.

- Patient states purposes of medication therapy, such as decrease in symptoms of PD, improved comfort, enhanced participation in activities of daily living, and increased nutritional status.
- Patient knows to contact the health care provider and states symptoms that should be reported, such as dry mouth, unresolved nausea or vomiting, fainting, or loss of appetite.
- Patient, family, significant others, and caregivers describe ways of preventing injury, such as using assistive devices, removing throw rugs, using night lights, and installing handrails throughout the home.

◆ IMPLEMENTATION

Nursing interventions associated with antiparkinsonian drugs vary somewhat depending on the drug class, but close monitoring and comprehensive patient education are required for all these drugs. With the onset of drug therapy, educate patients, family, and caregivers to keep a daily drug calendar or journal, with entries including the drugs prescribed, dosage, frequency and timing, therapeutic changes, and adverse effects. During the start of dopaminergic drug therapy, the patient will most likely need assistance when walking because of dizziness and possible syncope. Doses are given several hours before bedtime to decrease the incidence of insomnia, a known adverse effect of dopaminergic drugs. Oral doses are given with food to help minimize GI upset. Interaction of vitamin B₆ (pyridoxine hydrochloride) with levodopa was once a major concern because this vitamin was found to block the uptake of plain levodopa. However, the majority of patients taking a levodopa-carbidopa combination drug have no problems with vitamin B₆. If there is a problem, the health care provider needs to be consulted for further instructions. In addition, amino acids from dietary protein may interfere with the uptake of levodopa in the brain. While taking levodopa-carbidopa, the patient may continue to eat high-protein foods (e.g., meat, fish, poultry, and dairy products) but should use portion control (limiting meat portions to about the size of a deck of cards) and take the drug dose a half hour before a protein-containing meal. Timing is the most important factor, not the quantity of protein consumed over the course of the day. A nutritional consult may be beneficial to assist the patient in menu planning. A registered dietitian or nutritionist may also be helpful in teaching the patient about how to divide daily intake of protein among small, frequent meals so that minimal amounts of protein are ingested throughout the day and are consumed at the proper time. Consumption of well-balanced meals is important, as is increasing fluid intake. Patients should aim to drink at least 3 000 mL/day unless contraindicated. Drinking water is important, even if the patient is not thirsty or in need of hydration, to prevent and manage the adverse effect of constipation. Encourage the intake of foods that are natural laxatives, such as prunes, vegetables, and other foods high in fibre. If the adverse effect of dry

mouth is problematic, taking fluids and sucking on hard candies or lozenges may be helpful. Regular dental hygiene should be encouraged. If nausea or vomiting occurs or problems with edema are persistent (the patient gains 1 kg or more in 24 hours or 2.3 kg or more in 1 week), the health care provider should be contacted immediately.

With anticholinergic drugs, patients must take the medication as prescribed, after meals or at bedtime and not at the same time as other medications. Patients also need to know that it may take a few days to several weeks for the drugs to show their therapeutic effectiveness (e.g., improvement in tremors). Because of the risk of GI upset (i.e., nausea, vomiting), it is recommended that these drugs be taken with a light, bland snack, such as crackers or plain bread. These medications are generally taken at night because of their sedating properties. Measures to help prevent and treat dry mouth are encouraged, such as increasing fluid intake and sucking on sugar-free hard candies. See [Chapter 22](#) for further information about the use of these drugs, related interventions, and adverse effects to report. Bromocriptine is to be taken as prescribed and not abruptly stopped. Because this drug may cause GI upset, it is best taken with a snack. Any severe dizziness, GI upset, ataxia, extreme drowsiness, or visual changes must be reported immediately.

Patients who have been prescribed MAOs must be advised to avoid tyramine-containing foods (see [Box 16.1](#)) to reduce the risk for severe hypertension. In addition, MAO-B inhibitors, such as selegiline, must be given exactly as ordered. Selegiline is often given in upwardly titrated dosages, while levodopa-carbidopa dose amounts are decreased. Orthostatic hypotension may be a transient problem, so the patient must move and change positions slowly and purposefully. If dizziness is severe or if the patient experiences hallucinations, the health care provider should be contacted for further instructions.

The newer COMT inhibitors have been shown to have greater efficacy in patients with advanced forms of PD. After treatment using the various dosage forms of levodopa-carbidopa, a COMT inhibitor may be added to the therapeutic regimen. Onset of therapeutic effects is rapid. These drugs must be administered as prescribed and may be taken without regard to meals or food. These and other antiparkinsonian drugs must never be discontinued abruptly and require a gradual weaning period to avoid worsening of PD or other dangerous effects. Emphasize to patients and caregivers that all appointments with health care providers must be kept and all laboratory testing performed as ordered. Patients must also understand the importance of changing positions slowly and with purpose to avoid syncope due to drug-related orthostatic hypotension. Inform patients that entacapone may turn their urine brownish orange but that this is not harmful. As with all medications, patients must always keep with them a written list of prescription drugs, over-the-counter (OTC) drugs, vitamins, minerals, and natural health products they are taking. This list of medications needs to be updated frequently and should be taken each time patients visit the health care provider or are hospitalized. Having this list allows continuity of information with health care providers and helps to prevent errors or omission of medications.

It is most important in the care of patients with PD to be aware of all other forms of therapies that may be beneficial, such as support groups, water aerobics, and occupational therapy and physiotherapy. Some community resources that are available include community recreation facilities, transportation services, and Meals on Wheels. Educational materials and emotional support resources must be made available and shared with family members, caregivers, and significant others because of the long-term and progressive nature of the disease. Contacting research institutes about new treatment protocols may be a viable option for patients and family members during the course of the disease. See Patient Teaching Tips for more specific information.

◆ EVALUATION

Monitoring patients' responses to any of the antiparkinsonian drugs is crucial to documenting treatment success or failure. Therapeutic responses to antiparkinsonian drugs include an improved sense of well-being, improved mental status, increased appetite, ability to perform activities of daily living, improved

concentration and ability to think clearly, and a decrease in intensity of symptoms of PD (e.g., less tremor, a less shuffling gait, decreased muscle rigidity, fewer involuntary movements). In addition to monitoring for therapeutic responses, also monitor for adverse effects such as dizziness, hallucinations, nausea, insomnia (associated with indirect-acting dopamine receptor agonists such as selegiline, amantadine, and entacapone), ataxia, depression (associated with direct-acting dopamine receptor agonists such as bromocriptine and dopamine replacement drugs such as levodopa-carbidopa), palpitations, hypotension, and urinary retention. Patients need to understand the importance of immediately reporting to their health care provider any of the following signs and symptoms that indicate possible overdose: excessive twitching, drooling, or eye spasms. Therapeutic effects of COMT inhibitors (e.g., entacapone) may be noticed within a few days, whereas therapeutic effects of other antiparkinsonian drugs may take weeks to manifest. Adverse effects for which to monitor with COMT inhibitors include those mentioned previously, but fewer dyskinesias are seen than with dopamine agonists. See Special Populations: Older Adults box for points related to PD in older adults.

SPECIAL POPULATIONS: OLDER ADULTS

Antiparkinsonian Drugs

- Levodopa-carbidopa must be used cautiously and with close monitoring in older adults, especially those with a history of heart, kidney, liver, endocrine, pulmonary, ulcer, or mental health disorders or conditions.
- Often, levodopa-carbidopa is started at a low dose because of the increased sensitivity of older patients to these medications and the need to save larger dosages for a later time during treatment.
- Overheating is a problem in patients taking anticholinergics, so older adults taking these medications must avoid excessive exercise during warm weather and excessive heat exposure.
- One of the main challenges with the long-term use of levodopa-carbidopa is that its duration of effectiveness decreases over time; this is even more problematic for older adult patients. COMT inhibitors hold much promise for older adult patients who are experiencing the wearing-off phenomenon; they help turn the "off" times into "on" times so that the drug begins to work throughout the day.

PATIENT TEACHING TIPS

- Patients should be aware that all medications must be taken exactly as ordered. Around-the-clock dosing is usually prescribed to achieve steady blood levels, especially with dopamine agonists.
- Some patients will be allowed a certain amount of freedom in the dosing of their medications, depending on their individual needs. For example, when a patient is travelling or attending an important function, an extra dose of medication may be indicated to help with movement disorders.
- Patients should avoid alcohol, OTC drugs, and natural health products unless approved by the health care provider.
- Emphasize to patients the importance of taking medication as prescribed and not stopping the medication. It is important for patients, family, and caregivers to understand that medications must be taken at the dosage and time prescribed. Inability to adhere or remain adherent to protocols may lead to exacerbation of symptoms and development of complications. Missing a dose by even 30 minutes may lead to an "off" period that lasts hours. Parkinson Canada has a "Get It On Time" campaign designed to improve the quality of life of individuals with Parkinson's disease. This is an educational program helping health care providers, patients, families, and caregivers to understand the disease and the adverse effects that occur if medications are not administered on time.
- If a patient misses a dose of medication, the health care provider must be contacted for further instructions. Some health care providers inform patients initially that if they miss a dose to take it as soon as they remember, and, if it is close to the next dose time, to skip the missed dose and take the next dose.
- If experiencing orthostatic hypotension, patients need to understand the rationale for changing positions slowly and the need to increase intake of fluids and wear compression stockings, unless contraindicated. Patients with a history of heart failure must be monitored for signs and symptoms of fluid overload.
- Patients should be aware that sustained-release drug forms are not to be crushed, chewed, or altered in any way. The drug is to be taken in its whole form.

- With anticholinergics, warn patients about the adverse effect of dry mouth. Using artificial saliva drops or gum, engaging in frequent mouth care, drinking fluids, and sucking on sugarless gum or hard candy may be helpful.
- Inform patients taking entacapone that urine colour may darken and that this adverse effect is harmless.
- Encourage patients to report any change in vision (e.g., blurring), decline in mental alertness, confusion, or lethargy while taking any of the antiparkinsonian drugs. Any difficulty with urination, irregular pulse rate, or severe uncontrolled movements of the arms or legs must also be reported.
- Educate patients and their families that some antiparkinsonian drugs are often titrated to the patient's response and that it may take 3 to 4 weeks for a therapeutic response to become evident.
- The nonergot drug ropinirole may result in drowsiness, fatigue, and syncope. Emphasize to patients the importance of safety and instruct them on how to handle these adverse effects.
- Encourage patients to increase intake of fluids and dietary fibre to help prevent constipation associated with the disease process. Constipation is also an adverse effect of drug therapy.
- Inform patients that the COMT inhibitor entacapone needs to be taken with a meal or snack to minimize GI upset. Patients using this medication should also report to their health care providers any signs and symptoms of possible liver dysfunction such as jaundice or back or abdominal pain.
- Patients must immediately report to their health care providers any abnormal contractions of the head, neck, or trunk, as well as any syncope, falls, itching, or jaundice.
- Educate patients about the goal of therapy, especially if entacapone is being used to help manage the wearing-off phenomenon. This phenomenon is a waning of the effects of a dose of levodopa before the scheduled time of the next dose, resulting in diminished motor ability and performance and the experience of more disease symptoms. If a COMT inhibitor is added to levodopa-carbidopa, the wearing-off phenomenon is minimized, and the therapeutic effects of the regimen are maximized. The patient can then expect that the "off" time will be minimized and that the drugs will work throughout the day, which is the goal in the treatment of PD.
- Suggest resources such as Parkinson Canada (<http://www.parkinson.ca/>). This organization provides educational materials and support services for patients, families, and caregivers.
- Recommend involvement with an interdisciplinary team as required in the management of PD, including, for example, a movement disorder neurologist, geriatrician, nurse with experience in PD care, physiotherapist, occupational therapist, speech-language pathologist, registered dietitian, social worker, and spiritual care professional.

KEY POINTS

- The neurotransmitter abnormalities caused by PD include chronic, progressive degeneration of dopamine-producing neurons in the brain. Patients with this disease also have elevated acetylcholine levels and lowered dopamine levels.
- Signs and symptoms of this disease include bradykinesia (slow movements), muscle rigidity (cogwheel rigidity), tremors (e.g., pill-rolling), postural instability, and dystonias (abnormal muscle tone in any type of muscle).
- Dyskinesias occur as adverse effects of some of the antiparkinsonian drugs. Dyskinesias include motor difficulties while performing voluntary movements.
- Drugs used in the treatment of PD include amantadine, benzotropine, bromocriptine, levodopa-carbidopa, entacapone, ropinirole, and selegiline.
- Patient considerations include providing individual and family support along with options for care of the family member with PD. The disease is long term and lifelong, as well as debilitating. A holistic approach in which all aspects of the patient and family are considered and respected is the key to quality nursing care.

EXAMINATION REVIEW QUESTIONS

1. Which condition will alert the nurse to a potential caution or contraindication regarding the use of a dopaminergic drug for treatment of mild PD?
 - a. Diarrhea
 - b. Tremors
 - c. Angle-closure glaucoma
 - d. Unstable gait
2. A patient is taking entacapone as part of the therapy for PD. Which intervention by the nurse is appropriate at this time?
 - a. Notify the patient that this drug causes discoloration of the urine.
 - b. Limit the patient's intake of tyramine-containing foods.
 - c. Monitor results of kidney studies because this drug can seriously affect kidney function.
 - d. Increase fluid intake to prevent dehydration.
3. During patient teaching for antiparkinsonian drugs, the nurse will include which statement?
 - a. "The drug will be stopped when tremors and weakness are relieved."
 - b. "If a dose is missed, take two doses to avoid significant decreases in blood levels."
 - c. "Be sure to notify your physician if your urine turns brownish-orange."
 - d. "Take care to change positions slowly to prevent falling due to a drop in blood pressure."
4. A patient will be taking selegiline, 10 mg daily, in addition to dopamine replacement therapy for PD. The nurse will implement which precautions regarding selegiline?
 - a. Teach the patient to avoid foods containing tyramine.
 - b. Monitor for dizziness.

- c. Inform the patient that this drug may cause urine discoloration.
- d. Monitor for tachycardia and palpitations.
5. A patient with PD will start taking entacapone along with the levodopa-carbidopa he has been taking for a few years. The nurse recognizes that the advantage of taking entacapone is which of the following?
 - a. The entacapone can reduce on-off effects.
 - b. The levodopa may be stopped in a few days.
 - c. There is less GI upset with entacapone.
 - d. It does not cause the cheese effect.
6. The nurse is assessing a patient who has begun therapy with amantadine for PD. The nurse will look for which possible adverse effects? (Select all that apply.)
 - a. Nausea
 - b. Palpitations
 - c. Dizziness
 - d. Insomnia
 - e. Edema
7. The order reads: bromocriptine 10 mg per day PO. The medication is available in 2.5-mg tablets. How many tablets will the nurse give per dose?
8. A patient who has been taking levodopa-carbidopa for Parkinson's disease for over 1 year wants to start a low-carbohydrate/high-protein weight-loss diet. The nurse tells the patient that this type of diet may have what effect on his drug therapy?
 - a. There will be no problems with this diet while on this medication.
 - b. The high-protein diet can slow or prevent absorption of this medication.
 - c. The high-protein diet may cause increased blood levels of this medication.
 - d. The high-protein diet will cause no problems as long as the patient also takes pyridoxine (vitamin B₆).

CRITICAL THINKING ACTIVITIES

1. A patient has been taking levodopa for a few years and is now experiencing an increase in symptoms of PD. His physician gave him a new prescription for entacapone, and the patient is excited, stating, "My doctor said that I should see improvement in a few days." When the nurse reviews the patient's health history, the nurse notes a previous medical condition that may be of concern. What condition would this be, and what is the nurse's priority action?
2. A patient with PD will be starting therapy with amantadine. He asks the nurse, "How long will I have to take this medicine?" What would be the nurse's best response?
3. The nurse is assessing a patient who is visiting the clinic for a 2-month follow-up appointment after starting selegiline, 10 mg daily. The patient is pleased with the improvement in his PD symptoms but states, "My wife looked up this drug and told me that I can't eat cheese or drink wine anymore. I hate that, and I really don't want to take this medicine." What is the nurse's priority action at this time?

Psychotherapeutic Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Briefly discuss the etiology and pathophysiology of the various mental health disorders.
2. Identify the psychotherapeutic drug classes, such as anxiolytic drugs, antidepressants, mood-stabilizing drugs, and antipsychotics.
3. Discuss the mechanisms of action, indications, therapeutic effects, adverse effects, toxic effects, drug interactions, contraindications, and cautions associated with psychotherapeutic drugs.
4. Develop a collaborative plan of care that includes all phases of the nursing process for patients taking psychotherapeutic drugs.
5. Develop patient education guidelines for patients taking psychotherapeutic drugs.

KEY TERMS

Affective disorders Emotional disorders that are characterized by changes in mood. (p. 280)

Akathisia A movement disorder in which there is an inability to sit still; motor restlessness; can occur as an adverse effect of psychotropic medications. (p. 295)

Anxiety The unpleasant state of mind in which real or imagined dangers are anticipated or exaggerated. (p. 280)

Biogenic amine hypothesis (BAH) A theory suggesting that depression and mania are caused by alterations in the concentrations of dopamine, norepinephrine, serotonin, and histamine. (p. 285)

Bipolar disorder (BPD) A major psychological disorder characterized by episodes of mania or hypomania, cycling with depression. (p. 280)

Cardiometabolic syndrome A cluster of risk factors (increased glucose level, increased blood pressure, abnormal cholesterol levels, excess body fat around the waist) occurring together that increases the risk of heart disease, stroke, and type 2 diabetes. (p. 295)

Depression A mood disorder characterized by exaggerated feelings of sadness, melancholy, dejection, worthlessness, emptiness, and hopelessness that impact the patient's life and may be out of proportion to reality. Signs include withdrawal from social contact, loss of appetite, and insomnia. (p. 280)

Dopamine hypothesis A theory suggesting that dopamine dysregulation in certain parts of the brain is one of the primary contributing factors to the development of psychotic disorders (psychoses). (p. 281)

Dysregulation hypothesis A theory that views depression and affective disorders as caused not simply by decreased or increased catecholamine and serotonin activity but

by failure of the brain to regulate the levels of these neurotransmitters. (p. 286)

Dystonia A syndrome of abnormal muscle contraction that produces repetitive involuntary twisting movements and abnormal posturing of the neck, face, trunk, and extremities; often an adverse reaction to psychotropic medications. (p. 295)

Extrapyramidal symptoms Signs and symptoms that result from pathological changes to the pyramidal portions of the brain. Such symptoms include various motion disorders similar to those seen in Parkinson's disease and are an adverse effect associated with the use of various antipsychotic drugs. (p. 295)

Gamma-aminobutyric acid (GABA) An amino acid in the brain that functions to inhibit nerve transmission in the central nervous system. (p. 279)

Hypomania A less severe and less potentially hazardous form of mania. (p. 281)

Mania A period of abnormally and persistently expansive or irritable mood, including persistently increased goal-directed activity or energy. (p. 280)

Neuroleptic malignant syndrome An uncommon but serious adverse effect associated with the use of antipsychotic drugs and characterized by symptoms such as fever, cardiovascular instability, and myoglobinemia (presence in the blood of muscle breakdown proteins). (p. 294)

Neurotransmitters Endogenous chemicals in the body that serve to conduct nerve impulses between nerve cells (neurons). (p. 279)

Permissive hypothesis A theory postulating that reduced concentrations of serotonin (5-hydroxytryptamine) is the predisposing factor in individuals with affective disorders. (p. 286)

Psychosis (plural psychoses) A type of serious mental health disorder that can take several different forms and is associated with being out of touch with reality; that is, the individual is unable to distinguish imaginary from real circumstances and events; includes the presence of hallucinations (with or without insight), delusions, or both. (p. 281)

Psychotherapeutics Drugs used in the treatment of emotional and mental health disorders. (p. 280)

Psychotropic Capable of affecting mental processes; usually said of a medication. (p. 281)

Serotonin syndrome A rare collection of symptoms resulting from elevated levels of the neurotransmitter serotonin; may

occur with the use of any psychotropic drug that enhances brain serotonin activity (e.g., antidepressants, buspirone, tramadol; see [Box 17.1](#)). (p. 291)

Stigma Widespread negative perceptions of and prejudice toward a specific group of people, such as those with mental health disorders. (p. 280)

Tardive dyskinesia A serious adverse drug reaction characterized by abnormal and distressing involuntary body movements and muscle tension that is associated with antipsychotic medications. (p. 295)

OVERVIEW

Many people periodically experience the normal emotions of anxiety, depression, and grief. Often, such emotions are simply situational. They arise because of a specific event and subside with time. Treatment, if any, is often limited to psychotherapy and possibly short-term drug therapy. However, longer-term pharmacotherapy in conjunction with psychotherapy is usually recommended when a person's emotions or behaviours compromise quality of life, ability to carry out normal activities of daily living (ADLs), social functioning (interactions and relationships with others), or functioning in productive occupations (e.g., employment, school) over a prolonged period (at least several months).

The exact causes of mental health disorders are not fully understood. There are numerous theories that attempt to explain the etiology and pathophysiology of mental dysfunction. In the biochemical imbalance theory, mental health disorders are thought to arise as the result of abnormal levels of endogenous chemicals in the brain, referred to as **neurotransmitters**. The conduction of messages between neurons (nerve cells) by neurotransmitters is called *neurotransmission*. Neurotransmission occurs in both

the central nervous system (CNS) and the peripheral nervous system. The proposed mechanisms of both the pathology of and drug therapy for mental health disorders centre around neurotransmission within the brain. There is evidence indicating that brain levels of catecholamines (especially dopamine and norepinephrine; see Chapter 19) and indolamines (serotonin and histamine) play an important role in maintaining mental health. Other biochemicals necessary for the maintenance of normal mental function are the inhibitory neurotransmitter **gamma-aminobutyric acid (GABA)**, the cholinergic neurotransmitter acetylcholine (see Chapter 21), and some inorganic ions such as sodium, potassium, calcium, and magnesium. Drugs used to treat mental health disorders, including anxiety, affective disorders, and psychoses, work by blocking or stimulating the release of these endogenous neurotransmitters.

The symptoms of the different mental health disorders often overlap, which can make them difficult to accurately diagnose. Complicating this issue further is the subjectivity of patients' experience of their symptoms. A widely used reference is the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition, (*DSM-5*), published by the American Psychiatric Association and updated in 2013. It provides demographic information and diagnostic criteria for recognized mental health disorders. The *DSM-5* differs from previous editions as it uses a developmental approach and supports the examination of disorders across the lifespan, including in children and older adults. Often, a patient has a range of ongoing symptoms that meet the criteria for several mental health disorders. Such patients may be said to have a spectrum disorder; one example is autism spectrum disorder. As well, adults with chronic depression may also have a comorbid personality disorder, a comorbid anxiety disorder, or a substance use disorder. The challenge of comorbid substance use is especially troublesome and complex. Comorbidity between substance use disorders and other mental health disorders requires a comprehensive approach that identifies and evaluates both. Accordingly, any patient requesting assistance for substance use or another mental health disorder should be assessed for both and treated accordingly.

Patients with mental health disorders may also be more susceptible to various physical health problems than the general population. These patients are at greater potential for physical illnesses associated with cardiometabolic syndrome. Economic, educational, and psychosocial issues may preclude a person with a mental health disorder from seeking mental health care. Thus,

many patients self-medicate with alcohol, tobacco, and illegal drugs or unauthorized prescription drugs. This compounds the problem of their baseline mental health disorder.

Despite the development of newer, more effective treatments for mental health disorders, a longstanding societal **stigma** continues to be an obstacle for diagnosed patients. In 2009, the Mental Health Commission of Canada launched “Opening Minds,” the largest-ever national effort to reduce the stigma of mental health disorders in Canada. More recently, Bell Canada’s “Let’s Talk” popular awareness campaign was launched, and in 2011 and subsequent years, a designated day was dedicated to opening discussions about mental health disorders. The goal of this campaign is to end the impact of and the stigma around mental health issues across Canada. In addition, as mental health (especially depression) is the fastest growing workplace disability in Canada (**Mood Disorders Society of Canada, 2019**), Bell Canada is working with corporate Canada and the health care community to develop and adopt mental health best practices in the workplace (**Bell Canada, 2019**).

The treatment of mental health disorders is called **psychotherapeutics**. Ideal mental health care involves many components, including a carefully detailed patient interview (to help ensure accurate and complete diagnosis) and carefully chosen and regularly monitored drug therapy. Nonpharmacological treatments include psychotherapy, support groups, social and family support systems, and spiritual support systems. Many patients benefit from a combination of cognitive behavioural therapy and drug therapy. Other practices that promote mental health include physical exercise, good nutrition, and relaxation exercises, such as meditation and visualization. For individuals who experience refractory depression, a variety of options are available, such as electroconvulsive therapy (ECT), vagal nerve stimulation, transcranial magnetic therapy, electrical brain stimulation, or deep brain stimulation.

OVERVIEW OF MENTAL HEALTH DISORDERS

This chapter focuses on three common types of mental health disorders: anxiety disorders, affective disorders, and psychotic disorders. Anxiolytics, antidepressants, mood stabilizers, and antipsychotics are the main classes of psychotropic medications used to treat these mental health disorders.

Anxiety occurs as “multiple, excessive, age-inappropriate worries about a variety of issues that occur for an extended period of time” (**McBride, 2015**, p. 29). There are often associated symptoms, including feeling on edge or restless, being easily fatigued, muscle tension, difficulty sleeping, and problems with concentration. Anxiety may be based on anticipated or past experiences. It may also stem from exaggerated responses to imaginary negative situations or to common, everyday experiences. According to the *DSM-5*, persistent anxiety is divided clinically into several distinct disorders, including the following:

- Separation anxiety disorder
- Selective mutism
- Specific phobia
- Social anxiety disorder (social phobia)

- Panic disorder (e.g., depressive disorder with panic attacks, post-traumatic stress disorder [PTSD] with panic attacks)
- Panic attack (specifier)
- Agoraphobia
- Generalized anxiety disorder
- Substance- or medication-induced anxiety disorder
- Anxiety disorder due to another medical condition
- Other specified anxiety disorder
- Unspecified anxiety disorder

Anxiety is a normal reaction to stress. Approximately 2.6–8.6% of Canadians over the age of 15 will experience generalized anxiety disorder (**Government of Canada, 2016**). Anxiety may occur as a result of medical illnesses (e.g., cardiovascular or pulmonary disease, hypothyroidism, hyperthyroidism, pheochromocytoma, Cushing’s syndrome, hypoglycemia).

Affective disorders, also called *mood disorders*, are characterized by changes in mood and range from mania to depression. In Canada, over 5.6–12.6% of people aged 15 and older will experience some type of mood disorder during their lives (**Government of Canada, 2016**). An episode of **mania** is characterized by an abnormally elevated, expansive, or irritable mood for at least 1 week, plus the presence of at least three of the following additional symptoms: grandiosity (exaggerated belief in one’s importance), decreased need for sleep, pressured (intense) speech, flight of ideas (thoughts rapidly skip to distantly related ideas, in no logical progression), distractibility, increased involvement in goal-directed activities, or involvement in pleasurable activities that have a high potential for painful consequences. The manic episode must be severe enough to cause impairments in social or occupational functioning or to require hospitalization (**Brenner & Shyn, 2015**).

Depression is characterized by the presence of sad, empty, or irritable mood, accompanied by somatic and cognitive changes that significantly affect the individual’s capacity to function (**Canadian Psychological Association, 2017**). A major depressive episode is characterized by a depressed mood and a loss of interest or pleasure in daily activities, for longer than 2 weeks. At least five of the following symptoms must be present almost daily: depressed mood or irritability, feelings of worthlessness or guilt, loss of interest in normally pleasurable activities (anhedonia), fatigue or reduced energy level, reduced motivation and ability to meet routine responsibilities, drastic increase or decrease in appetite, lack of concentration, insomnia or hypersomnia, and recurrent thoughts of death or suicide (CPA, 2017). In addition to being associated with a reduction in quality of life and occupational and social functioning, depression is also accompanied by the occurrence of major sleep disturbances in up to 80% of patients. Despite recent advances in pharmacotherapy for depression, it remains undertreated and underdiagnosed.

Some patients may exhibit both mania and depression, experiencing periodic swings in emotions between these two extremes. This is referred to as **bipolar disorder (BPD)**. Bipolar disorder has a lifetime prevalence of 2% and a 12-month prevalence of 1% of the Canadian population (**Canadian Mental Health Association, 2013**).

An episode of **hypomania** is similar to one of mania, but less intense; it lasts for at least 4 days and has an impact on the individual's functioning. Some patients may exhibit rapid cycling (at least four depressive/hypomanic episodes per year.) These patients have a poorer prognosis and require frequent hospitalizations and complex management.

The burden of depression and other mental health disorders is on the rise globally. Even when they are successfully treated and remission is achieved, depressive disorders still inflict significant burden. Remission is rarely accompanied by a total disappearance of all symptoms. Residual symptoms, especially cognitive impairment or social dysfunction, can continue to reduce performance and cause considerable distress. The ever-present risk of relapse and recurrence also weighs heavily, generally reducing quality of life. The World Health Organization estimates that depressive disorders will be the leading cause of disease burden worldwide by 2030 (WHO, 2018). Depression is currently reported to have lifetime prevalence in Canadian adults over 18 of about 12% (Langlois, Samokhvalov, Rehm, et al., 2012).

Psychosis is a symptom or feature of severe mental health disorders that often impairs mental function to the point of causing significant disability in performing ADLs. A hallmark of psychosis is a loss of contact with reality. The primary psychotic disorders are schizophrenia and depressive and drug-induced psychoses. Schizophrenia may trigger hallucinations, paranoia, and delusions (false beliefs), and it is estimated to affect 1% of the population. The **dopamine hypothesis** of psychotic illness grows out of the observation that patients who experience psychosis often have excessive dopaminergic activity in the brain. Drug therapy is therefore aimed at reducing this activity. Note that this is in direct contrast to the treatment of Parkinson's disease (see Chapter 16), in which the therapeutic goal is to enhance dopaminergic activity in the brain.

Psychotropic drugs are among the most commonly prescribed drugs in Canada. Because of the inherent variability in description of symptoms and diagnoses, the effects of these drugs are less easily quantified than those of many other types of medications. Drug response may vary considerably among patients and depend on the dosage of psychotropic drugs as these drugs are highly dependent on clinical response. Drug selection is often a trial-and-error process, which can be long and frustrating for both health care providers and patients.

It is hoped that the emerging field of pharmacogenomics (see Chapter 5 and the Ethnocultural Implications box on Page 302) will eventually allow more proactive and improved customization of psychotropic drug therapy. Also, as more is learned about a drug after initial marketing, it is common for the approved indications for a given drug to expand over time. For example, a drug initially approved to treat depression may later be approved to treat social anxiety disorder or additional conditions. Most antidepressants are effective anxiolytic drugs and are often used as first-line treatment for anxiety disorders.

A common problem with psychotropic drug therapy, as with other types of drug therapy, is nonadherence to the prescribed regimen. Many people do not want to accept a diagnosis of a mental health disorder because of the associated stigma. As a result, they may remain in denial about the reality of their

TABLE 17.1 Selected Available Anxiolytic Drugs

Generic Name	Trade Name	Route

IM, Intramuscular; IV, intravenous; PO, oral.

mental health disorder, including the need to take psychotropic medications. They may also have legitimate fears about adverse effects, as well as fear of the unknown regarding their illness. For example, the weight gain associated with antipsychotics can be a reason for patient nonadherence. Finally, they may dread the prospect of having to remain on medication to control their symptoms. Such patients can often be helped by support groups and other social supports. As they adjust to their diagnoses, it is hoped that they will gain insight into the benefits of treatment to strengthen their own roles in maintaining their mental health.

ANXIETY DISORDERS

Anxiolytic Drugs

Primary anxiolytic drugs include the benzodiazepine drug class and the miscellaneous drug bupirone (Table 17.1). Although antidepressants are usually first-line drug therapy for the treatment of anxiety disorders, the benzodiazepines are the focus of this section. In addition, other drugs that are effective as anxiolytics include selective serotonin reuptake inhibitors (SSRIs), tricyclic antidepressants (TCAs), and monoamine oxidase inhibitors (MAOIs), all discussed in the section on antidepressants, antipsychotics (see later section on antipsychotic drugs), propranolol, and the antihistamine hydroxyzine hydrochloride (see Chapter 37).

Mechanism of Action and Drug Effects

All anxiolytic drugs reduce anxiety by reducing overactivity in the CNS. Benzodiazepines exert their anxiolytic effects by depressing activity in the brainstem and the limbic system. Benzodiazepines are believed to increase the action of GABA, which is an inhibitory neurotransmitter (i.e., inhibits reuptake of neurotransmitters such as serotonin, norepinephrine, and dopamine) in the brain that blocks nerve transmission in the CNS.

The drug bupirone is a miscellaneous anxiolytic in its own class and is described in further detail in its drug profile.

Indications

Benzodiazepines are the classic anxiolytic drug class; however, they are also associated with physical tolerance/dependence and misuse potential. Withdrawal and adverse effects do not offer any advantage over other classes, such as SSRIs. They are sometimes used for other indications, such as ethanol withdrawal (see Chapter 18), insomnia and muscle spasms (see Chapter 13), seizure disorders (see Chapter 15), and as adjuncts in anaesthesia (see Chapter 12). They are also used as adjunct therapy for depression because depressive and anxious symptoms often occur together. Benzodiazepines are effective for the short-term treatment of anxiety, as they stop symptoms of anxiety quickly. They do not prevent anxiety, nor are they effective for treating depressive symptoms. Therefore, they are not effective for use in patients with anxiety and co-morbid depression.

Contraindications

Contraindications to benzodiazepines include known drug allergy; narrow-angle glaucoma, due to their ability to cause mydriasis (pupil dilation); and pregnancy, due to their sedative properties and potential for teratogenic effects.

Adverse Effects

The most common undesirable adverse effect of benzodiazepines is an overexpression of their therapeutic effects, in particular CNS depression. Benzodiazepines can also cause hypotension. Of note are paradoxical (opposite of what would normally be expected) reactions to the benzodiazepines, including hyperactivity and aggressive behaviour. Such reactions are relatively uncommon. They are more likely to occur in children, in adolescents, and in older adults with dementia. Rebound disinhibition can occur in older adult patients upon tapering of doses or discontinuation of the benzodiazepines. In rebound disinhibition, an older adult patient experiences marked sedation for 1 to 2 hours, followed by marked agitation and confusion for several hours afterward. All benzodiazepines are potentially habit-forming and addictive. They have a rapid onset and duration of action and, therefore, can provide significant symptom relief; however, they must be used judiciously and at the lowest effective doses for the shortest period needed for symptom control.

Refer to Table 17.2 for more information on adverse effects. Older adult patients tend to be particularly sensitive to the

CNS sedating effects of benzodiazepines, which can increase the potential for falls; thus, lower doses are usually needed. Benzodiazepines taken by older adult patients may also have longer elimination half-lives due to decreased hepatic metabolism. In general, dosages of benzodiazepines for older adult patients should be approximately one third to one half of the recommended dosages for younger adults. In addition, it is possible to administer dosages of benzodiazepines every other day to reduce toxic effects.

Toxicity and Management of Overdose. Overdose of anxiolytics is usually not severe but may be associated with excessive sedation, hypotension, and seizures. There is no specific antidote, but in extreme cases, a cholinergic drug (see Chapter 21) may be used to treat anticholinergic adverse effects associated with anxiolytics. When benzodiazepines are taken alone, an overdose is generally not life threatening. When they are combined with alcohol or other CNS depressants, the outcome is much more severe. An overdose of benzodiazepines may result in any of the following symptoms: somnolence, confusion, coma, and respiratory depression. When overdose is suspected, gastric lavage may be instituted as soon as possible, and 50 to 100 g of activated charcoal may be introduced to and left in the stomach. Flumazenil is a benzodiazepine receptor blocker (antagonist) that is used as adjunctive therapy to reverse the effects of benzodiazepines. It is usually given to reverse benzodiazepine effects after procedures involving procedural sedation (see Chapter 12). The treatment regimen for the acute reversal of benzodiazepine effects is summarized in Chapter 13. Flumazenil may cause acute withdrawal syndrome, including seizures in patients taking benzodiazepines long term or those with a history of substance misuse.

Interactions

Several notable drug interactions occur with the use of benzodiazepines. Alcohol and other CNS depressants, when coadministered with benzodiazepines, can result in additive CNS depression, respiratory depression, and subsequent death. This serious consequence is more likely to occur in patients with kidney or liver compromise (e.g., older adults). Other drug interactions are listed in Table 17.3.

Dosages

Recommended dosages of selected antianxiety drugs are given in the table on p. 284.

TABLE 17.2 Adverse Effects of Selected Anxiolytic Drugs*	
Drug or Drug Class	Adverse Effects
Benzodiazepines	Amnesia, anorexia, sedation, lethargy, fatigue, confusion, drowsiness, dizziness, ataxia, headache, visual changes, hypotension, weight gain or loss, nausea, weakness
Miscellaneous	
bupirone hydrochloride	Paradoxical anxiety, dizziness, blurred vision, headache, nausea

*See also drug profiles for drug-specific information.

 DRUG PROFILES

Benzodiazepines

Benzodiazepines are widely used anxiolytic drugs. They are targeted substances and classified as Schedule IV controlled substances. For dosage and indication information, refer to the table on p. 284.

 alprazolam

Alprazolam (Xanax®) is most commonly used as an anxiolytic. It is also indicated for the specific anxiety disorder known as

TABLE 17.3 Drug Interactions of Selected Anxiolytic Drugs*

Drug Class	Interacting Drug(s)	Mechanism	Result
Benzodiazepines	CNS depressants (e.g., alcohol, opioids)	Additive effects	Enhanced CNS depression (e.g., sedation, confusion, ataxia)
	Oral contraceptives, azole antifungals, verapamil hydrochloride, diltiazem hydrochloride, opioids, valproic acid	Inadequate liver elimination of benzodiazepine	Enhanced benzodiazepine effects (e.g., CNS depression)
	rifampin	Enhanced benzodiazepine clearance	Reduced therapeutic effects
	theophylline	Antagonistic effects	Reduced sedative effects
	phenytoin	Reduced clearance	Potential for digoxin toxicity and phenytoin toxicity
Miscellaneous			
buspirone hydrochloride	CYP3A4 inhibitors, azole antifungals, verapamil hydrochloride, diltiazem hydrochloride	Reduced liver metabolism of buspirone hydrochloride	Enhanced buspirone hydrochloride effects
	rifampin	Enhanced buspirone hydrochloride clearance	Reduced therapeutic effects
	MAOIs	Unknown	Increased blood pressure

CNS, Central nervous system; MAOIs, monoamine oxidase inhibitors; SSRIs, selective serotonin reuptake inhibitors.

*See also drug profiles for drug-specific information.

panic disorder. Adverse effects include confusion, ataxia, headache, and others listed in Table 17.2. Interacting drugs include alcohol, antacids, oral contraceptives, and others listed in Table 17.3. It has moderate withdrawal effects. Alprazolam is available only for oral use, in tablet form.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	30–60 min	1–2 hr	10–15 hr	6 hr

▶▶ diazepam

Diazepam (Valium®), the longest-acting benzodiazepine, used to be the most commonly prescribed benzodiazepine; however, for treatment of anxiety, it has generally been replaced by the shorter-acting benzodiazepines alprazolam and lorazepam. Diazepam is indicated for relief of anxiety, management of alcohol withdrawal, reversal of status epilepticus or preoperative sedation, and, less frequently, as an adjunct for the relief of skeletal muscle spasms. Diazepam has active metabolites that can accumulate in patients with liver dysfunction because it is metabolized primarily in the liver. This accumulation can result in additive, cumulative effects that may be manifested as prolonged sedation, respiratory depression, or coma. For this reason, it is probably best avoided in patients with major liver compromise. Adverse drug effects include headache, confusion, slurred speech, and others listed in Table 17.2. Diazepam interacts with alcohol, oral contraceptives, and others, as shown in Table 17.3. Diazepam is available in oral and injectable dosage forms. It is generally not administered by intramuscular (IM) injection due to its poor and inconsistent absorption rate.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	30–60 min	1–2 hr	Ave. 100 hrs	12–24 hr

▶▶ lorazepam

Lorazepam (Ativan®) is an intermediate-acting benzodiazepine. Lorazepam is available in oral, sublingual, and injectable forms. It may be given intravenously or intramuscularly. It has excellent absorption and bioavailability when given intramuscularly, but it is irritating to the muscle and must be diluted. The conversion between injectable and oral dosage forms is 1:1. Lorazepam can be given by intravenous push, which is useful in the treatment of an acutely agitated patient. It is often administered as a continuous infusion to agitated patients who are undergoing mechanical ventilation. It is also used to treat or prevent alcohol withdrawal (see Chapter 18). Lorazepam has fewer active metabolites and less drug interactions.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	30–60 min	2 hr	11–16 hr	8 hr

Miscellaneous Drug

buspirone hydrochloride

Buspirone hydrochloride is an anxiolytic drug that is different both chemically and pharmacologically from the benzodiazepines. Its precise mechanism of action is unknown, but it appears to have agonist activity at both serotonin and dopamine receptors. It is indicated for treatment of anxiety and is always administered on a scheduled (not “as-needed”) basis, as opposed to the benzodiazepines that may be administered as needed or on a schedule. The only reported contraindication is drug allergy. Buspirone lacks the sedative properties and dependency potential of the benzodiazepines. Adverse effects include paradoxical anxiety, dizziness, blurred vision, headache, and nausea. Potential drug interactions include a potential for serotonin syndrome (see section on antidepressants). Patients receiving buspirone and antidepressants together need to be monitored carefully. It is recommended that MAOIs not be used

concurrently with buspirone due to the risk of hypertension. A washout period of at least 14 days after discontinuation of MAOI therapy must be allowed before buspirone is started. Other drugs that interact with buspirone include *inhibitors* of the cytochrome P450 enzyme system (see [Chapter 2](#))—specifically with CYP3A4 (e.g., ketoconazole [see [Chapter 48](#)], clarithromycin [see [Chapter 43](#)])—which can reduce buspirone clearance; and *inducers* of these same enzymes, which can enhance buspirone clearance and decrease its therapeutic effect. In either case, the buspirone dosage may need to be adjusted. Other interactions are listed in [Table 17.3](#). Buspirone is available only for oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	2–3 wk	40–90 min	2–3 hr	Unknown

AFFECTIVE DISORDERS

Several classes of drugs are used in the treatment of affective (emotional) disorders. The two main drug categories are mood-stabilizing drugs and antidepressant drugs.

MOOD-STABILIZING DRUGS

Mood stabilizers are drugs used to treat bipolar disorder (cycles of mania, hypomania, and depression). Clinical evidence indicates that the catecholamines (dopamine and norepinephrine) play an important pathophysiological role in the development of mania. Serotonin also appears to be involved. Lithium has been in use for many years and is still used to effectively alleviate the symptoms of acute mania. Lithium is available in two salt forms: lithium carbonate and lithium citrate (currently not available in Canada). Lithium is also effective for the maintenance treatment of bipolar disorder as well as bipolar depression

and mixed episodes. Lithium is thought to potentiate serotonergic neurotransmission. A variety of medications may be used in conjunction with lithium to regulate mood or achieve stability; they include benzodiazepines (described earlier), antipsychotic drugs (see later in the chapter), antiepileptic drugs (see [Chapter 15](#)), and dopamine receptor agonists (see [Chapter 16](#)). The antiepileptics valproic acid, lamotrigine, oxcarbazepine, and topiramate may be used when patients do not tolerate lithium. Lithium has a narrow therapeutic range and requires blood level monitoring. Antiepileptic drugs are often effective in treating mania, hypomania, and, to a lesser degree, depressive symptoms. Other evidence has shown that the atypical antipsychotic drugs risperidone, olanzapine, quetiapine, lurasidone hydrochloride, and ziprasidone hydrochloride monohydrate (see later) can also be effective in the acute treatment of mania and hypomania and also maintenance treatment of bipolar disorder. Available mood-stabilizing drugs are listed in [Table 17.4](#).

DRUG PROFILES

lithium

The mood-stabilizing effect of lithium is not fully understood. Lithium ions are thought to alter sodium ion transport in nerve cells, which results in a shift in catecholamine metabolism. The levels of lithium required to produce a therapeutic effect are close to the toxic levels (i.e., it has a narrow therapeutic index). For the management of acute mania, a lithium serum level of 1 to 1.5 mmol/L is usually required. Desirable long-term maintenance levels range between 0.6 and 1.2 mmol/L. Blood levels are best measured 8 to 12 hours after the last dose (roughly the midpoint of the drug half-life) because the half-life is usually between 18 and 24 hours. Both sodium and lithium are monovalent positive ions, and one can affect the other. Therefore, the patient's serum sodium levels require monitoring. Keeping sodium levels in the normal range (135 to 145 mmol/L) helps to

Dosages

Selected Anxiolytic Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications
alprazolam (Xanax)	Benzodiazepine	Adults PO: 0.25–1 mg bid/tid; do not exceed 3 mg/day Older adults PO: 0.125 mg bid/tid	Generalized anxiety disorder Generalized anxiety disorder
 diazepam (Valium)	Benzodiazepine	Adults PO: 2 mg–10 mg BID–QID Children PO: 0.12–0.8 mg/kg/day in divided doses Q6–8 hours (indication for muscle relaxation or anxiety)	Anxiety
 lorazepam (Ativan)	Benzodiazepine	Adults PO: 0.5–6 mg/day prn in 2–3 divided doses SL: 0.5–2 mg, 2–3 times per day. Maximum 6 mg/day	Generalized anxiety disorder

maintain therapeutic lithium levels. Patients should be advised not to drastically change their sodium intake while taking lithium and to avoid overhydration as well as dehydration.

Lithium is indicated for the treatment of manic episodes in bipolar disorder as well as for maintenance therapy to prevent such episodes. Contraindications to lithium therapy are relative and include dehydration, known sodium imbalance, and major kidney or cardiovascular disease because all of these conditions increase the risk of lithium toxicity. Kidney dysfunction of any degree can increase lithium levels. Older adult patients are particularly prone to this effect because kidney function normally declines with advancing age. Adverse effects tend to correlate with serum levels. Mild to moderate toxic reactions can occur at lithium levels from 1.5 to 2 mmol/L, and moderate to severe reactions occur at levels above 2 mmol/L. Toxicity manifestations include gastrointestinal (GI) discomfort, tremor, confusion, somnolence, seizures, and possibly death. The most serious adverse effect is cardiac dysrhythmia. Other effects include drowsiness, slurred speech, epilepsy-type seizures, choreoathetotic movements (involuntary wavelike movements of the extremities), ataxia (generalized disturbance of muscular coordination), and hypotension. Long-term treatment may cause hypothyroidism. Potentially interacting drugs include the thiazide diuretics (see Chapter 29), angiotensin-converting enzyme inhibitors (see Chapter 23), and nonsteroidal anti-inflammatory drugs (see Chapter 49), all of which can increase lithium toxicity. Lithium is available only for oral use.

ANTIDEPRESSANT DRUGS

Antidepressants are the pharmacological treatment of choice for major depressive disorders. In 2012, 42.6 million prescriptions for antidepressants were filled in Canada. The highest use for men is between the ages of 25 and 44 and for women between the ages of 25 and 79 (Rotermann, Sanmartin, Hennessy, et al., 2014). Not only are antidepressants effective in treating depression, they are also useful for treating other disorders, such as anxiety disorders, dysthymia (chronic low-grade depression), schizophrenia (as an adjunctive drug), eating disorders, and personality disorders. Some of the antidepressants are also used in the treatment of various medical conditions, including migraine headaches, chronic pain syndromes, sleep disorders, premenstrual syndrome, and hot flashes associated with menopause. Available antidepressants are listed in Table 17.4.

Many of the drugs currently used to treat affective disorders increase the levels of neurotransmitter concentrations in the CNS; these neurotransmitters include serotonin (also known as 5-hydroxytryptamine, or 5-HT), dopamine, and norepinephrine. This treatment is based on the belief that alterations in

the levels of these neurotransmitters are responsible for causing depression. A widely held hypothesis advanced to explain depression in these terms is the **biogenic amine hypothesis (BAH)**. It postulates that depression results from a deficiency of neuronal and synaptic catecholamines (primarily norepinephrine), and mania results from an excess of amines at the

Fig. 17.2 Permissive hypothesis. NE, norepinephrine; 5-HT, serotonin.

adrenergic receptor sites in the brain. This hypothesis is illustrated in [Figure 17.1](#).

Another hypothesis to explain the cause of depression is the [permissive hypothesis](#), which led to the creation of the SSRI drug class. The permissive theory postulates that reduced concentrations of serotonin are the predisposing factor in patients with affective disorders. Depression results from decreases in both the serotonin and catecholamine levels, whereas mania results from increased dopamine and norepinephrine levels but decreased serotonin levels. The permissive hypothesis is illustrated in [Figure 17.2](#). The [dysregulation hypothesis](#) is essentially a reformulation of the BAH. This theory views depression and other affective disorders not simply in terms of decreased or increased catecholamine activity but as a failure of the regulation of these systems.

Early and aggressive antidepressant treatment increases the chances for full remission. The first 6 to 8 weeks of therapy constitute the acute phase. The primary goals during this time are to obtain a response to drug therapy and improve the patient's symptoms. It is currently recommended that antidepressant drug therapy be maintained at the effective dose for an additional 8 to 14 months after remission of depressive symptoms. In choosing an antidepressant, the patient's previous psychotropic drug response history (if any) needs to be considered. Family history of depression with known drug responses is also helpful to know. Therapeutic response is measured primarily by subjective patient feedback. In addition, there are measurement tools available that attempt to quantify the patient's response to drug therapy, such as the Hamilton Rating Scale for Depression and the Symptom Checklist-90 anxiety factor scale.

Anxiety and depression commonly occur together and reinforce each other. Similarly, there is much crossover in terms of symptom control between antidepressant and anxiolytic drugs. There is a wide variation in response to antidepressant drug therapy, which can be attributed to genetic polymorphism (see [Chapter 5](#)). Identification of early versus late response to antidepressant therapy early during treatment may assist in guiding optimal therapeutic choices for patients experiencing depression ([Fabbri, Marsano, Balestri, et al., 2013](#)). Efficacy may take 3 to 6 weeks in many patients. Adverse effects may occur earlier than efficacy.

A nonresponse to antidepressant drug therapy is defined as failure to respond to at least 6 weeks of therapy with adequate drug dosages ([Al-Harbi, 2012](#)). Most patients who do not respond to the usual dosage of an antidepressant will respond to higher doses. Therefore, dose optimization, which involves careful upward titration of the dose for several weeks, is recommended before concluding that a given drug is inadequate. Often, a switch to a different pharmacological class of antidepressant is necessary; 40 to 60% of patients will respond to the second drug class tried. Benzodiazepine and antipsychotic drugs may also be used, either alone or as adjunct therapy. Evidence suggests that psychotherapy given with antidepressant medication is more effective than medication alone, although access to psychotherapy may be an issue.

The most severe cases of refractory depression may warrant ECT. ECT is a safe and effective treatment carried out in a post-anesthesia care unit setting under short-acting brief anesthesia and a muscle relaxant. There is some controversy over the positioning of electrodes; they can be positioned in the bifrontotemporal, right unilateral, and bifrontal positions. The electrical stimulus must be sufficient to stimulate seizure activity in the brain and lasts around 25 to 150 seconds. The number of treatments required for an effective course of ECT varies substantially between individuals. A typical course requires 6 to 12 treatments over a 2- to 4-week period, while patients with mania or schizophrenia may require a somewhat higher number of treatments. A typical adverse effect is memory impairment, both retrograde (patient forgets events prior to the seizure) and anterograde (patient forgets events after the seizure), which usually subsides within 1 to 6 months ([Enns & Reiss, 2015](#)).

Another, newer, alternative treatment to ECT is magnetic seizure therapy (MST). Rather than using electrical currents to

create seizures throughout the entire brain as with ECT, MST uses repetitive magnetic stimulation to produce targeted seizures in the prefrontal cortex, avoiding adverse effects on cognition. Another treatment that has gained attention is the use of ketamine (see [Chapter 12](#)) intravenously to relieve depression symptoms ([Melville, 2012](#)).

Treatment failure in cases of depression may be due to a misdiagnosis or failure to treat a concurrent mental health disorder (e.g., anxiety disorder, substance misuse) or comorbid nonpsychiatric illness (e.g., hypothyroidism). It may also be due to nonadherence to drug therapy. Careful choice of drug therapy to minimize adverse effects may improve patient adherence with treatment and therapeutic outcomes. Another reason for treatment failure may be the discouragement associated with depression itself. This alone may cause patients to give up prematurely on their drug therapy, especially because antidepressants often take several weeks to reach their full effect. Effective psychotherapy and support groups can help encourage patients to be consistent with prescribed psychotropic drug therapy, through patient education.

In 2004, Health Canada issued special warnings regarding the use of all classes of antidepressants in both adult and pediatric patient populations. Clinical trials and postmarketing reports indicated an increased potential for suicide and agitation-type emotional and behavioural changes in patients receiving these medications. As a result, current recommendations for all patients receiving antidepressants include regular monitoring for signs of worsening depressive symptoms, especially when the medication is first started or the dosage is changed. Patients need immediate evaluation if they report, or others observe, signs of worsening depression or other emotional instability. Most patients do not experience severe adverse effects from these medications, and many patients obtain significant relief.

TRICYCLIC ANTIDEPRESSANTS

Tricyclic antidepressants (TCAs) were the original first-generation antidepressants. Their use has largely been replaced with the SSRIs and serotonin–norepinephrine reuptake inhibitors (SNRIs). TCAs are considered second-line drug therapy in patients for whom SSRIs are inadequate or as adjunct therapy with newer drugs. TCAs are so named because of their characteristic three-ring chemical structure.

Mechanism of Action and Drug Effects

TCAs are believed to work by correcting imbalance in the neurotransmitter concentrations of serotonin and norepinephrine at the nerve endings in the CNS (the BAH). This is accomplished by blocking the presynaptic reuptake of the neurotransmitters, which makes them available for transmission of nerve impulses to adjacent neurons in the brain. Some also believe that these drugs may help regulate malfunctioning neurons (the dysregulation hypothesis).

Indications

Currently, TCAs are most commonly used to treat neuropathic pain syndromes and insomnia. With the advent of the newer-generation antidepressant classes, their use as

antidepressants is rare. Some TCAs have additional specific indications. For example, imipramine hydrochloride is used as an adjunct in the treatment of childhood enuresis (bedwetting), and clomipramine hydrochloride is useful in the treatment of obsessive-compulsive disorder. Because TCAs tend to increase appetite, leading to weight gain, they are sometimes used to treat anorexia nervosa.

Contraindications

Contraindications for TCAs include known drug allergy, use of MAOIs within the previous 14 days, and pregnancy. TCAs are also not recommended in patients with any acute or chronic cardiac problems or a history of seizures because both conditions are associated with a greater likelihood of death upon TCA overdose.

Adverse Effects

Undesirable effects of TCAs are a result of their effects on various receptors, especially the muscarinic receptors (a type of cholinergic receptor) and, to a lesser degree, adrenergic, histaminergic, dopaminergic, and serotonergic receptors. Blockade of cholinergic receptors results in undesirable anticholinergic adverse effects, the most common being constipation and urinary retention. Nortriptyline hydrochloride and desipramine hydrochloride have less anticholinergic activity, and they are preferred for use in older adults. Adrenergic and dopaminergic receptor blockade can lead to disturbances in cardiac conduction and hypotension. Histaminergic blockade can cause sedation, and serotonergic blockade can alter the seizure threshold and cause sexual dysfunction (see [Table 17.5](#)).

Toxicity and Management of Overdose

TCA overdoses are notoriously lethal. It is estimated that 70 to 80% of patients who die of TCA overdose do so before reaching the hospital, especially if the drugs are taken with alcohol. The primary organ systems affected are the CNS and the cardiovascular system. Death usually results from either seizures or dysrhythmias. Historically, it was taught that patients should not receive more than a 1-month supply of antidepressants because of the risk of suicide attempts. Many people choose to receive a 3-month supply to avoid paying more dispensing fees each time they fill a prescription.

There is no specific antidote for TCA poisoning. Management efforts are aimed at reducing drug absorption by administering multiple doses of activated charcoal. Administration of sodium bicarbonate speeds up elimination of the TCA by alkalinizing the urine. CNS damage may be minimized by the administration of diazepam, and cardiovascular events may be minimized by giving antidysrhythmics. Other care includes basic life support in an intensive care setting to maintain vital organ functions. These interventions must continue until enough of the TCA is eliminated to permit restoration of normal organ function.

Interactions

Increased anticholinergic effects are seen when TCAs are taken with anticholinergics and phenothiazines. When MAOIs are taken with TCAs, the result may be increased therapeutic and toxic effects, including hyperpyretic crisis (excessive fever). Other drug interactions are listed in [Table 17.6](#).

TABLE 17.5 Adverse Effects of Selected Mood Stabilizers and Antidepressants*

Drug or Drug Class	Adverse Effects
Mood Stabilizers	
lithium salts	GI discomfort, tremor, confusion, sedation, seizures, cardiac dysrhythmia, drowsiness, slurred speech, slowed motor abilities, weight gain, ataxia, hypotension, renal toxicity.
Antiepileptic drugs	Dizziness, drowsiness, GI upset, weight gain, hepatotoxicity, pancreatitis, unusual eye movements, visual changes, behavioural changes, ataxia
Antidepressants	
First Generation	
Tricyclics	Anorexia, dry mouth, blurred vision, constipation, gynecomastia, sexual dysfunction, altered blood glucose level, urinary retention, agitation, anxiety, ataxia, cognitive impairment, sedation, headache, insomnia, skin rash, photosensitivity, weight gain, orthostatic hypotension, blood dyscrasias
MAOIs	Dizziness, dyskinesias, nausea, syncope, hypotension
Second Generation	
Tetracyclics	
mirtazapine, maprotiline hydrochloride	Drowsiness, abnormal dreams, dry mouth, constipation, increased appetite, asthenia (muscle weakness)
SSRIs	Anxiety, dizziness, drowsiness, headache, mild GI disturbance, sexual dysfunction, asthenia, tremor
SNRIs	Dizziness, drowsiness, headache, GI upset, anorexia, hepatotoxicity, discontinuation/withdrawal syndrome
Miscellaneous	
trazodone hydrochloride, bupropion hydrochloride	Dizziness, headache, sedation, nausea, blurred vision, tachycardia

GI, Gastrointestinal; MAOIs, monoamine oxidase inhibitors; SNRIs, serotonin–norepinephrine reuptake inhibitors; SSRIs, selective serotonin reuptake inhibitors.

TABLE 17.6 Drug Interactions of Selected Mood-Stabilizing and Antidepressant Drugs*

Drug Class	Interacting Drug(s)	Mechanism	Result
Mood Stabilizers			
lithium salts	Thiazide diuretics, angiotensin-converting enzyme inhibitors, verapamil, diltiazem, NSAIDs, caffeine (causes decreased lithium levels)	Decreased lithium excretion	Increased lithium toxicity
Antiepileptic drugs	See Table 15-5.		
Antidepressants			
First Generation			
Tricyclics (TCAs)	carbamazepine, rifamycins	Enhanced TCA clearance	Reduced therapeutic effects
	carbamazepine	Reduced carbamazepine clearance	Potential for carbamazepine toxicity
	MAOIs	Enhance serotonergic effects	Potential for serotonin syndrome
	valproic acid	Reduced TCA clearance	Potential for TCA toxicity
	Anticholinergics	Additive anticholinergic effects	Potential for paralytic ileus
	Sympathomimetics	Enhanced sympathomimetic effects	Potential for cardiac dysrhythmias
Second Generation			
Tetracyclics			
mirtazapine, maprotiline hydrochloride	Alcohol, CYP inhibitors	Additive effects	Increased toxicity
SSRIs	MAOIs, linezolid, lithium, metoclopramide hydrochloride, buspirone hydrochloride, sympathomimetics, tramadol hydrochloride	Additive effects	Potential for serotonin syndrome
	Benzodiazepines	Reduced metabolism	Potential benzodiazepine toxicity
	warfarin sodium, phenytoin	Protein binding displacement	Potential for warfarin sodium or phenytoin toxicity
	propafenone hydrochloride	Increased propafenone levels	Potential for propafenone hydrochloride toxicity

TABLE 17.6 Drug Interactions of Selected Mood-Stabilizing and Antidepressant Drugs*—cont'd

Drug Class	Interacting Drug(s)	Mechanism	Result
SNRIs Duloxetine	SSRIs, triptans	Additive effects	Risk of serotonin syndrome
	NSAIDs, warfarin sodium	Additive effects	Risk of bleeding
	Alcohol	Additive liver toxicity	Increased risk of hepatotoxicity
Miscellaneous trazodone, bupropion	Azole antifungals, phenothiazines, protease inhibitors	Inadequate hepatic metabolism	Increased effects
	carbamazepine	Increased metabolism	Decreased therapeutic effects
	Alcohol, CNS depressants	Additive effects	Increased CNS depression

CNS, Central nervous system; NSAIDs, nonsteroidal anti-inflammatory drugs; MAOIs, monoamine oxidase inhibitors; SNRIs, serotonin–norepinephrine reuptake inhibitors; SSRIs, selective serotonin reuptake inhibitors; TCAs, tricyclic antidepressants.

Dosages

Recommended dosages of selected TCA drugs are given in the table on the next page.

DRUG PROFILES

TCAs are effective drugs in the treatment of various affective disorders, but they are associated with serious adverse effects. Therefore, patients taking them need to be monitored closely. For this reason, all antidepressants are available only with a prescription. Some natural health products used to treat depression, such as St. John's wort (see the Natural Health Products [Safety Alert]: St. John's wort box on the next page), are available over the counter but should not be taken with prescription antidepressants due to the risk of serotonin syndrome.

amitriptyline hydrochloride

Amitriptyline hydrochloride (Elavil®, Levate®) is the oldest and most widely used of all the TCAs. Its original indication was depression, but it is now more commonly used to treat insomnia and neuropathic pain. Contraindications include known drug allergy, pregnancy, and recent myocardial infarction. It has potent anticholinergic properties, which can lead to many adverse effects such as dry mouth, constipation, blurred vision, urinary retention, and dysrhythmias (see Table 17.5). Drug interactions are listed in Table 17.6. Amitriptyline is available only for oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	7–21 days	2–5 hr	13–36 hr	6–12 hr

MONOAMINE OXIDASE INHIBITORS

Monoamine oxidase inhibitors (MAOIs), along with TCAs, represent the first generation of antidepressant drug therapy; they are now rarely used as antidepressants but are used to treat Parkinson's disease, atypical depression, or mood disorder with

phobic trait. A serious disadvantage to the use of MAOIs is their potential to cause a hypertensive crisis when taken with stimulant medications or with a substance containing tyramine, which is found in many common foods and beverages (Table 17.7).

Currently, three MAOI antidepressants are available. Phenelzine sulfate and tranylcypromine sulfate are nonselective inhibitors of both monoamine oxidase (MAO) type A and MAO type B. Selegiline hydrochloride is a selective MAO-B inhibitor, also used to treat Parkinson's disease (see Chapter 16). Because these drugs inhibit the MAO enzyme system in the CNS, amines such as dopamine, serotonin, and norepinephrine are not broken down, and therefore higher levels of these substances occur. These higher levels, in turn, alleviate the symptoms of depression.

Most adverse effects of MAOIs stem from their interactions with food and other medications. A variety of over-the-counter (OTC) drugs (especially for coughs and colds) also can interact with MAOIs to cause adverse cardiovascular effects. For example, MAOIs may increase the CNS-depressant effects of diphenhydramine hydrochloride and cetirizine hydrochloride. Patients taking MAOIs need to read labels or consult the pharmacist when using any such products. Dosage information for selected MAOIs is given in the table on the previous page.

Sympathomimetic drugs can also interact with MAOIs, and together these drugs can cause a hypertensive crisis. MAOIs can markedly potentiate the effects of meperidine hydrochloride, and therefore their concurrent use is contraindicated. In addition, concurrent use of MAOIs with SSRIs carries the potential for serotonin syndrome. A washout period of 2 to 5 weeks between drugs is recommended.

Toxicity and Management of Overdose

Clinical symptoms of MAOI overdose generally do not appear until about 12 hours after ingestion. The primary signs and symptoms are cardiovascular and neurological in nature. The most serious cardiovascular effects are tachycardia and circulatory collapse, and the neurological symptoms of major concern are seizures and coma. Hyperthermia and miosis are also generally present in overdose. Treatment is aimed at eliminating the ingested toxin and protecting the organs at greatest potential for damage—the brain and heart. Recommended treatments are urine acidification to a pH of 5 and hemodialysis. Treatment

Dosages

Selected Mood-Stabilizing and Antidepressant Drugs

Drug	Pharmacological Class	Usual Dosage Range*	Current Health Canada–Approved Indications/Uses
Mood Stabilizers			
 lithium carbonate	Inorganic salt	600–1800 mg/day divided bid–tid	Acute mania, prevention of mania
Antidepressants			
First Generation			
 amitriptyline hydrochloride (Elavil, Levate)	Tricyclic	PO: 10–300 mg/day	Depression (more commonly used for insomnia and neuropathic pain)
Second Generation			
 bupropion hydrochloride (Wellbutrin®, Zyban®)	Miscellaneous	PO: 100–300 mg/day, divided bid	Depression (Wellbutrin), smoking cessation (Zyban)
 duloxetine hydrochloride (Cymbalta®)	SNRI	PO: 30–60 mg/day	Depression, generalized anxiety disorder, neuropathic pain associated with diabetic peripheral neuropathy
 fluoxetine hydrochloride (Prozac®)	SSRI	PO: 20–60 mg/day, in the morning	Depression, obsessive-compulsive disorder, bulimia nervosa, panic disorder, premenstrual dysphoric disorder
 mirtazapine (Remeron®)	Tetracyclic	PO: 15–45 mg at bedtime	Depression, bipolar disorder
 trazodone hydrochloride (Trazorel®)	Triazolopyridine	PO: 150–600 mg/day, divided bid–tid	Depression (more commonly used for insomnia)

PO, Oral; SNRI, serotonin–norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor.

*All dosages reflect usual adult dosage ranges. Pediatric dosages may be more variable and are best prescribed by a pediatrician.

NATURAL HEALTH PRODUCTS (SAFETY ALERT)

St. John's Wort (*Hypericum perforatum*)

Overview

St. John's wort preparations consist of the dried, above-ground parts of the plant species *Hypericum perforatum* gathered during flowering season. St. John's wort is available over the counter in numerous oral dosage forms. It is sometimes referred to as the "herbal Prozac."

Common Uses

Depression, anxiety, sleep disorders, nervousness

Adverse Effects

GI upset, allergic reactions, fatigue, dizziness, confusion, dry mouth, possible phototoxicity (especially in fair-skinned individuals)

Potential Drug Interactions

MAOIs, SSRIs, TCAs, cyclosporine, sympathomimetic amines, piroxicam, tetracycline, tyramine-containing foods, opioids, digoxin, estrogens, theophylline, warfarin

Contraindications

St. John's wort is contraindicated in patients with bipolar disorder, schizophrenia, Alzheimer's disease, and other forms of dementia.

of hypertensive crisis resulting from consumption of tyramine-containing foods or beverages may require intravenous administration of hypotensive drugs, along with careful monitoring in an intensive care setting.

TABLE 17.7 Food and Drink to Avoid When Taking Monoamine Oxidase Inhibitors

Food/Drink	Examples
High Tyramine Content—Not Permitted	
Aged mature cheeses	Cheddar, blue, Swiss
Smoked or pickled meats	Herring, sausage, corned beef, smoked fish or poultry, salami, pepperoni
Aged or fermented meats	Chicken or beef liver paté, game fish or poultry
Yeast extracts	Brewer's yeast
Red wines	Chianti, burgundy, sherry, vermouth
Italian broad beans	Fava beans
Moderate Tyramine Content—Limited Amounts Allowed	
Meat extracts	Bouillon, consommé
Pasteurized, light and pale beer	
Ripe avocado	
Low Tyramine Content—Permissible	
Distilled spirits	Vodka, gin, rye, Scotch (in moderation)
Non-aged cheeses	Processed cheese, mozzarella, cottage cheese, cream cheese
Chocolate and caffeinated beverages	
Fruit	Figs, bananas, raisins, grapes, pineapple, oranges
Soy sauce	
Yogurt, sour cream	

SECOND-GENERATION ANTIDEPRESSANTS

Since the 1980s, there has been much development in psychotropic pharmacotherapy. Several new antidepressants were introduced, including trazodone (Oleptro®, Trazorel) and bupropion (Wellbutrin); both are still commonly used. The SSRIs were also introduced. These include fluoxetine (Prozac), sertraline hydrochloride (Zoloft®), paroxetine hydrochloride (Paxil®), fluvoxamine maleate (Luvox®), citalopram hydrobromide (Celexa®), and escitalopram oxalate (Cipralex®). The SNRIs venlafaxine hydrochloride (Effexor®) and mirtazapine (Remeron), which have norepinephrine and specific serotonergic activity, came later, followed by two new SNRIs, duloxetine hydrochloride (Cymbalta) and desvenlafaxine succinate (Pristiq®). Desvenlafaxine succinate is the major active metabolite of venlafaxine. Currently available second-generation drugs are listed in [Table 17.4](#). Second-generation antidepressants are generally considered superior to TCAs and MAOIs in terms of their adverse effect profiles. It takes approximately the same amount of time to reach maximum clinical effectiveness with these drugs as it does with the TCAs and MAOIs—typically 4 to 6 weeks.

Mechanism of Action and Drug Effects

The inhibition of serotonin reuptake is the primary mechanism of action of the SSRIs, although these drugs may also have weak effects on norepinephrine and dopamine reuptake (see individual drug profiles). SNRIs inhibit the reuptake of both serotonin and norepinephrine, with the exception of bupropion, which is a weak norepinephrine–dopamine reuptake inhibitor. Patients should be educated about the time it takes before full therapeutic effects of antidepressant drugs are realized—commonly, several weeks.

Indications

Although depression is their primary indication, SSRIs and SNRIs have shown benefit in treating a variety of other mental and physical disorders. Examples include bipolar disorder, obesity, eating disorders, obsessive-compulsive disorder, panic attacks or disorders, social anxiety disorder, post-traumatic stress disorder, premenstrual dysphoric disorder, the neurological disorder myoclonus, and various substance misuse problems such as alcoholism. Bupropion (Zyban) is also used for smoking cessation.

Contraindications

Contraindications include known drug allergy and use of MAOIs in the previous 14 days. In addition, a significant history of heart disease or seizure may be a contraindication due to the relatively uncommon, but reported, cardiac effects and alterations in seizure threshold (see later discussion). Bupropion is also contraindicated in cases of eating disorders as well as in seizure disorders because it can lower the seizure threshold.

Adverse Effects

Second-generation antidepressants offer advantages over TCAs and MAOIs due to their improved adverse effect profiles. However, up to two thirds of all patients with depression may

BOX 17.1 Common Symptoms of Serotonin Syndrome

Common symptoms include:

- Delirium
- Agitation
- Tachycardia
- Sweating
- Myoclonus (muscle spasms)
- Hyperreflexia
- Shivering
- Coarse tremors
- Extensor plantar muscle (sole of foot) responses

In more severe cases, the following may occur:

- Hyperthermia
- Seizures
- Rhabdomyolysis
- Chronic kidney disease
- Cardiac dysrhythmias
- Disseminated intravascular coagulation

still discontinue therapy due to drugs' adverse effects. Some of the most common adverse effects are insomnia (partly due to reduced rapid eye movement sleep), weight gain, and sexual dysfunction. Sexual dysfunction caused by SSRIs is primarily a result of inability to achieve orgasm.

One potentially hazardous adverse effect of any drug or combination of drugs that have serotonergic activity is **serotonin syndrome**. Serotonin syndrome results from excessive effects of serotonin on the CNS; the agonist effects on 5-HT_{2A} receptors contributes most substantially to serotonin syndrome ([Bartlett, 2017](#); [Cooper & Sejnowski, 2013](#)). As mentioned, it usually results from taking medications, such as SSRIs, that elevate levels of serotonin either therapeutically or with intentional overdoses. However, it may also result from unintended drug interactions that elevate the effects of the serotonergic medication. The symptoms of this condition are listed in [Box 17.1](#). Fortunately, serotonin syndrome is usually self-limiting on discontinuation of the causative drugs. (Refer to [Table 17.5](#).)

Interactions

Second-generation antidepressants are highly bound to albumin. When given with other drugs that are also highly bound to protein (e.g., warfarin sodium, phenytoin), they compete for binding sites on the surface of albumin. This results in a more free, unbound drug and therefore a more pronounced drug effect.

Some of these drugs may also inhibit cytochrome P450 enzymes, although there is debate about this in the literature. The cytochrome P450 system is an enzyme system in the liver that is responsible for the metabolism of several drugs (see [Chapter 2](#)). Inhibition of this enzyme system results in higher levels of drugs, with the potential for toxicity.

To prevent potentially fatal pharmacodynamic interactions (e.g., serotonin syndrome) that can occur between these drugs and the MAOIs, a 2- to 5-week washout period is recommended between use of these two classes of medications. Other drug interactions are listed in [Table 17.6](#).

◆ Dosages

Recommended dosages of selected newer-generation antidepressants are given in the table on p. 290.

DRUG PROFILES

Second-generation drugs have proved to be effective antidepressants. They also generally have better adverse effect profiles than first-generation antidepressants. They are now considered first-line drugs in the treatment of patients with depression, including patients with concurrent symptoms of anxiety and patients with depression with suicidal ideation.

trazodone hydrochloride

Trazodone hydrochloride (Trazorel, Oleptro) belongs to the triazolopyridine drug class. It was the first of the second-generation antidepressants that could selectively inhibit serotonin reuptake but minimally affect norepinephrine reuptake. Trazodone has minimal adverse effects on the cardiovascular system, which is an advantage over the TCAs. It is indicated for the treatment of depression, and it is also commonly used as a nonaddictive drug treatment for insomnia. Contraindications include known drug allergy. Adverse effects include strong sedative qualities; these can be severe and can impair cognitive function in older adults. However, the sedating effect of trazodone is often advantageous in helping patients with depression—who commonly have comorbid anxiety or insomnia—to obtain effective sleep. Trazodone has also been associated, in rare cases, with transient nonsexual *priapism*. This is a dangerously sustained penile erection that is reportedly the result of alpha-adrenergic blockade. Trazodone interacts with azole antifungals (see Chapter 47), phenothiazines (see later in the chapter), and protease inhibitors (see Chapter 45), all of which can increase the risk of trazodone toxicity; carbamazepine (see Chapter 15), which can reduce trazodone levels at the same time as carbamazepine levels are increased; and CNS depressants (e.g., alcohol), whose effects can be potentiated by trazodone. It is also recommended that trazodone be started gradually after a patient has recently stopped MAOI therapy. Trazodone is available only for oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	up to 6 wks	30–100 minutes (food increases absorption, may delay peak to 2.5 hours)	5–9 hr	1–2 days

fluoxetine hydrochloride

Fluoxetine hydrochloride (Prozac) was the first SSRI marketed for the treatment of depression and is considered the prototypical SSRI. Since that time, it has become one of the most commonly prescribed of all drugs. Although it was initially indicated for the treatment of depression, the indications for fluoxetine have since expanded to include bulimia nervosa

and obsessive-compulsive disorder. Contraindications include known drug allergy and concurrent MAOI therapy. Adverse effects include anxiety, dizziness, drowsiness, insomnia, and others listed in Table 17.5. Interacting drugs include benzodiazepines (reduced benzodiazepine clearance; see Chapter 13), buspirone (reduced buspirone effects; see earlier in the chapter), antipsychotics (elevated antipsychotic levels), and propafenone hydrochloride (see Chapter 25). Other drug interactions are listed in Table 17.6. Fluoxetine is available only for oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1–4 wk	6–8 hr	1–3 days*	2–4 wk

*Active metabolite has a half-life of 7 to 10 days.

bupropion hydrochloride

Bupropion hydrochloride is a unique antidepressant in terms of both its structure and mechanism of action. It has relatively weak, but measurable, effects on brain serotonin activity but little to no activity on monoamine oxidase. It is a norepinephrine–dopamine reuptake inhibitor. Its strongest therapeutic action appears to be primarily on the dopaminergic and noradrenergic pathways.

Bupropion was originally indicated for treatment of depression but is now also indicated as an aid in smoking cessation. It is sometimes added as an adjunct antidepressant for patients experiencing sexual adverse effects secondary to SSRI therapy. Although the mechanism is unclear, the drug is often effective in this situation. A sustained-release form of bupropion, Zyban, was approved for smoking cessation treatment. Sustained-release bupropion was an innovative new treatment because it was the first nicotine-free prescription medicine used to treat nicotine dependence. Its exact mechanism of action in treating nicotine dependence is unknown, but it is believed to be a result of the drug's ability to modulate dopamine and norepinephrine levels in the brain. Both neurotransmitters are thought to play an important role in maintaining nicotine addiction. However, the newer smoking cessation drug varenicline tartrate (Champix®; see Chapter 18) is becoming popular for this purpose.

Bupropion is contraindicated in patients who have a known drug allergy, those with a seizure disorder (bupropion can lower the seizure threshold), those who currently have or previously have had anorexia nervosa or bulimia nervosa, and those currently taking an MAOI. Common adverse effects include dizziness, confusion, tachycardia, agitation, tremor, and dry mouth. Drugs that interact with bupropion include the azole antifungals (see Chapter 47) as well as other drugs metabolized by the cytochrome P450 enzyme system (see Chapter 2) and CNS depressants. Other drug interactions are listed in Table 17.6. Bupropion is available only for oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1–2 wks	3–5	~21 hr	1–2 days

mirtazapine

Mirtazapine (Remeron) is unique in that it promotes the presynaptic release of both serotonin and norepinephrine in the brain. This is due to its antagonist activity in the presynaptic α_2 -adrenergic receptors. It does not inhibit the reuptake of either of these neurotransmitters. It is strongly associated with sedation in more than 50% of patients because of its histamine 1 (H_1) receptor activity and therefore is usually dosed once daily at bedtime. Furthermore, although clearance of the drug may be somewhat reduced in older adults, no dosage adjustment is currently recommended. Mirtazapine is indicated for the treatment of depression, including that associated with bipolar disorder. It is also sometimes helpful (mechanism unknown) in reducing sexual adverse effects experienced by male patients receiving SSRI therapy. Mirtazapine is known to be an appetite stimulant and thus can be helpful in patients who are underweight and depressed or harmful in those who are already overweight. Mirtazapine is contraindicated in cases of drug allergy and concurrent use of MAOIs. Adverse effects include drowsiness, abnormal dreams, dry mouth, constipation, increased appetite, and asthenia. Drug interactions include additive CNS depressant effects with alcohol and CYP (liver enzymes) inhibitors (see [Chapter 2](#)). Mirtazapine is available only for oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1–3 wk	2 hr	20–40 hr	Unknown

duloxetine hydrochloride

Duloxetine hydrochloride (Cymbalta), like venlafaxine hydrochloride, is a delayed-release SNRI. These two drugs, along with trazodone, are the three top-selling antidepressants in Canada. Duloxetine hydrochloride is considered an analgesic/antidepressant/anxiolytic and is indicated for depression and generalized anxiety disorder. It is also indicated for pain resulting from diabetic peripheral neuropathy, fibromyalgia, chronic low back pain, and osteoarthritis of the knee. It is contraindicated in cases of known drug allergy and concurrent MAOI use, and it can worsen uncontrolled angle-closure glaucoma. Adverse effects include dizziness, drowsiness, headache, GI upset, anorexia, and hepatotoxicity. Drugs with which duloxetine hydrochloride interacts include SSRIs and triptans (increased risk of serotonin syndrome) and alcohol (increased risk of liver injury). Duloxetine hydrochloride is available only for oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action

PSYCHOTIC DISORDERS

Antipsychotic Drugs

Antipsychotic drugs are used to treat serious mental health disorders such as psychoses, schizophrenia, and autism.

Antipsychotics are also used to treat extreme mania (as an adjunct to lithium), bipolar disorder, depression that is resistant to other therapy, certain movement disorders (e.g., Tourette's syndrome), and certain other medical conditions (e.g., nausea, intractable hiccups). Antipsychotic use in children is increasing, specifically second-generation antipsychotics for irritability associated with autism spectrum disorder in children and adolescents ([Lambert, Panagiotopoulos, Davidson, et al., 2018](#)).

Antipsychotic drugs represent a significant advance in the treatment of mental health disorders, highlighted by the fact that early treatment of mental health disorders (before the 1950s) consisted of such extreme measures as isolation, physical restraint, shock therapy, and even lobotomy.

Phenothiazines are the largest chemical class of antipsychotic drugs, constituting about two thirds of all antipsychotics. They were also the original drugs in this category. As with many other drugs, phenothiazines were discovered by chance, in this case during research for new antihistamines. Chlorpromazine, isolated in 1951, was the first phenothiazine to be discovered in this way. The currently available antipsychotics are listed in [Table 17.8](#).

TABLE 17.8 Currently Available Antipsychotic Drugs

Generic Name	Trade Name	Route
Conventional		
Phenothiazines		
chlorpromazine hydrochloride		PO, IM, IV
fluphenazine		PO, IM, Subcut
perphenazine		PO
prochlorperazine		PO, PR, IM, IV
trifluoperazine hydrochloride		PO

ziprasidone hydrochloride monohydrate	Zeldox®	PO, IM
Quinolinone		
aripiprazole	Abilify®	PO, IM

IM, Intramuscular; IV, intravenous; PO, oral; PR, per rectum; Subcut, subcutaneous.

Overall, there are few differences among conventional, or first-generation, antipsychotics in their mechanisms of action. Therefore, selection of an antipsychotic is based primarily on the patient's tolerance and the need to minimize adverse effects. Of the currently available antipsychotic drugs, no single drug stands out for all patients as either more or less effective in the treatment of psychotic symptoms. Antipsychotic drug therapy does not normally provide a cure for psychoses but is a way of chemically controlling the symptoms of the illness.

More recently, a new generation of antipsychotic medications has evolved. These are referred to as *atypical antipsychotics*, as opposed to the conventional drugs, which can also be thought of as older-generation antipsychotics. Atypical antipsychotics differ from conventional drugs in that they tend to have better adverse effect profiles. The atypical antipsychotics still have adverse effects, but they are usually not as severe as those of conventional antipsychotic drugs.

Mechanism of Action and Drug Effects

All antipsychotics block dopamine receptors in the brain, which decreases dopamine concentration in the CNS. Specifically, the conventional phenothiazines block the dopamine receptors postsynaptically in certain areas of the CNS, such as the limbic system and the basal ganglia. These are the areas associated with emotions, cognitive function, and motor function. This receptor blocking produces a tranquilizing effect in patients who are psychotic. Both the therapeutic and toxic effects of these drugs are the direct result of the dopamine blockade in these areas. The atypical antipsychotic drugs block specific dopamine receptors called *dopamine 2 (D₂) receptors*, as well as specific serotonin receptors in the brain known as *2 (5-HT₂) receptors*. These more refined mechanisms of action of the atypicals are responsible for their improved efficacy and safety profiles, compared with older drugs (see Adverse Effects).

All antipsychotics show efficacy in reducing the positive symptoms of schizophrenia (including auditory and visual hallucinations, delusions, and conceptual disorganization), and these beneficial effects may even increase over time. The first-line treatment option for hallucinations in schizophrenia is antipsychotic medication (which blocks the dopamine D₂ receptors), producing a rapid decrease in severity. Unfortunately, conventional drugs are less effective in managing negative symptoms. Negative symptoms are apathy, social withdrawal, blunted affect, poverty of speech, and catatonia. It is these negative symptoms that account for most of the social and occupational dysfunction caused by schizophrenia. Fortunately,

atypical antipsychotics have improved efficacy in treating both positive and negative symptoms.

Indications

Antipsychotic drugs are indicated for psychosis associated with mental health disorders, most commonly schizophrenia. As more has been learned about these drugs, especially the atypical antipsychotic drugs, their indications have expanded to include anxiety and mood disorders. Certain antipsychotics (e.g., prochlorperazine maleate) are used as antiemetics (see Chapter 41). They block serotonin receptors and dopamine receptors in the chemoreceptor trigger zone in the brain and inhibit neurotransmission in the vagus nerve in the GI tract. Additional blocking of dopamine receptors in the brain stem reticular system also allows atypical drugs to have anxiolytic, or antianxiety, effects.

Contraindications

Contraindications to the use of antipsychotic drugs include known drug allergy, comatose state, significant CNS depression, brain damage, liver or kidney disease, blood dyscrasias, or uncontrolled epilepsy.

Adverse Effects

Common adverse effects caused by blockade of the alpha-adrenergic, dopamine, endocrine, histamine, and muscarinic (cholinergic) receptors are listed in Table 17.9. Possible severe hematological effects include agranulocytosis (low numbers of white blood cells [WBCs] in the blood) and hemolytic anemia. Integumentary effects may include exfoliative dermatitis. CNS effects include drowsiness, neuroleptic malignant syndrome, extrapyramidal symptoms, and tardive dyskinesia. **Neuroleptic malignant syndrome** is a relatively rare but potentially life-threatening adverse effect that is triggered by a reaction associated with antipsychotic medications or other medications that cause reduced dopamine activity (either through blockage of D₂ receptors or decreased availability of dopamine) in the CNS. Due to blockade of dopamine neurotransmission in the nigrostriatum, muscular rigidity can result. Dopamine blockade in the hypothalamus can produce altered thermoregulation (high fever), vital sign instability, and autonomic instability (irregular pulse or blood pressure, tachycardia, diaphoresis, and cardiac dysrhythmias; Agar, 2010). Additional signs may include elevated creatine phosphokinase, myoglobinuria (rhabdomyolysis), and acute kidney injury. Treatment involves prompt withdrawal of the causative medication and supportive treatment.

TABLE 17.9 Antipsychotics: Receptor-Related Adverse Effects	
Receptor	Adverse Effect
α-Adrenergic	Orthostatic hypotension, lightheadedness, reflex tachycardia
Dopamine	Extrapyramidal movement disorders, dystonia, parkinsonism, akathisia, tardive dyskinesia, hyperprolactinemia
Histamine	Sedation, drowsiness, hypotension, weight gain
Muscarinic (cholinergic)	Blurred vision, worsening of angle-closure glaucoma, dry mouth, tachycardia, constipation, urinary retention, decreased sweating

Extrapyramidal symptoms are involuntary motor symptoms similar to those associated with Parkinson's disease (see Chapter 16). This drug-induced state is known as *pseudoparkinsonism* and is characterized by symptoms such as **akathisia** (distressing motor restlessness) and acute **dystonia** (painful muscle spasms). Two anticholinergic medications, benztropine mesylate (Kynesia®) and trihexyphenidyl hydrochloride, are commonly used to treat these symptoms (see Chapter 15).

Tardive means “late-appearing”; **tardive dyskinesia** is characterized by involuntary contractions of oral and facial muscles (e.g., involuntary tongue-thrusting) and choreoathetosis (wave-like movements of the extremities) and usually appears only after continuous long-term antipsychotic therapy. Theoretically, these effects are possible with atypical antipsychotics as well; however, evidence suggests that the incidence with these drugs is lower.

Cardiovascular effects, caused by alpha receptor blockade, include orthostatic hypotension. In addition, electrocardiogram (ECG) changes, notably prolonged QT

interval, are associated with all classes of antipsychotic drugs. Baseline and periodic ECGs, as well as measurement of serum potassium and magnesium levels, can help to determine if a patient is at risk for such effects or to diagnose newly acquired cardiac dysrhythmias. Conventional drugs such as phenothiazines and haloperidol can also augment prolactin release, which can result in swelling of the breasts and milk secretion in women. Gynecomastia (breast tissue enlargement) can also be a distressing adverse effect in male patients (Table 17.10).

Adverse effects on the endocrine system associated with antipsychotics include insulin resistance, weight gain, and changes in serum lipid levels. Antipsychotics are associated with development of **cardiometabolic syndrome** (see Box 17.2), which can cause serious long-term health problems.

In 2011, Health Canada required manufacturers to update product labelling to include stronger wording regarding the use of antipsychotics in pregnant women. The new labelling includes more consistent information about the potential for abnormal muscle movements (extrapyramidal symptoms) and withdrawal symptoms in newborns whose mothers were treated with these drugs during the third trimester of pregnancy.

TABLE 17.10 Adverse Effects of Selected Psychotropic Drugs*

Drug or Drug Class	Adverse Effects
Conventional (e.g., haloperidol)	Akathisia, extrapyramidal symptoms, hypertension, neuroleptic malignant syndrome, confusion, headache, mild GI disturbance, dry mouth, amenorrhea, gynecomastia, visual disturbances, hyperpyrexia, edema, tardive dyskinesia, skin rash, photosensitivity, weight gain, urinary retention
Atypical (e.g., clozapine, risperidone)	Tachycardia, akathisia, agitation, asthenia, ataxia, seizures, dyskinesia, dizziness, drowsiness, headache, insomnia, dry mouth, dyspepsia, anxiety, increased appetite, weight gain

GI, Gastrointestinal.

*See also drug profiles for drug-specific information.

Interactions

Major drug interactions are listed in Table 17.11. Antihypertensives may have additive hypotensive effects and CNS depressants may have additive CNS-depressant effects when taken with antipsychotics. Grapefruit and grapefruit juice can enhance the effects of clozapine (by reducing its metabolism via the cytochrome P450 enzyme system). Because grapefruit affects many enzymes in the liver P450 system, it is wise for patients taking multiple medications to avoid this food.

Dosages

Recommended dosages of selected antipsychotic drugs are given in the table above.

BOX 17.2 Antipsychotic Use and Cardiometabolic Syndrome

Cardiometabolic syndrome involves the presence of at least three abnormal values out of the five following criteria: visceral obesity measured by waist circumference, blood pressure, fasting plasma glucose (FPG), high-density lipoprotein cholesterol level (HDL-C), and triglycerides (TGs) (Leiter, Fitchett, Gilbert, et al., 2011). Although not well understood, psychotropic drugs (especially atypical antipsychotics) are associated with increased weight gain and metabolic adverse effects. Several neurotransmitter systems have been implicated, such as histamine receptor blockade. Genetic predisposition may also play a role. Patients with schizophrenia who are treated with antipsychotic medications develop features of cardiometabolic syndrome at a rate that is approximately one and a half to two times higher than in the general population (Riordan, Antonini, & Murphy, 2011). All ages of patients are susceptible to the metabolic adverse effects of antipsychotics; however, children and adolescents are most vulnerable (Riordan et al., 2011). Complicating the potential

for developing cardiometabolic syndrome are lifestyle factors (sedentary lifestyle, food insecurity, high rates of smoking, and substance misuse) combined with stress and the negative symptoms of schizophrenia. Those on more than one drug may be at elevated potential for developing higher rates of cardiometabolic syndrome than those on monotherapy (Yogarathnam, Biswas, Vadivel, et al., 2013).

The mean age of death for individuals with schizophrenia is 61 years of age; life expectancy is reduced by 20%, with the majority of mortality due to physical illness (Yogarathnam et al., 2013). Indeed, cardiovascular disease is the most common cause of mortality in patients with schizophrenia, and incidence of diabetes is two to four times higher in patients with schizophrenia than in the general population (Riordan, Antonini, & Murphy, 2011).

All patients receiving treatment with antipsychotic medications require ongoing metabolic and lifestyle monitoring.

TABLE 17.11 Drug Interactions of Selected Antipsychotics*

Drug Class	Interacting Drug(s)	Mechanism	Result
Conventional and Atypical	Alcohol, other CNS depressants	Additive drug effects	Enhanced CNS depression; dystonia with alcohol
	Antihypertensives	Enhanced antihypertensive effects	Potential for hypotension
Conventional: Phenothiazines	Anticholinergics	Additive and antagonistic drug effects	Reduced phenothiazine efficacy; enhanced anticholinergic effects
	β -blockers	Additive drug effects	Potential toxicity of either drug
	Opioids	Additive drug effects	Excessive sedation, hypotension
	Levodopa-carbidopa	Uncertain	Diminished antiparkinsonian effects
	phenytoin	Uncertain	Can increase or reduce phenytoin levels
	Thiazide diuretics	Reduced diuretic clearance	Potential for hypotension
Atypicals*	CYP3A4 inhibitors (e.g., ketoconazole)	Reduced antipsychotic clearance	Potential for antipsychotic toxicity
	carbamazepine	Enhanced antipsychotic clearance	Reduced therapeutic effects

CNS, Central nervous system; CYP3A4, cytochrome P450 enzyme 3A4.

*See also drug profiles for drug-specific information.

DRUG PROFILES

Conventional antipsychotic drugs are still available on the Canadian market (see Table 17.8). However, much of their use in common clinical practice has been replaced by the atypical antipsychotic drugs, which generally have better adverse effect profiles. All antipsychotics are prescription-only medications that are indicated for the treatment of various psychotic disorders. No single drug stands out as more or less effective in the treatment of the symptoms of psychosis. Some of the factors to be considered before selecting an antipsychotic are the patient's history of response to a drug and the possible adverse effect profile. Starting at a low dose with titration to the lowest effective dose helps achieve a balance between symptom relief and adverse effects. For dosage information on profiled drugs, see the table on p. 298.

Butyrophenone

haloperidol

Haloperidol is structurally different from the thioxanthenes and the phenothiazines but has similar antipsychotic properties. It is indicated primarily for the long-term treatment of psychosis. However, it has been largely replaced by the atypical antipsychotics because of its adverse effects (see later). Haloperidol blocks D_2 receptors found in the chemoreceptor trigger zone and consequently may be used for the management of nausea in palliative patients. Haloperidol is contraindicated in patients who have shown a hypersensitivity reaction to it, those in a comatose state, those taking large amounts of CNS depressants, and those with Parkinson's disease (due to its antidopaminergic effects). It is a high-potency neuroleptic drug that has a favourable cardiovascular, anticholinergic, and sedative adverse effect profile, but it can cause extrapyramidal symptoms as well as tardive dyskinesia. Haloperidol is available in two salt forms: base (for oral use) and decanoate injection (for IM use only). Haloperidol decanoate has an extremely long duration of action, which has historically made it useful in treating patients

with schizophrenia who were nonadherent to their drug regimen. Other adverse effects are listed in Table 17.10. Drugs with which haloperidol interacts are listed in Table 17.11.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	2 hr	2–6 hr	13–35 hr	8–12 hr
IM (decanoate)	3–9 days	6 days	21 days	Decanoate: 1 mo

Atypical Antipsychotics

Between 1975 and 1990, no new antipsychotic drug was approved in Canada. In 1991, clozapine (Clozaril®), the first of the atypical antipsychotics, was approved. Clozapine was followed by risperidone (Risperdal®), olanzapine (Zyprexa®), quetiapine (Seroquel®), ziprasidone (Zeldox®), aripiprazole (Abilify®), paliperidone (Invega®), asenapine maleate (Saphris®), and lurasidone hydrochloride (Latuda®).

Atypical antipsychotics have several advantageous properties, including reduced effect on prolactin levels compared with conventional drugs and improvement in the negative symptoms associated with schizophrenia. They also seem to show a lower potential for neuromuscular malignant syndrome and tardive dyskinesia. All nine of the currently available atypical drugs have several pharmacological properties in common. Antagonist activity at the dopamine D_2 receptor is believed to be the mechanism of their antimanic activity. Serotonergic (serotonin agonist) activity at various serotonin (5-HT) receptor subtypes and α_2 -adrenergic (agonist) activity are both associated with antidepressant activity. α_1 -adrenergic receptor antagonist activity is associated with orthostatic hypotension, and histamine H_1 receptor antagonist activity is associated with both sedative and appetite-stimulating effects. This last effect accounts for the common adverse effect of weight gain that is

associated to various degrees with atypical antipsychotic drugs. This effect can cause or worsen obesity and can result in type 2 diabetes (see Box 17.2). Clozapine and olanzapine are associated with the most weight gain, risperidone and quetiapine are associated with less, and ziprasidone is considered weight neutral. Other atypical antipsychotics fall between the aforementioned drugs.

Sedative effects may diminish over time and can be helpful to patients with insomnia. Although these drugs all have similar pharmacological properties, they vary in their degree of affinity for the various types of receptors. These subtle pharmacological differences, along with often unknown and unpredictable physiological patient differences, help to explain why some patients respond better to one medication than another (or do not respond). In 2005, Health Canada issued a public health advisory concerning the use of atypical antipsychotic drugs in older adults for off-label, nonapproved uses. These medications are currently approved to treat schizophrenia and mania. In practice, however, they are also used to control behavioural symptoms of agitation in older adults with dementia, including dementia associated with Alzheimer's disease. Data showed that older adults given atypical antipsychotics for this reason were up to 1.7 times more likely to die during treatment than if they had not had the treatment. Health Canada recommends that health care providers re-evaluate the treatment plans of patients treated with these drugs and recommend nondrug approaches to manage behaviour symptoms.

Dosage information for atypical antipsychotics is given in the table on the next page.

clozapine

Clozapine (Clozaril) was the first of the atypical antipsychotics. Compared to conventional antipsychotic drugs, it more selectively blocks the dopaminergic receptors in the mesolimbic region of the brain. Conventional antipsychotic drugs block dopamine receptors in an area of the brain called the neostriatum, but blockade in this area is believed to cause extrapyramidal adverse effects. Because clozapine has weak dopamine-blocking abilities in the neostriatum, it causes minor or no extrapyramidal symptoms. Clozapine is therefore often the drug of choice for treatment of psychotic disorders in patients who also have Parkinson's disease because it will not worsen motor symptoms.

Clozapine has been extremely useful for the treatment of patients for whom therapy with other antipsychotic drugs has not been effective, especially those with schizophrenia. It is indicated for patients with schizophrenia who have shown high potential for suicidal behaviour and are resistant to other antipsychotics. Adverse effects include the potential for drug-induced agranulocytosis, a dangerous lack of WBC production. The occurrence of agranulocytosis is highest between 6 weeks and 18 weeks after starting clozapine treatment. For this reason, patients beginning clozapine therapy require weekly monitoring of WBC count for the first 6 months of therapy. The drug needs to be withheld if the count falls below $3.5 \times 10^9/L$ and until it rises above this value. It is also recommended that WBC counts be evaluated weekly for 4 weeks after discontinuation of the drug. Clozaril is available only through the Clozapine Risk Management Program, with which

both the patient and health care provider must be registered. Other adverse effects are listed in Table 17.10.

Clozapine is contraindicated in patients with known drug allergy; in those with myeloproliferative disorders, severe granulocytopenia, CNS depression, or narrow-angle glaucoma; and in patients who are comatose. Interacting drugs include alcohol and other CNS depressants (increased CNS depression), levodopa (diminished therapeutic effects), antihypertensives (risk of hypotension), and others listed in Table 17.11. Clozapine is available only for oral use.

Other atypical antipsychotics have features comparable to those of clozapine but do not require extensive WBC monitoring. Risperidone is described in the following profile as an example of these drugs. Orally disintegrating tablets are available for risperidone, and asenapine is available as a sublingual tablet. These dosage forms may improve adherence. The dosage is the same as for regular tablets. (Refer to the table on next page.)

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	6–12 wks	2.5hrs	12 hours (range 4–66 hours)	variable

risperidone

Risperidone (Risperdal) is an atypical antipsychotic that was introduced a few years after clozapine. It is even more active than clozapine at the serotonin (5-HT_{2A} and 5-HT_{2C}) receptors. It also has high affinity for alpha₁- and alpha₂-adrenergic receptors and histamine H₁ receptors. It has lower affinity for the serotonin 5-HT_{1A}, 5-HT_{1C}, and 5-HT_{1D} receptors and the dopamine D₁ receptor. This drug is indicated for refractory schizophrenia, including negative symptoms, and causes minimal extrapyramidal symptoms at therapeutic dosages of 1 to 6 mg/day. Risperidone is contraindicated in cases of known drug allergy. Adverse effects include elevated serum prolactin levels, abnormal dreams, insomnia, dizziness, headache, and others listed in Table 17.10. It is available in both oral and long-acting injectable forms.

In 2015, the drug manufacturer and Health Canada issued a limitation to the use of risperidone to severe dementia of the Alzheimer type, for psychosis and aggression. Tablets, oral solutions, and oral disintegrating tablets are affected. There is a higher risk of cerebrovascular adverse events in patients with mixed or vascular dementia, compared to those with dementia of the Alzheimer type.

Drugs interacting with risperidone include CNS depressants, antihypertensives, and others listed in Table 17.11. Risperidone is available for oral and injectable use. The long-acting injectable form is called Risperdal Consta®, and one IM injection lasts approximately 2 weeks. This form is at least one option for helping patients maintain adherence with the prescribed drug regimen. Patients must continue to take oral risperidone for 3 weeks after the first injection of the Consta dosage form to ensure adequate blood levels from the injection. Paliperidone palmitate is a long-acting injection (Invega Sustenna®) that lasts 1 month.

Dosages

Selected Antipsychotic Drugs

Drug	Pharmacological Class	Usual Dosage Range*	Indications/Uses
First Generation (Conventional)			
haloperidol	Butyrophenone, phenylbutylpiperidine	Adults PO: 0.5–5 mg bid–tid IM: For Schizophrenia: (as deconate) 10–20x oral daily dose (usual maintenance dose 200 mg IM monthly) For violent behavior/aggression/agitation: 2.5–10 mg IM (note, not the decanoate formulation) Children PO: 0.25–0.5 bid–tid	Acute psychosis of schizophrenia and mania, Tourette's syndrome, severe aggression or agitation
Second Generation (Atypical)			
clozapine (Clozaril)	Dibenzodiazepine	PO: 12.5 mg bid, titrate up to maximum of 300–900 mg/day, divided	Treatment-resistant schizophrenia
 risperidone (Risperdal)	Benzisoxazole	PO: 1–6 mg/day in either one or two doses IM depot form (Risperdal Consta): 25–50 mg every 2 wk	Schizophrenia, mania, aggression or psychosis associated with dementia, bipolar mania (monotherapy or as adjunctive therapy)

IM, Intramuscular; PO, oral

*All dosages reflect usual adult dosage ranges. Pediatric doses may be more variable and should be specified by a pediatric health care provider.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1–2 wk	1–2 hr	20–30 hr	7 days
IM	3 wk	Unknown	3–6 days	4–6 wk

NURSING PROCESS

ASSESSMENT

Before administering any of the psychotherapeutic drugs, perform a complete head-to-toe physical assessment and mental status examination. Document your findings. These data will serve as a comparative baseline for the patient during and after initiation of therapy.

Thoroughly assess the patient's neurological functioning, including level of consciousness, mental alertness, and level of motor and cognitive functioning. The Mini-Mental State Examination (MMSE) is one tool that may be used to assess cognitive status and help identify impairments often found in mental health disorders. The MMSE is simple to use, is cost-effective, and can be completed in about 20 minutes. The MMSE is available in most nursing assessments, nursing fundamentals, or psychiatric or mental health nursing textbooks. Points are scored in the areas of level of orientation, attention and calculation ability, recall, and language skills. Other mental health assessment tools include the Beck Depression Inventory, The Burns Anxiety Inventory, the six-item Blessed Orientation-Memory-Concentration Test, clock-drawing tasks, the Functional Activities Questionnaire (for those with dementia), the Alzheimer's Disease Assessment Scale, the Mattis Dementia Rating Scale, the Severe Impairment Battery, and the Hamilton

Rating Scale for Depression. In addition to performing assessments such as these, note baseline levels of motor responses and reflexes as well as the presence of any tremors or personality changes. Assess for the presence of cold, clammy hands; sweating; and pallor—these findings may be indicative of altered autonomic nervous response.

Constantly assess the patient for any suicidal ideations or tendencies, with attention to not only overt cues and behaviours but also to covert thoughts and ideation. This is important because of the potential for suicide with the use of psychotherapeutic drugs, with or without the concurrent use of other medications or alcohol. Suicide assessment tools are available and may help you identify an individual's potential for suicidal behaviours. One such tool, the Suicide Assessment Scale, has been found to be valid, reliable, and easy to use. The following are some questions that may be helpful: “What brings you to the doctor's office today?” “How has life been treating you?” “What are some of your worries or concerns?” “How would you describe your mood?” “Tell me about your thoughts.” People at the highest potential for dying by suicide in the near future have a specific suicide plan, the means to carry out the plan, a time frame for doing it, and an intention to do it. An immediate response is required—call 911, call a crisis centre, or take the person to an emergency room. Asking the direct question, “Are you thinking about wanting to die?” or “Are you thinking about suicide?” to someone who may be considering suicide is also recommended. IS PATH WARM is a 10–warning sign mnemonic for assessing suicide risk, developed by the [American Association for Suicidology \(2015\)](#), including: Ideation; Substance use; Purposelessness; Anxiety; Trapped; Hopelessness; Withdrawal; Anger; Recklessness; Mood changes.

Remember that many of the patients who require psychotherapeutic drugs are depressed and, as such, suffer from insomnia and possibly from self-neglect. Deterioration in health status and weight

loss or gain may also occur. Therefore, it is important to assess sleep habits and nutritional intake and to perform a head-to-toe physical examination for baseline and comparative purposes. Note any drug allergies as well as any contraindications, cautions, and potential drug interactions (see pharmacology discussion and [Tables 17.3, 17.6, and 17.11](#)). Assess and document blood pressure and pulse rate before, during, and after drug therapy. Postural blood pressures (i.e., blood pressure taken supine and then standing) are particularly important to note because of the possible drug-related adverse effects of orthostatic hypotension and dizziness. The more potent older drugs (e.g., MAOIs or TCAs) may lead to a significant drop in blood pressure and possible syncope, warranting even more skillful assessment and close monitoring (of blood pressure readings).

Review the results of any laboratory studies performed before and during the drug therapy. This is particularly important for patients who are receiving long-term drug therapy to prevent or identify any early complications or other possible adverse effects or toxicity. Laboratory studies may include, but are not limited to, tests to confirm serum therapeutic levels of the specific drug, and, if appropriate, a complete blood cell count (CBC), erythrocyte sedimentation rate, serum electrolyte and glucose levels, blood urea nitrogen, liver function studies, kidney function tests, serum levels of vitamin B₁₂, lipid and triglyceride levels, and thyroid studies. If the patient is experiencing dementia, other types of testing may be needed, such as genetic studies, computed tomography, or magnetic resonance imaging.

With psychotherapeutic drug therapy, assess the patient's mouth and oral cavity to make sure the patient has swallowed the entire oral dosage. This helps prevent hoarding or "cheeking" of medications, a form of nonadherence that may lead to drug toxicity or overdose. If the assessment shows that this is a potential risk, using liquid or rapid dissolving tablets dosage forms, when available, may minimize such problems. Other areas to assess include the patient's appetite, sleeping patterns, addictive behaviours, elimination difficulties, and allergic reactions. Note any new symptoms or problems.

◆ Benzodiazepines

Anxiety disorders are treated with the benzodiazepine drugs. Anxiolytic drugs, specifically the benzodiazepines, are associated with many contraindications, cautions, and drug interactions (see pharmacology discussion). When these drugs are used, the health care provider may order laboratory studies, such as CBC counts, serum electrolyte levels, and liver and kidney function studies (see earlier discussion). Blood pressure readings are also important to assess because of drug-related orthostatic hypotension. The baseline neurological examination needs to include assessment of alertness, orientation, and sensory and motor functioning, as well as any reports of ataxia, headache, or other neurological abnormalities. To complete a thorough medication profile, create a list of all medications taken, including any other psychotherapeutic drugs, all prescription drugs, OTC drugs, and natural health products. Diazepam, although one of the more commonly prescribed benzodiazepines, is generally used for seizure disorders and preoperative sedation and requires assessment regarding these uses (see Chapters 12 and 15). Specific concerns for children and older adult patients are presented in the Special Populations: Children box and the Special Populations: Older Adults box in the next column. Closely observe and assess older adult patients

SPECIAL POPULATIONS: CHILDREN

Psychotherapeutic Drugs

- Children are more likely to experience adverse effects from psychotropic drugs, especially extrapyramidal effects.
- The incidence of Reye's syndrome and other adverse effects is greater in children taking psychotropic drugs who have had chicken pox, CNS infections, measles, acute illnesses, or dehydration.
- Lithium may lead to decreased bone density or bone formation in children; therefore, children receiving it need to be closely monitored for signs and symptoms of lithium toxicity and bone disorders. The safety and efficacy of lithium dosing for those younger than 6 years of age is not established.
- TCAs generally are not prescribed for patients younger than 12 years of age. However, some antidepressants are used in children with enuresis, attention deficit hyperactivity disorder, or major depressive disorders and may be associated with adverse effects such as electrocardiographic changes, nervousness, sleep disorders, fatigue, elevated blood pressure, and GI upset.
- Children are generally more sensitive to the effects of most drugs, and psychotherapeutic drugs are no exception. Be aware of the risk of toxicity, which can be fatal. If confusion, lethargy, visual disturbances, insomnia, tremors, palpitations, constipation, or eye pain occur, contact the prescribing health care provider immediately.

SPECIAL POPULATIONS: OLDER ADULTS

Psychotherapeutic Drugs

- Older adults show higher serum levels of psychotherapeutic drugs because they have age-related changes in drug distribution and metabolism, less serum albumin, decreased lean body mass, less water in tissues, and increased body fat. They also have decreased kidney function. Because of these changes, older adults generally require lower doses of antipsychotic and antidepressant drugs than younger adults, and they are at greater potential for toxicity.
- Orthostatic hypotension, anticholinergic adverse effects, sedation, and extrapyramidal symptoms are more common in older adults taking psychotherapeutic drugs.
- Careful evaluation and documentation of baseline parameters, including neurological findings, are important to the safe use of psychotherapeutic drugs.
- Increased anxiety is often associated with the use of TCAs.
- Patients with a history of heart disease may be at greater potential for experiencing dysrhythmias, tachycardia, stroke, myocardial infarction, or heart failure.
- Lithium toxicity is more common in older adults, and lower doses are often necessary to achieve therapeutic levels. Close monitoring is important to its safe use in this age group. CNS toxicity, lithium-induced goitre, and hypothyroidism are more common in older adult patients.

for oversedation or profound CNS depression during drug therapy. Falls and resulting fractures are a common risk factor in older adults taking benzodiazepines. Older adults are often more sensitive to drugs and therefore more likely to experience adverse effects; their safety needs to be a constant concern.

Since eye problems may occur with the use of benzodiazepines, baseline visual testing using a Snellen chart or an eye examination conducted by the appropriate health care provider (i.e., an ophthalmologist or optometrist) is recommended. Allergic reactions to some of these medications (e.g., clonazepam) are characterized by a red raised rash. In addition, patients who are obese may experience toxicity in a shorter period. This susceptibility occurs because

several anxiolytic drugs are lipid soluble and have greater affinity for fatty tissues; therefore, their half-life is increased in patients who are obese. Give lorazepam cautiously (under close supervision) if a patient is suicidal because its use may be associated with suicide attempts. Administer alprazolam only after careful assessment of mental status, mood, sensorium, and sleep patterns.

Buspirone is another anxiolytic drug that is not a benzodiazepine. It is used because it has fewer adverse effects, such as decreased sedation and lack of dependency potential. However, it is associated with many drug interactions, cautions, and contraindications (see pharmacology discussion). It is also important to complete a general assessment of the neurological system and a mental health assessment.

◆ Mood-Stabilizing Drugs

As previously discussed in the pharmacology section, affective disorders are treated with mood-stabilizing drugs, antipsychotics, and antidepressant drugs. Before antimanic drugs such as lithium are administered, perform a thorough neurological examination. Also assess vital signs, especially blood pressure, hydration status, dietary intake, skin tone, and presence of edema. It is also important to assess baseline levels of consciousness and alertness, gait and mobility levels, and overall motor functioning. Poor coordination, tremors, and weakness may be symptoms of toxic blood levels of antimanic drugs. Laboratory studies often ordered before and during drug therapy include serum sodium, albumin, and uric acid levels. Serum levels of sodium are important to know because lithium toxicity is potentiated by the presence of hyponatremia and hypovolemia. During the initial phase of therapy, serum lithium levels must be assessed every 3 to 4 days (therapeutic levels are 0.6 mEq/L to 1.2 mEq/L; toxic levels are above 1.5 mEq/L). A urinalysis with specific gravity may also be ordered to assess volume status.

◆ Antidepressants

Assess for the many cautions, contraindications, and drug interactions before giving antidepressants (see pharmacology discussion). An assessment of suicide risk based on the identification and appraisal of warning signs that are present is important for all patients with a history of prior suicide attempt or suicidal ideation. Suicide must always be considered a potential risk when any psychotherapeutic medication, whether an antidepressant or other CNS-altering drug, is taken alone or in combination with other drugs or alcohol. Patients may hoard drugs for the purpose of suicide.

Second-generation antidepressants are associated with fewer and less severe adverse effects compared to the older TCAs and MAOI antidepressants. These second-generation drugs include SSRIs (fluoxetine [Prozac]) and SNRIs (duloxetine hydrochloride [Cymbalta]). However, with SSRIs, it is still important to assess and document neuromuscular and GI systems. Cautious use in older adults is recommended due to their increased potential for toxicity. Additionally, there is concern for the occurrence of serotonin syndrome (see Box 17.1), which includes symptoms such as agitation, tachycardia, sweating, and muscle tremors. Contraindications include the use of these drugs with some antipsychotic drugs and within 14 days of use of MAOIs. Assess for significant drug interactions, such as warfarin sodium and

phenytoin, due to their increased protein binding. Do not give SNRIs, such as duloxetine hydrochloride (Cymbalta), to patients with closed-angle glaucoma or those taking MAOIs. Liver function studies may be ordered prior to use of this drug because of the risk of liver toxicity. The miscellaneous antidepressant bupropion may be preferred over some of the other antidepressants because of fewer anticholinergic, antiadrenergic, and cardiotoxic effects (see pharmacology discussion). Assess the patient's baseline neurological, mental, and cardiac status before the drug is used. Because of delayed therapeutic effects, closely assess the patient for any suicidal tendencies or ideas. Assess the availability of family support systems as well as the need for any supportive resources.

TCAs, as an older class of antidepressants, are effective drugs but are associated with serious adverse effects. However, some patients do tolerate them. When patients are taking TCAs, monitor closely for potential adverse effects. It is not recommended to use TCAs with the natural health product St. John's wort. Amitriptyline is not to be used in patients with recent myocardial infarction and is associated with potent anticholinergic properties leading to dry mouth, constipation, blurred vision, urinary retention, and alterations in cardiac rhythm.

MAOIs are particularly dangerous and can cause death if taken in an overdose. It is important to closely monitor patients receiving MAOIs who have a history of suicide attempts or suicidal ideation. Patients should be monitored closely by a health care provider (e.g., psychiatrist, physician, or nurse practitioner) to ensure their safety and prevent harm to themselves or others. MAOIs are also known for their significant drug interactions (see Table 17.4), such as with meperidine hydrochloride, other opioids, other MAOIs, SSRIs, oral contraceptives, and buspirone. MAOIs, if taken with foods high in tyramine (see Table 17.7), are associated with a hypertensive crisis; therefore, closely monitor blood pressure readings, including postural blood pressure measurements. Orthostatic hypotension, an adverse effect of MAOIs, may lead to a high risk of dizziness, fainting, and possible falls or injury. If the patient is hospitalized, monitor supine and standing or sitting blood pressures at least every 8 hours or more frequently, if needed. Allow 1 to 2 minutes to elapse after taking the supine blood pressure before measuring standing or sitting pressures and pulse rate. Laboratory tests that are often ordered for patients taking these drugs include CBC counts and renal and liver function studies. In addition, it is crucial to understand that older adult patients should be given these drugs only if it is deemed necessary by a health care provider and only with careful monitoring. The extrapyramidal adverse effects (e.g., tremors) are often worse in older adults and may result in an inability to perform ADLs. This extrapyramidal reaction may lead to progressive deterioration of motor activities; thus, a thorough motor and neurological assessment is needed.

◆ Antipsychotics

To be safe and effective, the use of antipsychotics requires careful and skillful assessment of cardiovascular, cerebrovascular, neurological, GI, genitourinary, kidney, liver, and hematological functioning before and during drug therapy. The presence of significant disease in one or several organ systems may

lead to a more adverse response to a drug and may be dose limiting. Weight gain may occur, and if the patient is experiencing deleterious health effects because of weight gain, the patient's antipsychotic medication will need to be reassessed. Numerous adverse effects may be associated with many of these drugs (see earlier discussion); therefore, perform and document a thorough nursing history and mental status examination prior to the initiation of drug therapy. Identify possible drug interactions with any prescription drugs, OTC medications, or natural health products the patient is taking, as well as any conditions that represent cautions or contraindications to use of the antipsychotic drug (see pharmacology discussion).

Haloperidol is similar to other high-potency antipsychotics because its sedating effects are low but the incidence of extrapyramidal symptoms (see earlier discussion and [Chapter 16](#)) is high.

Atypical antipsychotics such as clozapine and risperidone have many contraindications, cautions, and drug interactions (see earlier discussion). Monitor liver and kidney function studies, CBC count, and urinalysis before and during therapy. Clozapine is associated with neutropenia, and monitoring of WBCs is required. Make sure to document blood pressure readings with close attention to postural readings because of the potential for the adverse effect of orthostatic hypotension. A drop of 20 mm Hg or more in the systolic blood pressure requires immediate attention and implementation of safety precautions. In addition, for older adults, health care providers may order reduced dosages to help prevent toxicity. Atypical antipsychotics are also associated with a high degree of sedation and must be used only when necessary and with extreme caution (close monitoring) in older adults and other patients who are at risk for falls or harm or who have limited motor and sensory capabilities. Carefully monitor heart sounds and assess for any abnormal heart rhythms in patients taking these drugs.

◆ NURSING DIAGNOSES

- Imbalanced nutrition, less than body requirements, as a result of consequences of the mental health disorder or the use of psychotherapeutic drugs
- Urinary retention as a result of the adverse effects of psychotherapeutic drugs
- Constipation as a result of the adverse effects of psychotherapeutic drugs
- Sexual dysfunction as a result of the adverse effects of psychotherapeutic drugs
- Sleep deprivation as a result of the mental health disorder or related drug therapy
- Reduced knowledge as a result of lack of information about specific psychotherapeutic drugs and their adverse effects
- Reduced social interaction as a result of various inadequacies felt by the patient due to illness or isolation from others
- Situational low self-esteem as a result of the mental health disorder and from the adverse effects of psychotherapeutic drugs, including sexual dysfunction
- Potential for injury to self as a result of the mental health disorder or possible adverse effects of psychotherapeutic drugs

◆ PLANNING

◆ Goals

- Patient will exhibit improved nutritional status, without weight loss.
- Patient will remain free from any alterations in urinary elimination patterns.
- Patient will regain or maintain normal bowel elimination patterns.
- Patient will remain free from or experience minimal alterations in sexual function.
- Patient will implement measures to minimize sleep deprivation.
- Patient will be adherent to medication therapy, take medication(s) as ordered, and remain free from complications associated with drug therapy.
- Patient will regain or maintain social interaction and open communication with family, friends, significant others, and members of the health care team.
- Patient will exhibit more positive self-image, healthier thought processes, and interactive processes.
- Patient will maintain safety with drug therapeutic regimen and without injury to self.

◆ Expected Patient Outcomes

- Patient shows healthy nutritional habits with appropriate weight gain and maintains a diet that includes a variety of foods from *Canada's Food Guide* (2019). (Culturally sensitive food guides are available on the Health Canada website for First Nations, Inuit, and Métis individuals [2010]—as of this writing, this part of the 2019 guide is under revision, in consultation with First Nations, Inuit, and Métis partners, as are suggestions of culturally specific foods that can make the guide more accessible to Canada's diverse population).
- Patient reports any problems with urinary hesitancy, urgency, or retention, or other discomfort over the lower abdominal area.
- Patient states measures to increase bowel elimination, such as increasing dietary fibre with fruits and vegetables while also increasing fluid intake.
- Patient reports any problems with bowel elimination, such as constipation or passing of hard stool.
- Patient openly communicates with partner and health care providers about difficulty with sexual functioning related to drug therapy.
- Patient openly identifies and discusses options for improving sexual functioning to assist with any altered patterns of sexual behaviour.
- Patient reports measures to increase healthier sleeping habits, including journalling and maintaining optimal sleep hygiene, through retiring at a regular time nightly, decreasing room noise and light, listening to calming music, using aromatherapy, and avoiding caffeine in the late afternoon or evening (see [Chapter 13](#) for sleep hygiene nursing interventions).
- Patient states reasoning for adherence to medication regimen, acknowledges the need to take the medication exactly as prescribed, and shows understanding of related drug safety measures.

- Patient has assistance at home in the daily monitoring of self-administration of medication(s).
- Patient states common adverse effects of psychotherapeutic drug therapy, such as confusion, sedation, constipation, nausea, dizziness, unsteady gait, dry mouth, changes in sexual performance, weight gain or loss, and loss or increase in appetite.
- Patient states adverse effects that necessitate reporting to the health care provider, such as unresolved constipation, urinary retention, increasing levels of sedation, and dizziness or fainting upon standing or changing positions.
- Patient demonstrates improved or no further deterioration in social integration, with healthier patterns of communication and participation in activities.
- Patient interacts openly and frequently with family, friends, significant others, and members of the health care team without suspicion or paranoia.
- Patient participates daily or more frequently in social interactions and activities and plans to engage in more social activities, as appropriate.
- Patient demonstrates improved self-concept and self-esteem in daily interactions with family, friends, and significant others, while experiencing fewer episodes of self-destructive and negative behaviours.
- Patient feels more positive about self, demonstrated by increased participation in ADLs, social activities, and family functions.
- Patient demonstrates safety with ADLs, including self-care measures, by moving slowly, changing positions slowly, and reporting excess dizziness or fainting episodes.

◆ IMPLEMENTATION

Regardless of the psychotherapeutic drug prescribed, several general nursing actions are important for safe administration. Once the patient's reading level and the most effective means of teaching and learning are identified, provide the patient with simple explanations about the drug, its action, and the length of time before therapeutic effects can be expected. Always use a psychosocial and holistic approach when caring for any patient with any illness. Monitor vital signs and document findings, especially during the initiation of therapy. The administration of psychotherapeutic medications to older adults and to patients with a history of hypertension and heart disease should be done with great care. All the psychotherapeutic drugs are to be taken exactly as prescribed, at the same time every day, and without failure. If omission occurs, contact the health care provider immediately. Abrupt withdrawal may have negative effects on the patient's physical and mental status. Solicit help from family members or others providing support in the care of the patient so that there are options for assistance with drug administration. Adherence to the medication regimen is crucial to effective symptom management; identify and utilize all support systems and resources to accomplish this.

◆ Benzodiazepines

Specific nursing interventions regarding the use of anxiolytic drugs include frequent monitoring of vital signs with

special attention to blood pressure and postural blood pressures. Encourage the use of elastic compression stockings and recommend that the patient change positions slowly to minimize dizziness and falls from orthostatic hypotension. Create a therapeutic environment for open communication—especially of all disturbing thoughts, including those of suicide. Check the patient's oral cavity for hoarding or cheeking of drugs. If medications are crushed, make sure they are not extended-release formulations. As well, some medications (e.g., olanzapine oral disintegrating tablet) melt instantly on the tongue, so caution needs to be used when opening the container so as not to touch the tablet. Use intravenous routes of administration only as prescribed and give over the recommended time, with the proper diluents and at a rate indicated by the manufacturer and health care provider. Always administer IM dosage forms in a large muscle mass and only as ordered or indicated (see [Chapter 10](#) for more information on parenteral administration). See Patient Teaching Tips for more information.

◆ Mood-Stabilizing Drugs

Safe use of the mood-stabilizing drug lithium depends on adequate hydration and electrolyte status because lithium may become toxic with dehydration and hyponatremia. See Patient Teaching Tips for more information.

◆ Antidepressants

With second-generation antidepressants, emphasize that it may take up to 4 to 6 weeks before therapeutic effects are evident. This 4- to 6-week time frame also applies to TCAs and MAOIs. Make sure the patient understands the need for patience and continues to take the medication as prescribed, even if the patient feels the condition is not improving. Carefully monitor the patient, be readily available, and provide supportive care during this time. The period just before therapeutic effects are seen, when the patient has increased energy, may be the time the patient is at highest potential for self-harm or suicide. Advise the patient to take the drug(s) with food and at least 120 to 180 mL of fluid. Assist with ambulation and other activities if the patient is weak or dizzy (from orthostatic hypotension) or if the patient is an older adult. Counsel the patient about potential sexual dysfunction (if appropriate) if this is an adverse effect of the drug. If sexual dysfunction occurs, provide information to the patient about various options (e.g., waiting to see if the adverse effect resolves, reducing the current dosage of the drug as ordered, taking a “drug holiday” if ordered by the health care provider). A drug holiday, if indicated, generally occurs in a hospital setting, and the drug is removed only under close monitoring. See Patient Teaching Tips for more specific information regarding SSRIs and SNRIs.

With the use of TCAs and MAOIs, educate the patient on adverse effects and drug or food interactions. Always emphasize the importance of keeping a list of all medications with the patient at all times. This can be on a smartphone or tablet. Pharmacies can also provide a list of medications for the patient to keep. Advise the patient to change positions purposefully and slowly. All health care providers need to be informed that the patient is taking these drugs and that if the drugs are to be discontinued,

the patient must be weaned off them. With TCAs, advise the patient to report any of the following to the health care provider if they occur: blurred vision, excessive drowsiness, sleepiness, urinary retention, constipation, or cognitive impairment. It is also important to inform patients that tolerance to sedation will occur with some second-generation antidepressants.

◆ Antipsychotics

Antipsychotic drugs must be taken exactly as prescribed to be effective. Different levels of paranoia or delusions may lead the patient to mistrust the nurse and other members of the health care team, so maintain a sufficient level of trust through consistency, empathy, and the establishment of a strong therapeutic relationship to help ensure adherence. Adherence is always a crucial issue for patients with psychotic illnesses because they are at higher potential for not taking medications, often because they begin to feel better and do not keep follow-up appointments. Nonadherence to the medical and treatment regimen is of major concern because the serum levels of drugs such as haloperidol must be within a therapeutic range for the patient to feel better, be functional, and not relapse. If serum levels of haloperidol are less than 4 ng/mL, the patient may show symptoms of the mental health disorder, whereas levels greater than 22 ng/mL may result in toxicity. Therefore, selection of an antipsychotic drug and its dosage, route of administration, potential for toxicity, and suicidal potential, as well as therapeutic communication and patient education, are all important factors for successful therapy. If an antipsychotic medication is determined to no longer be effective or necessary and the patient has been in therapy for a period of 3 to 6 months or longer, it may be advantageous to slowly taper the dose until the antipsychotic medication is discontinued or until the lowest effective dose is determined. While there is no best practice for tapering antipsychotics, it is recommended to do so slowly to avoid symptoms of withdrawal or rebound effects. Because most antipsychotic drugs are quite potent, be sure that oral dosage forms have been swallowed and not intentionally hidden in the side of the mouth (see previous discussion on cheeking of medications). Oral forms of antipsychotics are generally well absorbed and will cause less GI upset if taken with food or a full glass of water. Sucking on hard candy or gum may help to relieve dry mouth. With any of the dosage forms, perspiration may be increased; therefore, encourage the patient to avoid being exposed to heat or humidity or engaging in excessive activity. Excessive sweating can lead to dehydration and subsequent drug toxicity.

Haloperidol may not necessarily be the best drug to use because of the potential for undermedication or overmedication and troubling adverse effects (see Table 17.10). Therefore, other antipsychotics (e.g., clozapine and risperidone) may be preferred, as previously discussed. Clozapine and risperidone are therapeutically effective and carry a minimal risk of tardive dyskinesia and extrapyramidal symptoms. Clozapine is generally reserved as last-line therapy for treatment resistant schizophrenia due to very cumbersome monitoring (weekly, bi-monthly or monthly blood work monitoring for agranulocytosis), EKG, sialorrhea, substantial weight gain, orthostatic hypotension, sedation. In addition, they usually lead to improvement in cognitive behaviour. Clozapine is to be taken as ordered and is usually given in divided

CASE STUDY

Antidepressants

A 49-year-old patient, Alim, comes to the clinic with a history of depression. He tells you that he was treated for it by a doctor in another country, but he “ran out of pills” a week ago and did not know how to get a refill. He could not remember the name of the medication but said it was for “depression.” He has also been having trouble sleeping. After a psychiatric evaluation, he is given a 2-week prescription for fluoxetine (Prozac).

1. A few days later, Alim’s wife calls to describe “a terrible reaction” that he is having. She says that he is shaking and shivering, has a fever, and is somewhat confused and upset. She thinks he has a bad infection. What do you think has happened, and why?
2. What could have been done to prevent this problem?
3. After 2 weeks, Alim is given a prescription for trazodone (Trazorel) and is instructed to return to the office in 2 weeks. What advantage does this medication have for this patient?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

ETHNOCULTURAL IMPLICATIONS

Psychotherapeutic Drugs

Many racial and ethnic groups respond to drugs differently. For example, Asian people have lower drug metabolism activity than White people, regarding lower levels of various enzymes. Asian people often require lower dosages of benzodiazepines and TCAs because they have lower levels of the enzymes metabolizing these drugs (e.g., CYP2D6) and are therefore more sensitive to the drugs.

Diazepam follows a different metabolic pathway in Chinese and Japanese populations. These two groups are found to be poor metabolizers of this drug and its metabolite. Approximately 20% of Chinese and Japanese individuals metabolize diazepam poorly, which results in rapid drug accumulation. To prevent possible toxicity, lower dosages are generally required. Nurses need to be aware of this cultural variable and assess these patients for sedation, overdose, and other adverse reactions.

Researchers have also identified genetic variations that may explain individual differences in response to antidepressants. The serotonin transporter gene (5-HTT) may influence antidepressant response to SSRIs. This is an area of ongoing research.

doses; proper dosing is important for therapeutic effectiveness. If any changes in blood counts (e.g., leukopenia) are noted or if abnormal cardiac functioning (e.g., tachycardia) is identified, contact the health care provider immediately. In such a case, the medication may need to be discontinued, but only as ordered, and the patient should be monitored closely. Titration of doses of clozapine, either upward or downward, needs to be done carefully, with close monitoring of the patient for any exacerbation of the mental health disorder or suicidal tendencies.

Risperidone is to be given as ordered and administered by injection into a deep muscle mass. Always check hospital or facility policy or drug insert guidelines regarding the administration

of this drug. IM injection dosage forms may be ordered along with oral doses of risperidone or possibly another antipsychotic drug for several weeks, with maintenance doses of an IM injection given every 2 to 4 weeks, as ordered. Always alternate IM injection sites to maintain tissue integrity and muscle mass, and be sure that the site is not red, swollen, or irritated. Document and report any changes. Oral solution, tablets, and orally disintegrating tabs are other available dosage forms. Do not give oral solutions with cola or tea. Disintegrating tabs need to be dissolved under the tongue before swallowing with or without liquid. Always follow the health care provider's orders for administering this and all other drugs. The daily amount is usually given in two divided doses, with dosage decreased in older adults and in those with reduced kidney or liver function. Make sure you immediately report any excess sedation, anxiety, extrapyramidal symptoms, tardive dyskinesia, seizures, or stroke-like symptoms. Measuring vital signs and monitoring for any orthostatic hypotension are also important during treatment.

Once therapy with any of the antipsychotic drugs has been initiated, it is important for the nurse and other health care providers involved in the patient's care to monitor drug therapy closely during follow-up visits, including serum drug levels. If the patient is suspected of being nonadherent and serum drug levels are subtherapeutic, the patient needs to be re-evaluated by the prescribing health care provider for a possible change of drug or dosage form. The parenteral dosage form is available in a depot (longer-releasing) dosage preparation that releases the drug over 2 to 4 weeks, leading to increased adherence and often a better therapeutic outcome.

Patient education (see Patient Teaching Tips) and patient adherence with the drug regimen are keys to successful treatment, regardless of the mental health disorder. Often, it is the mental health disorder itself that causes patient nonadherence. Keeping communication open with the patient and family or caregivers is important to developing trust and a sense of empathy. Although patient education may have been thorough, emphasize that the patient may call the health care provider, clinic, or a hotline 24 hours a day. Keep phone numbers continuously updated. Make available ongoing professional counselling with a mental health care provider (psychiatrist, nurse practitioner, or other licensed mental health professional), as needed, so that the patient's progress is consistently monitored. Group therapy and support groups are also available for the patient and significant others.

◆ EVALUATION

Both the therapeutic effects of psychotropic medications and the patient's progress within the treatment regimen must always be

monitored during and even after therapy. Mental alertness, cognition, mood, ability to carry out ADLs, appetite, and sleep patterns are all areas that need to be closely monitored and documented. Encourage the patient to continue with other forms of therapy, in addition to drug therapy, with the goal of acquiring more effective coping skills. Other forms of treatment may include intense psychotherapy, relaxation therapy, stress reduction, and lifestyle changes. It is important to mention that blood levels of psychotropic drugs will need to be measured during follow-up visits to ensure that therapeutic levels are maintained. Such monitoring of serum drug levels helps identify both subtherapeutic and toxic levels.

The therapeutic effects of anxiolytic drugs are evidenced by improved mental alertness, cognition, and mood; fewer anxiety and panic attacks; improved sleep patterns and appetite; more interest in self and others; less tension and irritability; and fewer feelings of fear, impending doom, and stress. Watch for the adverse effects of hypotension, lethargy, fatigue, drowsiness, and confusion in patients taking anxiolytic drugs. In general, adverse reactions to antidepressants include drowsiness, dry mouth, constipation, dizziness, orthostatic hypotension, sedation, blood dyscrasias, sexual dysfunction, and dyskinesias. Overdose is evidenced by seizures or dysrhythmias.

Therapeutic effects of the mood stabilizer lithium are decreased mania and stabilization of the patient's mood. Lithium is usually better tolerated by the patient during manic phases than depressive phases. Adverse reactions to lithium include dysrhythmias, hypotension, sedation, slurred speech, slowed motor abilities, weight gain, and GI discomfort.

When used as antidepressants, SSRIs and SNRIs may take up to 6–8 weeks (up to 12 weeks if using for anxiety disorders) to reach full therapeutic effect. A therapeutic response to these drugs includes improved depression or mental status, improved ability to carry out ADLs, decreased insomnia, and improved mood, with minimal adverse effects of weight gain, headache, GI discomfort, insomnia, dizziness, drowsiness, and sexual dysfunction. Monitor the patient for symptoms of serotonin syndrome such as agitation, tachycardia, hyperreflexia, and tremors.

The therapeutic effects of the antipsychotic drugs include improvement in mood and affect, as well as alleviation of or decrease in psychotic symptoms (hallucinations, paranoia, delusions, garbled speech) once the patient has been taking the medication for several weeks. Careful monitoring of the patient's potential to injure self or others during the delay between the start of therapy and symptomatic improvement is crucial. Evaluation for adverse effects includes monitoring blood counts (clozapine) as well as noting any tic-like trembling movements of the hands, face, neck, and head; hypotension; and dry mouth (haloperidol).

PATIENT TEACHING TIPS

◆ Anxiolytic Drugs

- Encourage patients to avoid operating heavy machinery and driving until the adverse effects of sedation or drowsiness have resolved.
- Educate patients about the development of tolerance to the sedating properties of benzodiazepines with chronic use (see Chapter 13).

- Instruct patients not to take OTC drugs or natural health products without seeking advice from the health care provider.
- Remind patients to keep these and all psychotherapeutic drugs out of the reach of children.
- Inform patients that they must avoid alcohol and other CNS depressants.

- Advise patients to always carry a MedicAlert or other identification bracelet or necklace with their diagnoses and a list of their drugs and allergies. The drug list needs to be updated at least every 3 months.
- Emphasize to patients that medications must always be taken exactly as ordered and that sudden withdrawal should be avoided. If withdrawal of a drug is necessary, tapering or weaning of doses is needed. Benzodiazepines are usually recommended for short-term use.

❖ Mood-Stabilizing Drugs

- Instruct patients that lithium must be taken at the same time each day and give specific instructions on how to handle missed doses. Make sure the patient understands the importance of adequate hydration.
- Inform patients that the adverse effects of lithium are usually transient; however, excessive tremors, seizures, confusion, ataxia, and excessive sedation must be reported to the health care provider immediately.

❖ Monoamine Oxidase Inhibitors and Tricyclic Antidepressants

- Advise patients taking MAOIs to contact the prescriber immediately if any of the following signs and symptoms of overdosage or toxicity occur: tachycardia, hyperthermia, or seizures.
- If a patient is taking an MAOI, caution about avoiding OTC cold and flu products. Foods or beverages high in tyramine must also be avoided (see [Table 17.7](#)).
- When a patient is taking a TCA, any blurred vision, agitation, urinary retention, or ataxia needs to be reported to the prescriber immediately.
- Encourage patients to wear a MedicAlert or other identification bracelet or necklace indicating diagnoses and a list of current drugs.

❖ Selective Serotonin Reuptake Inhibitors and Serotonin–Norepinephrine Reuptake Inhibitors

- Inform patients that consumption of fibre supplements must occur at least 2 hours before or after the dosing of medication to avoid interference with drug absorption; however, dietary fibre intake is appropriate.
- Encourage patients to openly discuss any concerns about the medication and adverse effects, such as GI upset, sexual dysfunction, or tremors.

- Provide a listing of drug–drug interactions, such as the strong interaction between SSRIs and MAOIs, St. John's wort (a natural health product), and tryptophan (a serotonin precursor found in foods). Such interactions may pose a potential for the occurrence of serotonin syndrome (see earlier discussion). Cold products and OTC medications must be approved by the health care provider.
- Stress to patients that SSRIs must be taken carefully and as prescribed. Any increase in suicidal thoughts or extreme changes in mood need to be reported immediately to the health care provider.
- Emphasize the importance of regularly attending follow-up visits and contacting health care providers if there are any concerns. Many patients use antidepressants inconsistently or stop taking them prematurely. Inform the patient that discontinuation of SSRIs and SNRIs requires a tapering period of up to 1 to 2 months, as ordered. Discontinuation syndrome may occur with or without a tapering period; this includes symptoms of dizziness, diarrhea, movement disorders, insomnia, irritability, visual disturbance, lethargy, anorexia, and lowered mood.
- Tell patients that if there is ever any doubt as to whether too much of an antidepressant has been taken, they should contact the health care provider or seek emergency medical treatment immediately.

❖ Antipsychotics

- Advise patients to avoid hot baths, saunas, and hot climates with the use of antipsychotics because of the risk of further drop in blood pressure, especially upon standing (orthostatic hypotension). Injury may occur because of dizziness or fainting.
- Warn patients that haloperidol and other antipsychotics must never be stopped abruptly because of the high risk of inducing a withdrawal psychosis.
- Inform patients that drug interactions with clozapine include alcohol, CNS depressants, levodopa, and antihypertensives.
- Counsel patients taking clozapine that any sore throat, malaise, fever, or bleeding must be reported to a health care provider immediately because of possible drop in WBC counts.
- Educate patients with schizophrenia that they may require antipsychotics for their lifetime.

KEY POINTS

- Psychosis is a symptom of a mental health disorder that impairs mental function.
- A person experiencing psychosis cannot participate in everyday life and shows the hallmark sign of loss of contact with reality.
- Affective disorders are emotional disorders characterized by changes in mood. They range from mania (abnormally elevated emotions) to depression (abnormally reduced emotions) and include anxiety, a normal emotion that may be a healthy reaction but becomes pathological when it is life altering.
- Situational anxiety arises in response to specific life events, and nursing assessment is key to identifying patients who are at risk.
- SSRIs and SNRIs are often prescribed because of their superiority to older antidepressants.
- Nursing considerations regarding psychotherapeutic drugs include the need for skillful patient assessment with an emphasis on past and present medical history, a physical examination, and a thorough medication history and profile.

EXAMINATION REVIEW QUESTIONS

1. The nurse is caring for a patient experiencing ethanol withdrawal. The nurse expects to administer which medication or medication class as treatment for this condition?
 - a. lithium (Carbolith®)
 - b. Benzodiazepines
 - c. buspirone
 - d. Antidepressants
2. The nurse is teaching a patient receiving an MAOI. What food product should the nurse teach the patient to avoid?
 - a. Orange juice
 - b. Milk
 - c. Shrimp
 - d. Swiss cheese
3. The nurse calls a patient to schedule a follow-up visit after the patient has been treated for depression for 4 weeks. What concern will the nurse assess for during the conversation with the patient?
 - a. Weakness
 - b. Hallucinations
 - c. Suicidal ideation
 - d. Difficulty with urination
4. The nurse is caring for a patient who has been taking clozapine (Clozaril®) for 2 months. Which laboratory test(s) should be performed regularly while the patient is on this medication?
 - a. Platelet count
 - b. WBC count
 - c. Liver function studies
 - d. Kidney function studies
5. The nurse is giving medications to a patient. Which drug or drug class, when administered with lithium, increases the potential for lithium toxicity?
 - a. Thiazides
 - b. levofloxacin
 - c. calcium citrate
 - d. Beta blockers
6. The nurse is teaching a patient about treatment with an SSRI antidepressant. Which teaching considerations are appropriate? (Select all that apply.)
 - a. The patient should be told which foods contain tyramine and instructed to avoid these foods.
 - b. The patient should be instructed to use caution when standing up from a sitting position.
 - c. The patient should not take any products that contain the natural health product St. John's wort.
 - d. This medication should not be stopped abruptly.
 - e. Drug levels may become toxic if dehydration occurs.
 - f. The patient should be told to check with the health care provider before taking any OTC medications.
7. A patient with a feeding tube will be receiving risperidone (Risperdal®) 8 mg in 2 divided doses via a feeding tube. The medication is available in a 1 mg/mL solution. How many millilitres will the nurse administer for each dose?
8. A patient who has been taking lithium for 6 months has had severe vomiting and diarrhea from a gastrointestinal flu. The nurse will assess for which potential problem at this time?
 - a. Anxiety
 - b. Chest pain
 - c. Agitation
 - d. Dehydration

CRITICAL THINKING ACTIVITIES

1. A 22-year-old patient who has been taking lithium for 3 months has had severe vomiting and diarrhea from a gastrointestinal flu. What is the nurse's priority assessment at this time?
2. A 68-year-old patient has been taking an SSRI antidepressant for 5 weeks. His wife calls and expresses concern because he

has started to give away some of his keepsakes. What is the nurse's priority action?

3. A patient has been admitted to the hospital because of a suspected overdose of a TCA. What two problems are the nurse's priorities during this time?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Substance Misuse

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Discuss substance misuse and the significance of the problem in Canada.
2. Identify the drugs or chemicals that are most frequently misused.
3. Contrast the signs and symptoms of the most commonly misused drugs or chemicals.
4. Compare the treatments for drug withdrawal for the most commonly misused opioids; central nervous system depressants; amphetamines and other CNS stimulants; nicotine; and alcohol.
5. Describe alcohol misuse syndrome with a focus on signs and symptoms, mild to severe alcohol withdrawal symptoms, and associated treatment.
6. Describe other drug misuse syndromes, including their signs and symptoms, withdrawal symptoms, and treatment regimens.
7. Identify various assessment tools used in the nursing assessment of substance misuse.
8. Develop a collaborative plan of care, encompassing all phases of the nursing process, for a patient undergoing treatment for substance misuse and dependency.

KEY TERMS

Addiction Strong psychological or physical dependence on a drug or other psychoactive substance. (p. 309)

Amphetamine A drug that stimulates the central nervous system. (p. 311)

Detoxification A process of eliminating a toxic substance from the body; a medically supervised program for alcohol or opioid addiction. (p. 310)

Habituation Development of tolerance to a substance following prolonged medical use but without psychological or physical dependence (addiction). (p. 309)

Illicit drug use The use of a drug or substance in a way that it is not intended to be used or that is not legally approved for human administration. (p. 311)

Intoxication Stimulation, excitement, or stupefaction produced by a chemical substance. (p. 309)

Korsakoff's psychosis A syndrome of amnesia with confabulation (making up of stories) associated with chronic alcohol misuse; it often occurs together with Wernicke's encephalopathy. (p. 315)

Narcolepsy A sleep disorder characterized by sleeping during the day, disrupted night-time sleep, cataplexy, sleep paralysis, and hallucinations. (p. 312)

Opioid analgesics Synthetic pain-relieving substances that were originally derived from the opium poppy. Naturally occurring opium derivatives are called *opiates*. (p. 309)

Physical dependence A condition characterized by physiological reliance on a substance, usually indicated by tolerance to the effects of the substance and development of withdrawal symptoms when use of the substance is terminated. (p. 309)

Psychoactive properties Drug properties that affect mood, behaviour, cognitive processes, and mental status. (p. 311)

Psychological dependence A condition characterized by strong desires to obtain and use a substance. (p. 309)

Raves All-night parties that typically involve dancing, drinking, and the use of illicit drugs. (p. 312)

Roofies Pills that are classified as benzodiazepines; gained popularity as a recreational drug; chemically known as *flunitrazepam*. (p. 312)

Substance misuse The use of a mood- or behaviour-altering substance in a maladaptive manner that often compromises health, safety, and social and occupational functioning and causes legal problems. (p. 309)

Wernicke's encephalopathy A neurological disorder characterized by apathy, drowsiness, ataxia, nystagmus, and ophthalmoplegia; caused by thiamine (vitamin B₁) deficiency secondary to chronic alcohol misuse. (p. 315)

Withdrawal A substance-specific mental health disorder that occurs as a group of symptoms, varying in severity, following the cessation or reduction in use of a psychoactive substance that has been taken regularly. (p. 309)

OVERVIEW

Substance misuse affects individuals of all ages, genders, and ethnic and socioeconomic backgrounds. **Physical dependence** and **psychological dependence** on a substance are complex chronic disorders with remissions and relapses, such as with any other chronic illness. Relapses are common and are often reflective of other social issues that are yet to be addressed (e.g., housing, social support). Recognizing physical or psychological dependence and understanding the various treatment guidelines are important skills for health care providers caring for patients with these conditions. **Habituation** refers to situations in which a patient becomes accustomed to a certain drug (develops tolerance) and may have mild psychological dependence on it but does not show compulsive dose escalation, drug-seeking behaviour, or major withdrawal symptoms on drug discontinuation. This might occur, for example, in a postsurgical patient who receives opioid pain therapy regularly for only a few weeks.

In Canada, problematic substance misuse is estimated to affect one in five Canadians over the age of 15 ([Government of Canada, 2018a](#)). According to the 2012 *Canadian Community Health Survey*, approximately 21.6% of Canadians, about 6 million over the age of 15, meet the criteria for a substance use disorder over their lifetimes ([Pearson, Janz, & Ali, 2015](#)). Alcohol was the most commonly misused substance, at 18.1%. Marijuana was identified as the most commonly misused drug (6.8%), followed by psychotherapeutic drugs, pain relievers, tranquilizers, stimulants, and sedatives used for nonmedical purposes. Youth aged 15 to 24 had the highest rate of substance misuse disorder (11.9%), while the lowest rate, 1.9%, was among those aged 45 and older.

Substance misuse is strongly associated with many types of mental health disorders. Treatment of both disorders is often difficult, in part because of the much greater risk of drug interactions with the misused substances. Assessment, intervention, use of certain medications, specific **addiction** treatment strategies, and recovery monitoring are essential to the care of this patient population.

The focus of this chapter is on the three major classes of commonly misused substances (opioids, stimulants, and depressants) and two commonly misused individual drugs (alcohol and nicotine). A description of the category or the individual drug, possible effects, signs and symptoms of **intoxication** and **withdrawal**, peak period and duration of withdrawal symptoms, and drugs used to treat withdrawal are discussed. The list of substances of misuse in [Box 18.1](#) is not all-inclusive, but it contains some of the substances most commonly misused, currently. Not all these substances are discussed in this chapter. Refer to the Centre for Addiction and Mental Health's website (<http://www.camh.ca>) for more information.

Specific drugs used to treat withdrawal symptoms are discussed in the sections covering the drug whose withdrawal symptoms they are intended to treat. Pharmacological therapies are indicated for patients with addictive disorders to prevent life-threatening withdrawal complications, such as seizures and delirium tremens, and to increase adherence to psychosocial forms of addiction treatment.

BOX 18.1 Commonly Misused Substances

Major Categories

Opioids
Stimulants
Depressants

Individual Drugs

Alcohol
Anabolic steroids (see Chapter 36)
Cocaine
Fentanyl
Heroin
Dextromethorphan hydrobromide
Lysergic acid diethylamide (LSD)
Marijuana
Methamphetamine
Methylenedioxymethamphetamine (MDMA, ecstasy, E)
Nicotine
Phencyclidine (PCP)

OPIOIDS

Opioid analgesics are synthetic versions of pain-relieving substances that were originally derived from the opium poppy plant (see Chapter 11). More than 20 different alkaloids are obtained from the unripe seed of the opium poppy plant, only a few of which are clinically useful, including morphine and codeine. The other opioid analgesics currently used in medical practice are synthetic or semisynthetic derivatives of these two drugs.

Diacetylmorphine (better known as *heroin*) and opium are also opioids; they are classified as Schedule I drugs and are not available in Canada for therapeutic use. Heroin was banned in Canada in 1908 because of its high potential for misuse and the increasing number of heroin addicts. In Europe, heroin is available for medical treatment of pain, and governmental programs also exist to provide heroin to addicts with the goal of reducing crime.

Heroin is one of the most commonly misused opioids. Some others in the opioid category are codeine phosphate, hydrocodone, hydromorphone, meperidine hydrochloride, morphine, fentanyl, and oxycodone. For example, residual fentanyl remaining in used patches can be extracted and used in several ways, including chewing or smoking. Currently, heroin remains one of the top 10 most misused drugs in Canada and often is used in combination with the stimulant drug cocaine (discussed later, in Stimulants). It can be mixed with marijuana and smoked. When heroin is injected (also called *mainlining* or *skin-popping*), sniffed (known as *snorting*), or smoked, it binds with opiate receptors found in many regions of the brain. The result is intense euphoria, often referred to as a *rush*. This rush lasts only briefly and is followed by a relaxed, contented state that persists for a couple of hours. In large doses, heroin, like other opioids, can reduce or stop respiration.

Mechanism of Action and Drug Effects

Opioids work by blocking receptors in the central nervous system (CNS). When these receptors are blocked, the perception of pain is blocked. There are three main receptor types to which

opioids bind. These receptors and their physiological effects when stimulated are discussed in Chapter 11. The unique mixture of receptor affinities that a specific opioid possesses determines its therapeutic and toxic effects. One of the reasons that opioids are misused is their ability to produce euphoria.

The drug effects of opioids are primarily centred in the CNS. However, these drugs also act outside the CNS, and many of their unwanted effects stem from these actions. In addition to analgesia, opioids produce drowsiness, euphoria, tranquility, and other alterations of mood. The mechanism by which opioids produce the latter effects is not entirely clear. The effects of opioids can be collectively referred to as *narcosis* or *stupor*, which involves reduced sensory response, especially to painful stimuli. For this reason, opioid analgesics, along with other classes of drugs that produce similar effects, are also referred to as *narcotics* (see Chapter 3), especially by law enforcement authorities.

Indications

The intended drug effects of opioids are to relieve pain, reduce cough, relieve diarrhea, and induce anaesthesia. Many have a high potential for problematic use and are therefore classified as Schedule I controlled substances. Relaxation and euphoria are the most common drug effects that lead to misuse and psychological dependence. Sustained-release oxycodone is one example of an opioid analgesic that is controversial because it is often overprescribed and grossly misused. Numerous deaths were reported when the sustained-release form of oxycodone hydrochloride was crushed and the entire 12-hour supply was released at one time. OxyContin was removed from the Canadian market and replaced with OxyNeo®, a form that is more difficult to crush. With the unavailability of OxyContin, however, the illicit use of fentanyl has risen. Fentanyl, which can be over 40 times more potent than heroin, has accounted for hundreds of deaths in Canada alone, over recent years. Often, the user has no knowledge of the fentanyl having been mixed into fake OxyContin pills and heroin. The exempted codeine preparation Tylenol 1 is widely available in Canada without a prescription and is also subject to misuse.

Certain opioid drugs are used to treat opioid dependence. Historically, methadone has been used for this purpose. Its long half-life of 12 to 24 hours allows patients to be dosed once daily at federally approved methadone maintenance clinics and at pharmacies (witnessed ingestion). Methadone is a long-acting opioid agonist that reduces the craving for opioids, suppresses euphoria, and prevents withdrawal symptoms. In theory, the goal of such programs is to reduce the patient's dosage gradually, so that eventually the patient can live permanently drug free. Unfortunately, often, relapse rates are high in these programs. However, patients who remain on long-term opioid maintenance therapy in a medical setting still benefit by avoiding the hazards associated with obtaining and using illegal “street” drugs.

Contraindications

Contraindications to the therapeutic use of opioid medications include known drug allergy, pregnancy (high dosage or

BOX 18.2 Signs and Symptoms of Opioid Drug Withdrawal

Peak Period

1–3 days

Duration

5–7 days

Signs

Drug-seeking, mydriasis, piloerection, diaphoresis, rhinorrhea, lacrimation, vomiting, diarrhea, insomnia, elevated blood pressure and pulse rate

Symptoms

Intense desire for drugs, muscle cramps, arthralgia, anxiety, nausea, malaise

prolonged use is contraindicated), respiratory depression or severe asthma when resuscitative equipment is not available, and paralytic ileus.

Adverse Effects

Adverse effects of opioids can be separated into two groups: CNS and non-CNS. The primary adverse effects of opioids relate to their actions in the CNS, and the major ones include drowsiness, diuresis, miosis, convulsions, nausea, vomiting, and respiratory depression. Many of the non-CNS adverse effects are secondary to the release of histamine caused by opioids. Histamine release can cause vasodilation leading to hypotension, spasms of the colon leading to constipation, increased spasms of the ureter resulting in decreased urinary retention, and dilation of cutaneous blood vessels leading to flushing of the skin of the face, neck, and upper thorax. The release of histamine is also thought to cause sweating, urticaria, and pruritus.

Management of Withdrawal, Toxicity, and Overdose

According to the Government of Canada (2019), nearly 11 Canadians die every day from an opioid-related overdose or incident. The Canadian opioid crisis has become a national concern due to an increase in the numbers of families impacted by negative attitudes and beliefs surrounding opioid use. Stigma of opioid use impacts the people who use them and their families. Reduction in negative association to opioid use will enable people to get help and break down barriers to accessing needed resources, including withdrawal and overdose education.

Box 18.2 lists the signs and symptoms of opioid drug withdrawal, along with the time when these symptoms are most likely to occur and their duration. Many patients require a formal **detoxification** program while withdrawal symptoms are occurring. See Chapter 11 for a detailed discussion of physical dependence and the management of acute intoxication, toxicity, and overdose. Withdrawal symptoms include nausea, dysphoria, muscle aches, lacrimation, rhinorrhea, pupillary dilation, piloerection (hair standing on end), sweating, diarrhea, yawning, fever, and insomnia. Medications listed in Box 18.3 are intended to help decrease the desire for the misused opioid and reduce the severity of these withdrawal symptoms. The most serious adverse effect and the most common cause of death with opioids is respiratory depression.

BOX 18.3 Medications for Treatment of Opioid Withdrawal

Clonidine Hydrochloride (Catapres®) Substitution

Clonidine hydrochloride, 0.1 or 0.2 mg orally, is given every 4 to 6 hours, as needed for signs and symptoms of withdrawal, for 5 to 7 days. Days 2 to 4 are typically the most difficult days for the patient in detoxification. Check blood pressure before each dose, and do not give medication if patient is hypotensive.

Methadone Hydrochloride Substitution

A methadone hydrochloride test dose of 10 mg is given orally in liquid or as a crushed tablet. Additional 10- to 20-mg doses are given for signs and symptoms of withdrawal, every 4 to 6 hours for 24 hours after initial dose. Range for daily dose is 15 to 30 mg. Repeat total first-day dose in two divided doses (stabilization dose) for 2 to 3 days, and then reduce dosage by 5 to 10 mg/day until medication is completely discontinued.

Certain medications are used to prevent relapse drug use once an initial remission is achieved. They are useful only when concurrent counselling is provided, offering additional insurance against return to **illicit drug use**. For opioid misuse or dependence, naltrexone hydrochloride, an opioid antagonist, is administered. Naltrexone (Revia®), which is also available as an injection Vivitrol®, works by blocking the opioid receptors so that use of opioid drugs does not produce euphoria. When euphoria is eliminated, the reinforcing effect of the drug is lost. The patient needs to be free from opioids for at least 1 week before beginning this medication because naltrexone can produce withdrawal symptoms if given too soon. Naltrexone is also approved for use by patients who are alcohol-dependent to reduce cravings for alcohol and the likelihood of a full relapse if a slip occurs. Another opioid antagonist, naloxone hydrochloride, is used for opioid overdose and respiratory depression. It can be used alone or more commonly combined with buprenorphine hydrochloride (Suboxone®) or hydromorphone hydrochloride (Targin®; see Chapter 11). Naloxone kits are available in most community pharmacies and walk-in clinics in Canada without a prescription (Health Canada, 2019). The kits come with instructions on how to administer the drug via nasal spray and injection. Information about signs of overdose are also included in the kits. Paramedics and firefighters have used naloxone mainly through nasal spray route to reverse the increasing number of opioid overdoses in Canada. See Chapter 11 for how to administer naloxone and for more information.

STIMULANTS

The misuse of stimulants relates to their ability to cause elevation of mood, reduction of fatigue, a sense of increased alertness, and invigorating aggressiveness. **Amphetamine** is a group of stimulant drugs that is commonly misused. Chemically, three classes of amphetamine exist: salts of racemic amphetamine, dextroamphetamine, and methamphetamine. These classes vary with respect to their potency and peripheral effects. Another stimulant drug of misuse is cocaine, which also produces strong CNS stimulation. Cocaine was originally classified as a narcotic. It is considered a controlled substance by the correctional system and has been

TABLE 18.1 Various Forms of Amphetamine and Cocaine, With Street Names*

Chemical Name	Street Names
dimethoxymethylamphetamine	DOM, STP
methamphetamine (crystallized form)	Ice, crystal, glass, jibb, Tina
methamphetamine (powdered form)	Speed, meth, crank
methylenedioxyamphetamine	MDA
methylenedioxymethamphetamine	MDMA, ecstasy, E, Molly, love drug
methylenedioxypropylamphetamine	Ivory wave, purple wave, cloud nine, rave, vanilla sky, bliss, plant food
cocaine (powdered form)	Coke, dust, snow, flake, blow, girl, icing
cocaine (crystallized form)	Crack, crack cocaine, freebase rocks, rock, candy

*Street names for drugs are extensive and change along with societal trends.

treated as such in terms of secured storage in health care facilities. However, unlike the opioid analgesics, cocaine does not normally induce a state of narcosis or stupor and is therefore more correctly categorized as a stimulant drug. It is a Schedule I drug under the *Controlled Drugs and Substances Act* of Canada. Other commonly misused substances in the category of stimulants include methylphenidate hydrochloride and dextroamphetamine sulphate. Multiple slight chemical derivations of amphetamine exist. These “designer drugs” have **psychoactive properties** (affecting mood, behaviour, cognitive processes, and mental status) along with their stimulant properties that further enhance their misuse potential. Table 18.1 lists commonly misused forms of amphetamine and cocaine with some of their street names.

Methamphetamine is a chemical class of amphetamine, but it has a much stronger effect on the CNS than the other two classes of amphetamine. Methamphetamine is generally used in pill form, orally, or in powder form, by snorting or injecting. Methamphetamine has 15 to 20 times the potency of amphetamine sulphate, the original drug in this class. Crystallized methamphetamine—known as *ice*, *crystal*, or *crystal meth*—is a smokable and more powerful form of the drug. Methamphetamine users who inject the drug and share needles are at risk of human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS), as well as hepatitis B and C. Marijuana and alcohol are commonly listed as additional drugs of misuse in those admitted for treatment of methamphetamine misuse. Most recorded methamphetamine-related deaths involved the use of methamphetamine in combination with at least one other drug, such as alcohol, heroin, or cocaine. The over-the-counter (OTC) decongestant pseudoephedrine is commonly used to synthesize methamphetamine in secret drug laboratories, often in private homes. This practice has led to a dramatic increase in the misuse of this drug. Canada’s Precursor Control Regulations include requirements to control precursors and other substances used in the production of methamphetamine, including ephedrine, pseudoephedrine, and red phosphorus. In 2006, the National Drug Scheduling Advisory Committee recommended restricted retail

sales of all nonprescription drug products containing pseudoephedrine. Specific restrictions include allowing sales only from *behind* the pharmacy counter (Schedule II) and that combination formulations be sold only in pharmacies (Schedule III).

Another synthetic amphetamine derivative is methylenedioxymethamphetamine (MDMA, ecstasy, or E), which is also usually prepared in home laboratories. This drug tends to have more calming effects than other amphetamine drugs. It is usually taken in pill form but can also be snorted or injected. Users often feel a strong sense of social bonding with and acceptance of other people, hence the nickname “love drug.” The drug can also be energizing, which makes it popular at **raves** (all-night dance parties). Originally synthesized by Merck Pharmaceuticals in 1914, it was studied by the US Army as a “brainwashing” drug in the 1950s. In 2005, methamphetamine was reclassified from a Schedule III drug to a Schedule I drug of the *Controlled Drugs and Substances Act*, based on harms caused by methamphetamine production, trafficking, and misuse.

The newest synthetic stimulant to appear in Canada is bath salts, named because of the similarity to bath salt packaging that is used for distribution. Bath salts is composed of the primary chemical cathinone, 3,4-methylenedioxypyrovalerone (MDPV). Bath salts can be orally ingested, sniffed, snorted, smoked, or injected. The desired effects of euphoria, increased energy, expanded consciousness, and increased libido begin rapidly and typically last for 3 to 4 hours. Physiological symptoms include tachycardia, hypertension, pupil dilation, diaphoresis, tremor, and anxiety. Individuals ingesting this drug may also experience paranoia, restlessness, bizarre behaviour, and persecutory hallucinations. It is because of these latter effects that individuals co-ingest “downers” such as marijuana.

Cocaine is a white powder that is derived from leaves of the South American coca plant. Cocaine is either snorted or injected intravenously. It tends to give a temporary illusion of limitless power and energy but afterward leaves the user feeling depressed, edgy, and craving more. Cocaine and crack (a crystallized form of cocaine that is generally smoked) are highly addictive. Psychological and physical dependence can erode physical and mental health and can become so strong that these drugs dominate all aspects of an addict's life.

Mechanism of Action and Drug Effects

Stimulants work by releasing biogenic amines from their storage sites in the nerve terminals. The primary biogenic amine released is norepinephrine. Its release results in stimulation of the CNS, as well as cardiovascular stimulation, leading to increased blood pressure and heart rate and possible cardiac dysrhythmias. The effect on smooth muscle is seen primarily in the urinary bladder and results in contraction of the sphincter. This is helpful in treating enuresis but results in painful and difficult micturition otherwise.

Stimulants, particularly amphetamines, are potent CNS stimulants. This CNS stimulation commonly results in wakefulness, alertness, and a decreased sense of fatigue; elevation of mood with increased initiative, self-confidence, and ability to concentrate; often elation and euphoria; and an increase in motor and speech activity.

Indications

Stimulants have many therapeutic uses. Currently, their most common use is in the treatment of attention deficit hyperactivity disorder (see Chapter 14). Stimulants may be used to prevent or reverse fatigue and sleep, such as when they are used to treat **narcolepsy** (episodes of acute sleepiness). Another therapeutic effect of amphetamines is their ability to stimulate the respiratory centre. Stimulants are also used to reduce food intake and treat obesity; however, this therapeutic effect is limited because of rapid development of tolerance.

Contraindications

Contraindications to the therapeutic use of stimulant medications include drug allergy, diabetes, cardiovascular disorders, states of agitation, hypertension, known history of problematic drug use, and Tourette's syndrome.

Adverse Effects

Adverse effects of stimulants are commonly an extension of their therapeutic effects. The CNS-related adverse effects are restlessness, syncope (fainting), dizziness, tremor, hyperactive reflexes, talkativeness, tenseness, irritability, weakness, insomnia, fever, and sometimes euphoria. Confusion, aggression, increased libido, anxiety, delirium, paranoid hallucinations, panic states, and suicidal or homicidal tendencies can also occur, especially in patients with mental health disorders. Fatigue and depression usually follow CNS stimulation. Cardiovascular effects are common and include headache, chilliness, pallor or flushing, palpitations, tachycardia, cardiac dysrhythmias, anginal pain, hypertension or hypotension, and cardiac arrest. Excessive sweating can also occur. Gastrointestinal (GI) effects include dry mouth, metallic taste, anorexia, nausea, vomiting, diarrhea, and abdominal cramps. A sometimes fatal hyperthermia can also occur, driven partly by excessive drug-induced muscular contractions.

Management of Withdrawal, Toxicity, and Overdose

Box 18.4 lists the signs and symptoms of withdrawal from stimulants and indicates the peak period when these symptoms are most likely to occur and their duration. Death due to poisoning or toxic levels is usually a result of convulsions, coma, or cerebral hemorrhage and may occur during periods of either intoxication or withdrawal. Treatment of overdose is supportive and generally requires sedation of the patient.

DEPRESSANTS

Depressants are drugs that relieve anxiety, irritability, and tension when used as intended. They are also used to treat seizure disorders and induce anaesthesia. The two main pharmacological classes of depressants are benzodiazepines and barbiturates. Both drug classes are discussed further in Chapter 13.

Benzodiazepines are relatively safe although highly addictive with prolonged use. They offer many advantages over older drugs used to relieve anxiety and insomnia. However, they are often intentionally and unintentionally misused. Ingestion of benzodiazepines together with alcohol can be lethal. Another depressant that is neither a benzodiazepine nor a barbiturate is marijuana.

BOX 18.4 Signs and Symptoms of Stimulant Withdrawal

Peak Period

1–3 days

Duration

5–7 days

Signs

Social withdrawal, psychomotor retardation, hypersomnia, hyperphagia

Symptoms

Depression, suicidal thoughts and behaviour, paranoid delusions

Treatment

No specific pharmacological treatments to reduce cravings or reverse acute toxicity and no known antidotes

Derived from the cannabis plant, marihuana (*pot*, *grass*, or *weed*) is the most commonly misused drug worldwide. Marihuana is generally smoked as a cigarette (*joint*), rolled in a cigar wrapper (*blunt*), through a pipe, or in a water-chamber (*bong*) and can be mixed in food or tea. In 2014, the Centre for Addiction and Mental Health reported that Canada has one of the highest rates of marihuana use in the world (Centre for Addiction and Mental Health, 2014); and in 2017 approximately 4.4 million Canadians used cannabis, including 37% for medical purposes (Health Canada, 2017). Since becoming legal for consumption in Canada on October 17, 2018, approximately 646,000 people (double the previous estimate of 327,000 for non-medical use) tried cannabis for the first time (Statistics Canada, 2019). According to Statistics Canada's *National Cannabis Survey, First Quarter 2019*, half of first-time cannabis users were over the age of 45 and were using the drug for recreational and/or self-prescribed medicinal use.

A benzodiazepine that has gained popularity as a recreational drug is flunitrazepam (Rohypnol®). Flunitrazepam is not legally available for prescription in Canada, but it is legally sold in over 60 countries for the treatment of insomnia. This drug is often known as **roofies** and creates a sleepy, relaxed, drunken feeling that lasts 2 to 8 hours. Roofies are commonly used in combination with alcohol and other drugs. They are sometimes taken to enhance a heroin high or to mellow or ease the experience of coming down from a cocaine or crack high. Used with alcohol, roofies produce disinhibition and amnesia.

Roofies have gained a reputation as the “date rape” drug. Individuals have reported being sexually assaulted after being involuntarily sedated with roofies, which were often slipped into their drinks by their attackers. The drug has no taste or odour, so the victims do not realize what is happening. About 10 minutes after ingesting the drug, victims may feel dizzy and disoriented, simultaneously too hot and too cold, and nauseated. They may experience difficulty speaking and moving and then pass out. Individuals will have no memories of what happened while under the influence of the drug. Another popular date rape drug, used in similar fashion, is gamma-hydroxybutyric acid (GHB). GHB works by mimicking the natural inhibitory brain neurotransmitter gamma-aminobutyric acid (GABA). It

is also known as *liquid ecstasy*. These drugs are also used simply for their depressant and hallucinogenic effects.

Mechanism of Action and Drug Effects

Benzodiazepines and barbiturates work by increasing the action of GABA. GABA is an amino acid in the brain that inhibits nerve transmission in the CNS. The alteration of GABA in the CNS results in relief of anxiety, sedation, and muscle relaxation. The effects of depressants are primarily limited to the CNS. They can also cause amnesia and unconsciousness. They have moderate effects outside the CNS, causing slight blood pressure decreases.

The active ingredients of the marihuana plant are cannabinoids, the most active of which is Δ -9-trans-tetrahydrocannabinol (THC). THC exerts its effects on the body by chemically binding to and stimulating two cannabinoid receptors in the CNS (CB1 and CB2). Smoking the drug leads to acute sensorial changes that start within 3 minutes, peak in 20 to 30 minutes, and last for 2 to 3 hours. Effects last longer when the drug is taken via the oral route. Specific effects include mild euphoria, memory lapses, dry mouth, enhanced appetite, motor awkwardness, and distorted sense of time and space. THC also stimulates sympathetic receptors and inhibits parasympathetic receptors in heart tissue, which leads to tachycardia. Other effects include hallucinations, anxiety, paranoia, and unsteady gait.

Indications

There are many therapeutic uses of depressants. Benzodiazepines are used primarily to relieve anxiety, induce sleep, sedate, and prevent seizures. Barbiturates are used as sedatives and anticonvulsants and to induce anaesthesia. Medical uses for marihuana include treatment of persistent pain, reduction of nausea and vomiting associated with cancer treatment, and appetite stimulation in those with wasting syndromes, such as in patients with cancer or AIDS. In Canada, under Marihuana for Medical Purposes Regulations, authorized individuals have access to dried marihuana for medical use and, as of 2015, edible products as well as other derivatives. For example, patients approved for medical marihuana are now able to brew marihuana leaves in tea or bake cannabis into brownies or cookies for consumption.

Contraindications

Contraindications to the therapeutic use of depressant medications include known drug allergy, dyspnea or airway obstruction, angle-closure glaucoma, and porphyria (a metabolic disorder).

Adverse Effects

The most common undesirable effect of benzodiazepines and barbiturates is an overexpression of their therapeutic effects. The CNS is the primary area of the body adversely affected by these drugs. Drowsiness, sedation, loss of coordination, dizziness, blurred vision, headaches, and paradoxical reactions (insomnia, increased excitability, hallucinations) are the primary CNS adverse effects. Occasional GI effects include nausea, vomiting, constipation, dry mouth, and abdominal cramping. Other possible adverse effects are pruritus and skin rash.

Marihuana use is associated with specific problems in adolescents. Several essential neurodevelopmental phases occur during adolescence before the brain matures. Initially, the brain

BOX 18.5 Signs, Symptoms, and Treatment of Depressant Withdrawal

Peak Period

2–4 days for short-acting drugs
4–7 days for long-acting drugs

Duration

4–7 days for short-acting drugs
7–12 days for long-acting drugs

Signs

Increased psychomotor activity; agitation; muscular weakness; hyperthermia; diaphoresis; delirium; convulsions; elevated blood pressure, pulse rate, and temperature; tremors of eyelids, tongue, and hands

Symptoms

Anxiety; depression; euphoria; incoherent thoughts; hostility; grandiosity; disorientation; tactile, auditory and visual hallucinations; suicidal thoughts

Treatment of Benzodiazepine Withdrawal

A 7- to 10-day taper (10- to 14-day taper with long-acting benzodiazepines). Treat with diazepam (Valium®) 10 to 20 mg orally qid on day 1, and then taper until the dosage is 5 to 10 mg orally on the last day. Avoid giving the drug as needed (prn). Usually, diazepam is started in hospital but the weaning period may take months depending on the a) duration of chronic use and 2) dose of chronic use.

Treatment of Barbiturate Withdrawal

A 7- to 10-day taper or 10- to 14-day taper. Calculate barbiturate equivalence, and give 50% of the original dosage (if actual dosage is known before detoxification); taper. Avoid giving the drug prn. Note: This treatment can take weeks or months. Abruptly stopping a barbiturate can result in severe seizures.

prunes inefficient neurons and insulating axons, which ensures optimal functioning; however, these changes also make the brain susceptible to the effects of marihuana use. The area of the brain where the majority of fine-tuning takes place is the frontal lobe, where executive functions develop (e.g., decision making, judgement, planning, and problem solving). This underdeveloped area is most susceptible to the effects of marihuana. Consequently, long-term use of marihuana during adolescence can lead to issues with cognitive and psychomotor functioning, dependence, and mental health disorders such as schizophrenia, mood and anxiety disorders, eating disorders, and childhood behavioural disorders (e.g., attention deficit hyperactivity disorder; Centre for Addiction and Mental Health, 2014; Government of Canada, 2018b). Marihuana use is also associated with chronic respiratory symptoms (similar to those of tobacco misuse). A chronic, depressive “amotivational” syndrome has also been observed, especially among younger users. This is a complex issue and other recent studies have produced results that contradict the above long-term effects (Bechtold, Simpson, White, et al., 2015).

Toxicity and Management of Overdose

Box 18.5 lists the signs and symptoms of withdrawal from depressants and also indicates the peak periods when these symptoms are most likely to occur and their duration. Fatal poisoning is unusual with benzodiazepines when they are taken alone. When they are ingested with alcohol or barbiturates,

however, the combination can be lethal. Death is typically due to respiratory arrest. Abrupt withdrawal of benzodiazepines when they have been taken for prolonged periods has resulted in autonomic withdrawal symptoms, seizures, delirium, rebound anxiety, myoclonus (involuntary muscle contractions), myalgia, and sleep disturbances.

Flumazenil is a benzodiazepine reversal drug. It antagonizes the action of benzodiazepines on the CNS by directly competing for binding at the benzodiazepine receptors in the CNS, thereby reversing sedation. The dosage regimen to be followed for the reversal of procedural sedation or general anaesthesia induced by a benzodiazepine and the management of suspected benzodiazepine overdoses are summarized in Chapter 13 (Table 13.3).

Barbiturates and benzodiazepines are commonly implicated in suicides, especially in combination with alcohol. Depressants are not regularly prescribed over a long period. Relatively safe hypnotic drugs such as the benzodiazepines are preferred whenever possible, especially in patients who are emotionally unstable. Combinations of sedative-hypnotic compounds or hypnotics in combination with alcohol need to be avoided. Long-term use of hypnotic drugs leads to reduced control of insomnia, decreased rapid eye movement sleep, dependence, and drug withdrawal symptoms. Effects of marihuana use are usually self-limiting and resolve within a few hours.

ALCOHOL

Alcohol has been used since the beginning of human civilization. Individuals of Arab descent introduced the technique of distillation to Europe in the Middle Ages. Alcohol has been called the “elixir of life” and has been promoted as a remedy for practically all diseases, which led to the term *whisky*, which is Gaelic for “water of life.” Over time, it has been determined that the therapeutic value of ethanol is extremely limited, and long-term ingestion of excessive amounts is a major social and medical problem.

Mechanism of Action and Drug Effects

Alcohol, which is more accurately known as *ethanol* and abbreviated as ETOH, is a CNS depressant. It results in CNS depression by dissolving in lipid membranes in the CNS. The latest hypothesis is that ethanol causes a local disordering in the lipid matrix of the brain. This action has been termed *membrane fluidization*. Some also believe that ethanol may augment GABA-mediated synaptic inhibition and fluxes of chloride. As GABA is an inhibitory neurotransmitter in the brain, its enhancement causes CNS depression. The CNS is continuously depressed in the presence of ethanol. Effects of ethanol on circulation are relatively minor. In moderate doses, ethanol causes vasodilation, especially of the cutaneous vessels but also gastric vessels, and it produces warm, flushed skin, creating a feeling of warmth. Increased sweating may also occur. Heat is therefore lost more rapidly, and internal body temperature consequently falls. Although the short-term ingestion of ethanol, even in intoxicating doses, produces little lasting change in liver function, long-term ingestion is one of the primary causes of liver failure. Ethanol exerts a diuretic effect by inhibiting antidiuretic

hormone secretion, resulting in a decrease in renal tubular reabsorption of water.

Indications

Few legitimate uses of ethanol and alcoholic beverages exist. Ethanol is an excellent solvent for many drugs and is commonly employed as a vehicle for medicinal mixtures. When applied topically to the skin, ethanol acts as a coolant. Ethanol may also be used in liniments (oily medications used on the skin). Applied topically, ethanol is a popular skin disinfectant. More commonly, however, the type of alcohol used on the skin is isopropyl alcohol, which is similar in structure to ethanol but is more toxic and not drinkable.

Systemic uses of ethanol are primarily limited to the treatment of methyl alcohol and ethylene glycol intoxication (e.g., from drinking automotive antifreeze solution).

Adverse Effects

Long-term excessive ingestion of ethanol is associated with serious neurological and mental health disorders. These neurological disorders can result in seizures. Nutritional and vitamin deficiencies, especially of the B vitamins, can occur and can lead to **Wernicke's encephalopathy**, **Korsakoff's psychosis**, polyneuritis, and nicotinic acid deficiency encephalopathy.

Moderate amounts of ethanol may stimulate or depress respirations. Large amounts produce dangerous or lethal depression of respiration. Although circulatory effects of ethanol are relatively minor, acute severe alcoholic intoxication may cause cardiovascular depression. Long-term excessive use of ethanol has irreversible effects on the heart, such as cardiomyopathy.

When consumed on a regular basis in large quantities, ethanol produces a constellation of dose-related negative effects, such as alcoholic hepatitis or liver cirrhosis. Teratogenic effects are caused by the direct inhibitory action of ethanol on embryonic cellular proliferation early in gestation. This alcohol exposure can cause a wide spectrum of cognitive, behavioural, functional, and neurological deficits. *Fetal alcohol spectrum disorder* (FASD) is the nondiagnostic umbrella term for the wide range of effects of exposure to alcohol in utero. A diagnosis of FASD is complex and requires a comprehensive, multidisciplinary assessment. Fetal alcohol syndrome is the most severe form, characterized by craniofacial abnormalities, CNS dysfunction, and both prenatal and postnatal growth restriction in the infant. The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-5)* includes proposed criteria for neurodevelopmental disorder associated with prenatal alcohol exposure (ND-PAE). Pregnant women need to be educated about the effects of consuming alcohol during pregnancy, and appropriate treatment and counselling need to be arranged for pregnant women addicted to alcohol or any other drug of misuse.

Interactions

Alcohol can intensify the sedative effects of any medications that work in the CNS (e.g., sedative-hypnotics, benzodiazepines, antidepressants, antipsychotics, opioids). It can interact with the antibiotic metronidazole, causing a disulfiram reaction.

(See below for details.) Alcohol can also cause severe hepatotoxicity when taken with acetaminophen. Acute ingestion of alcohol can increase the bioavailability of the anticoagulant warfarin sodium, which increases the chances of bleeding. Chronic ingestion can cause warfarin sodium to be less effective, leading to increased risks of clots.

Toxicity and Management of Overdose

Box 18.6 lists the common signs and symptoms of ethanol withdrawal. Withdrawal can begin 6 to 12 hours after the last drink. Signs and symptoms may vary depending on the individual's usage pattern, the preferred type of ethanol, and the presence of concurrent disorders. Symptoms usually peak at 2 to 3 days, although they can last up to 7 days. A subacute withdrawal syndrome may last for weeks, characterized by insomnia, irritability, and craving. Older adults tend to have more severe withdrawal. Treatment of ethanol toxicity is supportive and strives to stabilize the patient and maintain the airway. Ethanol withdrawal can be life threatening. Alcohol withdrawal protocols involving symptom-triggered administration

BOX 18.6 Signs, Symptoms, and Treatment of Ethanol Withdrawal

Mild Withdrawal

Signs and Symptoms

Systolic blood pressure higher than 150 mm Hg, diastolic blood pressure higher than 90 mm Hg, pulse rate greater than 110 beats per min, temperature above 37.7°C, tremors, insomnia, agitation

Moderate Withdrawal

Signs and Symptoms

Systolic blood pressure 150 to 200 mm Hg, diastolic blood pressure 90 to 140 mm Hg, pulse 110 to 140 beats per min, temperature 37.7 to 38.3°C, tremors, insomnia, agitation

Severe Withdrawal (Delirium Tremens)

Signs and Symptoms

Systolic blood pressure higher than 200 mm Hg, diastolic blood pressure higher than 140 mm Hg, pulse rate higher than 140 beats per min, temperature above 38.3°C, tremors, insomnia, agitation

Treatment

Treatments include counselling and education, inpatient detoxification programs, and the 12-step program (Alcoholics Anonymous). Benzodiazepines are the drug treatment of choice for ethanol withdrawal. The dosages are variable and differ from institution to institution. Lower dosages are used for mild symptoms, and higher dosages are needed for severe withdrawal. The oral route is preferred; however, it is often necessary to use the intravenous route for patients experiencing severe withdrawal, who often require monitoring in a Critical Care Unit for cardiac and respiratory function, fluid and nutrition replacement, vital signs, and mental status. Restraints are indicated for a patient who is confused or agitated to protect the patient from self and to protect others (delirium tremens can be a terrifying and life-threatening state). Thiamine administration, multivitamins, hydration, and magnesium replacement may be indicated, depending on the severity of the withdrawal state.

American Psychiatric Association. (2013). *Diagnostic and statistical manual of mental disorders*, 5th ed). Arlington, VA: American Psychiatric Association.

of benzodiazepines have been established to reduce the duration of treatment and the cumulative benzodiazepine dose. The Clinical Institute Withdrawal Assessment for Alcohol, Revised (CIWA-Ar) is a validated assessment tool to guide benzodiazepine dosing in alcohol withdrawal. It is used extensively as part of symptom-triggered dosing regimens for benzodiazepines. This type of regimen promotes real-time coordination of the benzodiazepine dose to the severity of symptoms.

One pharmacological option for the treatment of alcoholism is disulfiram. (Disulfiram [Antabuse®] is no longer manufactured by a pharmaceutical company in Canada; it is available only from pharmacies that compound it.) Disulfiram works by altering the metabolism of alcohol. It is not a cure for alcoholism but helps patients who have a sincere desire to stop drinking. The rationale for its use is that patients know that if they are to avoid acetaldehyde syndrome (refer to Table 18.2), they cannot drink for at least 3 or 4 days after taking disulfiram. The adverse effects are uncomfortable and potentially dangerous for someone with any other major illnesses. For this reason, disulfiram is usually reserved as the treatment of last resort for patients who misuse alcohol, for whom other treatment options (e.g., Alcoholics Anonymous, psychotherapy) have failed but who still hope to avoid continued alcohol misuse. When ethanol is ingested by an individual previously treated with disulfiram, the blood acetaldehyde concentration rises 5 to 10 times higher than that in an untreated individual. Within 5 to 10 minutes of alcohol ingestion, the individual’s face feels hot, and soon afterward it is flushed and scarlet. After this, throbbing in the head and neck, nausea, copious vomiting, diaphoresis, dyspnea, hyperventilation, vertigo, blurred vision, and confusion occur. As little as 7 mL of alcohol will cause mild symptoms in a sensitive person. The effects last from 30 minutes to several hours. Once the symptoms wear off, the patient is exhausted and may sleep for several hours. Most of the signs and symptoms observed after the ingestion of disulfiram plus alcohol are attributable to the resulting increase in the concentration of acetaldehyde in the body. Acetaldehyde is a product of alcohol metabolism that is more toxic than alcohol itself. There have been a few published reports of localized disulfiram–alcohol skin reactions when alcohol preparations—even beer-containing shampoo—were placed on the skin. The usual dosage of disulfiram is 250 mg per day, or 125 mg per day in patients who experience adverse effects such as sedation, sexual dysfunction, and elevated liver enzyme levels.

TABLE 18.2 Disulfiram Adverse Effects: Acetaldehyde Syndrome	
Body System Affected	Signs and Symptoms
Cardiovascular	Vasodilation over the entire body, hypotension, orthostatic syncope, chest pain
Central nervous	Intense throbbing of the head and neck, leading to a pulsating headache, sweating, marked uneasiness, weakness, vertigo, blurred vision, confusion
Gastrointestinal	Nausea, copious vomiting, thirst
Respiratory	Difficulty breathing

A less noxious drug therapy option is the use of naltrexone (refer to the section on opioids earlier in the chapter). The newest drug treatment indicated for alcoholism is acamprosate calcium. It is used to prevent relapse in patients who are abstinent when starting the drug and who have additional psychosocial support. Its mechanism of action is not completely understood, but it may modulate glutamate and GABA receptors in the brain. Acamprosate calcium appears to restore the balance between these neurotransmitters, which are altered as a result of long-term alcohol intake. The usual dosage is two 333-mg tablets taken three times daily for 1 year. Diazepam is used for the treatment of seizures, the most common complication of alcohol withdrawal, and delirium tremens. Delirium tremens usually begins 5 to 7 days after the last drink and can last for several days. It is the most severe form of ethanol withdrawal and is characterized by disorientation, visual hallucinations, paranoid delusions, and sympathetic overdrive (fever, sweating, tachycardia, vomiting), which can progress to dysrhythmias and cardiovascular collapse.

NICOTINE

Nicotine was first isolated from the leaves of tobacco in 1828. The medical significance of nicotine stems from its toxicity, presence in tobacco, and propensity for eliciting dependence in its users. The long-term effects of nicotine and the untoward effects of the long-term use of tobacco are considerable. Although many people smoke because they believe cigarettes calm their nerves, smoking releases epinephrine, a hormone that creates physiological stress rather than relaxation in the smoker. The apparent calming effects may be a result of the increased deep breathing associated with smoking. The use of tobacco is addictive. Most users develop tolerance for nicotine and need greater amounts to produce the desired effect. Tobacco smokers become physically and psychologically dependent and will suffer withdrawal symptoms. Smoking is particularly dangerous in adolescents because their bodies are still developing and changing. The chemicals, including 200 known poisons, present in cigarette smoke can adversely affect adolescents’ maturation. One third of young people who are “just experimenting” end up becoming addicted by the time they are 20 years of age.

Mechanism of Action and Drug Effects

Nicotine works by directly stimulating the autonomic ganglia of the nicotinic receptors (see Chapter 21). Its site of action is the ganglion rather than the preganglionic or postganglionic nerve fibre. The organs throughout the body that are innervated by nerves stimulated by nicotine contain nicotinic receptors. These receptors are so named because they were originally tested with nicotine to measure their responses. Nicotine can have multiple unpredictable and dramatic effects on the body because nicotinic receptors are found in several systems, including the adrenal glands, skeletal muscles, and the CNS.

The major action of nicotine is transient stimulation, followed by more persistent depression of all autonomic ganglia. Small doses of nicotine stimulate the ganglion cells directly and facilitate the transmission of impulses. When larger doses of the

drug are applied, the initial stimulation is followed quickly by a blockade of transmission.

Nicotine markedly stimulates the CNS, including respiratory stimulation. This stimulation of the CNS is followed by depression. Nicotine can have dramatic effects on the cardiovascular system as well, resulting in increases in heart rate and blood pressure. The GI system is generally stimulated by nicotine, which produces increased tone and activity in the bowel. This often leads to nausea and vomiting and occasionally to diarrhea.

Indications

The nicotine found in nature (i.e., tobacco plants) has no therapeutic uses. It is medically significant because of its addictive and toxic properties. Once nicotine is formulated into products to reduce cravings and promote smoking cessation, then it can be considered a therapeutic drug. It is available as treatment to stop smoking as chewing gum, lozenges, inhaler, transdermal patches, and oral spray.

Adverse Effects

Nicotine primarily affects the CNS. Large doses can produce tremors and even convulsions. Respiratory stimulation also commonly occurs. The initial stimulation of the CNS induced by nicotine is quickly followed by depression. Death can even result from respiratory failure, which is thought to occur due to both central paralysis and peripheral blockade of respiratory muscles.

The cardiovascular effects of nicotine are increased heart rate and blood pressure. The effects of nicotine on the GI system are largely due to parasympathetic stimulation, which results in increased tone and motor activity of the bowel. Nicotine induces vomiting by both central and peripheral actions. Centrally, nicotine's emetic effects result from stimulation of the chemoreceptor trigger zone in the brain.

Management of Withdrawal, Toxicity, and Overdose

Acute nicotine toxicity generally occurs in children who accidentally ingest cigarettes. Treatment is supportive and may include activated charcoal. Smoking cessation is the primary cause for nicotine withdrawal, although discontinuation of any tobacco product can lead to this syndrome. An important and often overlooked problem in hospitalized patients is nicotine withdrawal, which manifests largely as cigarette craving. Irritability, restlessness, and a decrease in heart rate and blood pressure occur. Cardiac symptoms resolve over 3 to 4 weeks, but cigarette craving may persist for months or even years.

The nicotine transdermal system (patch), nicotine polacrilex (gum), and inhalers can be used to provide nicotine without the carcinogens found in tobacco and are now available over the counter. The patch uses a stepwise reduction in subcutaneous delivery to gradually decrease the nicotine dose, and patient treatment adherence seems to be higher than with the gum. Acute relief from withdrawal symptoms is most easily achieved with the use of the gum because rapid chewing releases an immediate dose of nicotine. The dose is approximately one half of the dose the average smoker receives in one cigarette, however, and the onset of action is 30 minutes, versus 10 minutes or less from smoking.

TABLE 18.3 Nicotine Cessation Therapies

Drug	Dosage	Recommended Duration of Use
Transdermal Nicotine Systems		
Habitrol®, Nicoderm®	7 mg/24 hr	2–4 wk
	14 mg/24 hr	2–4 wk
	21 mg/24 hr	4–8 wk
Nicorette® inhaler	10 mg/inhalation	6–12 wk
Lozenges: (Nicorette, Thrive) Oral spray: Nicorette Quick Mist Spray, Nic-Hit Spray Nicotine gum (Nic-Hit, Nicorette, Thrive®)	When the patient has a strong urge to smoke, a stick of gum is chewed; use gradually reduced over a 2–3 mo period	
Antidepressant		
bupropion hydrochloride (Zyban®)	15-mg sustained-release tabs	15 mg on days 1–3; then 150 mg bid for 7–12 wk
Partial Nicotine Agonist		
Varenicline tartrate (Champix)	0.5- or 1-mg tabs	12-wk regimen, beginning with 0.5 mg orally bid, titrated to 1 mg daily by day 8

These pharmacological changes in delivery minimize the immediate reinforcement and self-reward effects that are prominent with the rapid nicotine delivery of cigarette smoking.

A sustained-release form of the antidepressant bupropion hydrochloride (Zyban®; see Chapter 17) is approved as first-line therapy to aid in smoking cessation treatment. Extended-release bupropion hydrochloride is an innovative treatment because it is the first nicotine-free prescription medicine to treat nicotine dependence. Table 18.3 lists the currently available drugs for nicotine withdrawal therapy.

Varenicline tartrate (Champix®) both activates and antagonizes the alpha-4-beta-2 nicotinic receptors in the brain. This effect provides some stimulation to nicotine receptors while also reducing the pleasurable effects of nicotine from smoking. This drug has demonstrated greater efficacy than bupropion. The recommended 12-week treatment regimen begins with 0.5 mg orally twice daily, titrating up to 1 mg twice daily by day 8. An optional second 12-week regimen may be prescribed to help the patient maintain tobacco abstinence. The most common adverse effects are nausea, vomiting, headache, flatulence, insomnia, and taste disturbances. Drowsiness has also been reported, so it is important to advise patients about driving and engaging in other potentially hazardous activities until patients can determine how the drug may affect them. Although many highly addicted smokers are reporting significant success with varenicline tartrate, there are other warnings regarding its use. Specifically, case reports of psychiatric symptoms while using the drug have emerged, including agitation, depression, and suicidality, as well as worsening of pre-existing psychiatric illness. Appropriate patient education and follow-up regarding these adverse effects should be undertaken. Varenicline tartrate should not be used during pregnancy.

One of the newer trends to stop smoking is vaping, using vaping products, including electronic cigarettes (vapour- and/or e-cigarettes). Typically, an e-cigarette consists of a cartridge that contains nicotine, water, and a flavouring in a base of propylene glycol and glycerine; an atomizer with a heating element that turns the liquid into a vapour; and a battery for a light that glows similarly to a lit cigarette. Not all vaping products contain nicotine. Vaping products are available to individuals 18 years and over, but vaping has yet to be approved by Health Canada as a safe health practice.

❖ NURSING PROCESS

◆ ASSESSMENT

The purpose of a substance misuse assessment is to determine whether substance misuse exists, to evaluate the relationship between the misuse and other health concerns, and to begin the implementation of an effective health promotion and health restoration plan. Because of the prevalence of substance misuse and the role played by the professional nurse in a variety of settings, the nurse may be the first person to identify risky behaviour in a patient. Indications of misuse problems in patients may also become evident during hospitalization for an injury, illness, or surgery. However, even when substance misuse is not suspected, include questions about the use of alcohol, nicotine, opioids, and so on in the general nursing assessment and medication history (see Pharmacology section). Question all patients about the use and misuse of substances because addiction is found across the lifespan, in all cultures and in all types of individuals and may therefore be encountered in all clinical specialties. It is important to recognize that patients may underestimate or deny the use of and amount of substances taken. As well, misuse of substances including prescription medications may need to be assessed in family members because adolescents and other individuals in the home may be diverting parents' or other adults' prescription drugs.

The nurse's responsibilities relative to drug misuse and the nursing process must begin with the cultivation of excellent interpersonal communication skills and a nonjudgemental attitude. It is important to acknowledge and address your own individual beliefs about drug and alcohol use as well as any personal history of coping with addiction or dealing with addicted family members. This process will allow you to anticipate potential responses and behaviours toward this patient population and seek out resolution about these feelings. Acknowledging feelings and beliefs about this group of patients within a balanced perspective and ethical framework will allow you to resolve any personal animosity, judgemental attitudes, rejection, or enabling behaviours. Once you have dealt with detrimental behaviours and possible barriers to responsible and nonjudgemental care, focus on the patient and avoid being drawn into a misuser's manipulative behaviours and other negative conduct.

A thorough patient assessment and history must include specific questions about the substance(s) being used, the duration of misuse, related physical and mental health concerns, and withdrawal potential. In patients with suspected or confirmed substance misuse, honesty—on the part of the patient as well

as the family or significant other—may be problematic when answering questions about drug use. Therefore, establishing an environment conducive to communication is necessary and may be possible through use of open-ended questions during assessment. Additionally, be sure to maintain a nonjudgemental approach during the assessment as well as other phases of the nursing process. A medication history needs to include information about all drugs being used, including prescription drugs, OTC drugs, natural health products, and illicit or street drugs. Include the names of the drugs, doses, frequency, and duration of use. Be attentive to any clues a patient, family, or significant other may reveal, including behavioural and mood changes. A patient's reported use of multiple prescribed drugs as well as contact with multiple prescribers raises concern as a possible sign of drug misuse. In addition, laboratory findings are important to assess, including results of kidney and liver function studies and any drug screening studies. Assess and monitor results of HIV and hepatitis laboratory tests, if ordered. Monitor and document baseline vital signs.

Several assessment tools with established validity and reliability are available to nurses and health care providers for use with patients suspected of drug or substance misuse. The goal of adequate screening for alcohol and other drug misuse or addiction is to identify patients who have or are at potential for developing alcohol- or drug-related problems and to further engage these patients in discussion. This may help in further diagnosing and more accurately treating their misuse problem. Laboratory tests are available to detect alcohol and other drugs in the blood or urine. These are used to identify recent drug misuse rather than long-term use or dependence. However, there are other tests that are best used when assessing someone for confirmation of a diagnosis (Box 18.7).

The CAGE Questionnaire is available as a screening tool for alcohol use in adults and is used by many health care providers in the field of alcohol addiction. Even though it is simple and brief (consisting of only four questions), it has a noted accuracy rate of 93%. The CAGE Questionnaire has also been adapted to include drug use in adults (CAGE-AID). The CAGE or CAGE-AID should be preceded by the following two questions: (1) Do you drink alcohol? and (2) Have you ever experimented with drugs? If the patient has experimented with drugs, ask the CAGE-AID questions (modified by the italicized text). If the patient only drinks alcohol, ask the CAGE questions. See Box 18.8 for the CAGE and CAGE-AID questions. Each affirmative response earns one point. One point indicates a possible problem, while two points indicate a probable problem.

Other available screening tools include the Substance Abuse Subtle Screening Inventory (SASSI), the Michigan Alcoholism Screening Test—Geriatric Version (MAST-G) for use with older adult patients, and the Problem Oriented Screening Instrument for Teenagers (POSIT). If the findings of an assessment questionnaire are positive, the next step is to explore the history of the patient's alcohol or drug use (or both) and problems. Further observation is needed to identify any physical, psychological, and social signs of dependence and dysfunction. Maintaining communication with family members may also provide useful information. If misuse is identified by a history-taking process,

BOX 18.7 Diagnosis of Substance Use Disorder

The *Diagnostic and Statistical Manual of Mental Disorders (DSM-5)* (American Psychiatric Association, 2013) combines the *DSM-IV* categories of substance abuse and substance dependence into a single disorder measured on a continuum from mild to severe. Each specific substance is identified as a separate use disorder; however, the criteria for diagnosis remain the same for each substance. The occurrence of two or three of the symptoms listed below indicates a mild substance use disorder, four or five symptoms indicate a moderate substance use disorder, and six or more symptoms indicate a severe substance use disorder:

1. Taking the substance in larger amounts or for longer than you meant to
2. Wanting to cut down or stop using the substance but not managing to
3. Spending a lot of time getting, using, or recovering from use of the substance
4. Cravings and urges to use the substance
5. Not managing to do what you should at work, home, or school because of substance use
6. Continuing to use, even when it causes problems in relationships
7. Giving up important social, vocational, or recreational activities because of substance use
8. Using substances again and again, even when it puts you in danger
9. Continuing to use, even when you know you have a physical or psychological problem that could have been caused or made worse by the substance
10. Needing more of the substance to get the effect you want (tolerance)
11. Development of withdrawal symptoms that can be relieved by taking more of the substance

physical assessment, drug history profile, screening tests, or patient's confession, then confidentiality, privacy, and nonjudgemental behaviour are keys to ethical nursing practice. Refer to local laws for the reporting of the substance(s) and adhere to the Canadian Nurses Association *Code of Ethics for Registered Nurses* or other applicable nursing code of ethics in making a report (see Chapter 3).

Assessment of opioid misuse includes, in addition to the assessment data mentioned earlier, determination of the route being used for drug delivery (e.g., oral versus intravenous use). The use of intravenous drugs may give rise to other concerns such as HIV and AIDS or hepatitis. Respiratory assessment with attention to rate and rhythm are important because of the potential for respiratory depression with opioid overdose. Other, more specific signs and symptoms were described earlier in the chapter.

Assessment of CNS stimulant misuse requires careful questioning about and observation for adverse effects, toxicity, and withdrawal signs and symptoms. Some of the more commonly misused CNS stimulants are dextroamphetamine, methamphetamine (crystallized and powdered forms), and cocaine (see Table 18.1). Signs and symptoms of CNS stimulant misuse were previously discussed, such as changes in blood pressure and increased heart rate. However, the following information needs to be assessed and documented: (1) frequent vital signs; (2) thorough head-to-toe physical examination; (3) assessment of neurological functioning with attention to mydriasis (pupil dilation), hyperactive reflexes, headache, increased motor or speech activity, agitation, syncope, tremors, altered level of

BOX 18.8 CAGE and CAGE-AID Questions

In the past, have you ever:

1. Felt that you wanted or needed to cut down on your drinking or drug use?
2. Been annoyed or angered by others complaining about your drinking or drug use?
3. Felt guilty about the consequences of your drinking or drug use?
4. Had a drink or taken a drug in the morning (eye-opener) to decrease hang-over or withdrawal symptoms?

consciousness, and seizure activity; and (4) cardiac assessment with attention to increased heart rate (tachycardia), irregular heart rhythm (dysrhythmia), and hypertension or hypotension. Document and immediately report any abnormal assessment findings or the presence of an elevated temperature (hyperthermia, which may be fatal), reports of vomiting or headache, or flushing of the face.

The most dangerous substances in terms of withdrawal are CNS depressants such as alcohol, barbiturates, benzodiazepines, and synthetic cannabinoids (*K2*, *zinger*, or *spice* is a mixture of herbs, spices or shredded plant material that is typically sprayed with a synthetic compound chemically similar to THC, the psychoactive ingredient in marijuana). Misuse of CNS depressants is manifested by a decrease in vital signs and mental functioning (see previous discussion); therefore, frequent monitoring of vital signs and neurological status is needed for safe and prudent care. As with any drug, obtain a comprehensive, thorough nursing history and medication profile. Additional signs and symptoms of misuse are tremors and agitation, with possible progression to hallucinations and sometimes death with continued misuse. Because of the risk of respiratory and circulatory depression, always perform an assessment of the patient's ABCs (airway, breathing, and circulation). Early withdrawal (see Box 18.5) may be manifested by increased blood pressure and pulse rate and altered mental status. (See Pharmacology section for more specific information.) Marijuana, as a depressant, may cause dizziness, disorientation, euphoria, and difficulty with speech and motor activities. Long-term use of marijuana may lead to chronic, depressive, amotivational behaviour. Be sure you always assess for any different or unusual behaviours. Assessment of marijuana use includes appraisal of cognitive and motor function and assessment for the ability to carry out minor tasks.

The signs and symptoms of ethanol (alcohol) withdrawal and toxicity are presented in Box 18.6. As part of the assessment, include gathering data about possible drug interactions, especially the use of other CNS depressants such as opioids, sedatives, and hypnotics. It is important to monitor blood alcohol levels because they are directly a result of the health issues and signs and symptoms that appear.

Misuse of nicotine (a CNS stimulant) is associated with adverse effects such as increase in heart rate and blood pressure. It can also result in vomiting and increased bowel tone and motor activity. If the patient has a history of malnutrition, chronic lung disease, stroke, cancer, cardiac disease, or kidney or liver dysfunction, relevant laboratory tests are generally ordered, and their results need to be examined by the

nurse and all those involved in the patient's care. Assessment needs to include vital signs, breath sounds, oxygen saturation levels, and monitoring for changes in neurological functioning (e.g., level of consciousness, sensory and motor problems). Remember that smoking cessation and signs and symptoms of nicotine withdrawal may happen abruptly in

hospitalized patients. Signs and symptoms of a craving for nicotine include irritability, restlessness, and decrease in pulse rate and blood pressure, the observation of which will help in early identification of serious problems (see Special Populations: Older Adults and Special Populations: Adolescents boxes).

SPECIAL POPULATIONS: OLDER ADULTS

Alcohol and Substance Misuse

Alcohol and substance misuse among older adults is a hidden national epidemic. A substantial number of older adults are drinking at higher-than-recommended levels; thus, alcohol misuse is becoming a growing problem in this population and one that is often ignored or missed by many health care providers.

Alcohol misuse and alcoholism cut across gender, race, and nationality. In people 15 years of age or older, 75% of individuals identified as current drinkers. Alcohol remains the main substance of misuse among older adults. Approximately 58% of women and 75% of men over 65 years of age use alcohol. Problematic alcohol use occurs in approximately 6 to 10% of people over 65 years of age. Obviously, alcohol misuse is of major concern for the older adult population and necessitates thorough assessment for drug and chemical misuse in this group.

Misuse of other substances by older adults is also an overlooked and often ignored problem. Older adults who misuse drugs are often poor, frail, and hidden from health care and service providers. The stigma associated with these problems keeps them, as well as family members, from coming forward to report

problems. Although the overall rate of substance misuse is lower in older adults than in younger people, substance misuse in older adults is a significant and growing problem. It is complicated by the fact that many in this age group also use prescription and OTC medications. OTC drugs may cause adverse effects even when taken alone, and serious consequences may result when they are taken with alcohol. Significant problems are seen when the combination of alcohol with a drug results in intensification of the drug's action (e.g., heightened hypotensive effects when an antihypertensive drug is taken with alcohol); this can lead to increased adverse effects with significant negative consequences (such as dizziness and possible syncope due to a greater-than-intended drop in blood pressure, which can result in falls and injury). Some of the signals indicating an alcohol- or alcohol and medication-related problem in an older adult include trouble with memory after having a drink or taking a medication; loss of coordination, unsteadiness in walking or frequent falls; changes in sleeping habits; unexplained bruises; and irritability, sadness, depression, and being unsure of oneself.

OTC, Over-the-counter.

SPECIAL POPULATIONS: ADOLESCENTS

Misuse of Alcohol, Misuse of Over-the-Counter and Prescription Drugs, and Huffing Practices in Adolescents

Although statistics vary by province and territory, as many as 85% of Canadian adolescents have consumed alcohol, while 50% have consumed illegal drugs (Health Canada, 2013). As many as 25% of youth in Grades 7 to 12 misuse alcohol, opioids (fentanyl), and other high-risk substances (Government of Canada, 2018b). Rates of illicit drug use and risky drinking are higher in youth under the age of 25 than in other age groups. Surveys on student drug use have been conducted intermittently over the years in 9 of Canada's 10 provinces, as well as nationally. These include the British Columbia Adolescent Health Survey; the Alberta Youth Experience Survey; the Manitoba Student Alcohol and Drug Use Survey; the Ontario Student Drug Use and Health Survey; the Québec Health Survey of High School Students; the Student Drug Use Survey in the Atlantic Provinces; the Canadian Student Tobacco, Alcohol and Drugs Survey; and the Health Behaviour of School-Aged Children study. The Ontario Student Drug Use and Health Survey is used as an example in this chapter.

Adolescents are exposed to real drug hazards connected with some everyday products within the home. According to the 2013 Ontario Student Drug Use and Health Survey, a survey of Ontario students in Grades 7 to 12, the use of OTC and prescription drugs is rising, while alcohol consumption and smoking are at an all-time low. One percent of respondents reported inappropriately using stimulant drugs that are normally used to treat attention deficit hyperactivity disorder. This is consistent with the British Columbia 2013 survey. The misuse of OTC cold products, specifically dextromethorphan-containing products, is a significant issue and appears to be on the rise. Dextromethorphan is the most commonly

used and most effective nonprescription cough suppressant and is an ingredient in several OTC products, including Robitussin DM® cough syrup and liquid gel capsules. Some adolescents have discovered that taking dextromethorphan in large amounts leads to a "high" that is accompanied by hallucinations. The hallucinations have been documented to be similar to those associated with the street drug phencyclidine (PCP) and the anaesthetic ketamine (see Chapter 12). In 2013, almost 10% of Ontario students in Grades 7 to 12 reported use of cough or cold medication at least once in the past year to "get high." This statistic reflects an increasing trend from previous surveys. Two percent of students reported use of cough and cold medications six or more times in the past year. Dextromethorphan is available in over 140 preparations of the OTC drugs sold in the Canada, and for teens experimenting with drugs, it is cheap, easily obtained, and legal. Many of these OTC drugs also contain acetaminophen, which creates a potential consequence of acetaminophen toxicity.

Another, potentially new, concoction is called *sizzurp*, made of pop, dissolved Jolly Rancher candy, and prescription cough syrup containing the antihistamine promethazine hydrochloride and the opioid codeine phosphate. While this prescription drug is available only in the United States, it may be substituted by numerous products available in Canada.

One in five students admitted to abusing prescription drugs, and 75% of these admitted to stealing them, often from the home medicine cabinet. One in eight reported using a prescription opioid pain medication recreationally in the last year.

Continued

SPECIAL POPULATIONS: ADOLESCENTS—cont'd

Misuse of Alcohol, Misuse of Over-the-Counter and Prescription Drugs, and Huffing Practices in Adolescents

Additionally, it has been found that adolescents who misuse dextromethorphan and prescription medications may also misuse other drugs. Another problem is that of huffing or the misuse of inhalants, including the following substances: (1) volatile solvents—nail polish and paint thinner, (2) aerosols—deodorants and cooking sprays, (3) gases—butane cigarette lighter fluid and nitrous oxide (laughing gas), and (4) nitrites—cyclohexyl nitrite (found in room deodorizers) and amyl nitrite and butyl nitrite (sold on the street in small, sealed containers). Adolescents may also inhale “computer duster,” pressurized gases (e.g., tetrafluoroethane or difluoroethane) used to clean electronic equipment. When inhaled, all the above chemicals are quickly absorbed into the bloodstream via the lungs and then into organs with a large blood distribution, such as the brain and liver. The solvents lead to effects similar to those of alcohol intoxication. Long-term use can lead to kidney, liver, or brain damage. The hazardous short- or long-term effects that may occur with the additive effects of drugs include nausea, hot flashes, reduced mental status, dizziness, seizures, loss of coordination and balance, brain damage, and death.

The 2013 survey of Ontario students reported that 3.4% had sniffed glue or solvents at least once in the past year, which is a significant decrease from the previous report. The at-risk groups for inhalant misuse are students who have dropped out of school, people who have been physically or sexually abused or neglected, people who have been incarcerated or who are homeless, and members of Indigenous communities. Inhalant use often results in a euphoric feeling, but brain damage and even death can occur with just one huff. There is still a tremendous need for continued prevention and treatment efforts resulting from inhalant use. Education needs to begin early on in elementary school, so that children learn of the dangers of inhalant use and its potential damaging effects on the brain. Education and awareness are important to prevent misuse and abuse behaviours, and a child is never too young to learn about these types of dysfunctional and life-threatening behaviours. Parents, other family members and relatives, and caregivers need to be actively involved in any educational sessions about drugs that are misused and their related signs and symptoms.

CASE STUDY

Substance Misuse and Adolescents

You are a nurse and are having a discussion with a neighbour, Jared, who has a 14-year-old son, Cayden. Jared expresses concern about Cayden and substance misuse problems he has heard about.

1. Jared describes one of Cayden's friends, who was once a bright and motivated student but has become sullen and withdrawn, lacking the motivation he once had. In addition, he has a chronic cough but denies that he smokes cigarettes. This behaviour change may indicate misuse of what substance? Are there any long-term effects?

2. Jared mentions “huffing,” which Cayden told him has happened at several parties this year. Jared says, “Huffing is not harmful, right?” What will you tell him?

A few weeks later, Jared calls you because Cayden is extremely drowsy and unable to speak. Jared notes that his bottle of alprazolam (Xanax®) is almost empty and worries that his son has taken an overdose.

3. What will you do first? What treatment would you expect his son to receive?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

- Chronic low self-esteem resulting from the influence of substance misuse
- Potential for injury and falls resulting from substance misuse or abrupt withdrawal

◆ PLANNING

◆ Goals

- Patient will demonstrate patterns of more effective health maintenance.
- Patient will openly discuss the substance misuse and the benefits of a treatment regimen.
- Patient will gain improved self-esteem during treatment for substance misuse.
- Patient will remain free from injury during treatment for substance misuse and addiction.

◆ Expected Patient Outcomes

- Patient openly discusses perceived barriers to effective health maintenance.
- Patient exhibits healthy participation and cooperation with the therapeutic regimen for substance misuse disorders.
- Patient demonstrates a knowledge base about behaviours regarding substance misuse and addiction through discussion of expectations of recovery, benefits and short- and long-term effects of treatment, as well as signs and symptoms of withdrawal regimen.
- Patient verbalizes feelings of improved self-esteem and discusses healthy adaptation and coping skills in an open and secure treatment environment.

◆ NURSING DIAGNOSES

- Inadequate health management of self, resulting from perceived barriers of care due to substance misuse
- Reduced knowledge resulting from lack of information about addictive behaviours and drugs being misused

- Patient undergoes safe withdrawal from the misused substance with stabilization of the aggravated and dysfunctional physical and emotional state without injury to self or others.

◆ IMPLEMENTATION

The nurse plays a vital role in the care of patients manifesting misuse behaviours, intoxication, and withdrawal. It is also the nurse who, through the nursing process, helps to meet the patient's basic needs after developing a therapeutic relationship and teaches the patient, family, or significant others about addiction and its effect on the entire family. Nursing strategies for meeting actual or potential health problems are implemented for nursing diagnoses generated from assessment data. Nurses working with patients who misuse substances need a sound knowledge base as well as special understanding and empathy. Participation in training, seminars, and education about the process of substance misuse and related lifestyles is encouraged, to assist in understanding patients and developing comprehensive plans of care. Nursing interventions involve maximizing all the therapeutic plans and minimizing those factors that contribute to maladaptive or dysfunctional behaviours. Once therapeutic rapport has been established and a patient–nurse–health care provider contract has been agreed upon, maximizing recovery is the plan. Interventions are based on the patient's specific physical and emotional problems and carried out accordingly and in order of priority of basic needs. For example, if a patient is experiencing hallucinations from either use of a substance or from the withdrawal, the priority will be to manage the ABCs of care (airway, breathing, and circulation) and monitor vital signs and neurological and mental status, while providing a calm, quiet, nonjudgemental, and nonthreatening environment. Seizures may occur, so safety precautions are needed, including the use of protective measures such as padding of side rails and implementation of other seizure precautions (consult facility policies and procedures). For more information, see Special Populations: Older Adults and Special Populations: Adolescents boxes).

Substance withdrawal is treated with a multimodal approach that includes pharmacological and nonpharmacological interventions. Remain nonjudgemental while assisting in a patient's recovery and rehabilitation. Also, remain current in your knowledge about the different substances being misused as well as the various treatment and rehabilitation protocols in use. In all interventions, ensuring patient safety is of utmost importance. The patient's movement through the plan of care for withdrawal, recovery, and rehabilitation must be individualized and take place in a safe, secure, and nonthreatening environment. Patient education remains an essential part of patient care to help the patient, family, and significant others understand the need for long-term lifestyle changes. Whether it is disulfiram treatment for alcohol misuse or bupropion hydrochloride therapy for nicotine withdrawal, patients need careful instructions and information about their treatment regimen. In addition, patients need to be encouraged to be actively engaged in their treatment regimen, including planning, delivery, and ongoing decision making.

BOX 18.9 Organizations and Agencies Concerned With Substance Misuse

Alcoholics Anonymous
 Canadian Assembly of Narcotics Anonymous
 Canadian Centre for Substance Abuse
 Centre for Addiction and Mental Health
 Drug Education and Awareness for Life
 National Kids Help Phone

 Teen Challenge Canada
 TeenNet CyberIsle

Substance misuse has a major impact on family members and significant others. Families will also need treatment and therapeutic support. It is the caring, empathic, supportive, and educative responses by the nurse that will convey acceptance to the patient and family and help in the overall process of recovery and rehabilitation. A nonjudgemental attitude, caring, empathy, and quality care must always be at the centre of patient rights, as should be the Canadian Nurses Association's *Code of Ethics for Registered Nurses* (see Chapter 3), regardless of the admitting diagnosis or the type of substance being misused. Lifelong treatment is often indicated; the need for support during the long-term process of recovery must be emphasized and support recommended from within the family unit and extending outward to the community. (See Box 18.9 for a listing of various organizations and resources.) Methods to encourage recovery and minimize relapse need to be individualized for each patient and draw on all available resources, whether private or public. Communication techniques must be reinforcing and firm, yet sensitive to the patient's values and beliefs. Family members must be an integral part of all treatment and must participate in all educational sessions.

◆ EVALUATION

Patient safety is always of utmost importance during patient care but especially when the patient is experiencing the signs and symptoms of withdrawal. Patients may go from mild withdrawal to severe withdrawal and enter life-threatening situations within a period of a day or two, and therefore complete evaluation of the patient and environment must be ongoing. Evaluation of the recovery and rehabilitation process is important as well, with monitoring of the therapeutic effects of the treatment regimen as well as for any ill effects from the physiological or psychological withdrawal from the substance. Also part of this evaluation process is review of the availability of needed resources during and after hospitalization, including family support. In addition, report any abnormality in vital signs, laboratory test results, mental status, or other parameters, immediately. An ongoing evaluation needs to also examine the availability of emotional, social, cultural, spiritual, and financial support, and the nursing care plan should be revised as needed.

PATIENT TEACHING TIPS

- Ensure that relevant, nondiscriminatory, current, and accurate information—at various reading levels—is available to the patient, family, and significant others in regard to the specific misuse disorder, signs and symptoms, withdrawal, and treatment regimens. Making an informed decision about the treatment plan is best for everyone involved in the process of recovery and rehabilitation.
- Educate the patient, family, and significant others about available support groups and community resources.
- Be sure that the patient always understands the importance of having a current list of all medications readily available,

including treatment regimens for the misuse disorder. Include information about the drug, its action, why it is used and how, adverse effects, cautions, drug–drug and drug–food interactions, contraindications, dosing, and consequences of missed doses.

- Patients must be educated about their rights to ethical and empathic treatment, regardless of the reason for treatment. Two online resources available are: <http://www.ccsa.ca/> and <http://www.camh.ca/>. These sites provide downloadable information, resources, and treatment options for drug and chemical misuse.

KEY POINTS

- Physical dependence is a condition characterized by physiological reliance on a substance, usually indicated by tolerance to the effects of the substance and development of withdrawal symptoms when use of the substance is terminated.
- Psychological dependence is a condition characterized by strong desires to obtain and use a substance.
- *Habituation* refers to situations in which a patient becomes accustomed to a certain drug (develops tolerance) and may have mild psychological dependence on it but does not show compulsive dose escalation, drug-seeking behaviour, or major withdrawal symptoms upon drug discontinuation.
- Acamprosate calcium is used to maintain abstinence from alcohol in patients who are abstinent when starting the drug and who have additional psychosocial support. Its mechanism of action is not completely understood.
- A new medication for smoking cessation is varenicline tartrate, which has shown better efficacy than bupropion hydrochloride.
- Drug withdrawal symptoms vary with the class of drug and may even be the opposite of the drug's action. Signs and

symptoms of opioid withdrawal include mydriasis (pupil dilatation), rhinorrhea, diaphoresis, piloerection (goose bumps), lacrimation, diarrhea, insomnia, and elevated blood pressure and pulse rate. Signs and symptoms of CNS stimulant withdrawal include social isolation or withdrawal, psychomotor retardation, and hypersomnia. Signs and symptoms of CNS depressant withdrawal include increased psychomotor activity; agitation; muscular weakness; hyperthermia; diaphoresis; delirium; convulsions; elevated blood pressure, pulse rate, and temperature; and eyelid tremors. Ethanol withdrawal produces varying degrees of signs and symptoms, depending on the specific blood alcohol level. Delirium tremens is characterized by hypertensive crisis, tachycardia, and hyperthermia; it may be life threatening.

- Evaluation of the recovery and rehabilitation process is important, including monitoring of the therapeutic effects of the treatment regimen and monitoring for any physiological or psychological ill effects from the withdrawal of the misused substance.

EXAMINATION REVIEW QUESTIONS

1. A patient is experiencing withdrawal from opioids. The nurse expects to see which assessment finding most commonly associated with acute opioid withdrawal?
 - a. Elevated blood pressure
 - b. Decreased pulse
 - c. Lethargy
 - d. Constipation
2. During treatment for withdrawal from opioids, the nurse expects which medication to be ordered?
 - a. amphetamine (Dexedrine®)
 - b. clonidine (Catapres)
 - c. diazepam (Valium)
 - d. disulfiram (Antabuse)
3. The nurse is presenting a seminar on substance misuse. Which drug is no longer the most commonly used illicit drug in Canada?
 - a. Crack cocaine
 - b. Heroin

- c. Marihuana
- d. Methamphetamine

4. A patient who is taking disulfiram as part of an alcohol treatment program accidentally takes a dose of cough syrup that contains a small percentage of alcohol. The nurse expects to see which symptom as a result of acetaldehyde syndrome?
 - a. Lethargy
 - b. Copious vomiting
 - c. Hypertension
 - d. No ill effect because of the small amount of alcohol in the cough syrup
5. The nurse is assessing a patient for possible substance misuse. Which assessment finding indicates possible use of amphetamines?
 - a. Lethargy and fatigue
 - b. Cardiovascular depression
 - c. Talkativeness and euphoria
 - d. Difficulty swallowing and constipation

6. A patient experiencing ethanol withdrawal is beginning to show severe manifestations of delirium tremens. The nurse will plan to implement which interventions for this patient? (Select all that apply.)
 - a. Doses of an oral benzodiazepine
 - b. Doses of an intravenous benzodiazepine
 - c. Restraints if the patient becomes confused, agitated, or a threat to himself or others
 - d. Thiamine supplementation
 - e. Oral disulfiram (Antabuse) treatment
 - f. Monitoring in the Critical Care Unit
7. A patient has been admitted to the emergency department after a suspected overdose of benzodiazepines mixed with alcohol. The patient is lethargic and cannot speak. The nurse expects which immediate measures to be implemented? (Select all that apply.)
 - a. Prepare to administer naloxone (Suboxone)
 - b. Prepare to administer flumazenil
 - c. Monitor the patient for convulsions
 - d. Prepare for potential respiratory arrest
 - e. Apply restraints
8. The nurse is teaching a class about the effects of alcohol. Long-term excessive use of alcohol is associated with which of these problems? (Select all that apply.)
 - a. Coronary artery disease
 - b. Wernicke's encephalopathy

CRITICAL THINKING ACTIVITIES

1. A friend has revealed to the nurse that she has used crack cocaine often in the past few months and states that even though she enjoys the sensations, she can “stop at any time.” What is the nurse's priority action in this situation?
2. A patient is admitted to the hospital for major abdominal surgery, and the physician has ordered a transdermal nicotine patch to be used while the patient is hospitalized because the patient was a heavy smoker. While the patch is applied, the patient asks, “Why in the world would you want to give me nicotine when I'm trying to stop smoking?” What is the nurse's priority when answering the patient's question?
3. A patient has been admitted to the labour and delivery unit. She has a history of heavy use of alcohol and appears to be intoxicated. What are the potential effects of alcohol use on a fetus, and what would be priority concerns during the first few months of the newborn's life?

Adrenergic Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Briefly describe the functions of the sympathetic nervous system and the specific effects of adrenergic stimulation.
2. List the various drugs classified as adrenergic agonists or sympathomimetics.
3. Discuss the mechanisms of action, therapeutic effects, indications, adverse and toxic effects, cautions, contraindications, interactions, and available antidotes to overdose of the adrenergic agonists or sympathomimetics.
4. Develop a collaborative plan of care that includes all phases of the nursing process for patients taking adrenergic agonists.

KEY TERMS

Adrenergic agonists Drugs that stimulate and mimic the actions of the sympathetic nervous system; also called *sympathomimetics*. (p. 326)

Adrenergic receptors Receptor sites for the sympathetic neurotransmitters norepinephrine and epinephrine. (p. 326)

Alpha-adrenergic receptors A class of adrenergic receptors that is further subdivided into α_1 - and α_2 -receptors; α_1 - and α_2 -receptors exist postsynaptically, and α_2 -receptors also exist presynaptically. Both types are differentiated by their anatomical location in the muscles, other tissues, and organs regulated by specific autonomic nerve fibres. (p. 326)

Autonomic functions Bodily functions that are involuntary and result from the physiological activity of the autonomic nervous system. The functions often occur in pairs of opposing actions between the sympathetic and parasympathetic divisions of the autonomic nervous system. (p. 326)

Autonomic nervous system A branch of the peripheral nervous system that controls autonomic bodily functions; consists of the sympathetic and parasympathetic nervous systems. (p. 326)

Beta-adrenergic receptors A class of adrenergic receptors that is further subdivided into β_1 - and β_2 -receptors; located on postsynaptic cells that are stimulated by specific autonomic nerve fibres; β_1 -adrenergic receptors are located primarily in the heart, whereas β_2 -adrenergic receptors are located in the smooth muscle fibres of the bronchioles, arterioles, and visceral organs. (p. 326)

Catecholamines Substances that can produce a sympathomimetic response; either endogenous catecholamines (such as epinephrine, norepinephrine,

and dopamine) or synthetic catecholamine drugs (such as dobutamine). (p. 326)

Dopaminergic receptor A third type of adrenergic receptor (in addition to alpha-adrenergic and beta-adrenergic receptors); located in various tissues and organs and activated by the binding of the neurotransmitter dopamine, which can be either endogenous or a synthetic drug form. (p. 326)

Mydriasis Pupillary dilation, whether natural (physiological) or drug induced. (p. 329)

Ophthalmics Drugs that are used in the eye. (p. 329)

Positive chronotropic effect An increase in heart rate. (p. 329)

Positive dromotropic effect An increase in the conduction of cardiac electrical impulses through the atrioventricular node, which results in the transfer of nerve action potentials from the atria to the ventricles; ultimately leads to a systolic heartbeat (ventricular contractions). (p. 329)

Positive inotropic effect An increase in the force of contraction of the heart muscle (myocardium). (p. 329)

Sympathomimetics Drugs used therapeutically that mimic the catecholamines epinephrine, norepinephrine, and dopamine; also called *adrenergic agonists*. (p. 326)

Synaptic cleft The space between either two adjacent nerve cell membranes or a nerve cell membrane and an effector organ cell membrane (also called a *synapse*). This space is bordered by the presynaptic cleft, from which neurotransmitters are generally released, and the postsynaptic cleft, on which neurotransmitters generally act. (p. 327)

DRUG PROFILES

- ▶ dobutamine (dobutamine hydrochloride)*, p. 331
- ▶ dopamine (dopamine hydrochloride)*, p. 331
- ▶ epinephrine (epinephrine hydrochloride)*, p. 331
- midodrine, p. 332
- ▶ norepinephrine (norepinephrine bitartrate)*, p. 332
- phenylephrine hydrochloride, p. 332
- ▶ Key drug

* Full generic name is given in parentheses. For the purposes of this text, the more common, shortened name is used.

HIGH ALERT DRUGS

Dobutamine, p.331
Dopamine, p.331
Epinephrine, p.331
Norepinephrine, p.332
Phenylephrine, p.332

OVERVIEW

The body's nervous system is divided into two major branches: the central nervous system (CNS) and the peripheral nervous system (PNS; [Figure 19.1](#)). The CNS contains the brain and the spinal cord. The PNS is further subdivided into the somatic and autonomic nervous systems. The autonomic nervous system (ANS) is yet further subdivided into the parasympathetic (cholinergic) and the sympathetic (adrenergic) nervous systems. Understanding the ANS and its subclasses is critical in the study of pharmacology, as numerous drugs act in these systems. This chapter will focus on the adrenergic nervous system and related compounds.

Adrenergic compounds include several exogenous (synthetic) and endogenous (naturally produced in the body) substances. They have a wide variety of therapeutic uses, depending on their site of action and their effect on different types of adrenergic receptors. Adrenergics stimulate the sympathetic nervous system (SNS) and are also called **adrenergic agonists**. They are also known as **sympathomimetics** because they mimic the effects of the SNS neurotransmitters norepinephrine, epinephrine, and dopamine. These three neurotransmitters are chemically classified as **catecholamines**. In considering the adrenergic class of medications, it is helpful to understand how the SNS operates in relation to the rest of the nervous system.

SYMPATHETIC NERVOUS SYSTEM

[Figure 19.1](#) depicts the divisions of the nervous system and shows the relationship of the SNS to the entire nervous system. The SNS is the counterpart to the parasympathetic nervous system—together they make up the **autonomic nervous system**. They provide a check-and-balance system for maintaining the normal homeostasis of the **autonomic functions** of the human body.

There are receptor sites for the catecholamines norepinephrine and epinephrine throughout the body. These are referred to as **adrenergic receptors**. It is these receptor sites where

Fig. 19.1 The sympathetic nervous system in relation to the entire nervous system. ACh, Acetylcholine; NE, norepinephrine.

adrenergic drugs bind and produce their effects. Many physiological responses are produced when they are stimulated or blocked. Adrenergic receptors are further divided into **alpha-adrenergic receptors** and **beta-adrenergic receptors**, depending on the specific physiological responses caused by their stimulation. Both types of adrenergic receptors have subtypes (designated 1 and 2), which provide a further means of checks and balances that control stimulation and blockade, vasoconstriction and vasodilation of blood vessels, and the increased and decreased production of various substances. The α_1 - and α_2 -adrenergic receptors are differentiated by their location relative to nerves. The α_1 -adrenergic receptors are located on postsynaptic effector cells (the muscle, other tissue, or organ that the nerve stimulates). The α_2 -adrenergic receptors are located on the presynaptic nerve terminals. They control the release of neurotransmitters. The predominant alpha-adrenergic agonist response is vasoconstriction and CNS stimulation.

The beta-adrenergic receptors are all located on postsynaptic effector cells. The β_1 -adrenergic receptors are located primarily in the heart (a useful mnemonic to help remember this: β_1 —the body has 1 heart); the β_2 -adrenergic receptors are located in the smooth muscle fibres of the bronchioles (a complementary mnemonic: β_2 —the body has 2 lungs), arterioles, and visceral organs. A beta-adrenergic agonist response results in bronchial, gastrointestinal (GI), and uterine smooth muscle relaxation; glycogenolysis; and heart stimulation. [Table 19.1](#) provides a more detailed listing of the adrenergic receptors and the responses elicited when they are stimulated by a neurotransmitter or a drug that acts like a neurotransmitter ([Figure 19.2](#)).

Another type of adrenergic receptor is the **dopaminergic receptor**. When stimulated by dopamine, these receptors cause the vessels of the renal, mesenteric, coronary, and cerebral arteries to dilate, which increases blood flow to these tissues. Dopamine is the only substance that can stimulate these receptors. Catecholamine neurotransmitters are produced

TABLE 19.1 Adrenergic Receptor Responses to Stimulation

Location	Receptor	Response
Cardiovascular		
Blood vessels	α_1	Vasoconstriction
	β_2	Vasodilation
Heart muscle	β_1	Increased contractility
Atrioventricular node	β_1	Increased heart rate
Sinoatrial node	β_1	Increased heart rate
Pupillary muscles of iris	α_1	Mydriasis (dilated pupils)
Endocrine		
Kidney	β_1	Increased renin secretion
Liver	β_2	Glycogenolysis
Gastrointestinal		
Muscle	α_1, β_2	Decreased motility (relaxation of gastrointestinal smooth muscle)
Genitourinary		
Bladder sphincter	α_1	Constriction
Penis	α_1	Ejaculation
Uterus	α_1	Contraction
	β_2	Relaxation
Respiratory		
Bronchial muscles	β_2	Dilation (relaxation of bronchial smooth muscles)

by the SNS and are stored in vesicles located at the ends of nerves. When a nerve is stimulated, the vesicles move to the walls of the nerve endings and release their contents into the space between the nerve ending and the effector organ, known as the **synaptic cleft** or *synapse*. The released contents of the vesicle (catecholamines) then have the opportunity to bind to the receptor sites located along the effector organ (see [Figure 19.2](#)). Once the neurotransmitter binds to the receptors, the effector organ responds. The sympathetic branch of the ANS is often described as having a “fight-or-flight” function because it allows the body to respond in a self-protective manner to dangerous situations. Depending on the function of the particular organ, this response involves muscle contraction (e.g., skeletal muscles) or relaxation (e.g., smooth muscles in the GI system and airway), an increased heart rate, the increased production of one or more substances (e.g., stress hormones), or blood vessel constriction. This process is halted by the action of specific enzymes and by reuptake of the neurotransmitter molecules back into the nerve cell (neuron). Catecholamines are metabolized by two enzymes, monoamine oxidase (MAO) and catechol ortho-methyltransferase (COMT). Each enzyme breaks down catecholamines but in a different area. MAO breaks down the catecholamines inside the nerve ending, whereas COMT breaks down the catecholamines outside the nerve ending, at the synaptic cleft (see [Figure 19.2](#)). Neurotransmitter molecules may also be taken back up into the presynaptic nerve fibre by various protein pumps within the cell membrane. This phenomenon is known as *active transport*. This reuptake restores the catecholamine to the vesicle

and provides another means of maintaining an adequate supply of the substance for future sympathetic nerve impulses. This process is illustrated in [Figure 19.2](#).

ADRENERGIC DRUGS

Adrenergics are drugs with effects that are similar to or mimic the effects of the SNS neurotransmitters norepinephrine, epinephrine, and dopamine (collectively referred to as *catecholamines*). Catecholamines produce a sympathomimetic response. They are either endogenous substances, such as epinephrine, norepinephrine, and dopamine, or synthetic substances, such as dobutamine and phenylephrine hydrochloride. The three endogenous catecholamines are also available in synthetic drug form.

Catecholamine drugs that are used therapeutically produce the same result as endogenous catecholamines. When any of the adrenergic drugs is given, it bathes the area between the nerve and the effector cell (i.e., the synaptic cleft). Once there, the drug has the opportunity to induce a response. This can be accomplished in one of three ways: by direct stimulation, by indirect stimulation, or by a combination of the two (mixed-acting).

A direct-acting sympathomimetic binds directly to the receptor and causes a physiological response ([Figure 19.3](#)). Epinephrine is an example of such a drug. An indirect-acting sympathomimetic causes the release of catecholamine from the storage sites (vesicles) in the nerve endings; it then binds to the receptors and causes a physiological response ([Figure 19.4](#)). Amphetamines and other related anorexiant (see [Chapter 14](#)) are examples of such drugs. A mixed-acting sympathomimetic both directly stimulates the receptor by binding to it and indirectly stimulates the receptor by causing the release of the neurotransmitter stored in vesicles at the nerve endings ([Figure 19.5](#)). Ephedrine is an example of a mixed-acting adrenergic drug.

There are also noncatecholamine adrenergic drugs, such as phenylephrine hydrochloride and salbutamol. These are structurally dissimilar to the endogenous catecholamines and have a longer duration of action than either the endogenous or synthetic catecholamines. The noncatecholamine drugs show similar patterns of activity.

Adrenergic agents can also be classified as either selective or nonselective in their actions. For example, phenylephrine is considered a selective agonist, meaning it only affects one receptor subtype (α_1). Epinephrine and norepinephrine are considered nonselective agonists because they have action at both α - and β -receptors. Adrenergic drugs can act at different types of adrenergic receptors depending on the amount of drug administered. For example, dopamine may produce dopaminergic, β_1 , or α_1 effects, depending on the dose given. See [Table 19.2](#) for other examples of catecholamines and the dose-specific selectivity.

Although adrenergics work primarily at postganglionic receptors (the receptors that immediately innervate the effector organ, gland, or muscle) peripherally, they may also work more centrally in the nervous system at the preganglionic sympathetic nerve trunks. Their ability to do so depends on the potency of the specific drug and the dose used.

Fig. 19.2 Mechanism by which stimulation of a nerve fibre results in a physiological process; adrenergic drugs mimic this same process. *COMT*, Catechol ortho-methyltransferase; *MAO*, monoamine oxidase; *NE*, norepinephrine.

Fig. 19.3 Mechanism of physiological response to direct-acting sympathomimetics. *D*, Drug; *NE*, norepinephrine.

Fig. 19.4 Mechanism of physiological response to indirect-acting sympathomimetics. *D*, Drug; *NE*, norepinephrine.

Fig. 19.5 Mechanism of physiological response to mixed-acting sympathomimetics. *D*, Drug; *NE*, norepinephrine.

Adrenergic drugs are classified technically by their specific receptor activities, but they may also be categorized in terms of their clinical effects. For example, phenylephrine hydrochloride is both an α_1 -agonist and a vasoconstrictive drug (pressor), whereas salbutamol is both a β_2 -agonist and a bronchodilator. Both classifications are suitable for most clinical purposes. Clinically, it may be necessary to carefully choose an adrenergic

TABLE 19.2 Catecholamines and Their Dose–Response Relationship

Drug	Dosage	Receptor
dobutamine hydrochloride	Maintenance: 2–15 mcg/kg/min High: 40 mcg/kg/min	β_1 more than β_2 β_2 more than α_1
dopamine hydrochloride (available only in premixed 5% dextrose solution)	Low 0.5–3 mcg/kg/min Moderate: 3–10 mcg/kg/min High: >10 mcg/kg/min	Dopaminergic β_1 α_1
epinephrine hydrochloride (Adrenalin Chloride)	Low: 1–4 mcg/min High: 4–40 mcg/min	β_1 more than β_2 and α_1 α_1 more than or equal to β_1

drug with greater selectivity for a particular receptor type to avoid undesired clinical effects. In such a situation, detailed knowledge of the type and degree of receptor selectivity of different drugs becomes important.

Mechanism of Action and Drug Effects

To fully understand the mechanism of action of adrenergics, one must have a working knowledge of normal adrenergic transmission. This transmission takes place at the junction between the nerve (postganglionic sympathetic neuron) and the receptor site of the innervated organ or tissue (effector). The process of SNS stimulation is illustrated in [Figure 19.2](#) and was discussed earlier in this chapter. When adrenergic drugs stimulate α_1 -adrenergic receptor sites located on smooth muscles, vasoconstriction usually occurs. Binding to these α_1 -adrenergic receptors can also cause the relaxation of gastrointestinal smooth muscle; contraction of the uterus and bladder sphincter; male ejaculation; and contraction of the ciliary muscles of the eye, which causes the pupils to dilate (see [Table 19.1](#)). Stimulation of α_2 -adrenergic receptors, by contrast, actually tends to reverse sympathetic activity, but this action is not of great significance either physiologically or pharmacologically.

There are β_1 -adrenergic receptors on the myocardium and in the conduction system of the heart, including the sinoatrial node and the atrioventricular node. When these β_1 -adrenergic receptors are stimulated by an adrenergic drug, three effects result: (1) an increased force of contraction (**positive inotropic effect**), (2) an increase in heart rate (**positive chronotropic effect**), and (3) an increase in the conduction of cardiac electrical nerve impulses through the atrioventricular node (**positive dromotropic effect**). In addition, stimulation of β_1 -receptors in the kidney causes an increase in renin secretion. Activation of β_2 -adrenergic receptors produces relaxation of the bronchi (bronchodilation) and uterus and also causes increased glycogenolysis (glucose release) from the liver (see [Table 19.1](#)).

Indications

Adrenergics, or sympathomimetics, are used in the treatment of a wide variety of illnesses and conditions. Their selectivity for either α - or β -adrenergic receptors and their affinity for certain tissues or organs determine the settings in which

they are most commonly used. Some adrenergics are used as adjuncts to dietary changes in the short-term treatment of obesity. These drugs are discussed in greater detail in [Chapter 14](#).

Respiratory Indications

Bronchodilators are adrenergic drugs that have an affinity for the adrenergic receptors located in the respiratory system. Bronchodilators tend to preferentially stimulate the β_2 -adrenergic receptors rather than the α -adrenergic receptors and cause bronchodilation. Of the two subtypes of β -adrenergic receptors, these drugs are attracted more to the β_2 -adrenergic receptors, located on the bronchial, uterine, and vascular smooth muscles, and less so to the β_1 -adrenergic receptors, located on the heart. The β_2 -agonists are helpful in treating conditions such as asthma, bronchitis, and anaphylaxis. Common bronchodilators that are classified as predominantly β_2 -selective adrenergic drugs include formoterol fumarate dihydrate, salbutamol, salmeterol xinafoate, and terbutaline sulfate. These drugs are discussed in more detail in [Chapter 38](#). At low doses, epinephrine can selectively stimulate β_2 -receptors, producing muscle relaxation and a decrease in peripheral resistance. However, once epinephrine concentrations that bind to the α_1 -receptor are reached, vasoconstriction will occur.

Indications for Topical Nasal Decongestants

The intranasal application of certain adrenergics can cause the constriction of dilated arterioles and a reduction in nasal blood flow, which then decreases congestion. These adrenergic drugs work by stimulating α_1 -adrenergic receptors and have little or no effect on β -adrenergic receptors. The nasal decongestants include oxymetazoline hydrochloride, xylometazoline hydrochloride, and phenylephrine hydrochloride. They are discussed in more detail in [Chapter 38](#).

Ophthalmic Indications

Some adrenergics are applied to the surface of the eye. These drugs are called **ophthalmics**. Ophthalmics work much the same way as nasal decongestants except that they affect the vasculature of the eye. They stimulate α -adrenergic receptors located on small arterioles in the eye and temporarily relieve conjunctival congestion by causing arteriolar vasoconstriction. The ophthalmic adrenergics include epinephrine, naphazoline hydrochloride, phenylephrine hydrochloride, and tetrahydrozoline.

Adrenergics can also be used to reduce intraocular pressure, which makes them useful in the treatment of open-angle glaucoma; they can also dilate the pupils (**mydriasis**). Both of these properties make them useful for diagnostic eye examinations. Adrenergics produce these effects by stimulating α - or β_2 -adrenergic receptors, or both. The adrenergic used for this purpose is dipivefrin hydrochloride. Ophthalmic adrenergic drugs are discussed in more detail in [Chapter 57](#).

Cardiovascular Indications

The final group of adrenergic agents is used to support the cardiovascular system during heart failure or shock. These drugs are referred to as *vasoactive sympathomimetics*, *vasoconstrictive*

drugs (also known as *vasopressor drugs*, *pressor drugs*, or *pressors*), *inotropes*, or *cardioselective sympathomimetics*. They have a variety of effects on the various alpha- and beta-adrenergic receptors, and the effects can be related to the specific dose of the adrenergic drug. Common vasoactive adrenergic drugs include dobutamine, dopamine, epinephrine, midodrine hydrochloride, norepinephrine, and phenylephrine hydrochloride.

Contraindications

The only usual contraindications to the use of adrenergic drugs are known drug allergy and severe hypertension.

It is important to note that a common medication error is confusion between norepinephrine bitartrate and the brand name for phenylephrine hydrochloride, Neo-Synephrine®. These drugs are often both ordered for a patient at the same time, and, because the names sound alike, the wrong drug may be given. To avoid this confusion, pharmacies list these drugs by their trade names as well: norepinephrine bitartrate is called Levophed® and phenylephrine hydrochloride is called Neo-Synephrine.

Adverse Effects

Unwanted CNS effects of the adrenergic drugs include headache, restlessness, tremors, nervousness, dizziness, insomnia, and euphoria. Possible cardiovascular adverse effects include chest pain, vasoconstriction, hypertension, tachycardia (positive chronotropy), fluctuations in blood pressure, and palpitations or dysrhythmias. Effects on other body systems include anorexia, dry mouth, nausea, vomiting, and, rarely, taste changes. Adrenergics administered as ophthalmics or by nebulizer can have systemic effects. Other significant effects include sweating, nausea, vomiting, and muscle cramps. Vasoactive medications should be administered through a central line as opposed to a peripheral intravenous access. Vasoactive medications have a high rate of extravasation. If this should occur, phentolamine should be administered. See Special Populations: Older Adults—Use of Beta-Adrenergic Agonists box for additional information.

Toxicity and Management of Overdose

The toxic effects of adrenergic drugs are an extension of their common adverse effects (i.e., seizures from excessive CNS stimulation, hypotension or hypertension, dysrhythmias, palpitation, nervousness, dizziness, fatigue, malaise, insomnia, headache, tremor, dry mouth, and nausea). The two most life-threatening toxic effects involve the CNS and cardiovascular system. The first is seizures, which in the acute setting can be effectively managed with diazepam. The second is extreme elevation in blood pressure, which can result in intracranial bleeding. Such elevated blood pressure increases the risk of hemorrhage not only in the brain but elsewhere in the body as well. The most effective treatment in this situation is to lower the blood pressure using a rapid-acting sympatholytic (e.g., esmolol; see [Chapter 20](#)). This can directly reverse the adrenergic-induced state.

The majority of adrenergic compounds have extremely short half-lives, and thus their effects are transient. Therefore, when

SPECIAL POPULATIONS: OLDER ADULTS

Use of Beta-Adrenergic Agonists

- Several physiological changes occur in the cardiovascular system of older adults, including a decline in the efficiency and contractile ability of the heart muscle, a decrease in cardiac output, and diminished stroke volume. In most cases, older adults adjust to these changes without too much difficulty; however, if unusual demands are placed on the aging heart, problems and complications may arise. Examples of unusual demands include strenuous activities, excess stress, heat, and medication use. For instance, stress, heat, and use of beta-adrenergic agonists may lead to significant increases in blood pressure and pulse rate. Older adults may then react negatively, with a diminished ability to compensate adequately for these changes.
- Baroreceptors do not work as effectively in older adults. Reduced baroreceptor activity may lead to orthostatic hypotension, even without the impact of certain medications and their associated mechanism of action or adverse effects.
- Because of the possible presence of concurrent medical conditions (e.g., hypertension, peripheral vascular disease, and cardiovascular disease or cerebrovascular disease), monitor older adults carefully before, during, and after administration of adrenergic drugs.
- Advise older adult patients that any occurrence of chest pain, palpitations, headache, or seizures must be reported immediately to the health care provider, or emergency care should be accessed.
- Caution patients about the use of over-the-counter (OTC) drugs, natural health products, and other medications. This caution is due to possible drug–drug interactions as well as older adults' increased sensitivity to many drugs and other chemicals.
- Older adults may have decreased motor function and cognitive decline. Therefore, use additional equipment and certain facilitating aids (e.g., walkers, reachers, computer adaptations), and provide detailed instructions to help ensure proper dosing of medications.

these drugs are taken in an overdose, or when toxicity develops, stopping the drug causes the toxic symptoms to subside in a relatively short period of time. The recommended treatment for overdose is often managing the symptoms and supporting the patient. If death occurs, it is usually the result of either respiratory failure or cardiac arrest. The treatment of overdose is therefore aimed at supporting the respiratory and cardiac systems.

Interactions

Numerous drug interactions can occur with adrenergic drugs. Although many of the interactions result in a diminished adrenergic effect because of direct antagonism at and competition for receptor sites, as in the concurrent use of adrenergic antagonists (e.g., for hypertension) and adrenergics, some reactions can be life threatening. The following are some of the more serious drug–drug interactions involving adrenergic drugs. Administration of adrenergics with anaesthetic drugs or digoxin (see [Chapter 12](#)) can increase the risk of cardiac dysrhythmias. Tricyclic antidepressants (see [Chapter 17](#)), when given with adrenergics, can cause increased vasopressor effects and acute hypertensive crisis. Administration of adrenergic drugs with MAOIs may cause a possibly life-threatening hypertensive crisis (see [Chapter 17](#)). Antihistamines (see [Chapter 37](#)) and thyroid preparations (see [Chapter 32](#)) can also increase the effects of adrenergic drugs.

Laboratory Test Interactions

The alpha-adrenergic drugs can cause an increase in the serum levels of endogenous corticotropin (i.e., adrenocorticotrophic hormone), corticosteroids, and glucose. Beta-adrenergic drugs can cause eosinophilia, thrombocytopenia, and a decrease in serum potassium concentrations, rarely to hypokalemia levels. Therefore, the results of laboratory tests for these substances need to be interpreted with caution in patients receiving any of these medications.

Dosages

For dosage information on various adrenergic drugs, see the table on p. 332.

DRUG PROFILES

The four frequently used classes of adrenergic drugs are the bronchodilators (Chapter 38), ophthalmic drugs (Chapter 57), nasal decongestants (Chapter 37), and vasoactive drugs, which are emphasized in this Drug Profile and in Chapter 25. The receptor selectivity for the α_1 -, β_1 -, and β_2 -receptor subtypes is relative, as opposed to absolute. Thus, there may be some overlap of drug effects between the different adrenergic classes of drugs, especially at higher dosages. In contrast, dopamine receptors are more specific for dopamine itself or for specific dopaminergic drugs.

Vasoactive Adrenergics

Adrenergics used to support the cardiovascular system (e.g., a failing heart or shock) or to treat orthostatic hypotension are referred to as *vasoactive adrenergics*. The vasoactive adrenergics are potent, quick-acting, injectable drugs. Although dosage recommendations are provided in the table on p. 332, all of these drugs are titrated to the desired physiological response. For this reason, dosages for children are not given in the table. All of the vasoactive adrenergics (with the exception of midodrine) are rapid in onset, and their effects quickly cease when administration is stopped. Therefore, careful titration and monitoring of vital signs and electrocardiogram (ECG) are required.

dobutamine hydrochloride

Dobutamine hydrochloride is a β_1 -selective vasoactive adrenergic drug that is structurally similar to the naturally occurring catecholamine dopamine. Through stimulation of the β_1 -receptors on heart muscle (myocardium), it increases cardiac output by increasing contractility (positive inotropy), which increases the stroke volume, especially in patients with heart failure. Dobutamine is available only as an intravenous drug and is given by continuous infusion (see Dosages table on the next page).

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Less than 2 min	Less than 10 min	2–5 min	Less than 10 min

dopamine hydrochloride

Dopamine hydrochloride is a naturally occurring catecholamine neurotransmitter. It has potent dopaminergic as well as β_1 - and α_1 -adrenergic receptor activity, depending on the dosage. When used at low doses, dopamine can dilate blood vessels in the brain, heart, kidneys, and mesentery, which increases blood flow to these areas (dopaminergic receptor activity). For example, dopamine is used to maintain blood pressure in organs to be used for transplantation. At higher infusion rates, dopamine can improve heart contractility and output (β_1 -adrenergic receptor activity). At highest doses, dopamine causes vasoconstriction (α_1 -adrenergic receptor activity). Use of dopamine is contraindicated in patients who have a catecholamine-secreting tumour of the adrenal gland known as a *pheochromocytoma*. The drug is available only as a 5% dextrose solution and is given by continuous infusion (see Dosages table on the next page and Table 19.1).

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	2–5 min	Rapid	Less than 2 min	10 min

epinephrine hydrochloride

Epinephrine hydrochloride (Adrenalin®) is also an endogenous vasoactive catecholamine. It acts directly on both the α - and β -adrenergic receptors of tissues innervated by the SNS. It is considered the prototypical nonselective adrenergic agonist. Epinephrine is administered in emergency situations and is one of the primary vasoactive drugs used in many advanced cardiac life support protocols. The physiological response it elicits is dose related. At low dosages, it stimulates primarily β_1 -adrenergic receptors, increasing the force of contraction and heart rate. It is also used to treat acute asthma (see Chapter 38) and anaphylactic shock because it has significant bronchodilatory effects via the β_2 -adrenergic receptors in the lungs. In patients with anaphylaxis, epinephrine has potent, life-saving α_1 -adrenergic vasoconstrictor effects. As a result of the vasoconstriction, mucosal edema is reduced, which prevents and relieves upper airway obstruction and increases blood pressure. Consequently, shock is prevented and relieved. The β_1 -adrenergic effects lead to an increased rate and force of cardiac contractions. The effects of β_2 are increased bronchodilation and decreased release of histamine, as well as other mediators of inflammation from mast cells and basophils. At high dosages (e.g., when given intravenously), epinephrine stimulates primarily α -adrenergic receptors, causing vasoconstriction, which elevates the blood pressure (see Dosages table on the next page).

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Subcut	5–10 min	20 min	Variable	Unknown
IV	Less than 2 min	Rapid	Less than 5 min	5–30 min

midodrine hydrochloride

Midodrine hydrochloride is a prodrug (pharmacologically inactive form of the drug) that is converted metabolically in the liver to its active form, desglymidodrine. This active metabolite is responsible for the primary pharmacological action of midodrine hydrochloride, which is α_1 -adrenergic receptor stimulation. This α_1 stimulation increases the vascular tone of both arterioles and veins, resulting in peripheral vasoconstriction and increased systemic vascular resistance. Midodrine hydrochloride is primarily indicated for the treatment of symptomatic orthostatic hypotension. Midodrine hydrochloride is available as 2.5- and 5-mg tablets (see the Dosages table). Midodrine hydrochloride is usually given two to three times per day. The last dose of the day should not be given after 1800 hours to prevent supine hypertension.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	45–90 min	30 mins	25 mins for midodrine, but 3–4 hours for active metabolite (desglymidodrine)	6–8 hr

! norepinephrine bitartrate

Norepinephrine bitartrate (Levophed) acts predominantly by directly stimulating α -adrenergic receptors, which leads to

vasoconstriction. It also has some direct-stimulating β -adrenergic effects on the heart (β_1 -adrenergic receptors) but none on the lung (β_2 -adrenergic receptors). Norepinephrine is directly metabolized to dopamine and is used primarily in the treatment of hypotension and shock. It is given only by continuous infusion (see Dosages table).

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Rapid	1–2 min	Less than 5 min	1–2 min

! phenylephrine hydrochloride

Phenylephrine hydrochloride (Neo-Synephrine) works almost exclusively on the α -adrenergic receptors. It is used primarily for short-term treatment to raise blood pressure in patients in shock, to control specific dysrhythmias (supraventricular tachycardias) and to produce vasoconstriction in regional anaesthesia. It is also administered topically as an ophthalmic drug (see Chapter 57) and in some nasal decongestants (see Chapter 37; see Dosages table).

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Rapid	Rapid	Less than 5 min	15–20 min

Dosages

Selected Vasoactive Adrenergics

Drug	Pharmacological Class	Usual Dosage Range	Indications
 dobutamine hydrochloride	β_1 -adrenergic and dopaminergic	<i>Adults</i> IV infusion: 2.5–40 mcg/kg/min	Cardiac decompensation
 dopamine hydrochloride (premixed ready-to-use solution)	β_1 -adrenergic	<i>Adults</i> IV infusion: 2–50 mcg/kg/min	Shock syndrome, chronic cardiac decompensation
 epinephrine hydrochloride (Adrenalin Chloride®)	α - and β -adrenergic	<i>Adults</i> IV: 1–4 mcg/min (β dose); more than 20 mcg/min dose titrated to effect (α dose)	β dose used to treat bradycardias, severe left ventricular dysfunction or anaphylaxis; α dose used to treat profound hypotension or pulseless cardiac arrest
midodrine hydrochloride	α_1 -adrenergic	<i>Adults</i> PO: 10 mg tid, max 40 mg/day	Orthostatic hypotension
 norepinephrine bitartrate (Levophed)	α - and β -adrenergic	<i>Adults</i> IV infusion: 2–30 mcg/min	Hypotensive states
phenylephrine hydrochloride (Neo-Synephrine)	α -adrenergic	<i>Adults</i> IV infusion: 10 mg/250 or 500 mL IV solution, start at 0.5 mcg/kg/min with dosage range between 0.4–9.1 mcg/kg/min IM/Subcut: 2–5 mg IV: 0.1–0.5 mg	Hypotension or septic shock

IM, Intramuscular; IV, intravenous; PO, oral; Subcut, subcutaneous.

❖ NURSING PROCESS

◆ ASSESSMENT

Adrenergic agonist drugs have a variety of effects depending on the receptors they stimulate. Stimulation of the alpha-adrenergic receptors results in vasoconstriction. Stimulation of beta₁-adrenergic receptors produces heart stimulation, and stimulation of the beta₂-adrenergic receptors results in bronchodilation. Because of these properties, the use of adrenergic agonists requires careful patient assessment and monitoring to maximize therapeutic effects and minimize possible adverse effects. Focus assessment on a comprehensive health history, including past and present medical history. Include specific system-based questions, and identify cautions, contraindications, and drug interactions. Include the following health history questions in your assessment: (1) Medication history and allergies: What prescription medications do you regularly use (including self-administration of OTC drugs and natural health products)? Do you have allergies to any medication, foods, topical products, or environmental products? (2) Respiratory: Do you have a history of asthma and if so, how frequent and severe are the acute episodes? What factors exacerbate or help to alleviate asthma? Do you experience any other asthma-related symptoms such as dyspnea or chest pain? What treatments have you used for asthma and what have been their successes or failures? (3) Cardiovascular: Do you have a history of transient ischemic attack or cerebrovascular accident or stroke? Do you have a history of hypertension, hypotension, postural hypotension, or orthostatic hypotension? (Do you get dizzy when you stand up too quickly?) Do you have any cardiac irregularities or other cardiovascular disease? (4) Renal and liver: Do you have a history of kidney problems? Has anyone ever reported that your kidney or liver function studies were abnormal? Do you have a history of chronic kidney infections or any jaundice? (With altered kidney or liver function, there is the risk for altered excretion and metabolism of drugs, thus leading to possible toxicity.)

Performing a thorough head-to-toe physical assessment is also a significant part of data collection with adrenergic drugs. Thorough assessment of the cardiac system is important because the adrenergic agonist drugs may exacerbate pre-existing cardiac disorders. Baseline vital signs need to be thoroughly assessed with the use of adrenergic drugs; assess and document breath sounds, heart sounds, peripheral pulses, skin colour, and capillary refill. In addition to measurement of postural blood pressures and pulse rates, inquire about other relevant symptoms such as dizziness, lightheadedness, and syncope. Assessment of the patient's symptoms and the patient's perception of either disease progression or a decrease in symptoms is important for effective and successful treatment.

With other adrenergic drugs, such as those used for bronchodilating effects, perform a thorough respiratory assessment and document the patient's respiratory rate, rhythm, and depth, as well as the presence of normal or adventitious (abnormal) breath sounds. Ask about any reports of difficulty breathing or intolerance of activity or exercise. Assess and document pulse oximetry readings for oxygen saturation levels. Include in the assessment measurement of respiratory peak flow using a flow meter, as well

as measurement of the anterior–posterior diameter of the chest wall. A decrease in peak flow readings may indicate bronchospasms, whereas an increased anterior–posterior chest wall diameter is seen in chronic lung disorders, such as chronic obstructive pulmonary disease. Health care providers may also order additional respiratory function studies such as measurement of arterial blood gas levels. Older adults and young patients may react with increased sensitivity to adrenergic drugs. In addition, some of these drugs are used only for acute episodes of asthma, whereas other drugs are used long term as preventive drugs. For example, the drugs salmeterol xinafoate (see [Chapter 38](#)) and formoterol fumarate are *not* used to treat acute asthmatic episodes, whereas salbutamol is indicated for treatment of acute episodes.

Epinephrine and similar drugs are used for their cardiac, bronchial, antiallergic, ocular, and vasopressor effects. Focus assessment on vital signs, breath sounds, arterial blood gas levels, and ECG findings, if ordered. Assess and document liver and kidney function test results. In addition, assess each system related to the specific action of the drug.

Overall, adrenergic drugs work in similar ways, but individual drugs may have some differences in actions, indications, and overall considerations. If the general class of drugs and the way in which they work is known, then the relative assessment parameters, cautions, contraindications, drug interactions, and lifespan considerations are easy to determine. If the drug is a pure adrenergic agonist, the net effect is stimulation of alpha-adrenergic receptors with vasoconstriction of blood vessels and subsequent elevation of blood pressure and heart rate; expect specific effects from the drug and anticipate certain adverse effects. The drug may be used for the therapeutic effect of increased blood pressure, but an unwanted adverse effect could be a hypertensive crisis. If the drug is a beta-adrenergic agonist, it will stimulate both beta₁- and beta₂-receptors, which will lead to heart stimulation and bronchodilation. This beta₁ action can also result in too much stimulation, with severe tachycardia and possibly chest pain if coronary artery disease is present. Thus, by knowing the actions of a given drug, it is possible to draw conclusions about, anticipate, and be alert to the drug's therapeutic actions, adverse effects, cautions, contraindications, drug interactions, and toxicity.

◆ NURSING DIAGNOSES

- Reduced gas exchange related to asthma-induced bronchospasms
- Potential for decreased cardiac output related to cardiovascular adverse effects of adrenergic agonist drugs
- Diminished peripheral tissue perfusion related to intense vasoconstrictive reactions of medications
- Potential for acute pain related to adverse effects of tachycardia and palpitations
- Inadequate sleep pattern related to CNS stimulation caused by adrenergic drugs
- Limited knowledge of the therapeutic regimen, adverse effects, drug interactions, and precautions related to the use of adrenergic drugs

- Potential for nonadherence with drug therapy related to lack of information about the importance of taking the medication as ordered
- Potential for risk for injury related to possible adverse effects (nervousness, vertigo, hypertension, or tremors) or to potential drug interactions

◆ PLANNING

◆ Goals

- Patient will experience normal patterns of gas exchange and maintain an open airway.
- Patient will maintain normal cardiac output status.
- Patient will display adequate peripheral vascular or tissue perfusion.
- Patient will experience relief of pain and increased levels of comfort.
- Patient will experience improved sleep patterns.
- Patient will demonstrate adequate knowledge about the use of specific medications.
- Patient will remain adherent to the drug therapy regimen and without drug-related complications.
- Patient will remain free from injury related to drug therapy.

◆ Outcome Criteria

- Patient shows improvement in gas exchange and respiratory status with normal respiratory rate (12 to 20 breaths per minute), regular rhythm and depth, clearing breath sounds, and a normal pulse oximetry reading above 95%.
- Patient's blood pressure and pulse rate remain within normal limits (BP 120/80; pulse 60 to 100 beats per minute; mean arterial pressure [MAP] greater than 65).
- Patient's capillary refill is less than 3 seconds in fingers and toes.
- Patient's circulation in extremities remains intact.
- Patient's capillary refill is intact, with skin colour being pink and extremities warm to the touch.
- Patient's pedal pulse is intact and strong to palpation.

- Patient remains comfortable during drug therapy and takes medications exactly as prescribed.
- Patient remains free of increased heart rate and irregular heart rhythm.
- Patient uses relaxation therapy or massage and maintains healthy sleep patterns in a quiet, temperate room environment.
- Patient demonstrates proper use of drug therapy regimen and avoids overuse of medication, decreasing adverse effects.
- Patient states rationale for use of medications as well as timing, dosing, and scheduling of drug therapy.
- Patient states most common adverse effects of drug therapy.
- Patient states which adverse effects to report if they occur, such as chest pain, irregular heart rhythm, dizziness, increased occurrence of palpitations, and overall feeling of discomfort, anxiety, or restlessness.
- Patient reports taking medication exactly as prescribed for maintenance or acute use and without adverse or toxic reactions.
- Patient remains free from self-injury as related to safe and as-prescribed self-administration of drug therapy.

◆ IMPLEMENTATION

Many of the drugs discussed in this chapter are often only administered in specialty care areas, such as Critical Care Units or emergency departments. Always refer to agency-specific protocols for administration of adrenergic drugs. There are several nursing interventions that may maximize the therapeutic effects of adrenergic drugs and minimize their adverse effects. These interventions include checking the package inserts concerning dilutional solutions to ensure compatibility with parenteral dosage forms. For example, subcutaneous administration of the adrenergic agonist epinephrine for patients with asthma requires careful calculations and accurate dosing to ensure safety. A tuberculin syringe used with subcutaneous epinephrine may be used to help with accurate dosing for both adults and children.

Use of epinephrine and some of the other pure alpha-adren-ergics may not be indicated for shock-related symptoms because

CASE STUDY

Dopamine Infusion

Janos, an 82-year-old retired real estate agent, is receiving dopamine at a dose of 5 mcg/kg/min via infusion pump for heart failure. He is being monitored by a cardiac monitor. He has a history of hypothyroidism and takes a daily dose of thyroid replacement hormone. Yesterday, Janos's vital signs were as follows:

Blood pressure: 150/88 mm Hg

Pulse rate: 92 beats/min

Respiration rate: 16 breaths/min

His heart rhythm showed sinus rhythm with rare ectopic beats. While at rest, he had no shortness of breath but did experience some dyspnea when getting up to the bedside commode. He has edema in his lower legs rated as 2+ edema.

1. Explain how this dose of dopamine works to help treat Janos's heart failure.
2. What would you expect to happen if the dose were set to 1 mcg/kg/min? 20 mcg/kg/min?

This morning, you make rounds and find that Janos's vital signs are as follows:

Blood pressure: 170/94 mm Hg

Pulse rate: 120 beats/min

Respiration rate: 22 breaths/min

The heart monitor shows sinus tachycardia with two to three ectopic beats per minute. Janos is reporting palpitations and some shortness of breath at rest but says, "I've felt this before when I've had bad spells with my heart. I'm sure it will pass."

3. Do you think there is a concern at this time? Explain your reasoning and what should be done.
4. The physician decides to titrate the dopamine infusion to 3 mcg/kg/min, which you do immediately. How quickly should you see a response from the patient to this decrease in dosage?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

these drugs lead to vasoconstriction of the renal vessels and potential kidney damage or shutdown. Therefore, when a patient is in shock and requires medications, norepinephrine is generally the drug of choice. Norepinephrine is used because, in specific dosage ranges, it helps treat a shock-related syndrome through its ability to produce vasoconstriction of peripheral blood vessels and increase blood pressure without vasoconstriction of the renal vasculature. This lack of renal vasculature vasoconstriction helps improve perfusion through the kidneys and thus salvages the kidneys (while increasing blood pressure). With administration of norepinephrine

LEGAL & ETHICAL PRINCIPLES

Infiltrating Intravenous Infusions

Nurses often encounter an infiltrating infusion in the routine care of many of their patients. Every action taken is important in ensuring that the nurse has acted as any prudent nurse would, and this prudence is essential to maintain the standard of care for the patient. The assessment and action taken by the nurse can be important for the patient, as in the case of *Macon-Bibb County Hospital Authority v. Ross* (1985).

Situation

At approximately 1452 hours, Ms. Ross arrived at the emergency department with dyspnea, bradycardia, and a blood pressure of 250/150 mm Hg. She became unresponsive, and at 1455 hours went into respiratory arrest. She was intubated by a respiratory therapist. At approximately 1458 hours, she received intravenous sodium nitroprusside in an intravenous site in her right wrist. Sodium nitroprusside was used to decrease her severely elevated blood pressure. By 1513 hours, Ms. Ross's blood pressure was 120/90 and the sodium nitroprusside was discontinued, as prescribed. Actual events are documented as follows: At 1528 hours, the patient had no blood pressure at all and the physician had prescribed intravenous administration of dopamine to elevate her blood pressure; dopamine was actually administered at 1531 hours to increase her then nonexistent blood pressure. She was then transferred to the cardiac care unit at approximately 1630 hours, after the blood pressure stabilized. At midnight, a nurse noted that the intravenous catheter site had a "bruise, bluish in colour." The next notation was at 1100 hours the following day. The patient's right arm was noted to be swollen and sore, with a large blistered area around the intravenous catheter site. The same description was noted again at 1600 hours. There was no evidence that a physician was consulted or informed until 1850 hours. At this time, the blistered area was shown to a physician, but it was not until later in the evening that another physician cleansed the blistered area and treated it as a burn. The patient's lower right arm was permanently scarred and it was undisputed that the injury was a result of the infiltration of the dopamine.

It was noted that although an infiltration may result from an improper technique, it may also be related to the size of the needle, the status of the patient's veins, or specific intolerance to an intravenous catheter. However, according to the expert nurse's testimony, supported by evidence-informed references, dopamine should be infused into a "large vein," such as in the antecubital fossa, to minimize the risk of extravasation (leakage of fluid). In addition, dopamine needs to be monitored continuously and the infusion very closely regulated. The antidote to counter the effects of dopamine extravasation is phentolamine mesylate (Regitine®), and damage may be decreased or reversed if this is given within a specified time period. It is essential that nurses are educated about the intravenous administration of dopamine in order to minimize the consequences of extravasation, as in this case.

Data adapted from *Macon-Bibb County Hospital Authority v. Ross*, 335 SE2d 633 GA (176 Ga. App. 221 1985). Retrieved from http://www.legale.com/decision/1985397176GaApp221_1302.xml/MACON-BIBB%20COUNTY%20HOSP.%20AUTH.%20v.%20ROSS.

and similar drugs, check the intravenous site frequently (e.g., every hour, as needed) to be sure that the site remains intact and that the drug is being infused at the proper rate. Phentolamine mesylate is often used for the treatment of infiltration (see Chapter 20). Also, with intravenous infusions, use only clear solutions and a proper dilutional solution, always administer the drug with an intravenous infusion pump, and closely monitor the cardiac system (through attention to vital signs, heart sounds, or ECG monitoring). For example, patients receiving drugs such as dopamine and dobutamine by intravenous infusion would be on a cardiac monitor and require frequent nursing assessments. Give all of these drugs per the manufacturer's directions and at suggested infusion rates to avoid precipitating dangerously high blood pressure and pulse rate and subsequent complications. (See Legal & Ethical Principles box regarding issues that can arise with incorrect intravenous infusions causing infiltration.)

When adrenergics are administered via an inhaler or nebulizer, provide the patient with complete, thorough, and age-appropriate instructions about the correct use, storage, and care of equipment. Instruct the patient on how to use a spacer correctly, as use of this device with the inhaler is often ordered. A spacer provides more effective delivery of inhaled doses of drugs (see Patient Teaching Tips as well as Chapter 7). When the adrenergics are dosed for bronchodilating effects, often two adrenergics are prescribed. This is because different medications are associated with different pharmacokinetics and actions. One inhaler may be for use in acute situations and the other for long-term and preventive use. With this type of treatment regimen, the patient needs to receive thorough, simple, and complete instructions and explanations about the method of delivery and about the drugs used. This will help to minimize risk of overdose and reduce potential severe adverse effects such as hypertension, severe tachycardia, tremors, and CNS overstimulation.

Emphasize in patient teaching that adrenergic medications are to be used only as prescribed in regard to amount, timing, and spacing of doses. Because of their synergistic effects, when adrenergic medications are used in combination with other types of bronchodilators (especially in patients with asthma), the patient must be clear about what to do before, during, and after the dose is delivered. If taking an inhaled dosage form, the patient may also be prescribed an oral or parenteral form of a drug of the same class or a similar drug. The reason for the use of more than one drug of the same drug class, and the use of more than one route of administration, is to achieve combined therapeutic effects. In educating the patient, pay extremely close attention to these regimes in order to prevent exacerbation of adverse effects, minimize drug interactions, and prevent severe vascular and cardiovascular adverse effects. Advise the patient to immediately report any chest pain, palpitations, blurred vision, headache, or seizures.

Patients with chronic lung disease who are receiving adrenergic drugs also need to avoid anything that may exacerbate their respiratory condition (e.g., certain foods or allergens, cigarette smoking) and implement measures that may help diminish their risk of respiratory infection. These measures may include avoiding those who are ill with colds and flu, avoiding crowded areas, remaining well nourished and rested, and maintaining

fluid intake of up to 3 000 mL per day to ensure adequate hydration (unless contraindicated). It may be helpful for the patient to keep a journal of symptoms and note any improvement or worsening in the treated condition while taking the medications.

Salmeterol xinafoate is not to be used for relief of acute symptoms, and education about its dosing is important. The dosage of salmeterol xinafoate is usually 1 puff twice daily at 12-hour intervals. Always recheck orders and directions. If another type of inhalant is used, such as a corticosteroid, instruct the patient to use the bronchodilator first, with a 5-minute waiting period prior to taking the second drug. All equipment should be rinsed after use. Educate patients about the importance of rinsing the mouth thoroughly after the use of any inhalant form of medication, to prevent irritation and infection. See [Chapter 38](#) for further discussion of salmeterol xinafoate. If ophthalmic forms of adrenergic drugs are used, make sure that the medication has not expired and is also a clear solution. Do not allow the eye-dropper to touch the eye when the drug is applied, to help prevent contamination of the remaining solution. With ophthalmic administration, drops and ointments should be applied into the conjunctival sac—not directly onto the cornea.

Oral midodrine hydrochloride is to be taken exactly as prescribed. This medication is usually ordered to be given with fluids before the patient gets out of bed in the morning. Doses of the drug are also often front-loaded in the dosing schedule so that most of the doses occur in the morning, when patients with orthostatic intolerance are usually more symptomatic. Patients need to avoid taking this medication after 1800 hours if possible, to prevent insomnia and possible supine hypertension.

◆ EVALUATION

Therapeutic effects of adrenergic drugs are summarized as follows. For vasoactive drugs, therapeutic effects include improved cardiac output (with increased urinary output), return to normal vital signs (e.g., blood pressure of 120/80 mm Hg or higher, or gradual increases in blood pressure as indicated, and pulse rate greater than 60 but less than 100 beats per minute), improved skin colour (from pallor to pink) and temperature (from cool to warm) in the extremities, improved peripheral pulses, and increased level of consciousness. Therapeutic effects of drugs given for bronchial indications include a return to a normal respiratory rate (more than 12 but fewer than 20 breaths per minute), improved breath sounds throughout the lung field with fewer adventitious sounds than prior to intervention, increased air exchange in all areas of the lungs, decreased to no coughing, less dyspnea, improved partial pressure of oxygen and pulse oximeter readings, and tolerance of slowly increasing levels of activity. Therapeutic effects of midodrine hydrochloride include improved levels of functioning and improved performance of activities of daily living, fewer episodes of postural intolerance (dizziness, lightheadedness, and syncopal episodes), and increased energy.

To evaluate for the occurrence of adverse effects with adrenergic drugs, monitor for stimulation of the systems that are affected, such as the cardiac system and the CNS. Adverse effects such as dysrhythmias, hypertension, and tachycardia may occur. Be sure to monitor for chest pain.

PATIENT TEACHING TIPS

- Patients should be informed that medications must always be taken as prescribed. Excessive dosing may cause CNS and cardiovascular stimulation, with tremors, nervousness, insomnia, tachycardia, and palpitations.
- Instructions to patients for the use of inhaled forms of medication, including nebulizers, inhalers, and metered-dose inhalers (see [Chapter 10](#)), must be clear and concise.
- Instruct patients to report any dyspnea, distress, chest pain, heart palpitations, or worsening of respiratory symptoms.
- Instruct patients to consult a health care provider before taking any OTC medications or natural health products.
- Midodrine hydrochloride requires careful dosing, as ordered. Encourage patients taking this medication to keep a journal to record adverse effects, improvements in symptoms, and any worsening of symptoms.

KEY POINTS

- Catecholamines are substances that produce a sympathomimetic response. The naturally occurring or endogenous catecholamines include epinephrine, norepinephrine, and dopamine. An example of an exogenous catecholamine is dobutamine.
- Patients with a chronic respiratory disease, such as chronic obstructive pulmonary disease or chronic asthma, must avoid contact with individuals who may have infections, to help minimize situations that would exacerbate the original problem. Respiratory irritants must be avoided.
- Midodrine hydrochloride use requires careful blood pressure monitoring, so patient education about supine blood pressures and regular documentation of measured blood pressure values are crucial to the effective use of the drug.
- Inhaled forms of beta₂-agonists are used for their bronchodilating action and must be taken only as prescribed, with caution to avoid overuse of the drug. Overdosage of these drugs may lead to severe cardiovascular, CNS, and cerebrovascular adverse effects and stimulation.

EXAMINATION REVIEW QUESTIONS

1. The nurse caring for a patient who is receiving beta₁-agonist drug therapy should monitor for which of the following effects?
 - a. Increased heart contractility
 - b. Decreased heart rate
 - c. Bronchoconstriction
 - d. Increased GI tract motility
2. During a teaching session for a patient receiving inhaled salmeterol xinafoate, the nurse emphasizes that the drug is indicated for which condition?
 - a. Rescue treatment of acute bronchospasm
 - b. Prevention of bronchospasm
 - c. Reduction of airway inflammation
 - d. Long-term treatment of sinus congestion
3. For a patient receiving a vasoactive drug such as intravenous dopamine, which action by the nurse is most appropriate?
 - a. Monitor the gravity drip infusion closely and adjust as needed.
 - b. Assess the patient's heart function by checking the radial pulse.
 - c. Assess the intravenous site hourly for possible infiltration.
 - d. Administer the drug by intravenous boluses, according to the patient's blood pressure.
4. A patient is receiving dobutamine for shock and is reporting feeling more "skipping beats" than yesterday. What will the nurse do next?
 - a. Monitor for other signs of a therapeutic response to the drug.
 - b. Titrate the drug to a higher dose to reduce the palpitations.
 - c. Discontinue the dobutamine immediately.
 - d. Assess the patient's vital signs and cardiac rhythm.
5. A patient is receiving a drug that is characterized as having a negative chronotropic effect. The nurse would expect to monitor for which physiological effect?
 - a. Reduced blood pressure
 - b. Decreased heart rate
 - c. Decreased ectopic beats
 - d. Increased force of heart contractions
6. The nurse is monitoring a patient who is receiving an infusion of a beta-adrenergic agonist. Which adverse effects may occur with this infusion? (Select all that apply.)
 - a. Mild tremors
 - b. Bradycardia
 - c. Tachycardia
 - d. Palpitations
 - e. Drowsiness
 - f. Nervousness
7. An order reads, "Dopamine 3 mcg/kg/min IV." The solution available is 400 mg in 250 mL D₅W, and the patient weighs 80 kg (176 pounds). The nurse will set the intravenous infusion pump to run at how many mL/hour?

CRITICAL THINKING ACTIVITIES

1. While making initial morning rounds, the nurse checks the insertion site of a patient's dopamine infusion and finds the area swollen and cool to the touch. What is the nurse's priority action? Describe what the nurse will do following the initial action.
 2. A patient with chronic obstructive pulmonary disease is experiencing an episode of bronchospasm and wants to use his salmeterol xinafoate inhaler. What is the priority action in this situation?
 3. A patient is experiencing a severe anaphylactic reaction after a dose of an antibiotic, and the emergency team is present. The nurse is expecting to give what drug first? Explain your answer.

Adrenergic-Blocking Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Briefly review the functions of the sympathetic nervous system and the specific effects of adrenergic-blocking drugs.
2. List the various drugs categorized as adrenergic antagonists (blockers) or sympatholytics.
3. Discuss the mechanisms of action, therapeutic effects, indications, adverse and toxic effects, cautions,
4. Develop a collaborative plan of care that includes all phases of the nursing process for patients taking adrenergic antagonists.

KEY TERMS

Acrocyanosis Decreased amount of oxygen delivered to the extremities, causing the feet or hands to turn blue. (p. 340)

Adrenergic receptors Specific receptor sites located throughout the body for the endogenous sympathetic neurotransmitters norepinephrine and epinephrine. (p. 339)

Agonists Drugs with a specific receptor affinity that produce a “mimic” response. (p. 339)

Angina Paroxysmal (sudden) chest pain caused by myocardial ischemia. (p. 342)

Antagonists Drugs that bind to specific receptors and inhibit or block the response of the receptors. (p. 339)

Dysrhythmias Irregular heart rhythms; almost always called *arrhythmias* in clinical practice. (p. 342)

Extravasation The leaking of fluid from a blood vessel into the surrounding tissues, as in the case of an infiltrated intravenous infusion. (p. 340)

First-dose phenomenon Severe and sudden drop in blood pressure after the administration of the first dose of an alpha-adrenergic blocker. (p. 340)

Intrinsic sympathomimetic activity The paradoxical action of some beta-blocking drugs (e.g., acebutolol) that mimics the activity of the sympathetic nervous system. (p. 342)

Lipophilicity The chemical attraction of a substance (e.g., drug molecule) to lipid or fat molecules. (p. 343)

Orthostatic hypotension A sudden drop in blood pressure when a person stands up; also referred to as *postural hypotension* or *orthostasis*. (p. 340)

Pheochromocytoma A vascular adrenal gland tumour that is usually benign but secretes epinephrine and norepinephrine and thus often causes central nervous system stimulation and substantial blood pressure elevation. (p. 340)

Raynaud’s disease A narrowing of small arteries that limits the amount of blood circulation to the extremities, causing numbness of the nose, fingers, toes, and ears in response to cold temperatures or stress. (p. 340)

Sympatholytics Drugs that inhibit the postganglionic functioning of the sympathetic nervous system. (p. 339)

Fig. 20.1 Alpha-blocker mechanisms for alpha-adrenergic competitive and noncompetitive blockade.
A, Antagonist; NE, norepinephrine.

OVERVIEW

The autonomic nervous system consists of the parasympathetic and sympathetic nervous systems. The class of drugs discussed in this chapter works primarily on the sympathetic nervous system (SNS). As discussed in Chapter 19, the adrenergic agonist drugs stimulate the SNS. These drugs are called **agonists** because they bind to receptors and cause a response. Adrenergic blockers have the opposite effect and are therefore referred to as **antagonists**. They bind to adrenergic receptors but, in doing so, inhibit or block stimulation by the SNS. They are also referred to as **sympatholytics** because they lyse, or inhibit, SNS stimulation.

Throughout the body, there are receptor sites for the endogenous sympathetic neurotransmitters norepinephrine and epinephrine (see Table 19.1). Such receptors are known as **adrenergic receptors**, and two basic types are found—alpha and beta. There are subtypes of both the alpha- and beta-adrenergic receptors, designated 1 and 2. The α_1 - and α_2 -adrenergic receptors are differentiated by their location on nerves. The α_1 -adrenergic receptors are located on the muscle, other tissue, or organ that the nerve is stimulating (postsynaptic effector cells). The α_2 -adrenergic receptors are located on the actual nerves that stimulate the presynaptic effector cells. The α_2 -receptors are inhibitory in nature. Thus, it is actually the stimulation of

α_2 -receptors that causes inhibitory effects of the SNS. α_2 active drugs (e.g., clonidine) are discussed in Chapter 23. The beta₁-adrenergic receptors are located primarily on the heart; the beta₂-adrenergic receptors are located primarily on the smooth muscles of the bronchioles and blood vessels. It is at these various receptors that adrenergic blockers act. They are classified by the type of adrenergic receptor they block—alpha or beta—or, in a few cases, both. Hence, they are called *alpha blockers*, *beta blockers*, or *alpha-beta blockers*.

Alpha Blockers

The alpha-adrenergic-blocking drugs, or alpha blockers, interrupt stimulation of the SNS at the α_1 -adrenergic receptors. More specifically, alpha blockers work either by direct competition with norepinephrine or by a noncompetitive process. Fig. 20.1 illustrates these two mechanisms. Alpha blockers have a greater affinity for the alpha-adrenergic receptor than norepinephrine does and therefore can chemically displace norepinephrine molecules from the receptor. Selective adrenergic blockade at these receptors leads to effects such as vasodilation, reduced blood pressure (by decreasing total systemic vascular resistance and venous return), miosis (constriction of the pupil), and reduced smooth muscle tone in organs such as the bladder and prostate. Currently available alpha blockers are listed in Table 20.1.

TABLE 20.1 Currently Available Adrenergic-Blocking Drugs

Generic Name	Trade Name	Route
α_1-BLOCKERS		
alfuzosin hydrochloride	Xatral®	PO
doxazosin mesylate	Cardura®	PO
phentolamine mesylate	Rogitine®	IM, IV
prazosin hydrochloride	Minipress®	PO
terazosin hydrochloride	Hytrin®	PO
tamsulosin hydrochloride	Flomax®	PO
β-BLOCKERS		
Nonselective		
carvedilol*		PO
labetalol hydrochloride*	Trandate®	PO, IV
nadolol	Nadol®	PO
pindolol	Visken®	PO
propranolol hydrochloride*	Inderal®	PO, IV
sotalol hydrochloride	Rylosol®	PO
timolol maleate	Timoptic®	PO, IV, ophthalmic
Cardioselective		
acebutolol hydrochloride	Sectral®	PO
atenolol	Tenormin®	PO
bisoprolol fumarate		PO
esmolol hydrochloride	Brevibloc®	IV
nebivolol hydrochloride	Bystolic®	PO
metoprolol tartrate	Lopressor®	PO, IV

IM, Intramuscular; IV, intravenous; PO, oral.

*Has antagonist activity at α_1 , β_1 , and β_2 receptors.

Mechanism of Action and Drug Effects

The alpha blockers such as alfuzosin, doxazosin, prazosin, and terazosin cause both arterial and venous dilation, which reduces systemic vascular resistance and blood pressure. These drugs are used to treat hypertension (see Chapter 23). There are also alpha-adrenergic receptors in the prostate and bladder. By blocking or inhibiting α_1 receptors, these drugs reduce smooth muscle contraction of the bladder neck and the prostatic portion of the urethra. For this reason, alpha blockers are given to patients with benign prostatic hyperplasia (BPH) to decrease resistance to urinary outflow. This reduces urinary obstruction and relieves some of the effects of BPH. Tamsulosin and alfuzosin are used exclusively for treating BPH, whereas terazosin and doxazosin can be used for both hypertension and BPH.

Other alpha blockers can inhibit responses to adrenergic stimulation. These drugs noncompetitively block alpha-adrenergic receptors on smooth muscle and various exocrine glands. Because of this action, they are useful in controlling or preventing hypertension in patients who have a **pheochromocytoma**, a tumour that forms on the adrenal gland on top of the kidney and secretes norepinephrine, causing SNS stimulation. The alpha blockers are also useful in the treatment of patients with increased endogenous alpha-adrenergic agonist activity, which results in vasoconstriction. Three conditions in which

this occurs are **Raynaud's disease**, **acrocyanosis**, and frostbite. Phentolamine in particular can reverse potent vasoconstriction and restore blood flow to ischemic tissue.

Still other alpha blockers are effective at counteracting the effects of injected epinephrine and norepinephrine. They do this by causing systemic vasodilation and reducing systemic resistance by blocking catecholamine-stimulated vasoconstriction. Because of their potent vasodilating properties and their fast onset of action, they are used to prevent skin necrosis and sloughing after the **extravasation** (infiltration) of vasopressors such as norepinephrine or epinephrine, as well as inotropic agents such as dobutamine. When these drugs extravasate (leak out of the blood vessel into the surrounding tissue), they cause vasoconstriction and ultimately tissue death, or necrosis. If the vasoconstriction is not reversed quickly, an entire limb can be lost.

Contraindications

Contraindications to the use of alpha-blocking drugs include known drug allergy and peripheral vascular disease and may also include liver or kidney disease, coronary artery disease, peptic ulcer, and sepsis.

Adverse Effects

The primary adverse effects of alpha blockers are those related to their effects on the vasculature. **First-dose phenomenon**, which is a severe and sudden drop in blood pressure after the administration of the first dose of an alpha-adrenergic blocker, can cause patients to fall or faint. All patients must be warned about this adverse effect before they take their first dose of an alpha blocker. **Orthostatic hypotension** can occur with any dose of an alpha blocker, and patients must be warned to rise and transfer slowly from a supine position. The primary adverse effects of the alpha blockers are listed by body system in Table 20.2.

Toxicity and Management of Overdose. In an acute oral overdose, consultation with a Poison Control Centre is recommended. The patient's stomach should be emptied, usually by gastric lavage. After this, activated charcoal is administered to bind to the drug and remove it from the stomach and the circulation. With overdoses of both oral and injectable forms, symptomatic and supportive measures are to be instituted as needed. Blood pressure support with the administration of fluids, volume expanders, and vasopressor drugs, and the administration of anticonvulsants such as diazepam for the control of seizures, are examples of such measures.

Interactions

The most severe drug interactions with alpha blockers are those that potentiate the effects of the alpha blockers. The alpha blockers are highly protein bound and compete for binding sites with other drugs that are also highly protein bound (see Chapter 2). Because of the limited sites for binding on proteins and the increased competition for these sites, more free alpha-blocker molecules circulate in the bloodstream. More active drug results in a more pronounced drug effect. Some of the common drugs that interact with alpha blockers and the results of these interactions are listed in Table 20.3.

Dosages

For dosage information on alpha blockers, refer to the table on p. 342.

TABLE 20.2 Alpha Blockers: Adverse Effects

Body System	Adverse Effects
Cardiovascular	Palpitations, orthostatic hypotension, tachycardia, edema, chest pain
Central nervous	Dizziness, headache, anxiety, depression, weakness, numbness, fatigue
Gastrointestinal	Nausea, vomiting, diarrhea, constipation, abdominal pain
Other	Incontinence, dry mouth, pharyngitis

TABLE 20.3 Alpha Blockers: Common Drug Interactions

Drug	Interacting Drug	Mechanism	Result
phentolamine	β -blockers, alcohol, erectile dysfunction drugs	Additive effects	Profound hypotension
	epinephrine	Antagonism	Reduced phentolamine effects
tamsulosin	warfarin	Competition for plasma protein-binding sites	Risk of bleeding
	antihypertensives, erectile dysfunction drugs, alcohol	Additive effects	Risk of hypotension

DRUG PROFILES

The alpha blockers are commonly used to treat hypertension or BPH. They include phentolamine, terazosin, alfuzosin, tamsulosin, and prazosin. Prazosin is discussed in [Chapter 23](#).

phentolamine mesylate

Phentolamine mesylate (Rogitine®) is an alpha blocker that reduces systemic vascular resistance and is sometimes used to treat hypertension. It is used to treat the high blood pressure caused by pheochromocytoma and also in the diagnosis of this catecholamine-secreting tumour. To help establish a diagnosis of pheochromocytoma, a single intravenous dose of phentolamine is given to the patient with hypertension. If blood pressure falls rapidly, it is highly likely that the patient has a pheochromocytoma. Phentolamine is available only as an intravenous preparation. It is most commonly used to treat the extravasation of vasoconstricting intravenous drugs such as norepinephrine, epinephrine, dobutamine, and dopamine, which when given intravenously can leak out of the vein, especially if the intravenous tube is not correctly positioned. If such a drug is allowed to extravasate into the surrounding tissue, the result is intense vasoconstriction, decreased blood flow, necrosis, and potential loss of the limb. Phentolamine 5 to 15 mg in 10 mL of normal saline solution is administered into the interstitial catheter prior to removal to direct phentolamine into the area of extravasation as soon as possible. This action causes alpha-adrenergic receptor blockade and vasodilation, which in turn increases blood flow to the ischemic tissue and prevents permanent damage. The use of the drug may be effective up to 12 hours post extravasation of the vasoconstrictor. Its use is contraindicated in patients who have shown a hypersensitivity to it, those who have experienced a myocardial infarction, and those with coronary artery disease. Adverse effects include tachycardia, dizziness, gastrointestinal upset, and others listed in [Table 20.2](#). Drugs with which phentolamine interacts include alcohol (a disulfiram-like reaction; see [Chapter 18](#)) and erectile dysfunction medications such as sildenafil citrate (causing additive

hypotensive effects; see [Chapter 36](#)). Epinephrine and ephedrine can counteract the desired effects of phentolamine. Phentolamine is also available for intraoral submucosal injection (Oraverse®) for reversal of soft tissue anaesthesia. The recommended dosages are given in the table below.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Immediate	Unknown	19 min	10–30 min
Oral Inj	Unknown	20 min	2–3 hr	30–45 min

tamsulosin hydrochloride

Tamsulosin hydrochloride (Flomax®) is an alpha blocker used primarily to treat BPH and is exclusively indicated for male patients. A similar drug with the same indication is alfuzosin. These drugs block alpha-adrenergic receptors on smooth muscle within the prostate and bladder. This blockage results in relaxation of the smooth muscle fibres and improved urinary flow. Terazosin and doxazosin mesylate are used to treat BPH as well as hypertension. Contraindications to tamsulosin hydrochloride include known drug allergy and concurrent use of erectile dysfunction drugs such as sildenafil citrate. Adverse effects include headache, abnormal ejaculation, rhinitis, and others listed in [Table 20.2](#). Interacting drugs include other alpha blockers, calcium channel blockers, and erectile dysfunction drugs (which cause additive hypotensive effects); drugs that induce or inhibit liver enzymes may reduce or enhance the effects of tamsulosin hydrochloride, respectively. It is available only for oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Unknown	4–7 hr	15 hr	Unknown

Dosages

Selected Alpha-Adrenergic-Blocking Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications
 phentolamine mesylate (Rogitine)	α -blocker	<i>Adults</i> IV: 1–5 mg bolus; 0.1–2 mg/min infusion <i>Adults</i> 5–10 mg diluted in 10 mL NS injected into extravasation site within 12 hr <i>Children</i> 0.1–0.2 mg/kg into extravasation site	Hypertensive episodes with pheochromocytoma α -adrenergic drug extravasation
tamsulosin hydrochloride (Flomax)	α_1 -blocker	<i>Adults</i> PO: 0.4 mg once daily	Benign prostatic hypertrophy

IV, Intravenous; NS, normal saline; PO, oral.

Beta Blockers

Mechanism of Action and Drug Effects

The beta-adrenergic-blocking drugs (beta blockers) block SNS stimulation of the beta-adrenergic receptors by competing with norepinephrine and epinephrine. The beta blockers can be either selective or nonselective, depending on the type of beta-adrenergic receptors they antagonize. As mentioned earlier, β_1 -adrenergic receptors are located primarily in the heart. Beta blockers that are selective for these receptors are called *cardioselective beta blockers*, or *β_1 -blocking drugs*. Other beta blockers block both β_1 - and β_2 -adrenergic receptors and are referred to as *non-selective beta blockers*. β_2 receptors are located primarily on the smooth muscles of the bronchioles and blood vessels. In addition, beta blockers can be further categorized according to whether they do or do not have **intrinsic sympathomimetic activity**. Drugs with intrinsic sympathomimetic activity (acebutolol, pin-dolol) not only block beta-adrenergic receptors but also partially stimulate them. This was initially believed to be an advantageous characteristic, but clinical experience has not borne this belief out. Two beta blockers, carvedilol and labetalol, also have an alpha-receptor blocking activity, especially at higher doses. [Table 20.1](#) lists currently available beta blockers.

Cardioselective β_1 blockers block the β_1 receptors on the surface of the heart. This reduces myocardial stimulation, which in turn reduces heart rate, slows conduction through the atrioventricular (AV) node, prolongs sinoatrial (SA) node recovery, and decreases myocardial oxygen demand by decreasing myocardial contractile force (contractility). Nonselective beta blockers have not only these cardiac effects, but they also block β_2 receptors on the smooth muscle of the bronchioles and blood vessels as well.

Smooth muscle surrounds the airways, or bronchioles, in the lungs. When the β_2 receptors in the bronchioles are blocked, the result is smooth muscle contraction and narrowing of the airways. This may lead to shortness of breath. In addition, the smooth muscle that surrounds blood vessels can cause dilation or constriction, depending on whether the β_1 or β_2 receptors are stimulated. When β_2 stimulation is blocked, the muscles are then stimulated by unopposed sympathetic activity at the β_1 receptors, which causes them to contract. This contraction causes increased systemic vascular resistance.

Furthermore, catecholamines promote glycogenolysis, the production of glucose from glycogen, and mobilize glucose in response to hypoglycemia. Nonselective beta blockers impair this process and impede the secretion of insulin from the pancreas, which causes elevation of blood glucose levels.

Finally, beta blockers can cause the release of free fatty acids from adipose tissue. This may result in moderately elevated blood levels of triglycerides and reduced levels of high-density lipoprotein (HDL).

Indications

Indications for beta blockers include **angina**, myocardial infarction, cardiac dysrhythmias, hypertension, and heart failure. Beta blockers possess anti-ischemic as well as antiatherogenic and antidysrhythmic properties.

Beta blockers work by decreasing the demand for myocardial energy and oxygen consumption, which helps to shift the supply-and-demand ratio to the supply side and allows more oxygen to reach the heart muscle. This in turn helps relieve pain in the heart muscle caused by the lack of oxygen.

Beta blockers are also considered to be cardioprotective because they inhibit stimulation by the circulating catecholamines. Myocardial infarction causes catecholamines to be released. Unopposed stimulation by catecholamines would further increase the heart rate and the contractile force, thereby increasing myocardial oxygen demand. When a beta blocker occupies myocardial β_1 receptors, circulating catecholamine molecules are prevented from binding to the receptors. Thus, beta blockers protect the heart from being stimulated by catecholamines. Because of this characteristic, beta blockers are commonly given to patients after they have experienced a myocardial infarction.

Beta blockers also have a profound effect on the conduction system of the heart. The AV node normally receives impulse stimulation from the SA node and slows it down so that the ventricles have time to fill before they are stimulated to contract. Conduction in the SA node, which spontaneously depolarizes at the most frequent rate, is slowed by beta blockers, which results in a decreased heart rate. Beta blockers also slow conduction through the AV node. These effects on the conduction system of the heart make the drugs useful in the treatment of various types of irregular heartbeat rhythms called **dysrhythmias** (see Chapter 26).

Beta blockers are useful in treating hypertension because of their ability to reduce SNS stimulation of the heart, including reducing heart rate and the force of myocardial contraction (systole). Traditionally, beta blockers were thought to worsen heart failure. However, recent studies have shown the benefit of using beta blockers. Certain beta blockers such as carvedilol and metoprolol have produced the best results to date. The form of heart failure that includes a component of diastolic dysfunction responds favourably to beta blockers.

Because of their **lipophilicity** (attraction to lipid or fat), some beta blockers (e.g., propranolol) can easily gain entry into the central nervous system and are used for the prophylaxis of migraine headaches rather than for acute attacks. In addition, the topical application of timolol maleate to the eye has been effective in treating ocular disorders such as glaucoma (see [Chapter 57](#)).

Contraindications

Contraindications of beta blockers include known drug allergies and may include acute decompensated heart failure (i.e., an acute exacerbation), cardiogenic shock, heart block or bradycardia, pregnancy, severe pulmonary disease, and Raynaud's disease.

Adverse Effects

The adverse effects of beta blockers are primarily extensions of their pharmacological activity. Most effects are mild and diminish with time. Some of the most serious undesirable effects can be caused by acute withdrawal of the drug. For example, sudden withdrawal may exacerbate underlying angina and precipitate a myocardial infarction or cause rebound hypertension.

Beta₂ receptors normally induce glucose production by stimulating both hepatic glycogen breakdown (glycogenolysis) and pancreatic release of glucagon and by delivering that glucose to the system. When this process is blocked, low blood sugar may occur. Therefore, blockage of beta₂ receptors can cause hypoglycemia. Beta blockers also delay recovery from hypoglycemia in patients with type 1 diabetes (but rarely in those with type 2). In addition, the nonselective beta blockers can interfere with the normal responses to hypoglycemia, such as tremor, tachycardia, and nervousness, in essence masking the signs and symptoms of hypoglycemia. Conversely, nonselective beta blockers such as metoprolol and atenolol are thought to contribute to the development of hyperglycemia by impairing the release of insulin from the pancreatic beta cell ([Fonseca, 2010](#)). Therefore, beta blockers can result in either hypoglycemia or hyperglycemia, depending on the physiological effect. It is theorized that the lipoprotein effects of beta blockers may be from unopposed alpha-adrenergic stimulation, which leads to reduced peripheral lipoprotein lipase activity and thus reduced catabolism of very low-density lipoproteins and triglycerides. Cardioselective beta blockers such as carvedilol, labetalol, and nebivolol have a more favourable effect on glucose and cholesterol control. Lower doses have little to no effect on lipoprotein parameters ([Fonseca, 2010](#)).

Adverse effects induced by beta blockers are listed by body system in [Table 20.4](#).

Toxicity and Management of Overdose. For overdoses of both oral and injectable dosage forms, treatment consists primarily of symptomatic and supportive care. Consultation with a Poison

TABLE 20.4 Beta Blockers: Common Adverse Effects

Body System	Adverse Effects
Cardiovascular	Atrioventricular block, bradycardia, heart failure
Central nervous	Dizziness, fatigue, depression, drowsiness, unusual dreams
Gastrointestinal	Nausea, vomiting, constipation, diarrhea
Hematologic	Agranulocytosis, thrombocytopenia
Metabolic	Hyperglycemia or hypoglycemia, dyslipidemia
Other	Erectile dysfunction, alopecia, bronchospasm, wheezing, dry mouth

TABLE 20.5 Beta Blockers: Drug Interactions

Drug	Mechanism	Result
Antacids (aluminum hydroxide type)	Decrease absorption	Decreased β -blocker activity
Antimuscarinics, anticholinergics	Antagonism	Reduced β -blocker effects
Diuretics, cardiovascular drugs, alcohol	Additive	Additive hypotensive effects
Neuromuscular blocking drugs	Additive	Prolonged neuromuscular blockade
Oral antihyperglycemic drugs	Mask effects of hypoglycemia	Delayed recovery from hypoglycemia

Control Centre is recommended. For oral overdose, the stomach should be emptied immediately by induction of emesis or by gastric lavage. Atropine sulphate may be given for the management of bradycardia. If bradycardia persists, norepinephrine or dopamine may be administered. If bradycardia or symptomatic heart failure persists, placement of a transvenous heart pacemaker may be considered. For the treatment of severe hypotension, vasopressors are titrated until the desired blood pressure and heart rate are achieved. Intravenously administered diazepam may be useful for the treatment of seizures. Most beta blockers are dialyzable; therefore, hemodialysis may be useful in enhancing elimination in the event of a severe overdose.

Interactions

Most of the drug interactions with beta blockers result from either the additive effects of coadministered medications with similar mechanisms of action or the antagonistic effects of various drugs. Nonselective beta blockers may mask the tachycardia from hypoglycemia caused by insulin and sulfonylureas, and the hypoglycemic effect of insulin and sulfonylureas may be enhanced (see [Chapter 33](#)). Some of the common drugs that interact with beta blockers and the resulting effects are given in [Table 20.5](#).

Dosages

For dosage information on selected beta blockers, refer to the table on p. 345.

DRUG PROFILES

The numerous beta blockers that are currently available are listed in Table 20.1. Several beta blockers are profiled in the following sections. Contraindications, adverse reactions, and drug interactions are comparable for these drugs and are listed previously (see Table 20.4 and Table 20.5).

atenolol

Atenolol (Tenormin®) is a cardioselective beta blocker that is commonly used to prevent future myocardial infarctions in patients who have previously had one. It is also used in the treatment of hypertension and angina and in the management of thyrotoxicosis to help block the symptoms of excessive thyroid activity. Atenolol is available for oral use. Recommended dosages are given in the table on p. 345.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1 hr	2–4 hr	6–7 hr	24 hr

carvedilol

Carvedilol has many effects, including acting as a nonselective beta blocker, an α_1 blocker, a calcium channel blocker (at high dosages), and possibly an antioxidant. Its action on beta receptors is 10 times stronger than that on α_1 receptors. It is used primarily in the treatment of heart failure, but it is also beneficial in the treatment of hypertension and angina. It has been shown to slow the progression of heart failure and to decrease the frequency of hospitalization in patients with mild to moderate (class II or III) heart failure. Carvedilol is most commonly added to digoxin, furosemide, and angiotensin-converting enzyme inhibitors when used to treat heart failure. Carvedilol is available for oral use. Recommended dosages are given in the Dosages table on p. 345.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	20–120 min	1–4 hr	6–8 hr	8–24 hr

esmolol hydrochloride

Esmolol hydrochloride (Brevibloc®) is a strong, short-acting β_1 blocker. It is used primarily in acute situations to provide rapid temporary control of the ventricular rate in patients with supraventricular tachydysrhythmias. Because of its very short half-life, it is given only as an intravenous infusion and is titrated to achieve the serum levels that control the patient's symptoms. Recommended dosages are given in the table on p. 345.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	2–10 min	6 min	9 min	15–20 min

labetalol hydrochloride

Labetalol hydrochloride (Trandate®) is unusual in that it can block both alpha and beta receptors. It is used in the treatment of severe hypertension and in hypertensive emergencies to quickly lower blood pressure before permanent damage occurs. Labetalol is available for oral and parenteral use. Recommended dosages are given in the table on the next page.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	2–5 min	5–15 min	5.5 hrs	2–4 hr
PO	20–120 min	1–4 hr	6–8 hr	8–24 hr

metoprolol tartrate

Metoprolol tartrate (Lopressor®) is a β_1 blocker that has become a favourite of cardiologists for use in patients after myocardial infarction. Recent studies of metoprolol have shown increased survival in patients given the drug after they have experienced a myocardial infarction. Metoprolol is available for oral and parenteral use. Recommended dosages are given in the table on the next page.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	1 min	20 min	3–8 hr	5–8 hr
PO	1 hr	2–4 hr	3–8 hr	10–20 hr

propranolol hydrochloride

Propranolol hydrochloride (Inderal®) is the prototypical nonselective β_1 - and β_2 -receptor-blocking drug. It was one of the first beta blockers to be used. Lengthy experience with the use of propranolol has revealed its many uses. In addition to the indications mentioned for metoprolol, propranolol has also been used in the treatment of the tachydysrhythmias associated with cardiac glycoside intoxication and for the treatment of hypertrophic subaortic stenosis, pheochromocytoma, thyrotoxicosis, migraine headache, essential tremor, and many other conditions. The same contraindications that apply to the cardioselective beta blockers discussed earlier apply to propranolol as well. Its use is contraindicated in patients with bronchial asthma. Propranolol is available for oral and parenteral use. Recommended dosages are given in the table on p. 345.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	2 min	1–4 hr	3–5 hr 3–5 hr; long-acting agent	3–6 hr
PO	1–2 hr	1–4 hr; long-acting agent 6 hr	8–10 hr	6–12 hr

Dosages

Selected Beta-Adrenergic-Blocking Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications
 atenolol (Tenormin)	β_1 -blocker	<i>Adults</i> PO: 50–200 mg/day once daily or divided bid	Hypertension, angina pectoris
carvedilol	α - and β -blocker	<i>Adults</i> PO: 3.125 mg bid; may double dose every 2 wk to highest tolerated dose, max 50 mg/day	Heart failure
 esmolol hydrochloride (Brevibloc)	β_1 -blocker	<i>Adults</i> IV: Loading dose, 0.5 mg/kg/min over 1 min, followed by 4 min maintenance of 0.05 mg/kg/min and evaluate	Supraventricular tachydysrhythmias
labetalol hydrochloride (Trandate)	α_1 - and β -blocker	<i>Adults</i> PO: 200–1200 mg/day divided bid IV: 10–20 mg over 2 min with additional doses of 40 mg at 10-min intervals until desired effect to max 300 mg; maintenance infusion of 2 mg/min initially and titrated to response	Hypertension Severe hypertension
 metoprolol tartrate (Lopressor)	β_1 -blocker	<i>Adults</i> PO: 100–400 mg/day divided bid SR tabs: 100–200 mg/day a.m. IV/PO: 3 bolus injections of 5 mg at 2-min intervals followed in 15 min by 50 mg PO q6h for 48 hr; thereafter 100 mg PO bid	Hypertension angina pectoris, late myocardial infarction Early myocardial infarction
 propranolol hydrochloride (Inderal LA)	β -blocker	<i>Adults</i> PO: 80–320 mg/day divided tid–qid PO: 10–30 mg tid–qid before meals and at bedtime PO: 80–160 mg/day divided	Angina pectoris, hypertension Dysrhythmias Migraine prophylaxis
sotalol hydrochloride (Rylosol)	β -blocker (potassium blockage)	<i>Adults</i> PO: 160–320 mg/day divided BID	Life-threatening ventricular dysrhythmias

IV, Intravenous; PO, oral; SR, sustained release.

sotalol hydrochloride

Sotalol hydrochloride (Rylosol®) is a nonselective beta blocker that has potent antidysrhythmic properties. It is commonly used for the management of difficult-to-treat dysrhythmias. Often, these dysrhythmias are life-threatening ventricular dysrhythmias such as sustained ventricular tachycardia. Sotalol has properties characteristic of both a class II and class III antidysrhythmic drug (see Chapter 26). Because it is a nonselective beta blocker, it causes some of the unwanted adverse effects typical of these drugs (e.g., hypotension) and dysrhythmias. It is used in select patients due to its potentially serious adverse effects. Sotalol is available only for oral use. Recommended dosages are given in the table above.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1–2 hr	2.5–4 hr	12 hr	8–16 hr

NURSING PROCESS

ASSESSMENT

Adrenergic-blocking drugs, or sympatholytics, produce a variety of effects on the patient, depending on the type of receptor(s) blocked. Because of the impact of these drugs on the cardiac and respiratory systems, their use requires careful assessment to minimize adverse effects and maximize therapeutic effects. Understanding the basic anatomy and physiology of adrenergic receptors and their subsequent actions if stimulated or blocked is critical to carrying out assessment and other aspects of the nursing process and drug therapy. If an adrenergic-blocking drug is nonselective, it blocks both alpha and beta (β_1 and β_2) receptors. Alpha-receptor blocking affects blood vessels, whereas β_1 -receptor blocking affects heart rate, and β_2 blocking affects bronchial smooth muscle. Therefore, a nonselective adrenergic blocker will have the following actions: (1) alpha blocking leading to blockade of the sympathetic stimulation of blood vessels, resulting in vasodilation and a subsequent decrease in blood pressure; (2) β_1 blocking leading to

blockade of the sympathetic effects on heart rate, contractility, and conduction with resulting bradycardia, negative inotropic effects (i.e., decrease in contractility), and a decrease in conduction; and (3) beta₂ blocking leading to blockade of the sympathetic effects on bronchial smooth muscle, with the net effect of bronchoconstriction. However, if the drug is only an alpha-, beta₁-, or beta₂-adrenergic blocker, the resulting effect will be related to the specific receptor being blocked (or combination of receptors, depending on the drug). An understanding of these basic physiological concepts is necessary to critical thinking and decision making in the administration of these drugs.

Begin a thorough assessment by gathering information about the patient's allergies and past and present medical conditions. Conducting a system overview and taking a thorough medication history is also part of this process. It is essential to perform a cardiac assessment, including blood pressure and heart rate, prior to the administration of adrenergic-blocking drugs. Specifically, an apical pulse rate must be taken for 1 minute prior to the administration of a beta blocker. Ask the following questions and document the findings: Do you have any allergies to medications or foods? Do you have any history of chronic obstructive pulmonary disease, asthma, other respiratory diseases, hypertension or hypotension, heart disease, bradycardia, heart failure, or cardiac dysrhythmias? This information is crucial because the action and adverse effects of alpha and beta blockers may cause additional health risks to individuals with these problems. For example, alpha blockers may precipitate hypotension; thus, patients with baseline low blood pressure readings need more frequent blood pressure monitoring or they may not tolerate the drug at all. Beta-blocking drugs may precipitate bradycardia, hypotension, heart block, heart failure, bronchoconstriction, or increased airway resistance. Therefore, any pre-existing condition that might be worsened by the concurrent use of any of these medications may then represent a contraindication or caution. More specifically, with beta₁-blocking drugs, patients with pre-existing bradycardia, decreased heart contractility, heart failure, or decreased conduction with heart block cannot take these drugs without exacerbation of these conditions. As another example, patients with a history of asthma, emphysema, bronchitis, or any condition causing increased airway resistance or bronchoconstriction cannot take beta₂-blocking drugs without experiencing further bronchoconstriction and negative effects on their underlying disease condition. Given the actions and adverse effects of the drug, it is also important to assess intake and output, daily weights, breath sounds, and blood glucose levels, especially if the patient has diabetes. For a complete listing of drug interactions, see [Tables 20.3 and 20.5](#).

◆ NURSING DIAGNOSES

- Reduced airway clearance related to the adverse effect of bronchoconstriction caused by beta-adrenergic drugs as well as any underlying restrictive airway conditions
- Diminished peripheral tissue perfusion related to the adverse effects of hypertension and the adverse effects of the adrenergic-blocking drugs (hypotension)
- Inadequate nutrition, less than body requirements, due to nausea and vomiting related to the adverse effects of the adrenergic blockers

- Limited knowledge related to lack of information about the therapeutic regimen, drug adverse effects, drug interactions, and precautions to be taken during drug treatment
- Potential risk for injury related to possible adverse effects of the adrenergic-blocking drugs (e.g., orthostatic hypotension, dizziness, syncope, and numbness and tingling of the fingers and toes)

◆ PLANNING

◆ Goals

- Patient will maintain or regain effective airway clearance and airway exchange.
- Patient will maintain or regain adequate peripheral tissue perfusion.
- Patient will experience improved nutritional status.
- Patient will demonstrate adequate knowledge about use of specific medications, their adverse effects, and the appropriate dosing routine to be followed at home.
- Patient will remain free from injury related to adverse effects of drug therapy.

◆ Outcome Criteria

- Patient states that respirations are performed with ease and in a regular rhythm, without any bronchospasm, wheezing, or difficulty.
- Patient states that blood pressure readings are within normal ranges.
- Patient experiences minimal adverse effects of drug therapy, specifically minimal hypotension.
- Patient states adequate dietary intake of the following: grains, vegetables, fruits, dairy, and protein-rich foods.
- Patient states the rationale for both pharmacological and nonpharmacological treatment of hypertension or other indications for drug therapy.
- Patient states the importance of adhering to the medication therapy regimen and taking medication as prescribed.
- Patient reports effective blood pressure lowering or other desired therapeutic effects of treatment with an adrenergic blocker without risks and complications such as syncope, dizziness, and hypotension.
- Patient demonstrates the correct method of self-measurement of blood pressure using a digital cuff device.
- Patient states the potentially occurring conditions that necessitate informing the health care provider, such as palpitations, chest pain, insomnia, and excessive agitation.
- Patient remains free from injury due to taking medication as prescribed and preventing or managing adverse reactions.
- Patient keeps all follow-up appointments with the health care provider to maintain safe therapy.
- Patient follows instructions to avoid sudden withdrawal of hypertensive drugs to prevent rebound hypertensive crises and experiences minimal complications.

◆ IMPLEMENTATION

Several nursing interventions can maximize the therapeutic effects of adrenergic-blocking drugs and minimize their adverse effects. To help minimize dry mouth, encourage intake

CASE STUDY

Beta Blockers

Frank, a 58-year-old high school music teacher, has been hospitalized after experiencing a myocardial infarction. He is married with two adult children. His physician told him that his myocardial infarction was “mild,” but that Frank must make some lifestyle changes, including exercise and dietary changes. Frank has a history of asthma; he stopped smoking cigarettes 5 years ago and has had no recent problems. His history also includes gallbladder removal at 50 years of age. Frank’s pulse rate has ranged from 78 to 112 beats/min; his blood pressure has

been within normal range, 118/74 to 122/80 mm Hg. He is preparing for discharge and has the following prescriptions:

aspirin, enteric-coated, 81 mg daily, PO

metoprolol 75 mg PO BID

clopidogrel 75 mg daily

ramipril 5 mg BID

atorvastatin 80 mg daily

nitrolingual spray 0.4 mg PO PRN

1. Explain the purpose of the metoprolol order for Frank. After Frank has been home for a week, the home health nurse calls him to check on how he is doing. Frank tells the nurse that he was “about to call the doctor” because he has been feeling more and more short of breath, even though he has been resting at home.
2. What could be causing this problem? What do you expect will happen as a result? Two months later, Frank is in the office for a follow-up visit. He seems upset, even though his blood pressure is within normal range, his cardiac function is stable, and he has had no further breathing problems. He tells the nurse, “I feel exhausted all the time. I do not have any energy. I don’t care what the doctor tells me, I’m going to stop that new pill. I’m having a terrible problem and I know it’s because of that medicine.”
3. What do you suspect is causing Frank to be so upset, and what will be done about it? Will the beta blocker be discontinued today? Explain your answer.

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

of water within any restrictions and frequent rinsing or spraying of the mouth with over-the-counter dental products indicated for dry mouth. Sugarless gum or candy may also be helpful for dry mouth. When adrenergic-blocking medications are given intravenously, this usually takes place in specialty care areas and according to agency protocols. Heart monitoring is usually recommended. Encourage patients taking alpha blockers to change positions slowly and with purpose to prevent or minimize orthostatic hypotension with subsequent dizziness or syncope. Alpha blockers and their indications in the treatment of hypertensive disease or hypertensive crises are discussed further in Chapter 23. Use of the newer alpha blocker tamsulosin hydrochloride in patients with BPH is quite common, and patients taking

this drug need to inform all health care providers—including dentists—that this is part of their medical regimen, especially before any type of surgery. In addition, any activity leading to vasodilation needs to be avoided to prevent orthostatic hypotension with resultant dizziness, lightheadedness, and syncope. This includes alcohol intake; excessive exercise; exposure to hot climates; and use of saunas, hot tubs, and hot showers or baths. When either an alpha blocker or beta blocker is used, count the apical pulse rate for 1 full minute. Measure and document both supine and standing blood pressures. Contact the health care provider immediately if the patient has any problems with dizziness, fainting, or lightheadedness; if the systolic blood pressure is lower than 100 mm Hg; or if the pulse rate is lower than 60 beats per minute. Daily weight measurement is important to monitor the progress of therapy and monitor for the adverse effect of edema. A good rule of thumb is to follow up if the patient shows an increase of 1 kg or more over a 24-hour period or 2.3 kg or more within 1 week. Keeping a daily journal documenting weights, blood pressure readings, pulse rates, adverse effects, and overall feelings of wellness or lack thereof will be important to the monitoring of the therapeutic regimen. Other symptoms to report to the health care provider include muscle weakness, shortness of breath, and collection of fluid in the lower extremities as manifested by weight gain or difficulty in putting on shoes or socks. Patients taking any of the adrenergic-blocking medications must be weaned off the drug slowly because an abrupt discontinuation could lead to rebound hypertension or chest pain. The health care provider will designate a period of time for weaning, generally over a period of 1 to 2 weeks. Understanding basic anatomy and physiology and how receptors work will help guide nursing actions related to these drugs. See Patient Teaching Tips for more specific information.

◆ **EVALUATION**

Therapeutic effects for which to monitor in patients receiving adrenergic-blocking drugs include, but are not limited to, a decrease in blood pressure, pulse rate, and palpitations (in patients with related problems before drug therapy); alleviation of the symptoms of the disorder for which the drug was indicated; a return to normal blood pressure and pulse with lowering of the blood pressure toward 120/80 mm Hg and the pulse toward 60 beats per minute in patients with diagnosed hypertension; and a decrease in chest pain in patients with angina. Also monitor patients for adverse effects associated with these medications, including bradycardia, depression, fatigue, and hypotension. See [Tables 20.2 and 20.4](#) for other potential adverse effects.

PATIENT TEACHING TIPS

- Provide patients with written and verbal information about drug indications, actions, adverse effects, cautions, contraindications, and interactions with other drugs. This information needs to be age-appropriate and tailored to the specific learning needs of the patient.
- Emphasize the need to wear a MedicAlert bracelet or necklace identifying the specific medical diagnosis and provide a list of all medications. The patient needs to understand the importance of carrying this information (in handwritten or electronic form), having it available at all times, and updating

it regularly and whenever there are major changes in the diagnosis or treatment regimen. Recommend to patients that they maintain a record of blood pressure readings by date and time. This information may then be shared with other health care providers.

- Caution patients to take medications exactly as prescribed and to never abruptly discontinue them due to the risk of rebound hypertension. If there is concern about omitted or skipped doses, patients need to contact their health care provider immediately.
- Caffeine and other central nervous system stimulants must be avoided while taking adrenergic-blocking drugs to prevent further irritability of the cardiac and central nervous systems and subsequent negative effects on health status.
- Encourage patients to contact their health care provider upon the occurrence of palpitations, chest pain, confusion, weight gain (1 kg or more in 24 hours or 2.3 kg or more in 1 week), dyspnea, nausea, or vomiting. Other problems to report include swelling in the feet and ankles, shortness of breath, excessive fatigue, dizziness, and syncope.

- The alpha blocker tamsulosin hydrochloride must be taken as directed and with caution in patients with blood pressure problems (e.g., hypotension). The drug must also be used with caution by older adults and while driving or engaging in other activities requiring alertness because the adverse effects of this drug include blurred vision, dizziness, and drowsiness.
- Caution patients to change positions slowly to avoid dizziness and syncope. Excessive exercise, exposure to hot climates, use of a sauna or tanning bed, and alcohol consumption exacerbate vasodilation from the adrenergic-blocking drugs and lead to a greater drop in blood pressure with additional risk of dizziness and syncope.
- Constipation may develop as an adverse effect. Increasing intake of fluids and fibre, as well as increasing exercise, may help to prevent constipation.
- Technology advancements such as applications for smartphones or tablets may assist patients with keeping up-to-date medication lists as well as recording vital signs.

KEY POINTS

- Adrenergic-blocking drugs block the stimulation of the alpha-, beta₁-, or beta₂-adrenergic receptors, with the net result of blocking the effects of either norepinephrine or epinephrine on the receptor. This blocking action leads to a variety of physiological responses, depending on which receptors are blocked. Knowing how these receptors work allows the nurse to understand and predict the expected therapeutic effects of the drugs as well as the expected adverse effects.
- With alpha blockers, the predominant response is vasodilation. This is due to the blocking of the alpha-adrenergic effect of vasoconstriction, which results in blood vessel relaxation.
- Vasodilation of blood vessels with the alpha blockers results in a drop in blood pressure and a reduction in urinary obstruction, which may lead to increased urinary flow rates. Monitor for these effects in patients taking alpha blockers.
- Beta blockers inhibit the stimulation of beta-adrenergic receptors by blocking the effects of the SNS neurotransmitters norepinephrine, epinephrine, and dopamine. Stimulation of beta₁ receptors leads to an *increase* in heart rate, conduction, and contractility. Stimulation of beta₂ receptors leads to an *increase* in bronchial smooth muscle relaxation, or bronchodilation. Blocking of beta₁ receptors leads to a

decrease in heart rate, conduction, and contractility. Blocking of beta₂ receptors leads to a *decrease* in bronchial smooth muscle relaxation, or bronchoconstriction.

- Beta blockers are classified as either selective or nonselective. Selective beta blockers are also called cardioselective beta blockers and block only the beta-adrenergic receptors in the heart that are located on the postsynaptic effector cells (i.e., the cells that nerves stimulate). The beneficial effects of the cardioselective beta blockers include decreased heart rate, reduced cardiac conduction, and decreased myocardial contractility with no bronchoconstriction. These drugs are a good choice for patients with hypertension who also experience bronchospasm associated with asthma or another pulmonary disease.
- Nursing considerations for patients taking alpha and beta blockers include teaching patients that they must weigh themselves daily, avoid sudden changes in position, and increase their intake of fluids and fibre. Weight gain, dizziness, fainting, a decrease in apical heart rate below 60 beats per minute, or a blood pressure of less than 100 mm Hg systolic or less than 60 mm Hg diastolic needs to be reported immediately.

EXAMINATION REVIEW QUESTIONS

1. When a patient has experienced extravasation of a systemic infusion of dopamine, the nurse will inject the alpha blocker phentolamine (Rogitine) into the area of extravasation and expect which effect?
 - a. Vasoconstriction
 - b. Vasodilation
 - c. Analgesia
 - d. Hypotension
2. When administering beta blockers, the nurse will follow which guideline for administration and monitoring?
 - a. The drug may be discontinued at any time.
 - b. Orthostatic hypotension rarely occurs with this drug.
 - c. Tapering off the medication is necessary to prevent rebound hypertension.
 - d. The patient needs to stop taking the medication at once upon a 1.5- to 2-kg weight gain in a week.

3. The nurse providing teaching for a patient who has a new prescription for beta₁ blockers will anticipate that these drugs may result in which effect?
 - a. Tachycardia
 - b. Tachypnea
 - c. Bradycardia
 - d. Bradypnea
4. A patient who has recently had a myocardial infarction has started therapy with a beta blocker. The nurse explains that the main purpose of the beta blocker for this patient is to:
 - a. Cause vasodilation of the coronary arteries
 - b. Prevent hypertension
 - c. Increase conduction through the SA node
 - d. Protect the heart from circulating catecholamines
5. Before initiating therapy with a nonselective beta blocker, the nurse will assess the patient for a history of which condition?
 - a. Hypertension
 - b. Liver disease
 - c. Pancreatitis
 - d. Asthma
6. A patient is taking an alpha blocker as treatment for benign prostatic hyperplasia. The nurse will monitor for which potential drug effects? (Select all that apply.)
 - a. Orthostatic hypotension
 - b. Increased blood pressure
 - c. Increased urine flow
 - d. Headaches
 - e. Bradycardia
7. A child in the pediatric intensive care unit has been receiving a dopamine infusion. This morning while on rounds, the nurse noted that the intravenous infusion has infiltrated. After stopping the infusion, the nurse prepares to administer phentolamine (Regitine). The ordered dose is 0.2 mg/kg, to be injected into the area of extravasation. The child weighs 39 lb. How many milligrams will the nurse administer? (Round to tenths.)
8. The nurse is reviewing the mechanism of action of alpha-adrenergic drugs. Adrenergic blockade at the alpha receptors leads to which effects? (Select all that apply.)
 - a. Miosis
 - b. Vasodilation
 - c. Vasoconstriction
 - d. Bradycardia
 - e. Reduced blood pressure

CRITICAL THINKING ACTIVITIES

1. A 46-year-old woman has been prescribed labetalol (Trandate) for the control of tachycardia and hypertension. What is the nurse's priority in responding when the patient states, "Well, if it doesn't work after a month or two, I'll just quit taking it!"?
 2. You are reviewing orders and find one for propranolol. When going to the automated drug-dispensing machine to retrieve the drug, the nurse finds propranolol (Inderal LA) in the drawer. Should you give the drug? What is your priority action at this time?
 3. A 73-year-old man is given a new prescription for tamsulosin hydrochloride (Flomax) for treatment of BPH. He lives at home with his wife and uses a cane to help him walk because of the effects of a stroke he had 5 years ago. During the patient education session, the nurse should emphasize which issue of highest priority?

Cholinergic Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Briefly review the functions of the autonomic nervous system and the impact of the parasympathetic division.
2. List the various drugs classified as cholinergic agonists (also called *parasympathomimetics*).
3. Discuss the mechanisms of action, therapeutic effects, indications, adverse and toxic effects, drug interactions, cautions, contraindications, dosages, routes of administration, and any antidotal management for the various cholinergic agonists (or parasympathomimetics).
4. Develop a collaborative plan of care that includes all phases of the nursing process for patients taking cholinergic agonists.

KEY TERMS

Acetylcholine (ACh) The neurotransmitter responsible for transmission of nerve impulses to effector cells in the parasympathetic nervous system. (p. 350)

Acetylcholinesterase (AChE) The enzyme responsible for the breakdown of acetylcholine (also referred to simply as *cholinesterase*). (p. 351)

Alzheimer's disease A disease of the brain characterized by progressive mental deterioration manifested by confusion, disorientation, and loss of memory, ability to calculate, and visual-spatial orientation. (p. 352)

Atony A lack of normal muscle tone. (p. 352)

Cholinergic crisis Severe muscle weakness and respiratory paralysis due to excessive acetylcholine; often seen in patients with myasthenia gravis, as an adverse effect of drugs used to treat the disorder. (p. 353)

Cholinergic receptor A nerve receptor that is stimulated by acetylcholine. (p. 350)

Miosis Contraction of the pupil. (p. 352)

Muscarinic receptors Cholinergic receptors located postsynaptically in the effector organs, such as smooth muscle, heart muscle, and glands supplied by parasympathetic fibres. (p. 351)

Nicotinic receptors Cholinergic receptors located in the ganglia (where presynaptic and postsynaptic nerve fibres meet) of both the parasympathetic nervous system and the sympathetic nervous system, so named because they can be stimulated by the alkaloid nicotine. (p. 350)

Parasympathomimetics Drugs that mimic the parasympathetic nervous system; also referred to as *cholinergic agonist drugs*. (p. 353)

DRUG PROFILES

bethanechol (bethanechol chloride)*, p. 353

donepezil (donepezil hydrochloride)*, p. 354

memantine (memantine hydrochloride)*, p. 354

physostigmine (physostigmine salicylate)*, p. 354

Key drug

* Full generic name is given in parentheses. For the purposes of this text, the more common, shortened name is used.

OVERVIEW

Cholinergics, *cholinergic agonists*, and *parasympathomimetics* are terms referring to the class of drugs that stimulate the parasympathetic nervous system.

PARASYMPATHETIC NERVOUS SYSTEM

The parasympathetic nervous system is the branch of the autonomic nervous system with nerve functions generally opposite to those of the sympathetic nervous system (Figure 19-1 and Figure 21.1). The parasympathetic nervous system controls homeostasis and the body at rest. It restores the body to a state of calm (e.g., slows heart rate, relaxes smooth muscle, constricts bronchioles, constricts pupils). **Acetylcholine (ACh)** is the neurotransmitter responsible for the transmission of nerve impulses to effector cells in the parasympathetic nervous system and is essential for processing memory and learning. A **cholinergic receptor** is a receptor that binds the ACh and mediates its actions. There are two types of cholinergic receptors, as determined by their location and their action. **Nicotinic receptors** are located in the ganglia of both the parasympathetic

Fig. 21.1 The parasympathetic and sympathetic nervous systems and their relationships to one another. ACh, Acetylcholine; NE, norepinephrine.

Fig. 21.2 The sympathetic, parasympathetic, and somatic nervous systems. Note the location of the nicotinic and muscarinic receptors within the parasympathetic nervous system.

and sympathetic nervous systems. They are called *nicotinic* because they can be stimulated by nicotine. The other type of cholinergic receptor is the muscarinic receptor. **Muscarinic receptors** are located postsynaptically in the effector organs (i.e., smooth muscle, heart muscle, and glands) supplied by the parasympathetic fibres. They are called *muscarinic* because they are stimulated by the alkaloid muscarine, a substance isolated from mushrooms. [Figure 21.2](#) shows how the nicotinic and muscarinic receptors are arranged in the parasympathetic nervous system.

BOX 21.1 Cholinergic Drugs

Direct-Acting Drugs

bethanechol chloride (Duvoid)
carbachol (Miostat Ophthalmic)
pilocarpine hydrochloride (Akarpine®, Salagen®, Diocarpine® [see [Chapter 57](#)], others)
succinylcholine chloride (Quelcin®; see [Chapter 12](#))

Indirect-Acting Drugs

donepezil hydrochloride (Aricept)
edrophonium chloride (Tensilon®)
galantamine hydrobromide (Reminyl®)
neostigmine methylsulfate (Prostigmin®)
pyridostigmine bromide (Mestinon®)
rivastigmine hydrogen tartrate (Exelon)

CHOLINERGIC DRUGS

Cholinergic drugs mimic the effects of ACh. These drugs can stimulate cholinergic receptors directly or indirectly. Direct-acting cholinergic agonists bind directly to cholinergic receptors and activate them. Indirect-acting cholinergic agonists stimulate the postsynaptic release of ACh at the receptor site; this then allows the ACh to bind to and stimulate the receptor. Indirect-acting cholinergic drugs (also known as *cholinesterase inhibitors*) work by inhibiting the action of **acetylcholinesterase (AChE)**, the enzyme responsible for breaking down ACh. AChE is also referred to as *cholinesterase*. There are two categories of cholinesterase inhibitors: reversible inhibitors and irreversible inhibitors. Reversible cholinesterase inhibitors bind to cholinesterase for a short period of time, whereas irreversible cholinesterase inhibitors have a long duration of activity, and the body must then generate new enzymes to override the effects of the irreversible drugs. [Box 21.1](#) lists the direct- and indirect-acting cholinergics.

Mechanism of Action and Drug Effects

When ACh binds directly to its receptor, stimulation occurs. Once binding takes place on the membranes of an effector cell of the target tissue or organ, the permeability of the cell changes, and calcium and sodium are permitted to flow into the cell. This then depolarizes the cell membrane and stimulates the effector organ.

The effects of direct- and indirect-acting cholinergics are seen when the parasympathetic nervous system is stimulated. There are many mnemonics to aid in remembering these effects. One is to think of the parasympathetic nervous system as the “rest-and-digest” system, in contrast to the “fight-or-flight” sympathetic nervous system.

Cholinergic drugs are used primarily for their effects on the gastrointestinal (GI) tract, bladder, and eye. These drugs stimulate the intestines and bladder, which results in increased gastric secretions, GI motility, and urinary frequency. They also decrease the production of aqueous humor and stimulate constriction of the pupil, termed **miosis**; this action helps to decrease intraocular pressure. In addition, cholinergic drugs cause increased salivation and sweating. Cardiovascular effects include decreased heart rate and vasodilation. Pulmonary effects include constriction of the bronchi of the lungs and narrowing of the airways.

At recommended doses, cholinergic drugs primarily affect the muscarinic receptors, but at high doses, the nicotinic receptors can also be stimulated. The desired effects come from muscarinic receptor stimulation; many of the undesirable adverse effects are due to nicotinic receptor stimulation. The various effects of the cholinergic drugs are listed in [Table 21.1](#), according to the receptors stimulated.

Indications

Direct-Acting Drugs

Direct-acting drugs, such as carbachol and pilocarpine, are used topically to reduce intraocular pressure in patients with glaucoma or in those undergoing ocular surgery (see [Chapter 57](#)). These drugs are poorly absorbed orally, which limits their use to primarily topical application. However, pilocarpine hydrochloride tablets are used to treat excessively dry mouth (xerostomia) resulting from a disorder known as *Sjögren's syndrome* and for salivary gland hypofunction caused by radiotherapy for cancer of the head and neck or in autoimmune diseases such as rheumatoid arthritis or lupus.

The direct-acting cholinergic drug bethanechol (Urecholine®) is administered orally. Bethanechol affects the detrusor muscle of the urinary bladder and also the smooth muscle of the GI tract. It causes increased bladder and GI tract tone and motility, which increases the movement of contents through these areas. It also causes the sphincters in the bladder and the GI tract to relax, allowing them to empty. Bethanechol is also used to treat **atony** of the bladder and GI tract. Atony, when a muscle loses the ability to contract, can occur after a surgical procedure. Another direct-acting cholinergic is succinylcholine, administered intravenously, which is used as a neuromuscular blocker in general anaesthesia (see [Chapter 12](#)) and in critical care areas.

TABLE 21.1 Cholinergic Drugs: Drug Effects

Body Tissue/Organ	RESPONSE TO STIMULATION	
	Muscarinic	Nicotinic
Pulmonary		
Bronchi (lungs)	Increased secretion, constriction	None
Cardiovascular		
Blood vessels	Dilation	Constriction
Heart rate	Slowed	Increased
Blood pressure	Decreased	Increased
Ocular		
Eye	Miosis (pupil constriction), decreased accommodation	Miosis (pupil constriction), decreased accommodation
Gastrointestinal		
Tone	Increased	Increased
Motility	Increased	Increased
Sphincter	Relaxed	None
Genitourinary		
Tone	Increased	Increased
Motility	Increased	Increased
Sphincter	Relaxed	Relaxed
Glandular Secretions		
	Increased intestinal, lacrimal, salivary, and sweat gland secretion	No response
Skeletal Muscle		
	No response	Increased contraction

Indirect-Acting Drugs

Indirect-acting drugs work by increasing ACh concentrations at the receptor sites, which leads to stimulation of the effector cells. Indirect-acting drugs cause skeletal muscle contraction and are used for the diagnosis and treatment of myasthenia gravis. Myasthenia gravis is a rare autoimmune neuromuscular disease characterized by varying degrees of weakness of the skeletal muscles of the body. It is caused by a defect in the function of ACh at the neuromuscular junctions. Indirect-acting drugs' ability to inhibit AChE also makes them useful for the reversal of neuromuscular blockade, produced either by neuromuscular blocking drugs (NMBDs) or by anticholinergic poisoning. For this reason, the indirect-acting drug physostigmine is considered the antidote for anticholinergic poisoning and poisoning by irreversible cholinesterase inhibitors such as organophosphates and carbonates, common classes of insecticides. Physostigmine is a restricted drug in Canada and only available through the Special Access Programme.

Indirect-acting cholinergic drugs are also used to treat **Alzheimer's disease**, a neurological disorder in which patients have decreased levels of ACh. In the treatment of Alzheimer's disease, cholinergic drugs increase concentrations of ACh in

the brain by inhibiting cholinesterase. These drugs do not stop or reverse the progression of Alzheimer's disease; however, the increase in ACh helps to enhance or maintain memory and learning capabilities. There are three cholinesterase inhibitors used to treat Alzheimer's disease: donepezil (Aricept®), galantamine (Reminyl®), and rivastigmine hydrogen tartrate (Exelon®). All are indirect-acting cholinergic drugs. It has been reported that as few as 15 to 30% of patients treated with these drugs actually see benefit. However, indirect-acting drugs may cause small improvements in cognitive, functional, and global effects in those with mild to moderate disease, while marginal effects are seen in patients with severe disease, who are on long-term treatment, and who are of advanced age (Buckley & Salpeter, 2015). The efficacy of cholinesterase inhibitors appears to taper off over time, with minimal benefit seen after 1 year.

The most commonly used of these medications is donepezil. Patient response to these drugs is highly variable. For this reason, a failure to respond to maximally titrated doses of one of these drugs should not necessarily rule out an attempt at therapy with another drug in this same class. In the absence of any recently approved new therapies, the focus of manufacturers of the cholinesterase inhibitors has been on altering the formulations and dosage of current medications. One example is the rivastigmine patch (18mg/10 cm²/24 hr and 27 mg/15 cm²/24 hr) for use across all stages. Memantine (Ebixa®) is also used to treat Alzheimer's disease, but it is not a cholinesterase inhibitor. Memantine monotherapy produces small benefits in cognitive function in moderate to severe dementia, without significant adverse effects. For dosage information for all of these drugs, refer to the table on p. 355.

Contraindications

Contraindications to the use of cholinergic drugs include known drug allergy, GI or genitourinary (GU) tract obstruction, bradycardia, defects in cardiac impulse conduction, hyperthyroidism, epilepsy, hypotension, or chronic obstructive pulmonary disease. Parkinsonism (see Chapter 16) is listed as a precaution to these drugs; however, rivastigmine hydrogen tartrate (Exelon) is used in patients with Parkinson's disease who also have dementia.

Adverse Effects

The primary adverse effects of cholinergic drugs are the consequence of overstimulation of the parasympathetic nervous system. They are extensions of the cholinergic reactions that affect many body functions. The major effects are listed by body system in Table 21.2. The effects on the cardiovascular system are complex and may include syncope, hypotension with reflex tachycardia, hypertension, or bradycardia, depending on whether the muscarinic or nicotinic receptors are stimulated.

Toxicity and Management of Overdose

There is little systemic absorption of topically administered cholinergic drugs and therefore little systemic toxicity. When administered locally in the eye, they can cause temporary ocular changes such as transient blurring and dimming of vision. Systemic toxicity with topically applied cholinergics is seen most

TABLE 21.2 Cholinergic Drugs: Adverse Effects

Body System	Adverse Effects
Cardiovascular	Bradycardia or tachycardia, hypotension or hypertension, conduction abnormalities (atrioventricular block and cardiac arrest), syncope
Central nervous	Headache, dizziness, convulsions, ataxia
Gastrointestinal	Abdominal cramps, increased secretions, nausea, vomiting, diarrhea, weight loss
Respiratory	Increased bronchial secretions, bronchospasms
Other	Lacrimation, sweating, salivation, miosis

commonly when longer-acting drugs are given repeatedly over a long period. This can result in overstimulation of the parasympathetic nervous system and all the attendant responses. Treatment is generally symptomatic and supportive, and the administration of a reversal drug (e.g., atropine sulphate) is rarely required.

The likelihood of toxicity is greater for cholinergics that are given orally or intravenously. The most severe consequence of an overdose of a cholinergic drug is a **cholinergic crisis (also called cholinergic poisoning or cholinergic toxicity)**. Symptoms include circulatory collapse, hypotension, bloody diarrhea, shock, and cardiac arrest. Early signs include abdominal cramps, salivation, flushing of the skin, nausea, and vomiting. Transient syncope, transient complete heart block, dyspnea, and orthostatic hypotension may also occur. These symptoms can be reversed promptly by the administration of atropine sulphate, a cholinergic antagonist. Severe cardiovascular reactions or bronchoconstriction may be alleviated by epinephrine, an adrenergic agonist. One way of remembering the effects of cholinergic poisoning is to use the acronym SLUDGE, which stands for salivation, lacrimation, urinary incontinence, diarrhea, gastrointestinal cramps, and emesis.

Interactions

Anticholinergics (such as atropine sulphate), antihistamines, and sympathomimetics may antagonize cholinergic drugs and lead to a reduced response to them. Other cholinergic drugs may have additive effects.

Dosages

For recommended dosages of the cholinergic drugs, refer to the table on p. 355.

DRUG PROFILES

bethanechol chloride

Bethanechol chloride (Duvoid®) is a direct-acting cholinergic agonist. It is used in the treatment of acute postoperative and postpartum nonobstructive urinary retention and for the management of urinary retention associated with neurogenic atony of the bladder. It has also been used to prevent and treat bladder dysfunction induced by phenothiazine and tricyclic antidepressants (TCAs) (see Chapter 17). In addition, it is used in the treatment of postoperative GI atony and gastric

retention and chronic refractory heartburn, and in diagnostic testing for infantile cystic fibrosis. Bethanechol is available orally. Contraindications include known drug allergy, hyperthyroidism, peptic ulcer, active bronchial asthma, heart disease or coronary artery disease, epilepsy, and Parkinson's disease. The drug is to be avoided in patients in whom the strength or integrity of the GI tract or bladder wall is questionable or who have conditions in which increased muscular activity could prove harmful, such as known or suspected mechanical obstruction.

Adverse effects include syncope, hypotension with reflex tachycardia, headache, seizures, GI upset, and asthmatic attacks. Drugs that interact with bethanechol include AChE inhibitors (i.e., indirect-acting cholinergics), which can enhance the adverse effects of bethanechol. For recommended dosages refer to the table on the next page.

PHARMACOKINETICS				
Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	30–90 min	Less than 30 min	Unknown	1–6 hr

 donepezil hydrochloride

Donepezil hydrochloride (Aricept) is a cholinesterase inhibitor drug that works centrally in the brain to increase levels of ACh by inhibiting AChE. It is used in the treatment of mild to moderate Alzheimer's disease. Similar cholinesterase inhibitors include galantamine hydrobromide and rivastigmine hydrogen tartrate. Rivastigmine hydrogen tartrate is also approved for treating dementia associated with Parkinson's disease. Contraindications for donepezil include known drug allergy. Adverse effects are normally mild and resolve on their own. These effects can often be avoided by careful dose titration. They include GI upset (including ulcer risk due to increased gastric secretions), GI bleeding, seizures, drowsiness, dizziness, insomnia, and muscle cramps. The effects on the cardiovascular system are complex and may include bradycardia, syncope, hypotension with reflex tachycardia, and hypertension. Interacting drugs include anticholinergics (which counteract donepezil effects) and nonsteroidal anti-inflammatory drugs (see Chapter 49). Donepezil is available only for oral use, as both a tablet and a rapid-acting, orally disintegrating tablet. Recommended dosages are given in the table on the next page.

PHARMACOKINETICS				
Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	3 wk	3–4 hr	70 hr	2 wk

memantine hydrochloride

Memantine hydrochloride (Ebixa) is not a cholinergic drug but is included here in the discussion of drugs for Alzheimer's disease. It is classified as an *N*-methyl-D-aspartate (NMDA) receptor

antagonist, owing to its inhibitory activity at the NMDA receptors in the central nervous system. NMDA receptors are glutamate-activated ion channel receptors found throughout the nervous system. The NMDA receptor is significant for its role in controlling synaptic plasticity and memory function (Zhang, Li, Feng, et al., 2016). Stimulation of these receptors is believed to be part of the Alzheimer's disease process. Memantine blocks this stimulation and thereby helps to reduce or arrest the patient's symptoms of cognitive degeneration. As with all other currently available medications for this debilitating illness, the effects of this drug are likely to be temporary but may still afford some improvement in quality of life and general functioning for some patients. Its only current contraindication is known drug allergy. Reported adverse effects are relatively uncommon but include hypotension, headache, GI upset, musculoskeletal pain, dyspnea, ataxia, and fatigue. No clearly defined drug interactions are listed. Memantine is available only for oral use. For the recommended dosage, refer to the table on this page.

PHARMACOKINETICS				
Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Unknown	5 hr	70 hr	Unknown

 pyridostigmine bromide

Pyridostigmine bromide (Mestinon®, Mestinon SR®) is a synthetic quaternary ammonium compound and is structurally similar to other drugs in this class, including edrophonium chloride and neostigmine. All are indirect-acting cholinergic drugs that work to increase ACh by inhibiting AChE. Pyridostigmine bromide has been shown to improve muscle strength and is used to relieve the symptoms of myasthenia gravis; it is the most commonly used drug for the symptomatic treatment of this disease. Edrophonium chloride (Tensilon®) is an indirect-acting cholinergic drug that is commonly used to diagnose myasthenia gravis. It can also be used to differentiate between myasthenia gravis and cholinergic crisis. Edrophonium prevents the breakdown of ACh, which then helps stimulate the muscles. Cholinergic crisis causes the muscles to stop responding to ACh, resulting in flaccid paralysis and respiratory failure. The flaccid paralysis from cholinergic crisis can be distinguished from myasthenia gravis by the use of edrophonium—it worsens the paralysis caused by cholinergic crisis but strengthens the muscle in the case of myasthenia gravis.

Neostigmine and pyridostigmine bromide are also useful for reversing the effects of nondepolarizing NMBDs (see Chapter 12) after surgery. They are also used in the treatment of severe overdoses of TCAs because of the significant anticholinergic effects associated with the TCAs. Neostigmine and pyridostigmine are also used as an antidote after toxic exposure to non-drug anticholinergic agents, including those used in chemical warfare. Contraindications to these drugs include known drug allergy, prior severe cholinergic reactions, asthma, gangrene, hyperthyroidism, cardiovascular disease, and mechanical obstruction of the GI or GU tracts. Interacting drugs include

Dosages

Selected Cholinergic Agonist Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications/Uses
 bethanechol chloride (Duvoid)	Muscarinic (direct-acting)	<i>Adults</i> PO: 10–50 mg tid–qid (usually start with 5–10 mg, repeating hourly until urination, max 50 mg/cycle)	Postoperative and postpartum functional urinary retention; neurogenic atony
 donepezil hydrochloride (Aricept)	Anticholinesterase inhibitor (indirect-acting)	<i>Adults</i> PO: 5–10 mg/day as a single dose	Alzheimer's disease
pyridostigmine bromide (Mestinon)	Anticholinesterase (indirect-acting)	<i>Adults</i> PO: 180–540 mg/day divided bid	Myasthenia gravis; antidote for neuromuscular blocker toxicity

PO, oral.

the anticholinergic drugs, which counteract the therapeutic effects of indirect-acting cholinergic drugs. Pyridostigmine bromide is available in oral form. Recommended dosages are given in the Dosages table below.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	15–45 min	1–2 hr	3–4 hr	Up to 6 hr

NURSING PROCESS

ASSESSMENT

Cholinergic drugs, or **parasympathomimetics**, produce a variety of effects stemming from their ability to stimulate the parasympathetic nervous system and mimic the action of ACh. These effects include a decrease in heart rate, an increase in GI and GU tone through increased contractility of the smooth muscle of the bowel and bladder, an increase in the contractility and tone of bronchial smooth muscle, increased respiratory secretions, and miosis or pupillary constriction. Therefore, if the patient has any pre-existing conditions, such as heart block, or the patient is taking other drugs that mimic the actions of the parasympathetic nervous system, adverse effects or toxicity may increase. Before cholinergic drugs are given, perform a thorough head-to-toe physical assessment and obtain a nursing history and medication history (including prescription drugs, over-the-counter [OTC] drugs, and natural health products). Document drug allergies and past and present medical conditions as well. Identify cautions, contraindications, and drug interactions. Assess and document vital signs, with special attention to baseline blood pressure readings because of the potential for orthostatic hypotension.

Before a drug for Alzheimer's disease such as donepezil or memantine is used, assess the patient for allergies, cautions, contraindications, and drug interactions. Perform a close assessment and documentation of the patient's neurological status, with attention to short- and long-term memory; level of alertness; motor, cognitive, and sensory functioning; any suicidal tendencies or ideations; musculoskeletal intactness; and GI, GU, and cardiovascular functioning. Assess urinary patterns

NATURAL HEALTH PRODUCTS

Ginkgo (*Ginkgo biloba*)

Overview

The dried leaf of the Ginkgo tree contains flavonoids, terpenoids, and organic acids that help ginkgo preparations exert their positive effects as antioxidants and inhibitors of platelet aggregation.

Common Uses

To prevent memory loss, peripheral arterial occlusive disease, vertigo, tinnitus

Adverse Effects

Stomach or intestinal upset, headache, bleeding, allergic skin reaction

Potential Drug Interactions

Aspirin, nonsteroidal anti-inflammatory drugs, warfarin, heparin, anticonvulsants, ticlopidine, clopidogrel, dipyridamole, tricyclic antidepressants

Contraindications

None

so that any problems with urinary retention may be identified. Report any abnormalities or patient-reported discomfort to the prescriber immediately. Presence or absence of family support systems is important to note because of the chronic nature of this illness. Once the patient has begun taking medication, it is critical for the nurse to continue to assess the patient's response to the drug. Note any changes in symptoms within the first 6 weeks of therapy. Journaling by the patient or a family member or caregiver may be helpful to the health care provider when assessing for any positive changes, adverse effects, or lack of improvement. Ginkgo may be used by some patients for additional cognitive benefits when added to conventional treatment with cholinesterase inhibitors, despite controversy over its efficacy in the prevention and treatment of dementia (Canevelli et al., 2014; see Natural Health Products: Ginkgo).

NURSING DIAGNOSES

- Inadequate cardiac output related to the adverse cardiovascular effects of hypotension and bradycardia
 - Reduced knowledge of the therapeutic regimen, adverse effects, drug interactions, and precautions for cholinergic drugs related to lack of experience with drug therapies

- Potential risk for injury related to the possible adverse effects of cholinergic drugs, such as bradycardia and hypotension, with subsequent risk for falls or syncope

◆ PLANNING

◆ Goals

- Patient will maintain normal cardiac output and status due to taking medication exactly as prescribed.
- Patient will demonstrate adequate knowledge about the safe use of prescribed medication, its adverse effects, and appropriate dosing at home.
- Patient will remain free from injury resulting from the adverse effects of the medication.

◆ Outcome Criteria

- Patient, caregiver, or family member states the symptoms to report to a health care provider immediately, such as dizziness, syncope, excess fatigue, and lightheadedness with heart rate changes.
- Patient has blood pressure and pulse rate monitored and recorded daily.
- Patient's blood pressure and pulse rate stay within normal ranges or without significant drops while on medication.

CASE STUDY

Donepezil (Aricept) for Alzheimer's Disease

Elsa is a 72-year-old woman married to Fred, age 73 years. Fred has noticed that Elsa is becoming more forgetful, but he did not worry about it until she got lost while driving home from the grocery store. Fred makes an appointment for Elsa to see their health care provider, Dr. Sapienza. After the examination, Dr. Sapienza tells Fred, in private, that she thinks that Elsa is in the early stages of Alzheimer's disease but will order some tests to rule out other problems. Fred then accompanies Dr. Sapienza while she tells Elsa of the tentative diagnosis. Understandably, Elsa is upset to hear this news.

1. In her discussion with Elsa and Fred, Dr. Sapienza mentions a drug called donepezil (Aricept) that can be used in the early stages of Alzheimer's disease. It may be started after a few diagnostic tests are performed. After Dr. Sapienza leaves the room, Elsa asks the nurse, "What will this drug do for me? Will it stop the Alzheimer's disease?" How will the nurse reply? Several diagnostic tests are performed, including a complete blood count, serum electrolyte levels, vitamin B₁₂ levels, liver and thyroid function tests, and a magnetic resonance imaging scan to rule out other neurological disease. Results of all tests are within normal limits. Dr. Sapienza decides to prescribe donepezil, 5 mg daily, for Elsa.
2. After a week, Fred calls the nurse to ask about giving Elsa an OTC antihistamine for her allergies. "She always needs an allergy pill this time of year." He also says that she needs to take a pain pill for her mild arthritis but is not sure whether to use acetaminophen or ibuprofen. What will the nurse tell Fred?
3. After 6 weeks, Fred brings Elsa back to the doctor's office for a follow-up appointment. Fred privately tells Dr. Sapienza that he is "upset" because he has noticed little improvement. Elsa tells Dr. Sapienza that she feels "fine" and has not noticed any problems. What do you think will be Dr. Sapienza's next order at this time? Is Elsa's response to the donepezil typical? Explain your answer. For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

- Patient, caregiver, or family member states the importance of scheduling and keeping follow-up appointments with health care providers related to the management of the disorder for which medication has been prescribed and the monitoring for therapeutic or adverse effects.
- Patient, caregiver, or family member demonstrates understanding that medications are not curative but are for symptomatic control.
- Patient, caregiver, or family member demonstrates understanding that it may take several weeks for medications (e.g., medications for Alzheimer's disease) to have therapeutic effects.
- Patient, caregiver, or family member demonstrates an understanding about the need to implement safety measures to avoid falls, such as taking time to move slowly from lying or sitting to standing, making purposeful movements, and using compression stockings.

◆ IMPLEMENTATION

Several nursing interventions may help to maximize the therapeutic effects of cholinergic drugs and minimize their adverse effects. If the patient has undergone surgery and cholinergic drugs are indicated, encourage ambulation and increased intake of fluids and fibre, unless contraindicated. Early ambulation helps to increase GI peristalsis and possibly prevent the need for drugs such as bethanechol, which is used to treat decreased or absent peristalsis related to surgery or anaesthesia. However, do not administer these drugs if a mechanical obstruction is suspected. Use of these drugs in such a situation may possibly result in bowel perforation. It is always preferable to use nonpharmacological measures rather than pharmacological regimens to treat the anticipated postoperative problems of decreased peristalsis or urinary retention. For drugs used to treat myasthenia gravis, give the oral medication approximately 30 minutes before meals to allow for onset of action and therapeutic effects (e.g., decreased dysphagia [difficulty swallowing]). Atropine sulphate is the antidote to cholinergic overdose; therefore, this medication needs to be readily available and given per the health care provider's order.

None of the drugs used for Alzheimer's disease provides a cure, but these drugs do improve function and cognition to some degree. It is crucial to discuss with the patient and family, with empathy and compassion, the fact that the disease has no cure. The diagnosis of Alzheimer's disease or other causes of dementia is shocking, at best. Those involved in the care of the patient need to be honest in sharing information with the patient, family, significant others, and caregivers about the fact that any of these drugs are given only for symptomatic improvement and not for a cure. Always follow ethical standards of practice when working with patients, and adhere to the Canadian Nurses Association's *Code of Ethics for Registered Nurses*. This code outlines behaviours required to maintain a high level of professionalism as well as specific actions that demonstrate respect for patients' rights in any patient care situation. However, any sharing of information with the patient, family, significant others, and caregivers must be done with the approval of the health care provider, with good intent, in adherence with any research protocol, and with the goal of being a patient advocate.

When beginning any of these medications, the patient will most likely require continued assistance with activities of daily living and ambulation because the medication may increase dizziness and cause gait imbalances at the initiation of treatment. The patient, family members, and caregivers also need to understand the importance of taking the medication exactly as ordered. It is critical for the patient and family or caregiver to understand correct dosages and exact scheduling of medications in order to achieve the drug's maximum therapeutic effects. In addition, instruct the patient and anyone involved in the patient's daily care about how the medication should be taken (e.g., taking the drug with food to decrease GI upset). Blister packaging of medications may assist patients and caregivers to enhance patients' adherence to their medication schedule. This is especially important for those who are older, have cognitive impairment, or are taking a large number of medications. The patient must be weaned off all drugs over a period of time designated by the health care provider because of the potential for a rapid decline in cognitive functioning. Educate the patient and family or caregiver about the use of the drug, its adverse effects, possible interactions, and potential for harm, and emphasize the importance of *not* withdrawing the medication abruptly. Provide additional resources as needed.

Most of the cholinergic agonists have dose-limiting adverse effects that include severe GI disturbances such as nausea and vomiting. Blood pressure readings and pulse rates need to be taken and recorded before, during, and after initiation of therapy. Maintenance of a journal that records daily doses of drugs, ability of the patient to participate in activities of daily living, motor ability, gait, mental status, cognition, and any adverse effects will provide valuable information to any health care provider or caregiver involved in the patient's day-to-day care.

Dosages of these medications may be changed by the health care provider after about 6 weeks if no therapeutic response occurs. Monitor blood pressure, pulse rate, and electrocardiogram results throughout therapy. Instruct the patient, family, or caregiver to report any heart problems such as decrease in pulse rate (less than 60 beats per minute) or drop in blood pressure. A cholinergic crisis, resulting from overdosage of medication, may be manifested by abdominal cramps, flushing of the skin, and nausea and vomiting (early signs and symptoms),

progressing to circulatory collapse, hypotension, and cardiac arrest. Dissolving forms of the medication donepezil are to be placed on the tongue and allowed to dissolve before the patient drinks fluids or swallows.

In summary, because most of the cholinergic drugs are used to treat patients diagnosed with Alzheimer's disease, monitor the patient's family and other support personnel closely, and be sure that their questions are answered fully and their needs met. Often, family members, significant others, and caregivers have many questions as well as short- and long-term concerns. Preplanning education addressing these concerns is an important part of a holistic approach to patient care and to the meeting of patient needs. Often the best place to begin in terms of education is to prepare answers to the following questions that are often posed: What should we expect for our loved one? What will happen to the person emotionally and physically? What treatments are available and what drugs are deemed safe? What are the common adverse effects of drug therapy, and how can they be minimized? What are appropriate diet, fluid intake, and exercise for our loved one? (See Evidence in Practice box: Exercise and Improved Cognition.) Are there natural health products or OTC drugs that would help with the disease, or should they be avoided? What will we need to do for long-term care or other living situations for our loved one? What are the expected costs of our loved one's care now and in the future? What are the costs of drug therapy? What might other costs be? What kind of help can we all receive emotionally? What about emotional support for our loved one? How can this disease affect intimate relationships? What about durable power of attorney and living wills? Other types of wills? Are these needed right away if we do not have these legal documents already? How do we all go on with our lives when our loved one is changing so drastically? Will life ever be normal again? What about research and clinical trials for treatment regimens? Should we pursue other treatments or do nothing new? What about drugs that are not Health Canada-approved? How long will this process take? What can we expect over time? Alzheimer Society Canada (<http://www.alzheimer.ca>) provides information, resources, support, counselling, and education that can address many of the above questions. An additional resource is the Canadian Geriatrics Society (<http://www.canadiangeriatrics.ca>), which promotes excellence in the medical care of older adult Canadians.

EVIDENCE IN PRACTICE

Exercise and Improved Cognition

Review

As the average age of the population in Canada and elsewhere continues to rise, the number of people worldwide living with Alzheimer's disease is expected to rise from the current 44.4 million to more than 135.5 million by 2050. It has been estimated that if the onset of dementia could be delayed by about 12 months, there would be approximately 9.2 million fewer cases worldwide. Several clinical trials have examined the ability of pharmacological therapies such as cholinesterase inhibitors (e.g., donepezil), and vitamin E to prevent progression to dementia in those at risk for Alzheimer's disease, but outcomes have been largely negative. Many studies have suggested that physical activity may reduce the risk for cognitive decline. This study is one of the first to demonstrate that exercise improves memory recall and brain function (measured by functional magnetic resonance imaging [fMRI]) in older adults experiencing mild cognitive impairment.

Type of Evidence

This study was a randomized, controlled trial consisting of two physically inactive groups of individuals (average age of 78); the study group of 17 participants had mild cognitive impairment while the control group of 18 participants had healthy brain function. Both groups were of similar age, gender, education, and genetic risk and had similar medication use. Both groups participated in a 12-week exercise program consisting of walking on a treadmill at moderate intensity under the supervision of a personal trainer.

Before and after the exercise program, both groups completed memory tests. The first was an fMRI famous-name discrimination task. This memory test requires the participants to identify famous names as their brain activity is measured. The second was a neuropsychological battery. This test, the Rey Auditory

Continued

EVIDENCE IN PRACTICE—cont'd

Exercise and Improved Cognition

Verbal Learning Test, involves having participants recall words read to them from a list over five consecutive attempts, and once more after being distracted with a different list.

Results of Study

The participants with mild cognitive impairment and the control group significantly improved their memory scores from baseline on the Rey Auditory Verbal Learning Test. The participants in both groups significantly increased their cardiorespiratory fitness by 10%.

Link of Evidence to Nursing Practice

An important achievement of this study is its demonstration of the potential benefit of the simple, nonpharmacological intervention of exercise, which is almost universally available, in the prevention of cognitive decline. For these

participants as well as many other patients with physical diseases or mental health disorders, the benefits of exercise go beyond improvement in cognition and include a positive impact on mood, quality of life, and cardiovascular function, as well as a decrease in falls and disability. Although advances are being made in health and technology and people are living longer, there is a need to find alternative therapies, as well as therapies that are nonpharmacological and simple, to prevent and treat diseases such as Alzheimer's disease and other catastrophic brain disorders. Nurses can educate patients and family members on the importance of habitual exercise as well as encourage the provision of consistent medical care, a suitable environment, adequate nutritional intake, and social interaction to help prevent mental and physical deterioration associated with certain disease states. These simple measures are easy to implement and may contribute significantly to the improvement of the individual's well-being in later life.

◆ EVALUATION

Monitor patients for the following therapeutic effects: (1) in patients with myasthenia gravis, a decrease in the signs and symptoms of the disease; (2) in patients experiencing a decrease in GI peristalsis postoperatively, an increase in bowel sounds, the passage of flatus, and the occurrence of bowel movements (all indicating an increase in peristalsis); and (3) in patients who have a hypotonic bladder with urinary retention, micturition (voiding) within approximately 60 minutes of the administration of bethanechol. Also monitor for adverse effects of these medications,

including increased respiratory secretions, bronchospasm, nausea, vomiting, diarrhea, hypotension, bradycardia, and conduction abnormalities. For other adverse effects, refer to [Table 21.2](#).

Therapeutic effects of the drugs used to manage Alzheimer's disease-related dementia or cognitive impairment include a reduction in the symptoms of the disease, but in most cases it takes up to 6 weeks for these effects to become apparent. Varying degrees of improvement in mood and a decrease in confusion usually occur. Adverse effects include nausea, vomiting, dizziness, and others (see individual drug profiles for specific information).

PATIENT TEACHING TIPS

- Instruct patients and caregivers that medications must be taken exactly as ordered and with meals to minimize GI upset. Medications are never to be increased except on the advice of the health care provider. Give specific instructions on what to do if a medication dose has been omitted.
- Establish that intervals between doses of medication need to be timed consistently to optimize therapeutic effects and minimize adverse effects and toxicity.
- Encourage patients, family, significant others, or caregivers to call the health care provider if there is any increased muscle weakness, abdominal cramps, diarrhea, dizziness, ataxia, or difficulty breathing.
- Share information about community resources with patients, caregivers, family, and significant others. Such resources may include, but are not limited to, Meals on Wheels; local, provincial or territorial, and national chapters of Alzheimer Society Canada; adult day programs or alternate care

resources; special prescription services; and respite care or home health care services.

- Signs and symptoms of improvement of myasthenia gravis include a decrease in or absence of ptosis (eyelid drooping) and diplopia (double vision), a decrease in difficulty chewing and swallowing, and an improvement in muscle weakness. If a medication is being taken for myasthenia gravis, the patient needs to take it 30 minutes before meals so that the drug begins to act before the patient chews and swallows. This will help strengthen the muscles required for eating.
- Patients should be informed that sustained-release or extended-release dosage forms must be taken in their entirety and should not be crushed, chewed, or broken in any way.
- Patients need to have a MedicAlert bracelet or necklace or carry a medical alert card at all times—these should include all medical diagnoses and provide access to a list of medications and allergies and outline any special requirements in regard to emergency treatment.

KEY POINTS

- *Cholinergics, cholinergic agonists, and parasympathomimetics* are all appropriate terms for the class of drugs that stimulate the parasympathetic nervous system, which is the branch of the autonomic nervous system that opposes the sympathetic nervous system.
- The primary neurotransmitter of the parasympathetic nervous system is acetylcholine, and there are two types of cholinergic receptors: nicotinic and muscarinic.
- Nursing considerations for the administration of cholinergic drugs include giving the drug as directed and monitoring the patient carefully for the occurrence of bradycardia, hypotension, headache, dizziness, respiratory depression, and bronchospasms. If these signs and symptoms occur in a patient taking cholinergics, contact the health care provider immediately.
- It may take about 6 weeks for a therapeutic response to occur with some of the medications used with Alzheimer's disease.
- Patients taking cholinergics need to change positions slowly to avoid dizziness and fainting that may result from the adverse effect of orthostatic hypotension.

EXAMINATION REVIEW QUESTIONS

1. The nurse is reviewing the use of bethanechol (Duvold) in a patient who is experiencing postoperative urinary retention. Which statement best describes the mechanism of action of bethanechol?
 - a. It causes decreased bladder tone and motility.
 - b. It causes increased bladder tone and motility.
 - c. It increases the sensation of a full bladder.
 - d. It causes the sphincters in the bladder to become tighter.
2. The family of a patient who was recently diagnosed with Alzheimer's disease asks about the new drug prescribed to treat this disease. The patient's wife says, "I'm so excited that there are drugs that can cure this disease! I can't wait for him to start treatment." Which reply from the nurse is most appropriate?
 - a. "The sooner he starts on the medicine, the sooner it can have this effect."
 - b. "These effects won't be seen for a few months."
 - c. "These drugs do not cure Alzheimer's disease. Tell me what you understand about what starting this treatment would mean for your husband."
 - d. "His response to this drug therapy will depend on how far along he is in the disease process."
3. The nurse is giving a dose of bethanechol (Urecholine) to a postoperative patient. The nurse is aware that contraindications to bethanechol include:
 - a. Bladder atony
 - b. Peptic ulcer
 - c. Urinary retention
 - d. Hypothyroidism
4. A patient took an accidental overdose of a cholinergic drug while at home. The patient comes to the emergency department with severe abdominal cramping and bloody diarrhea. The nurse anticipates which drug will be ordered to treat this patient?
 - a. atropine sulphate
 - b. physostigmine
 - c. bethanechol (Duvold)
 - d. phentolamine (Rogitine®)
5. The nurse is reviewing the orders for a newly admitted patient who is to start edrophonium chloride (Tensilon). The nurse understands this drug is ordered for which reason?
 - a. To reduce symptoms and delay the onset of Alzheimer's disease
 - b. To treat the symptoms of myasthenia gravis
 - c. To aid in the diagnosis of myasthenia gravis
 - d. To reverse the effects of nondepolarizing NMJs after surgery
6. When giving intravenous cholinergic drugs, the nurse must watch for symptoms of a cholinergic crisis, such as which of the following? (Select all that apply.)
 - a. Peripheral tingling
 - b. Hypotension
 - c. Dry mouth
 - d. Syncope
 - e. Dyspnea
 - f. Tinnitus
7. A patient who has had an accidental overdose of tricyclic antidepressants is to receive physostigmine, 1.5 mg IM stat. The medication is available in a vial that contains 2 mL, with a concentration of 1 mg/mL. How much medication will the nurse draw up into the syringe for this dose?
8. The nurse is teaching a patient about the possible adverse effects of donepezil (Aricept) for Alzheimer's disease. Which of these are possible adverse effects? (Select all that apply.)
 - a. Constipation
 - b. GI upset
 - c. Drowsiness
 - d. Dizziness
 - e. Blurred vision

CRITICAL THINKING ACTIVITIES

1. An older adult neighbour wants to take ginkgo (*Ginkgo biloba*) because he is worried about “losing his mind.” He asks you if this drug would help him. He has lived alone since being widowed last year and does not have any family members in the area. What is your best answer for this neighbour? Review the Natural Health Products: Ginkgo box in this chapter as well as other sources, if desired.
2. A patient who has been newly diagnosed with myasthenia gravis received a dose of pyridostigmine bromide (Mestinon) in the morning, just before breakfast. She says, “Oh, I know

this won’t cure me, but I’m so glad that this drug makes me feel better. Will it last all day?” What is the priority when the nurse is teaching this patient about pyridostigmine bromide?

3. A patient is admitted to the emergency department after an industrial accident in which he was exposed to a large amount of organophosphate insecticide. The patient is having difficulty breathing. What is the nurse’s priority of action at this time, and what antidote will be prepared?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Cholinergic-Blocking Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Briefly review the functions of the sympathetic nervous system and the specific effects of blocking cholinergic receptors (also referred to as *parasympatholytic effects*).
2. List the drugs classified as cholinergic antagonists or parasympatholytics.
3. Discuss the mechanisms of action, therapeutic effects, indications, adverse and toxic effects, drug interactions, cautions, contraindications, dosages, routes of administration, and any antidotal management for the cholinergic antagonists.
4. Develop a collaborative plan of care that includes all phases of the nursing process for patients taking cholinergic antagonists.

KEY TERMS

Cholinergic-blocking drugs Drugs that block the action of acetylcholine and substances similar to acetylcholine at receptor sites in the brain. (p. 361)

Mydriasis Dilation of the pupil of the eye caused by contraction of the dilator muscle of the iris. (p. 362)

Parasympatholytics Drugs that reduce the activity of the parasympathetic nervous system; also called *anticholinergics*. (p. 361)

DRUG PROFILES

atropine (atropine sulphate)*, p. 364

glycopyrrolate, p. 365

oxybutynin chloride, p. 365

scopolamine (scopolamine hydrobromide)*, p. 365

tolterodine (tolterodine L-tartrate)*, p. 365

Key drug

* Full generic name is given in parentheses. For the purposes of this text, the more common, shortened name is used.

OVERVIEW

The parasympathetic nervous system is the branch of the autonomic nervous system with nerve functions generally opposite those of the sympathetic nervous system (refer to Chapters 19 and 20 for a discussion of the sympathetic nervous system and Chapter 21 for further discussion of the parasympathetic nervous system). For example, the parasympathetic nervous system slows the heart rate, increases intestinal and gland activity, and relaxes sphincter muscles in the gastrointestinal (GI) tract. Acetylcholine is the neurotransmitter responsible for the transmission of nerve impulses to effector cells in the parasympathetic nervous system. A cholinergic receptor is one that binds acetylcholine and mediates its actions. This chapter focuses on cholinergic-blocking drugs,

which inhibit the effects of the parasympathetic nervous system.

Cholinergic-Blocking Drugs

Cholinergic blockers, *anticholinergics*, **parasympatholytics**, and *antimuscarinic drugs* are all terms that refer to the class of drugs that block or inhibit the actions of acetylcholine in the parasympathetic nervous system. These drugs were first discussed in Chapter 16 in relation to treatment of Parkinson's disease.

Cholinergic blockers have many therapeutic uses and are one of the oldest groups of therapeutic drugs. Originally, they were derived from various plant sources, but today they are only part of a larger group of cholinergic blockers that also includes synthetic and semisynthetic drugs. **Box 22.1** lists the currently available cholinergic blockers.

Mechanism of Action and Drug Effects

Cholinergic-blocking drugs block the action of the neurotransmitter acetylcholine at the muscarinic receptors in the parasympathetic nervous system. Acetylcholine that is released from a stimulated nerve fibre is then unable to bind to the receptor site and fails to produce a cholinergic effect. That is why the cholinergic blockers are also referred to as *anticholinergics*. Blocking the parasympathetic nerves allows the sympathetic (adrenergic) nervous system to dominate. Because of this, cholinergic blockers have many of the same effects as the adrenergics (see Chapter 19). **Fig. 22.1** illustrates the site of action of the cholinergic blockers in the parasympathetic nervous system.

Cholinergic blockers are largely *competitive antagonists* as they compete with acetylcholine for binding at the muscarinic receptors of the parasympathetic nervous system. Once they have bound to the receptor, they inhibit cholinergic nerve transmission. This generally occurs at the neuroeffector junction, or the point where the nerve ending reaches the effector organs, such as smooth muscle, heart muscle, and glands. Cholinergic blockers have little effect at the nicotinic receptors, although at high doses they can have partial blocking effects there.

The major sites of action of the cholinergic-blocking drugs are the heart, respiratory tract, GI tract, urinary bladder, eye, and exocrine glands (e.g., sweat gland, salivary gland). Anticholinergics have the opposite effects of the cholinergics (see Chapter 21) at these sites of action. Anticholinergic effects on the cardiovascular system are seen as an increase in heart rate. Respiratory system effects are dry mucous membranes and bronchial dilation. In the GI tract, cholinergic blockers cause a decrease in GI motility, GI secretions, and salivation. In the genitourinary (GU) system, anticholinergics lead to decreased bladder contraction, which can result in urinary retention. In the skin, anticholinergics reduce sweating. Finally, they increase intraocular pressure and cause the pupils to dilate. This occurs because the ciliary muscles and the sphincter muscle of the iris

are innervated by cholinergic nerve fibres. Cholinergic blockers keep the sphincter muscle of the iris from contracting. The result is dilation of the pupil (**mydriasis**) and paralysis of the ocular lens (cycloplegia). This can be detrimental to patients with glaucoma because it results in increased intraocular pressure (see Chapter 57). These and other effects are listed by body system in **Table 22.1**. Many of the cholinergic-blocking drugs are available in a variety of forms, including intravenous, intramuscular, oral, and subcutaneous preparations.

Indications

In the central nervous system (CNS), cholinergic blockers (e.g., benztropine) have the therapeutic effect of decreasing muscle rigidity and diminishing tremors. This is beneficial in the treatment of both Parkinson's disease (see Chapter 16) and drug-induced extrapyramidal reactions such as those associated with antipsychotic drugs (see Chapter 17). These conditions involve dysfunction of the extrapyramidal parts of the brain and include motor dysfunctions such as chorea, dystonia, and dyskinesia.

Cardiovascular effects of anticholinergics are related to their cholinergic-blocking effects on the heart's conduction system. At low dosages, the anticholinergics may slow the heart rate through their effects on the cardiac centre in the medulla. At high dosages, cholinergic blockers block the inhibitory vagal (i.e., parasympathetic or cholinergic) effects on the pacemaker cells of the sinoatrial and atrioventricular nodes, which leads to acceleration of the heart rate because of unopposed sympathetic activity. Atropine is used primarily in the management of cardiovascular disorders, such as in the diagnosis of sinus node dysfunction, the treatment of patients with symptomatic second-degree atrioventricular block, and the provision of advanced life support in the treatment of sinus bradycardia that is accompanied by hemodynamic compromise. It also has ophthalmic uses such as relaxing the ciliary muscle of the eye, causing the pupil to dilate to facilitate an eye examination (see Chapter 57).

When the cholinergic stimulation of the parasympathetic nervous system is blocked by cholinergic blockers, the sympathetic nervous system's effects go unopposed. In the respiratory tract, this results in decreased secretions from the nose, mouth, pharynx, and bronchi. It also causes relaxation of the smooth muscles in the bronchi and bronchioles, which results in decreased airway resistance and bronchodilation. Because of this, the cholinergic blockers have proved beneficial in treating exercise-induced bronchospasms, asthma, and chronic

BOX 22.1 Cholinergic Blockers Grouped According to Chemical Class

obstructive pulmonary disease. They are also used preoperatively to reduce salivary secretions, which aids in intubation and other procedures (e.g., endoscopy) involving the oral cavity.

Gastric secretions and the smooth muscles responsible for producing gastric motility are all controlled by the parasympathetic nervous system, which is primarily under the control of muscarinic receptors. Cholinergic blockers antagonize these receptors, causing decreased secretions, relaxation of smooth muscle, and reduced GI motility and peristalsis. For these reasons, cholinergic blockers are commonly used in the treatment of irritable bowel disease and GI hypersecretory states.

Anticholinergics are useful in the treatment of GU tract disorders such as reflex neurogenic bladder and incontinence. They relax the detrusor muscles of the bladder and increase constriction of the internal sphincter. The ability of cholinergic blockers to decrease glandular secretions also makes them potentially useful drugs for reducing gastric and pancreatic secretions in patients with acute pancreatitis.

Contraindications

Contraindications to the use of anticholinergic drugs include known drug allergy, angle-closure glaucoma, acute asthma or other respiratory distress, myasthenia gravis, acute cardiovascular instability (some exceptions were listed previously), GI or GU tract obstruction (e.g., benign prostatic hyperplasia), GI (e.g., ulcerative colitis, paralytic ileus) or GU (e.g., urinary retention) illness, and cognitive impairment.

Adverse Effects

Anticholinergic drugs cause widely varied adverse effects. The adverse effects of cholinergic blockers are listed by body system in Table 22.2. Certain patient populations are more susceptible to the effects of anticholinergics. These populations include infants, children with Down syndrome, individuals with spastic paralysis or brain damage, and older adults. Older adults are extremely sensitive to the CNS effects of anticholinergics, and it is not uncommon for them to develop cognitive

impairments and delirium, as well as an increased risk for falls, due to anticholinergic effects. The risk of adverse effects increases with the use of medications with strong anticholinergic properties, higher doses of medications with anticholinergic properties, and the greater total number of medications with anticholinergic properties. Moreover, older adult patients, as a result of normal age-related physiological changes (e.g., decreased kidney function) and pre-existing clinical conditions (e.g., dementia), are much more sensitive to the adverse effects of medications with anticholinergic properties (see Evidence in Practice box).

Toxicity and Management of Overdose. The dosage of cholinergic blockers is particularly important because there is a small difference between therapeutic and toxic dosages. Drugs with this characteristic are commonly referred to as having a *low therapeutic index* (see Chapter 2). The treatment of cholinergic-blocker overdose consists of symptomatic and supportive therapy. Consultation with a provincial or territorial Poison Control Centre is recommended. The patient should be hospitalized, with continuous monitoring, including continuous electrocardiographic monitoring. The stomach should be emptied by whichever means is most appropriate, usually through lavage. Activated charcoal has proven to be effective in removing from the GI tract any drug that has not yet been absorbed. For charcoal to be “activated,” common charcoal is heated in the presence of a gas that causes the charcoal to develop porous spaces that, when ingested, trap chemicals. Fluid therapy and other standard measures used for the treatment of shock are instituted as needed. Delirium, hallucinations, coma, and cardiac dysrhythmias respond favourably to treatment with the cholinergic drug physostigmine (see Chapter 21). Its routine use as an antidote for cholinergic-blocker overdose is controversial because it has the potential to produce severe adverse effects (e.g., seizures, cardiac asystole), so it is usually reserved for the treatment of patients who show extreme delirium or agitation. It is available in Canada only through the Special Access Programme.

TABLE 22.1 Cholinergic Blockers: Drug Effects

Body System	Cholinergic-Blocking Effects
Cardiovascular	Small doses: decrease heart rate Large doses: increase heart rate
Central nervous	Small doses: decrease muscle rigidity and tremors Large doses: cause drowsiness, disorientation, hallucinations
Visual	Dilate pupils (mydriasis), decrease accommodation by paralyzing ciliary muscles (cycloplegia)
Gastrointestinal	Relax smooth muscle tone of GI tract, decrease intestinal and gastric secretions, decrease motility and peristalsis
Genitourinary	Relax detrusor muscle of bladder, increase constriction of internal sphincter; these two effects may result in urinary retention
Glandular	Decrease bronchial secretions, salivation, and sweating
Respiratory	Decrease bronchial secretions, dilate bronchial airways

TABLE 22.2 Cholinergic Blockers: Adverse Effects

Body System	Cholinergic-Blocking Effects
Cardiovascular	Increased heart rate, dysrhythmias (tachycardia, palpitations)
Central nervous	Excitation, restlessness, irritability, disorientation, hallucinations, delirium, ataxia, drowsiness, sedation, confusion
Visual	Dilated pupils (causing blurred vision), increased intraocular pressure
Gastrointestinal	Decreased salivation, dry mouth (xerostomia), gastric secretions, and motility (causing constipation)
Genitourinary	Urinary retention
Glandular	Decreased sweating
Respiratory	Decreased bronchial secretions

EVIDENCE IN PRACTICE

Cumulative Use of Strong Anticholinergics and Incident Dementia: A Prospective Cohort Study**Review**

Anticholinergics block the action of acetylcholine activity and function to balance the neurotransmitters dopamine and acetylcholine. Anticholinergics affect the area of the brain that facilitates memory and learning. These drugs are used to treat a variety of disorders, including incontinence, GI cramps, and urinary muscular spasms. Medications with strong anticholinergic effects (e.g., antihistamines, with the adverse effect of drowsiness) may cause acute cognitive impairment and increase the risk for dementia.

Type of Evidence

The researchers in this study tracked 3 434 men and women 65 years or older with no dementia at study entry. This prospective population-based cohort study used participants from Adult Changes in Thought (ACT), a long-term study conducted by the University of Washington and Group Health, based in Seattle. Recruitment occurred from 1994 through 1996 and from 2000 through 2003. Participants who died were replaced. All participants were followed every 2 years. Group Health's pharmacy records were used to identify both prescription and over-the-counter medications that each participant took in the 10 years before starting the study. Participants' health was tracked for an average of 7 years.

Results of Study

The most common anticholinergic classes used over the 7 years were tricyclic antidepressants, first-generation antihistamines, and bladder antimuscarinics. Over the mean follow-up of 7.3 years, 797 participants (23.2%) developed dementia. The majority of these, or 637 (79.9%), developed Alzheimer's disease. Dementia risk increased as the cumulative dose increased. Taking an anticholinergic drug for 3 years or more was associated with a 54% higher dementia risk than taking the same dose for 3 months or less.

Link of Evidence to Nursing Practice

It is important to note that this study found that high cumulative anticholinergic use is correlated with an increased risk for dementia. Although further research is necessary, increased attention to this potential medication-related risk is important. Adverse effects are associated with anticholinergic use over time. It is recommended that health care providers assess high-risk prescription and over-the-counter anticholinergics, particularly those in use by older adults. While avoiding all anticholinergics is not always clinically possible, increasing awareness of the most problematic medications is important. Medications with anticholinergic properties should be avoided in older adult patients whenever possible. If clinically necessary, anticholinergics should be used at the lowest dose and for the shortest duration possible.

Source: Gray, S. L., Anderson, M. L., Dublin, S., et al. (2015). Cumulative use of strong anticholinergics and incident dementia: A prospective cohort study. *Journal of the American Medical Association Internal Medicine*, 175(3), 401–407. <https://doi.org/10.1001/jamainternmed.2014.7663>

Interactions

The drug interactions most commonly reported for the anticholinergics are additive anticholinergic effects when taken with other drugs that possess anticholinergic adverse effects, such as amantadine hydrochloride (see Chapter 16), antihistamines (see Chapter 37), and tricyclic antidepressants (see Chapter 17). Reduced antipsychotic effects of phenothiazines (see Chapter 17) are seen when they are taken with anticholinergic drugs, and increased effects of digoxin (see Chapter 25) are seen when it is combined with anticholinergics.

Dosages

For dosage information on selected cholinergic blockers, refer to the table on page 366.

 DRUG PROFILES

Among the oldest and best known, naturally occurring cholinergic blockers are the belladonna alkaloids. Of these, atropine is the prototypical drug. It has been in use for hundreds of years and continues to be widely administered because of its effectiveness. Besides atropine, scopolamine is the other major, naturally occurring drug, derived from a variety of plants within the potato family.

Cholinergic blockers are used in the treatment of a variety of illnesses and conditions, ranging from irritable bowel syndrome to the symptoms of the common cold, and are also administered preoperatively to dry up secretions. Cholinergic blockers minimize gurgling and crackling sounds and can be used prophylactically in patients who are unconscious and dying; however, there is controversy about their usefulness. These drugs

are the synthetic counterparts of the plant-derived belladonna alkaloids and are more specific in binding predominantly with muscarinic receptors. Synthetic cholinergic blockers are also associated with fewer adverse effects than plant-derived ones. Adverse effects and drug interactions are comparable for the different anticholinergic drugs and are detailed in Table 22.2, unless otherwise noted.

 atropine sulphate

Atropine sulphate is a naturally occurring antimuscarinic. It is used for its cholinergic-blocking effects on the heart and its effects on the smooth muscles of the bronchi and intestines. Atropine is effective in the treatment of many of the conditions that are previously listed in the Indications section. Because atropine causes increased heart rate, it is used to treat symptomatic bradycardia. If inadequate perfusion exists, atropine 0.5 mg intravenously push, via a pre-filled syringe, is administered every 3 to 5 minutes, up to a maximum of 3 mg. Atropine is also used as an antidote for anticholinesterase inhibitor toxicity or poisoning as it blocks the overstimulation of the muscarinic receptors, reducing cardiovascular adverse events (Weinbroun, 2005). It is also used preoperatively to reduce salivation and GI secretions, as is glycopyrrolate. Atropine use is contraindicated in patients with angle-closure glaucoma, adhesions between the iris and lens, certain types of asthma (that are not cholinergic associated), advanced liver or kidney disease, hiatal hernia associated with reflux esophagitis, intestinal atony, obstructive GI or GU conditions, and severe ulcerative colitis. It is available as a parenteral injection in several concentrations, as well as in ophthalmic forms (Chapter 57). It is also combined with the opiate diphenoxylate hydrochloride to make Lomotil® tablets, a common antidiarrheal preparation. Adverse effects may include bloating, constipation,

loss of appetite, and severe stomach pain with nausea and vomiting. Overdose of atropine (usually from taking excessive Lomotil) is associated with flushing, dry skin and mucous membranes, mydriasis, altered mental status, and fever. Other serious effects include sinus tachycardia, urinary retention, hypertension, hallucinations, respiratory depression, and cardiovascular collapse. See previous discussion on toxicity management. Recommended dosages are given in the table on page 366.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Immediate	2–4 min	2.5 hr	4–6 hr

glycopyrrolate

Glycopyrrolate is a synthetic antimuscarinic drug that blocks receptor sites in the autonomic nervous system, controlling the production of secretions and the concentration of free acids in the stomach. It may be used as a preoperative medication to reduce salivation and excessive secretions in the respiratory and GI tracts. It is contraindicated in patients who are hypersensitive to it and in those with angle-closure glaucoma, myasthenia gravis, GI or GU obstruction, tachycardia, liver disease, myocardial ischemia, ulcerative colitis, or toxic megacolon. Glycopyrrolate is to be used cautiously when prescribed to older adults who are at increased risk of anticholinergic effects. Glycopyrrolate is available parenterally. Recommended dosages are given in the table on the next page.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	1 min	10–15 min	Variable	4 hr

oxybutynin chloride

Oxybutynin chloride (Ditropan®) is a synthetic antimuscarinic drug used for the treatment of overactive bladder. It is also used as an antispasmodic for neurogenic bladder associated with spinal cord injuries and congenital conditions such as spina bifida. Contraindications include drug allergy, urinary or gastric retention, and uncontrolled angle-closure glaucoma. Oxybutynin chloride is available for oral use. A transdermal patch (Oxytrol®) and a gel (Gelnique®) are also available and approved for treatment of overactive bladder. Recommended dosages are given in the table on the next page.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Unknown	1 hr	2–3 hr	Unknown

scopolamine hydrobromide

Scopolamine hydrobromide is a naturally occurring cholinergic blocker and one of the principal belladonna alkaloids. It is the most potent antimuscarinic for the prevention of motion

sickness. It works by correcting the imbalance between acetylcholine and norepinephrine in the medulla, particularly in the vomiting centre. Ipratropium bromide, a derivative of scopolamine, has potent therapeutic effects on the lungs and is discussed in Chapter 38. For the prevention of motion sickness, scopolamine is available in a transdermal delivery system, a patch that can be applied just behind the ear, 12 hours before travel (see Chapter 41). It is considered a natural health product by Health Canada. Transdermal scopolamine may cause drowsiness, dry mouth, and blurred vision.

Although not Health Canada–approved, scopolamine (either by patch or by subcutaneous injection) has been used in palliative and end-of-life care. Loss of the ability to swallow may result from weakness and decreased neurological function. Consequently, the gag reflex and reflexive clearing of the oropharynx decline, resulting in the accumulation of secretions. This buildup of saliva and oropharyngeal secretions may lead to gurgling, crackling, or rattling sounds as air moves across pooled secretions, collectively known by the unfortunate term “death rattle.” During the last stages of life, these secretions can be distressing to families. Blockade of the parasympathetic nervous system results in decreased production of secretions in the salivary, bronchial, and GI tracts; however, it is not effective on secretions that are already present. Scopolamine crosses the blood–brain barrier and may result in more CNS effects, such as sedation, disorientation, hallucinations, and delirium, particularly in older adults when using a scopolamine transdermal patch.

Using scopolamine with CNS depressants or alcohol may increase sedation. Scopolamine is also available in parenteral formulations for injection by various routes: intravenous, intramuscular, and subcutaneous. The contraindications that apply to atropine apply to scopolamine as well. Recommended dosages are given in the table on the next page.

PHARMACOKINETICS

Transdermal	4–12 hr	6 hr	Variable	72 hr

tolterodine tartrate

Tolterodine tartrate (Detrol, Detrol LA) is a muscarinic receptor blocker used for the treatment of urinary frequency, urgency, and urge incontinence caused by bladder (detrusor) overactivity. Another drug that is commonly used to treat these conditions is oxybutynin chloride (profiled previously), which is also one of the most commonly prescribed. Other older-generation drugs include hyoscine butylbromide and the tricyclic antidepressant imipramine hydrochloride. These drugs are less commonly used today because of their antimuscarinic adverse effects, particularly dry mouth. Newer drugs for this purpose include solifenacin succinate (Vesicare), darifenacin hydrobromide (Enablex®), trospium chloride (Sanctura®), and fesoterodine fumarate (Toviaz). The newer drugs are associated with a much lower incidence of dry mouth, in part because of their

Dosages

Selected Cholinergic-Blocking (Anticholinergic) Drugs

Drug	Usual Dosage Range	Indications
 atropine sulphate	<i>Infants and Children</i> IM/Subcut: 0.01–0.02 mg/kg/dose; max 0.5 mg IV: 0.02–0.05 mg/kg every 15–20 minutes until effect <i>Adults</i> IM: 0.5 mg q3–5 minutes (max 3 mg) IV: 1–2 mg/dose; repeat every 5–60 min until disappearance of muscarinic symptoms	Treatment of bradycardia Anticholinesterase effect for organophosphate or carbamate poisoning (e.g., insecticides) Treatment of bradycardia, cardiopulmonary resuscitation Anticholinesterase effect for organophosphate or carbamate poisoning (e.g., insecticides)
glycopyrrolate	<i>Children and Adults</i> IM/IV: 0.005 mg/kg 30–60 min preoperative <i>Children and Adults</i> 0.2 mg for each 1 mg of neostigmine or 5 mg of pyridostigmine	Preoperative control of secretions Reversal of neuromuscular blockade
oxybutynin chloride (Ditropan XL, Oxytrol [transdermal patch], Gelnique [topical gel])	<i>Children over 5 yr</i> PO: 5 mg bid–tid <i>Adult and child older than 5 yr</i> PO: 5 mg bid–tid <i>Adults only</i> PO ER tab: 5–30 mg/day as single or divided doses Transdermal patch: 1 patch (3.9 mg/day) applied twice weekly (every 3–4 days) (for overactive bladder) Topical gel: 1 sachet (1g)/day	Antispasmodic for neurogenic bladder (e.g., following spinal cord injury), overactive bladder
scopolamine hydrobromide (generic, transdermal patch)	<i>Children</i> IM/IV/Subcut: 0.006 mg/kg/dose <i>Adults</i> IM/IV/Subcut: 0.3–0.8 mg Transdermal patch: 1.5 mg patch behind ear q3days (delivers approx 1 mg scopolamine over 3 days); apply at least 12 hr before transportation	Preoperative control of secretions Preoperative control of secretions Motion sickness
 tolterodine tartrate (Detrol, Detrol LA)	<i>Adults</i> PO: 1–2 mg bid PO ER cap: 2–4 mg daily	Treatment of overactive bladder

ER, Extended release; IM, intramuscular; IV, intravenous; PO, oral; Subcut, subcutaneous.

pharmacological specificity for the bladder as opposed to the salivary glands.

Tolterodine is to be avoided in patients with angle-closure glaucoma, urinary retention, or gastric retention. In patients with markedly decreased liver function or who are poor metabolizers of drugs that inhibit cytochrome P450 enzyme 3A4 (e.g., erythromycin or ketoconazole), the dose is reduced to 1 mg twice a day rather than the recommended dose of 2 mg twice a day. Tolterodine is available only for oral use. Recommended dosages are given in the table below.

PHARMACOKINETICS

NURSING PROCESS

ASSESSMENT

The drugs known as *parasympatholytics*, *cholinergic blockers*, *cholinergic antagonists*, or *anticholinergics* produce a number of physiological effects that result from the blocking of cholinergic receptors. These effects include smooth muscle relaxation, decreased glandular secretion, and mydriasis (pupil dilation). Knowing the way these drugs work and the related physiology will assist you in the safe assessment and nursing care of patients taking these drugs. A thorough medical history; a complete medication history with a listing of prescription drugs, over-the-counter (OTC) drugs, and natural health products; as well as a thorough head-to-toe assessment will help to identify the presence of any contraindications, cautions, or potential drug interactions associated with the cholinergic-blocking drugs (see earlier discussion). The assessment

data will help in documenting baseline findings and provide information for evaluating drug effectiveness. Lifespan considerations for young patients and older adults include the need for close assessment and monitoring because of the increased susceptibility of these groups to the adverse effects of restlessness, irritability, disorientation, constipation, urinary retention, blurred vision (from pupil dilation), and tachycardia; thus, older adults require more careful assessment and monitoring. See Special Populations: Older Adults for information about the care of older adults with an overactive bladder. It is of utmost importance to assess adult patients for the use of medications that have cholinergic-blocking properties. Using anticholinergic rating scales to assess the magnitude of anticholinergic burden can help health care providers achieve this goal and ultimately enhance safety in older adult patients. A variety of anticholinergic risk rating scales are available. One tool is the Anticholinergic Risk Scale, a ranked categorical list of commonly prescribed medications with anticholinergic potential (Salahudeen, Duffull, & Nishtala, 2015). Medications are classified on a scale of 0 to 3 points, based on their probability of causing anticholinergic effects, such as dry mouth;

dry eyes; constipation; and dizziness and confusion, which may result in falls.

In assessment associated with atropine and other cholinergic blockers, check for allergies, glaucoma, certain eye conditions (e.g., adhesions in the iris and lens of the eye), gastroesophageal reflux disease, poor intestinal motility, obstructions of the GI and GU systems, and severe ulcerative colitis. These conditions and others may be exacerbated by the cholinergic blockers (see earlier discussion in this chapter and discussions in Chapters 19 to 21) and would be considered contraindications. Address the associated cautions, contraindications, and drug interactions with dicyclomine, glycopyrrolate, and oxybutynin chloride. Also, note any disorders of the bladder or GI tract. Apply the transdermal dosage form of scopolamine only after the order has been reviewed and the skin assessed.

SPECIAL POPULATIONS: OLDER ADULTS

Overactive Bladder

Overactive bladder is estimated to affect approximately 18.1% of Canadians (21.2% of women and 14.8% of men) over the age of 35, and its incidence increases with age (Corcos et al., 2017). Some questions to pose to adults and older adults about this condition include the following:

- Do you suddenly experience a strong urge to urinate?
- Do you urinate more than eight times in a 24-hour period?
- Do you have to get up more than two times during the night to urinate?
- Do you have “wetting” accidents?
- Are these “wetting” accidents related to the uncontrollable urge to urinate?

NOTE: Patients who answer yes to some of these questions need to be encouraged to contact the primary health care provider. Referral to a urologist may or may not be necessary.

Various treatments are available in Canada, including the use of solifenacin succinate (Vesicare), which is to be taken once daily and treats all of the major symptoms of overactive bladder, including urgency, frequency, and urge-related incontinence. Solifenacin succinate was found to reduce the number of incontinence episodes over 12 weeks, in studies of the drug involving more than 3 000 patients with overactive bladder symptoms. With 5- to 10-mg dosing of the drug, there was alleviation of all of the major symptoms. Use of this drug is contraindicated in patients with glaucoma, certain GI or GU tract problems, severe constipation, or urinary retention. Adverse effects include dry mouth, constipation, and blurred vision. If a patient experiences severe abdominal pain or is constipated for 3 or more days, the patient should contact a health care provider immediately.

NURSING DIAGNOSES

- Potential risk for constipation related to adverse effects of cholinergic-blocking drugs
- Inadequate knowledge related to the lack of information about the therapeutic regimen, adverse effects, drug interactions, and precautions for the use of cholinergic-blocking drugs
- Potential risk for injury related to decreased sweating and loss of normal heat-regulating mechanisms due to the impact of the drug on temperature-regulating mechanisms

PLANNING

Goals

- Patient will experience minimal adverse effects such as constipation.
- Patient will demonstrate adequate knowledge about the use of the specific medications, adverse effects, and appropriate dosing at home.
- Patient will remain free from injury resulting from the adverse effect of inability to regulate sweating.

Outcome Criteria

- Patient states various measures to regain normal bowel patterns and avoids constipation by consuming additional fluids and increasing fibre in daily dietary intake.
 - Patient increases fluids up to 2 000 mL (preferably of water) per day.
 - Patient eats foods high in fibre, such as generous amounts of vegetables, fruits, and legumes, to take in approximately 40 g per day.
 - Patient uses a natural fibre supplement, if not contraindicated, such as a psyllium-based fibre product.
- Patient states the rationale for the use of cholinergic blockers, such as in preoperative preparation, for decreasing adverse effects associated with drugs used for Alzheimer's disease, and in irritable bowel syndrome.
- Patient states the more common adverse effects associated with cholinergic blockers, such as dry mouth, constipation, and urinary retention.

- Patient states those adverse effects that need to be reported immediately to a health care provider if they occur, such as unresolved constipation, pain over the bladder region and inability to urinate, or chest pain.
- Patient states measures to help decrease the impact of reduced ability to sweat, such as avoiding the following: hot climates, vigorous exercising (especially in heated or hot environments), saunas, and hot tubs.
- Older adult patients identify their increased risk of being overwhelmed by the decreased ability to sweat and the need for adherence to the above stipulations.

IMPLEMENTATION

A preventive focus for nursing care is important to the effective use of cholinergic-blocking drugs. Some conditions may be amenable to lifestyle modification rather than pharmacotherapy, and minimal doses may be used to achieve desired effects. There are several nursing interventions that may maximize the therapeutic effects of these drugs and minimize the adverse effects. Some important nursing interventions include giving the drug at the same time each day and according to the health care provider's order and giving the medication with adequate fluid intake (1 400 to 2 000 mL of water daily).

Because drugs such as atropine and glycopyrrolate are compatible with some of the commonly used opioids (e.g., meperidine hydrochloride, morphine sulphate), they may be used in combination with these drugs and mixed in the same syringe for parenteral dosing. Checking for the compatibility of drugs combined in the same syringe is important with any medication. Always double-check compatibility for patient safety. If a cholinergic-blocking drug is given via the ophthalmic route, always check the concentration of the drug and, once it is given, apply light pressure with a tissue to the inner canthus of the eye for approximately 30 to 60 seconds. This helps to minimize the possibility of systemic absorption of the drug.

Atropine may be combined with other cholinergic-blocking drugs for treatment of lower urinary tract discomfort or to help decrease GI and GU hypermotility, but the drug should be given via the correct route and with proper dosing as prescribed. The anticholinergic adverse effect of dry mouth may be managed with frequent mouth care, oral rinses, increase in fluids, and use of sugar-free gum or hard candy. Oxybutynin chloride needs to be taken as directed, either 1 hour before or 2 hours after meals, if tolerated. Tolterodine must be taken as directed and with food. Transdermal forms of these medications (e.g., scopolamine, oxybutynin) are to be applied to the skin only after the previous dosage form has been removed and

CASE STUDY

Transdermal Scopolamine

Julie, a 53-year-old elementary schoolteacher, has been admitted to the palliative care unit with a terminal cancer diagnosis. As the patient's condition has deteriorated, she has developed increased secretions that have become distressing for the family. The health care provider has prescribed scopolamine 0.4 mg subcutaneously q4 hours.

1. Scopolamine can be administered subcutaneously. What nursing intervention would be most appropriate for a patient receiving end-of-life care and about to receive scopolamine?
2. Julie becomes lethargic and difficult to rouse. The patient's partner cannot understand what is happening. How should the nurse respond to the partner's concern?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

the area gently cleansed of residual medication. Transdermal patches may be applied to any dry, nonhairy, nonirritated area. Rotation of transdermal sites is recommended to decrease skin irritation. Also associated with the cholinergic-blocking drugs are the adverse effects of constipation and inability to sweat or perspire. Because these may be significant to patients, include education on how to minimize these adverse effects. See the Patient Teaching Tips below for more information on these specific drugs.

EVALUATION

Monitoring of goals and outcome criteria is a starting point for effective evaluation of therapy with cholinergic-blocking drugs. In particular, their therapeutic effects include the following: (1) in patients with Parkinson's disease, improved ability to carry out activities of daily living and fewer problems with tremors, salivation, and drooling; (2) decreased GI symptoms, such as hyperacidity, abdominal pain, heartburn, nausea, and vomiting, with improved comfort; (3) decreased GU hypermotility, with increased comfort and improved patterns of voiding with an increase in time between voidings; (4) fewer bronchospasms with induction of anaesthesia and fewer problems with thickened, viscous secretions in patients, before, during, and after surgery. Monitor patients for the occurrence of adverse effects such as constipation, tachycardia, palpitations, confusion, sedation, drowsiness, hallucinations, urinary retention, and decreased sweating leading to hot and dry skin. Toxic effects of cholinergic-blocking drugs include delirium, hallucinations, and cardiac dysrhythmias.

PATIENT TEACHING TIPS

- Patients should be informed that medications need to be taken exactly as prescribed. Overdosage of cholinergic-blocking drugs may cause life-threatening problems, especially in the cardiovascular and central nervous systems.
- Cholinergic blockers may lead to dry mouth. Regular and thorough oral hygiene is required of patients taking these drugs, including brushing teeth twice daily and using dental floss. Dry mouth may be minimized by increasing fluid intake, if not contraindicated; using artificial saliva drops;

chewing sugar-free gum; or sucking on sugar-free hard candy, as needed. Encourage regularly scheduled dental visits because of the risk of dental caries and gum disease with dry mouth. The use of Waterpik® devices may stimulate gums and help prevent gum disease.

- Patients should exercise with caution and avoid excessive sweating because of drug-induced altered sweating. This may cause hyperthermia in older adults or those with already altered sweating mechanisms.
- If patients experience sedation or blurred vision, they need to avoid driving and engaging in activities that require quick decision making, alertness, or clear vision, such as operating heavy machinery, taking tests, and making important decisions. The adverse effects of sedation will decrease over time.
- Encourage patients to wear dark or tinted glasses or sunglasses because of the increased sensitivity to light associated with these medications.
- Patients must understand the importance of always consulting a health care provider before taking any other medications, including prescription drugs, OTC medications, or natural health products.
- Older adult patients have existing age-related changes in body temperature-regulating mechanisms. With these medications, especially at high dosages, there is an increased risk of heat stroke or hyperthermia because of the drug's interference with the body's heat-regulating mechanisms. To prevent hyperthermia, older adults need to stay in shaded areas or inside an air-conditioned or cooled environment when external temperatures are warm; remain well hydrated with cool fluids; wear protective clothing and hats; avoid saunas, hot tubs, excessive heat, and strenuous exercise in warm environments; keep portable fans on hand; and maintain adequate ventilation in heated environments.
- For patients taking cholinergic blockers, all health care providers need to be informed about the treatment regimen and must be given a list of the patient's drugs. The primary health care provider needs to be contacted if there is any unresolved constipation, palpitations, alterations in gait, excessive dizziness, or inability to void.
- Patients may manage constipation with increased dietary intake of fluids and fibre or through the use of OTC fibre-containing supplements, such as psyllium products.

KEY POINTS

- *Cholinergic blockers, parasympatholytics, anticholinergics, and antimuscarinics* are all terms that refer to the drugs that block or inhibit the actions of acetylcholine in the parasympathetic nervous system.
- The use of cholinergic blockers allows the sympathetic nervous system to dominate. These drugs are classified chemically as natural, semisynthetic, and synthetic cholinergic blockers. They may be competitive antagonists (blockers)

and compete with acetylcholine at the muscarinic receptors. In high dosages, they result in partial blocking actions at the nicotinic receptors. Anticholinergics bind to and block acetylcholine at muscarinic receptors located on the cells stimulated by the parasympathetic nervous system.

- The nurse should assess for possible contraindications such as benign prostatic hypertrophy, glaucoma, tachycardia, myocardial infarction, heart failure, and hiatal hernia.

EXAMINATION REVIEW QUESTIONS

1. The nurse is providing education about cholinergic-blocking drug therapy to an older adult patient. Which would be an important point to emphasize for this patient during patient teaching?
 - a. Avoid exposure to high temperatures.
 - b. Limit liquid intake to avoid fluid overload.
 - c. Begin an exercise program to avoid adverse effects.
 - d. Stop the medication if excessive mouth dryness occurs.
2. A patient has been prescribed a cholinergic-blocking drug. Prior to administration, what contraindications would be most concerning to the nurse?
 - a. Chronic bronchitis
 - b. Peptic ulcer disease
 - c. Irritable bowel syndrome
 - d. Benign prostatic hypertrophy
3. When assessing for the adverse effects of cholinergic-blocking drug therapy, the nurse would expect to find that the patient reports which drug effect?
 - a. Diaphoresis
 - b. Dry mouth
 - c. Diarrhea
 - d. Urinary frequency
4. Which of the following therapeutic effects caused by drug-induced extrapyramidal effects would the nurse monitor in a patient receiving a cholinergic-blocking drug?
 - a. Decreased muscle rigidity and tremors
 - b. Increased heart rate
 - c. Decreased bronchial secretions
 - d. Decreased GI motility and peristalsis
5. The nurse is to administer a cholinergic-blocking drug to a patient. The nurse will determine whether the patient is taking any drugs that may potentially interact with the anticholinergic, including which of the following?
 - a. Opioids, such as morphine sulphate
 - b. Antibiotics, such as penicillin
 - c. Tricyclic antidepressants, such as amitriptyline
 - d. Anticonvulsants, such as phenobarbital
6. A patient has been given a prescription for transdermal scopolamine patches for motion sickness to use during a cruise vacation. What teaching instructions will the nurse provide to the patient? (Select all that apply.)

- a. “Apply the patch as soon as you board the ship.”
 - b. “Apply the patch 12 hours before boarding the ship.”
 - c. “The patch needs to be placed on a nonhairy area on your upper chest or upper arm.”
 - d. “The patch needs to be placed on a nonhairy area just behind your ear.”
 - e. “Change the patch every 3 days.”
 - f. “Rotate the application sites.”
7. The preoperative order for an adult patient reads: “Scopolamine hydrobromide, 0.7 mg IM on call for surgery.” The

medication is available in vials of 0.4 mg/mL. How many millilitres will the nurse administer for this dose? (Round to tenths.)

8. The nurse is assessing a patient who has a prescription for dicyclomine (Bentylol). Which condition is considered a contraindication to this medication?
- a. GI atony
 - b. Irritable bowel syndrome
 - c. Overactive bladder
 - d. Diabetes mellitus

CRITICAL THINKING ACTIVITIES

1. The nurse is preparing to administer atropine and an opioid, ordered as standard preoperative medications, to a 75-year-old woman who will be undergoing minor surgery. When checking her medical history, the nurse notes that she has a history of smoking and has angle-closure glaucoma. What is your priority action at this time in regard to administration of the preoperative medications? Explain your answer.
2. A patient develops symptomatic bradycardia with hypotension and prescribed atropine. The order was to administer 0.5 mg of atropine sulphate to the patient intravenously. The prefilled syringe concentration is 1 mg/mL. How much

atropine should the nurse administer to the patient? What other nursing priority action should be prepared for this patient?

3. A patient who has a history of heart failure starts taking oxybutynin (Ditropan) for urge incontinence. One week later, she calls the office and tells the nurse, “I get so thirsty on this drug. I’ve been drinking lots of water, but I can’t seem to drink enough water to keep from getting thirsty!” What is the nurse’s best response to this patient?

Antihypertensive Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Briefly discuss the normal anatomy and physiology of the autonomic nervous system, including the events that take place within the sympathetic and parasympathetic divisions as related to long-term and short-term control of blood pressure.
2. Define *hypertension*.
3. Compare primary (essential) and secondary hypertension and their related manifestations.
4. Describe the protocol for treating hypertension as detailed in the Canadian Hypertension Education Program Guidelines, including the rationale for its use.
5. List the criterion pressure values (in millimetres of mercury) for the hypertension categories of normal pressure, prehypertension, hypertension stage 1, and hypertension stage 2.
6. Using the most recent guidelines, compare the various drugs used in the pharmacological management of hypertension in regard to mechanisms of action, specific indications, adverse effects, toxic effects, cautions, drug interactions, contraindications, dosages, and routes of administration.
7. Discuss the rationale for the nonpharmacological management of hypertension.
8. Develop a collaborative plan of care that includes all phases of the nursing process for patients receiving antihypertensive drugs.

KEY TERMS

alpha₁ blockers Drugs that primarily cause arterial and venous dilation through their action on peripheral sympathetic neurons. (p. 376)

Antihypertensive drugs Medications used to treat hypertension. (p. 374)

Cardiac output The amount of blood ejected from the left ventricle, measured in litres per minute. (p. 372)

Centrally acting adrenergic drugs Drugs that modify the function of the sympathetic nervous system in the brain by stimulating alpha₂ receptors. Alpha₂ receptors are inhibitory in nature and thus have a reverse sympathetic effect and cause a decrease in blood pressure. (p. 376)

Essential hypertension Elevated systemic arterial pressure for which no cause can be found; also called *primary* or *idiopathic hypertension*. (p. 373)

Hypertension A common, often asymptomatic disorder in which blood pressure persistently exceeds 140 mm Hg or diastolic pressure exceeds 90 mm Hg. (p. 372)

Malignant hypertension Extremely high blood pressure, usually above 180/120. (p. 373)

Orthostatic hypotension A common adverse effect of adrenergic-blocking drugs involving a sudden drop in blood pressure when patients change position, especially when rising from a seated or horizontal position. (p. 376)

Prodrug A drug that is inactive in its given form and which must be metabolized to its active form in the body, generally by the liver, to be effective. (p. 380)

Secondary hypertension High blood pressure caused by another disease, such as kidney, pulmonary, endocrine, or vascular disease. (p. 373)

epirenone, p. 385

hydralazine (hydralazine hydrochloride)*, p. 384

losartan (losartan potassium)*, p. 383

nebivolol hydrochloride, p. 379

sodium nitroprusside, p. 384

treprostinil (treprostinil sodium)*, p. 386

Key drug

* Full generic name is given in parentheses. For the purposes of this text, the more common, shortened name is used.

HIGH ALERT DRUGS

Sodium nitroprusside, p. 384

OVERVIEW

Hypertension, defined as a persistent systolic pressure of greater than 140 mm Hg or a diastolic pressure greater than 90 mm Hg, affects an estimated 7.5 million Canadians ([Hypertension Canada, 2015](#)). Globally, the prevalence of hypertension is highest in Africa and in low- and middle-income nations, and it affects approximately 1 billion people worldwide, designating it the most common disease state ([World Health Organization, 2013](#)). Canadians who are Black, Indigenous, or of South Asian heritage, and individuals of low socioeconomic status, are at greater risk for developing hypertension ([Heart and Stroke Foundation, 2018](#); see *Ethnocultural Implications* box). As the population ages, the incidence of hypertension will continue to increase ([Heart and Stroke Foundation, 2018](#)).

Hypertension is a major risk factor for coronary artery disease, cardiovascular disease, and death resulting from cardiovascular causes. It is the most important risk factor for stroke and heart failure, and it is also a major risk factor for kidney failure and peripheral vascular disease. There is indisputable evidence in regard to the relationship between blood pressure and risk of cardiovascular disease; the higher the blood pressure, the greater the chance of developing cardiovascular disease. For people 40 to 70 years of age, the risk of developing cardiovascular disease

ETHNOCULTURAL IMPLICATIONS

Antihypertensive Drug Therapy

The following are some important generalizations about demographics and the drugs used to treat hypertension:

- Beta blockers and angiotensin-converting enzyme inhibitors have been found to be more effective in lowering blood pressure in people who are White than in people who are Black.
- Calcium channel blockers and diuretics have been shown to be more effective in patients who are Black than in patients who are White.

- Captopril used as monotherapy to treat hypertension has been found to elicit a lesser response in patients who are Black because they are considered to have lower renin levels than in the general treatment population.
- Losartan sodium, used as monotherapy for hypertension, has been found to be less effective in patients who are Black than in other racial groups because of their lower renin levels.

These findings are important to remember in the care of patients, whether they are in an inpatient setting, are being seen by a health care provider, or are being screened by a nurse in the community. The significance of these ethnocultural factors is that they allow a better understanding of the dynamics of pharmacological treatment in patients with hypertension of different ethnic groups and also underscore the importance of a thorough nursing assessment that includes attention to ethnocultural influences. Such ethnocultural factors also allow an appreciation of individual responses to drug therapy and aid in selecting first-line drugs and achieving more successful treatment of the disease.

Canadian Indigenous Population and Hypertension

There remains limited literature focusing on hypertension and Canadian Indigenous populations. Indigenous populations experience greater health concerns of cardiovascular disease such as angina, myocardial infarction, coronary artery disease, and stroke, despite lower measures of blood pressure (Foulds, Bredin, & Warburton, 2016). The prevalence of hypertension in Inuit populations is 19% and in First Nations, it is 21.8% ([Hypertension Canada, 2015](#)). The Canadian Heart Health Strategy recommended that Canada end “the heart health crisis among Aboriginal/Indigenous peoples by actively involving them in developing their own solutions and plans and providing culturally safe and appropriate support” (Smith, 2009). The Heart and Stroke Foundation of Canada has developed A Guide for Aboriginal Peoples. On the website, there is specific information that addresses the gap in Indigenous health and begins to inform Canadians about the specific needs of all Indigenous peoples.

doubles with each 20 mm Hg increase in systolic blood pressure (SBP) or 10 mm Hg increase in diastolic blood pressure (DBP).

To gain insight into the treatment of hypertension requires a basic understanding of blood pressure. Blood pressure is determined by the product of **cardiac output (CO)** (4 to 8 L/min) and systemic vascular resistance (SVR). The mean arterial pressure (MAP) is a product of CO and SVR. The MAP is calculated as $\frac{1}{3}(\text{SBP} - \text{DBP}) + \text{DBP}$. The MAP may be a better indicator of tissue perfusion as two thirds of the cardiac cycle are spent in diastole; a MAP of ≥ 60 is believed to be necessary to maintain adequate tissue perfusion. Cardiac output is the amount of blood ejected from the left ventricle and is measured in litres per minute. SVR, or afterload, is the resistance to blood flow that is determined by the diameter of the blood vessel and the vascular musculature. It is calculated by dividing blood pressure

Fig. 23.1 Normal regulation of blood pressure and corresponding mechanisms. *ACE*, angiotensin-converting enzyme; *CNS*, central nervous system.

by cardiac output. Numerous factors interact to regulate these two major variables and keep blood pressure within normal limits. These are illustrated in [Figure 23.1](#); they are the same factors that can cause hypertension and they are the targets of action of many of the antihypertensive drugs.

The diagnosis and management of hypertension have varied considerably over the years, resulting in a great deal of misunderstanding in how to treat this disorder. Since 2000, the Canadian Hypertension Education Program (CHEP) and the Heart and Stroke Foundation of Canada have produced and updated yearly evidence-informed recommendations for the detection, assessment, and treatment of hypertension, assembled by the 43 members of the CHEP evidence-based recommendations task force. Each year, the recommendations focus on a change from previous guidelines or an important initiative (See <https://www.guidelines.hypertension.ca/> for CHEP guidelines). Hypertension Canada's (formerly Canadian Hypertension Education Program CHEP) intent is to educate health care providers and the general public about the consequences of hypertension and the importance of adequate prevention and treatment in order to reduce the burden of cardiovascular disease. Nurses have a key role to play in the primary prevention, detection, and treatment of hypertension.

To identify those with hypertension, all adults require ongoing regular assessment of blood pressure. More recent Hypertension Canada guidelines include the classification of high-normal blood pressure. Those individuals who have high-normal blood pressure (130–139/85–89 mm Hg) are considered at higher risk of developing hypertension. It is estimated that of those who have high-normal blood pressure and are overweight, 40% will develop hypertension within 2 years, while an additional 20% will develop hypertension within 4 years. Previous guidelines had recommended a stepped-care pharmacological approach to treating hypertension; many health care providers believe that this approach no longer adequately

reflects the current range of pharmacological alternatives available. Individualized therapy was proposed as a more appropriate treatment strategy. The individualized approach continues to be emphasized. Many patients will require two or more medications, even as initial therapy, depending on their individual cardiovascular risk factors such as obesity, diabetes, and family history.

The classification scheme used to categorize individual cases of hypertension has been simplified based on blood pressure measurements. See www.hypertension.ca for the Hypertension Canada algorithm for the assessment of patients with hypertension.

Hypertension can also be defined by its cause. When the specific cause of hypertension is unknown, it may be called **essential hypertension** (or *idiopathic* or *primary hypertension*). About 90 to 95% of cases of hypertension are of this type. **Secondary hypertension** accounts for the other 5 to 10%. Secondary hypertension is most commonly the result of another disease such as a pheochromocytoma (adrenal tumour), pre-eclampsia of pregnancy (a pregnancy complication involving acute hypertension, among other symptoms), renal artery disease, sleep apnea, thyroid disease, or parathyroid disease. It may also result from the use of certain medications such as atypical antipsychotics (see [Chapter 17](#)). If the cause of secondary hypertension can be eliminated, blood pressure usually returns to normal. If untreated, hypertension can cause damage to end organs such as the heart, brain, kidneys, and eyes. **Malignant hypertension** is extremely high blood pressure, with levels usually above 180/120, and is considered and treated as a medical emergency. It develops rapidly and usually results in organ damage.

Hypertension in children is increasing in prevalence and may persist into adulthood with the associated long-term health risks that are common with a diagnosis of hypertension (see *Special Populations: Children*).

SPECIAL POPULATIONS: CHILDREN

Hypertension

It is estimated that 7% of children and adolescents in Canada have prehypertension (high-normal) or hypertension (Statistics Canada, 2016), although calculated ranges vary between 1 and 5%. Because hypertension is considered a “silent killer,” as it is usually asymptomatic, it is reasonable to assume that many children and adolescents remain undiagnosed. A secondary cause of hypertension is likely to be found in patients who have not reached adolescence; after puberty, hypertension is likely to be of primary (essential) etiology.

The strongest risk factor for essential hypertension in children of all ages and both genders is an elevated body mass index (BMI). Children who are overweight or obese have a twofold to threefold increased risk of hypertension. Insulin resistance and an adverse lipid profile often accompany adiposity (visceral obesity), and it is suggested that this trio of manifestations progresses more rapidly in children and adolescents who are prehypertensive or hypertensive, compared with children who are normotensive.

As with adults, nonpharmacological management (e.g., weight loss, exercise, reduction of dietary salt and fat) is often the initial strategy and may suffice to reduce blood pressure. Drugs used for the management of adult hypertension are also used in children and adolescents; however, angiotensin-converting enzyme inhibitors, angiotensin II receptor blockers, and calcium channel blockers have the strongest data to support their use in children and adolescents, although data availability is quite limited. Early treatment is indicated to decrease the risk of cardiovascular complications in adulthood.

Screening for hypertension in children and adolescents to prevent cardiovascular disease. *Pediatrics*, 131(3), 490–525. <https://doi.org/10.1542/peds.2012-3523>

The objective of antihypertensive therapy is the reduction of cardiovascular and renal morbidity and mortality. According to the 2018 Hypertension Canada guidelines, the goal is to achieve a pressure of less than 140/90 when taken on a non-automated office blood pressure machine (non-AOBP) and a pressure of less than 135/85 when taken on an automatic office blood pressure machine (AOBP), which is associated with a decrease in cardiovascular disease complications. In patients with hypertension and concurrent diabetes or concurrent nondiabetic chronic kidney disease, the goal is less than 130/80 mm Hg and 140/90 mm Hg, respectively.

Fortunately, many significant advances have been made in both the methods of treating hypertension and the understanding of the disease process. Large numbers of clinical trials have shown that adequately treating hypertension can prevent or delay cardiovascular disease. Over the past 40 years, the development of new antihypertensive medications has had an enormous impact on the quality of life of people with hypertension. Drug therapy for hypertension first became available in the early 1950s, with the introduction of ganglionic blocking drugs. However, unpleasant adverse effects and inconsistent therapeutic effects were common problems with these **antihypertensive drugs**. In 1953, the vasodilator hydralazine was introduced, and in 1958, the thiazide diuretics became available.

Since that time, several additional drug categories have been developed, including loop diuretics (also called

BOX 23.1 Categories and Subcategories of Antihypertensive Drugs

- Adrenergic Drugs
 - Centrally and peripherally acting adrenergic neuron blockers
 - Centrally acting α_2 -receptor agonists
 - Peripherally acting α_1 -receptor blockers
 - Peripherally acting β -receptor blockers (β -blockers)
 - Cardioselective (β_1 -receptor blockers)
 - Nonselective (β_1 - and β_2 -receptor blockers)
 - Peripherally acting dual α_1 - and β -receptor blockers
- Angiotensin-Converting Enzyme Inhibitors
- Angiotensin II Receptor Blockers
- Calcium Channel Blockers
 - Benzothiazepines
 - Dihydropyridines
 - Phenylalkylamines
- Diuretics
 - Loop diuretics
 - Potassium-sparing diuretics
 - Thiazides and thiazidelike diuretics
- Vasodilators
 - Act directly on vascular smooth muscle cells, *not* through α - or β -receptors
- Direct Renin Inhibitors

potassium-depleting diuretics), potassium-sparing diuretics, beta blockers (beta receptor antagonists), angiotensin-converting enzyme (ACE) inhibitors, α_1 antagonists, α_2 agonists, angiotensin II receptor blockers (ARBs), calcium channel blockers (CCBs), vasodilators, and the newest class, the direct renin inhibitors. Although some of the medications mentioned in this chapter represent older classes of drugs, all are current therapeutic options listed in the Hypertension Canada treatment guidelines for hypertension.

ANTIHYPERTENSIVE DRUGS

Drug therapy for hypertension needs to be individualized. Important considerations in planning drug therapy are whether the patient has multiple medical problems and what impact drug therapy will have on the patient's quality of life. For example, sexual dysfunction in males is a common adverse effect of almost any antihypertensive drug and is the most common reason for nonadherence to drug therapy. Demographic factors, ethnocultural implications, the ease of medication administration (e.g., a once-a-day dosing schedule or transdermal administration), and cost are other important considerations.

There are seven main categories of pharmacological drugs used to treat hypertension: diuretics, adrenergic drugs, ACE inhibitors, ARBs, CCBs, vasodilators, and direct renin inhibitors. All of these antihypertensive drugs (with the exception of diuretics) have some vasodilatory action. Drugs in any of these classes may be used alone or in combination. The various categories and subcategories of antihypertensive drugs are listed in **Box 23.1**. The diuretics are discussed in detail in **Chapter 29**.

Comparison of Autonomic and Somatic Motor Systems

Fig. 23.2 Location of the acetylcholine and norepinephrine receptors within the parasympathetic and sympathetic nervous systems.

REVIEW OF AUTONOMIC NEUROTRANSMISSION

There are two divisions of the autonomic nervous system (ANS): the parasympathetic (PSNS) and sympathetic (SNS) nervous systems. Stimulation of the ANS is controlled by the neurotransmitters acetylcholine and norepinephrine. Receptors for both divisions of the ANS are located throughout the body in a variety of tissues. ANS physiology can be reviewed in greater detail in the introductory sections of Chapters 19 to 22. Receptors in the SNS are called *adrenergic* or *noradrenergic* receptors (i.e., alpha or beta receptors). Receptors located between the postganglionic fibre and the effector cells (i.e., postganglionic receptors) are called the *muscarinic* or *cholinergic* receptors in the PSNS. Physiological activity at muscarinic receptors is stimulated by acetylcholine and cholinergic agonist drugs (see Chapter 21) and is inhibited by cholinergic antagonists (anticholinergic drugs; see Chapter 22). Similarly, physiological activity at adrenergic receptors is stimulated by norepinephrine, epinephrine, and adrenergic agonist drugs (see Chapter 19) and is inhibited by antiadrenergic drugs (adrenergic blockers, i.e., alpha or beta receptor blockers; see Chapter 20). Nicotinic receptors are found on the postganglionic cell bodies in all autonomic ganglia and cause depolarization by opening both sodium and potassium channels. Figure 23.2 shows how these various receptors are arranged in both the PSNS and SNS and indicates their corresponding neurotransmitters.

DIURETICS

The diuretics are a highly effective class of antihypertensive drugs. They are first-line antihypertensives in the Hypertension Canada guidelines for the treatment of hypertension (see Figure

First Line Treatment of Adults with Systolic/Diastolic Hypertension Without Other Compelling Indications

TARGET <140/90 mmHg (non-automated measurement method)
Initial Treatment

[†] Long-acting diuretics like indapamide and chlorthalidone are preferred over shorter acting diuretics like hydrochlorothiazide.

* β -blockers are not indicated as first-line therapy for age 60 and above.

**** Recommended SPC choices are those in which an ACE-I is combined with a CCB, an ARB with a CCB, or an ACE-I or ARB with a diuretic**

Renin angiotensin system (RAS) inhibitors are contraindicated in pregnancy and caution is required in prescribing to women of child-bearing potential

Fig. 23.3 First Line Treatment of Adults with Systolic/Diastolic Hypertension Without Other Compelling Indications. (Source: Hypertension Canada. (2018). Hypertension Canada's 2018 guidelines for diagnosis, risk assessment, prevention, and treatment of hypertension in adults and children. Retrieved from <https://guidelines.hypertension.ca/wp-content/uploads/2018/12/Hypertension-Canada-2018-Guidelines-for-Diagnosis-Risk-Assessment-Prevention-and-Treatment-of-Hypertension-in-Adults-and-Children.pdf>.)

23.3). They may be used as monotherapy or in combination with drugs of other antihypertensive classes. Their primary therapeutic effect is decreasing volumes of plasma and extracellular fluid, which results in decreased preload. This leads to a decrease in cardiac output and total peripheral resistance, all of which decrease the workload of the heart. This large group of

antihypertensives is discussed in detail in [Chapter 29](#). The thiazide diuretics (e.g., hydrochlorothiazide and chlorthalidone) are the most commonly used diuretics for hypertension.

ADRENERGIC DRUGS

Adrenergic drugs are a large group of antihypertensive drugs, as shown in [Box 23.1](#). The alpha blockers and combined alpha and beta blockers were described in detail in Chapter 20. The adrenergic drugs discussed here exert their antihypertensive action at different sites.

Mechanism of Action and Drug Effects

Five specific drug subcategories are included in the adrenergic antihypertensive drugs, as indicated in [Box 23.1](#). Each of these subcategories of drugs can be described as having central action (in the brain) or peripheral action (at the heart and in blood vessels). These drugs include the adrenergic neuron blockers (central and peripheral), the α_2 receptor agonists (central), the α_1 receptor blockers (peripheral), the beta receptor blockers (peripheral), and the combination α_1 and beta receptor blockers (peripheral).

The centrally acting α_2 -adrenergic receptor agonists clonidine and methyldopa act by modifying the function of the SNS. Stimulation of the SNS leads to an increased heart rate and force of contraction, the constriction of blood vessels, and the release of renin from the kidneys; the result is hypertension. The **centrally acting adrenergic drugs** act by stimulating the α_2 -adrenergic receptors in the brain. The α_2 -adrenergic receptors are unique in that receptor stimulation actually reduces sympathetic outflow, in this case from the central nervous system (CNS). This reduction results in a lack of norepinephrine production, which reduces blood pressure. Stimulation of the α_2 -adrenergic receptors also affects the kidneys, reducing the activity of renin. Renin is the hormone and enzyme that converts the protein precursor angiotensinogen to the protein angiotensin I, the precursor of angiotensin II, a potent vasoconstrictor that raises blood pressure.

In the periphery, the **α_1 blockers** doxazosin mesylate, prazosin hydrochloride, and terazosin hydrochloride also modify the function of the SNS. They do so by blocking the α_1 -adrenergic receptors. When α_1 -adrenergic receptors are stimulated by circulating norepinephrine, they produce increased blood pressure. When these receptors are blocked, blood pressure is decreased. The drug effects of the α_1 blockers are primarily related to their ability to dilate arteries and veins, which reduces peripheral vascular resistance and subsequently decreases blood pressure. This reduction produces a marked decrease in the systemic and pulmonary venous pressures and an increase in cardiac output. The α_1 blockers also increase urinary flow rates and decrease outflow obstruction by preventing smooth muscle contractions in the bladder neck and urethra. This can be beneficial in cases of benign prostate hyperplasia (BPH).

The beta blockers also act in the periphery and include propranolol hydrochloride, metoprolol tartrate, and atenolol, as well as several other drugs. These drugs are discussed in more detail in Chapters 24 and 26 because they are also used for angina and conduction problems. Their effects are related to their reduction of

the heart rate through β_1 receptor blockade. Furthermore, beta blockers also cause a reduction in the secretion of the hormone renin (see section on ACE inhibitors), which in turn reduces both angiotensin II-mediated vasoconstriction and aldosterone-mediated volume expansion. Long-term use of beta blockers also reduces peripheral vascular resistance.

The dual-action α_1 and beta receptor blocker labetalol hydrochloride (Trandate®) acts in the periphery at the heart and blood vessels. They have the dual antihypertensive effects of reduction in heart rate (β_1 receptor blockade) and vasodilation (α_1 receptor blockade). [Figure 23.4](#) illustrates the site and mechanism of action for the various antihypertensive drugs.

Indications

All of the drugs mentioned in this section are used primarily for the treatment of hypertension, either alone or in combination with other antihypertensive drugs. Various forms of glaucoma may also respond to treatment with some of these drugs. Clonidine is also used for menopausal flushing and has several off-label uses (that is, uses not approved by Health Canada but still common), including prophylaxis for migraine headaches and managing withdrawal symptoms in opioid, nicotine, or alcohol withdrawal (see [Chapter 18](#)). The α_1 blockers doxazosin mesylate, prazosin hydrochloride, and terazosin hydrochloride have been used to relieve the symptoms associated with BPH (see [Chapter 20](#)). They have also proven to be effective in the management of severe heart failure when used with cardiac glycosides (see [Chapter 25](#)) and diuretics (see [Chapter 29](#)).

Contraindications

Contraindications to the use of the adrenergic antihypertensive drugs include known drug allergy and may also include acute heart failure, concurrent use of monoamine oxidase inhibitors (see [Chapter 17](#)), severe depression, peptic ulcer, and severe liver or kidney disease. Asthma may also be a contraindication to the use of any noncardioselective beta blocker. The use of vasodilating drugs may also be contraindicated in cases of heart failure that is secondary to diastolic dysfunction.

Adverse Effects

The most common adverse effects of adrenergic drugs are bradycardia with reflex tachycardia, orthostatic and postexercise hypotension, dry mouth, drowsiness, dizziness, depression, edema, constipation, and sexual dysfunction (e.g., erectile dysfunction; see [Chapter 36](#) for drugs related to sexual dysfunction). Other effects include headaches, sleep disturbances, nausea, rash, and palpitations. There is a high incidence of **orthostatic hypotension** (a sudden drop in systolic BP of greater than or equal to 20 mm Hg or a drop in diastolic BP greater than or equal to 10 mm Hg when assuming a standing position) in patients taking alpha blockers. When the patient changes positions, a situation known as *first-dose syncope*, in which the hypotensive effect is severe enough to cause the patient to lose consciousness with even the first dose of medication, can occur. Educate patients taking these medications to change positions slowly.

In addition, the abrupt discontinuation of the centrally acting α_2 receptor agonists can result in rebound

hypertension, characterized by a sudden and high elevation of blood pressure. This may also be true for other antihypertensive drug classes, especially beta blockers. Nonselective blocking drugs are also commonly associated with bronchoconstriction (due to unrestrained parasympathetic tone) as well as metabolic inhibition of glycogenolysis in the liver, which can lead to hypoglycemia. However, hyperglycemic episodes are also among the adverse effects reported for this drug class as adrenergic drugs can impair insulin release (Dungan, Merrill, Long, et al., 2019).

Any change in the dosing regimen for cardiovascular medications should be undertaken gradually and with appropriate patient monitoring and follow-up. Although the same is also true for most other classes of medications, abrupt dosage changes of cardiovascular medications, either up or down, can be especially hazardous for the patient. Some of these drugs can also cause disruptions in blood counts as well as in serum electrolyte levels and kidney function. Periodic monitoring of white blood cell count, serum potassium and sodium levels (see also Evidence in Practice box), and urinary protein levels is recommended.

EVIDENCE IN PRACTICE

Reduced Dietary Sodium in Hypertension Management

Background

This Canadian survey investigated Canadians' concerns, actions, and reported barriers related to limiting sodium intake, as well as support for a 2010 government-led policy geared toward lowering Canadians' sodium intakes.

Type of Evidence

The researchers from the University of Toronto and University of Guelph conducted an online survey of Canadians about their knowledge, attitudes, and behaviours related to sodium, as well as barriers to limiting sodium consumption. A representative sample of the Canadian population in terms of age, sex, province, and education was used in the survey. In addition, taking into consideration the proposed federal Bill C-460, intended to legislate a formal set of recommendations, the researchers also sought to determine the level of support Canadians had for a number of sodium reduction initiatives.

Results of Study

There is strong public support for sodium reduction strategies, with 76% of Canadians supporting mandatory warning labels on high-sodium products and 68% believing that regulations about maximum allowable levels of sodium in foods in grocery stores, restaurants, and public facilities such as hospitals, schools, and government buildings. Eighty percent would like the food industry to lower the amount of sodium in food. However, little support for taxing foods high in sodium or for subsidization of foods lower in sodium was reported. Of interest, 67% of respondents were concerned about their sodium intake (particularly those with high blood pressure and older adults). Fifty percent were actively lowering their sodium intake but thought that not adding salt at the table was adequate. In contrast, others were not limiting their salt intake because they had good health and normal blood pressure.

Link of Evidence to Nursing Practice

Approximately 2 million Canadians have hypertension as a consequence of excess dietary intake of sodium, which is a key risk contributing to the disease burden in Canada (Hypertension Canada, 2018; Hypertension Canada, 2019). Hypertension is the leading risk factor for mortality in Canada and worldwide. Recommendations for salt intake vary depending on the source, with a range of 2 000 to 3 200 mg of sodium per day. According to Health Canada (2012), the average Canadian has a daily sodium intake of over 3 400 mg (equivalent to 1.5 teaspoons), and more than

90% of Canadian children aged 4 to 8 years exceed dietary sodium guidelines. The majority of this sodium intake (77%) is found primarily in processed, packaged, and restaurant foods. Foods that make up 19% of the sodium in individuals' diets are pizzas, hamburgers, hotdogs, and sandwiches, with soups accounting for 7% and pasta, 6%. Estimates are that one quarter of Canadian adults (approximately 7.5 million) have hypertension, with more than 9 in 10 Canadians expected to develop high blood pressure if they have an average lifespan of about 80 years. While Health Canada's new *Eating Well with Canada's Food Guide* publication recommends that Canadians reduce their sodium intake, the World Health Organization (WHO, 2014) advocates a regulated approach. The WHO suggests that governmental policies restricting the amount of sodium food industries add to food is more effective than simply recommending a reduction in sodium intake. Nurses can play a significant role in educating their patients about hypertension and how to reduce sodium intake. Reducing dietary sodium intake within the context of a healthy diet can substantially reduce the incidence of hypertension among Canadians with normal blood pressure. Therefore, a population health approach to reducing dietary sodium is an appropriate strategy.

The Hypertension Canada 2018 recommendations for lifestyle modifications to prevent and treat hypertension include the following:

- Recommended dietary sodium intake is less than 87 mmol, or 5 g per day (equal to 2 000 mg of sodium per day). NOTE: The terminology of sodium and salt content is confusing. Conversion: 2 300 mg sodium is approximately one teaspoon of salt (sodium chloride), 100 mmol of sodium or salt, or 5.8 g (5 800 mg) of salt (NaCl). Further information can be found at: <https://www.canada.ca/en/health-canada/services/publications/food-nutrition/sodium-intake-canadians-2017.html#a5>.
- Perform 30 to 60 minutes of aerobic exercise 4 to 7 days per week.
- Maintain a healthy body weight (body mass index 18.5 kg/m² to 24.9 kg/m²) and waist circumference (smaller than 102 cm for men and smaller than 88 cm for women).
- Limit alcohol consumption to no more than 15 drinks per week in men or 10 drinks per week in women.
- Follow a diet that is reduced in saturated fat and cholesterol and that emphasizes fruits, vegetables, and low-fat dairy products, dietary and soluble fibre, whole grains, and protein from plant sources (Dietary Approaches to Stop Hypertension [DASH] diet).
- Consider stress management in selected individuals with hypertension.

TABLE 23.1 Adrenergic Drugs: Drug Interactions			
Drug	Interacts With	Mechanism	Result
clonidine	TCAs, MAOIs, appetite suppressants, amphetamines	Opposing actions	Decreased hypotensive effects
	Diuretics, nitrates, other antihypertensive drugs	Additive	Increased hypotensive effects
	β-blockers	Additive	May potentiate bradycardia and increase the rebound hypertension in clonidine withdrawal
doxazosin mesylate	CNS depressants, alcohol	Additive	Increased CNS depression
	β-blockers and other hypotensive drugs	Additive	Increased hypotension
	verapamil hydrochloride	Increased serum prazosin levels	Increased hypotension

CNS, Central nervous system; MAOIs, monoamine oxidase inhibitors; TCAs, tricyclic antidepressants.

Interactions

Adrenergic drugs can cause additive CNS depression when taken with alcohol, benzodiazepines, and opioids. Other drug interactions that can occur with selected adrenergic drugs are summarized in Table 23.1. This list is merely representative and is not exhaustive. Always keep a drug information handbook available to check when a specific drug interaction is suspected. Pharmacists are also excellent resources.

Dosages

For dosage information on selected adrenergic antihypertensive drugs, refer to the table on the next page.

DRUG PROFILES

Alpha₂-Adrenergic Receptor Stimulators (Agonists)

Of the two alpha₂ receptor agonists—clonidine and methyldopa—clonidine is by far the most commonly used and the prototype drug for this class. Methyldopa is commonly used to treat hypertension in pregnancy. However, these drugs are not typically prescribed as first-line antihypertensive drugs because their use is associated with a high incidence of adverse effects such as orthostatic hypotension, fatigue, and dizziness. They may be used as adjunct drugs in the treatment of hypertension after other drugs have failed or may be used in conjunction with other antihypertensives such as diuretics.

clonidine hydrochloride

Clonidine hydrochloride (Catapres®, Dixarit®) is used primarily for its ability to decrease blood pressure. It is also useful in the management of opioid withdrawal. Clonidine has a better safety profile than the other centrally acting adrenergics. It must not be discontinued abruptly as this will lead to severe rebound hypertension. Its use is contraindicated in patients who have shown hypersensitivity reactions to it. It is available for oral use only. For recommended dosages refer to the table below.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	30–60 min	3–5 hr	6–20 hr	8 hr

Alpha₁ Blockers

The alpha₁ blockers include doxazosin mesylate (Cardura®), prazosin hydrochloride (Minipress®), tamsulosin hydrochloride (Flomax CR®), and terazosin hydrochloride (Hytrin®). Their use is contraindicated in patients who have shown a hypersensitivity to them. They are not recommended for use during pregnancy. They are available only as oral preparations. Tamsulosin hydrochloride is not used to manage blood pressure but is indicated solely for symptomatic management of BPH. This use is described further in Chapters 19 and 35.

doxazosin mesylate

Doxazosin mesylate (Cardura) is a commonly used alpha₁ blocker. It reduces peripheral vascular resistance and blood pressure by dilating both arterial and venous blood vessels. It has been shown to be beneficial in the treatment of hypertension and the

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1–2 hr	2–3 hr	15–22 hr	Less than 24 hr

relief of the symptoms of obstructive BPH. It is available for oral use. For recommended dosages, refer to the table on this page.

Dual-Action Alpha₁ and Beta Receptor Blockers Beta Receptor Blocker

nebivolol hydrochloride

Nebivolol hydrochloride (Bystolic®) is the newest beta blocker, released in 2013. It is a beta₁-selective blocker, approved for use in hypertension. Nebivolol hydrochloride is similar to other beta₁-selective blockers; however, in addition to blocking beta₁ receptors, it also produces an endothelium-derived, nitric oxide-dependent vasodilation, which results in a decrease in SVR. It is promoted as reducing sexual dysfunction. Like other beta blockers, it should not be stopped abruptly but must be tapered over 1 to 2 weeks. Dosing starts at 5 mg/day and may be increased at 2-week intervals to a maximum of 20 mg/day.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

The ACE inhibitors are members of a large group of antihypertensive drugs. There are a number of ACE inhibitors available for clinical use in addition to various combination drug products in which a thiazide diuretic or a CCB is combined with an ACE inhibitor. Combination products tend to improve adherence since the patient is taking fewer drugs. ACE inhibitors are safe and efficacious and are often used as one of the first-line drugs in the treatment of both heart failure and hypertension. They are also used as first-line drugs in patients with concurrent diabetes for kidney protection. The available ACE inhibitors, drug combinations, and dosing schedules are summarized in Table 23.2. The drugs that make up the class of ACE inhibitors are quite similar to one another and differ in only a few of their chemical properties; however, there are some differences among them in their clinical properties.

Captopril has the shortest half-life and therefore must be dosed more frequently than any of the other ACE inhibitors. This may be an important drawback for patients with a history of nonadherence to their medication regimen. On the other hand, it may be best to start with a drug that has a short half-life in a patient who is critically ill, so that if problems arise they will be short-lived. Both captopril and enalapril can be dosed multiple times a day.

Dosages

Selected Antihypertensive Drugs: Adrenergic Agonists and Antagonists

Drug	Pharmacological Class	Usual Dosage Range	Indications
▶ clonidine hydrochloride (Catapres, Dixarit)	Centrally acting α ₂ -receptor agonist	<i>Adults</i> PO: Initial dose 0.2–0.6 mg/day divided bid	Hypertension (may have other off-label uses including treatment of psychiatric, cardiovascular, and gastrointestinal problems as well as opioid withdrawal and menopausal hot flashes)
doxazosin mesylate (Cardura)	Peripherally acting α ₁ -receptor antagonist	<i>Adults</i> PO: Initial dose 0.1 mg/day; titrate up to maximum of 16 mg/day	Hypertension

PO, Oral.

TABLE 23.2 ACE Inhibitors: Distinguishing Characteristics

Drug (Trade Name)	Combination With Hydrochlorothiazide	Dose Schedule
benazepril hydrochloride (Fortekor®, Lotensin®)	None	Once a day
captopril (Capoten®)	None	Multiple
cilazapril (Inhibace®)	Inhibace Plus®	Once a day
enalapril sodium (Vasotec®)	Vaseretic®	Multiple
fosinopril sodium	None	Once a day
lisinopril (Prinivil®, Zestril®)	Zestoretic®	Once a day
perindopril erbumine (Coversyl®)	None	Once a day
quinapril hydrochloride (Accupril®)	Accuretic®	Once a day
ramipril (Altace®)	Altace HCT®	Once to twice daily
trandolapril (Mavik®)	None	Once a day

ACE, Angiotensin-converting enzyme; HCT, hydrochlorothiazide.

Captopril and lisinopril are the only two ACE inhibitors that are not prodrugs. A **prodrug** is a drug that is inactive in its administered form and must be metabolized to its active form by the liver and/or gastrointestinal (GI) tract to be effective. This characteristic of captopril and lisinopril is an important advantage in treating a patient with liver dysfunction; all of the other ACE inhibitors are prodrugs, and their transformation to active form is dependent upon liver function to reveal the active drug.

Enalapril is the only ACE inhibitor available in a parenteral preparation. All of the newer ACE inhibitors, such as benazepril hydrochloride, fosinopril sodium, lisinopril, quinapril hydrochloride, and ramipril have long half-lives and long durations of action, which allows once-a-day dosing. A once-a-day medication regimen promotes better patient adherence.

When used in pregnancy during the second and third trimesters, ACE inhibitors may cause significant fetal morbidity or mortality, so they should be discontinued as soon as possible if pregnancy is detected. ACE inhibitors are to be used by pregnant women only if there are no safer alternatives.

Mechanism of Action and Drug Effects

The development of ACE inhibitors was spurred by the discovery of an animal substance found to have beneficial effects in humans. This particular substance was the venom of a South American viper, which was found to inhibit kininase activity. Kininase is an enzyme that normally breaks down bradykinin, a potent vasodilator in the human body.

As their name implies, these drugs inhibit angiotensin-converting enzyme, which is responsible for converting angiotensin I (formed through the action of renin) to angiotensin II. Angiotensin II is a potent vasoconstrictor and induces aldosterone secretion by the adrenal glands. Aldosterone stimulates sodium and water resorption, which can raise blood pressure. Together, these processes are referred to as the renin–angiotensin–aldosterone system. By inhibiting this process, blood pressure is lowered.

The primary effects of the ACE inhibitors are cardiovascular and renal. Their cardiovascular effects are due to their ability to reduce blood pressure by decreasing SVR. They do this by preventing the breakdown of the vasodilating substance bradykinin and substance P (another potent vasodilator), thus preventing the formation of angiotensin II. These combined effects decrease afterload, or the resistance against which the left ventricle must pump to eject its volume of blood during contraction. ACE inhibitors are beneficial

in the treatment of heart failure because they prevent sodium and water resorption by inhibiting aldosterone secretion. This causes diuresis, which decreases blood volume and return to the heart. This in turn decreases preload, or the left ventricular end-diastolic volume, and the work required of the heart.

Indications

The therapeutic effects of the ACE inhibitors are related to their potent cardiovascular effects. They are excellent antihypertensives and adjunctive drugs for the treatment of heart failure. They may be used alone or in combination with other drugs such as diuretics in the treatment of hypertension or heart failure.

The beneficial hemodynamic effects of the ACE inhibitors have been studied extensively. Because of their ability to decrease SVR (a measure of afterload) and preload, ACE inhibitors can stop the progression of left ventricular hypertrophy, which is sometimes seen after a myocardial infarction. This pathological process is known as *ventricular remodelling*. The ability of ACE inhibitors to prevent this process is termed a *cardioprotective effect*. ACE inhibitors have been shown to decrease morbidity and mortality rates in patients with heart failure. They are considered the drugs of choice for hypertensive patients with heart failure. ACE inhibitors also have been shown to have a protective effect on the kidneys because they reduce glomerular filtration pressure. This is one reason why they are among the cardiovascular drugs of choice for patients diagnosed with diabetes. Numerous studies have shown that the ACE inhibitors reduce proteinuria, and they are considered by many to be standard therapy for patients with diabetes to prevent the progression of diabetic nephropathy. The various therapeutic effects of the ACE inhibitors are listed in Table 23.3, which lists the biochemicals on which ACE inhibitors act and the resulting beneficial hemodynamic effects.

Contraindications

Contraindications to the use of ACE inhibitors include known drug allergy, especially a previous reaction of angioedema (e.g., laryngeal swelling) to an ACE inhibitor. Patients with a baseline potassium level of 5 mmol/L or higher may not be suitable candidates for ACE inhibitor therapy because these drugs can promote hyperkalemia (see later discussion). Kidney function decline is a precaution. Although kidney protective, starting an ACE inhibitor in a patient with significant kidney decline would be further detrimental to kidney function. All ACE inhibitors

TABLE 23.3 ACE Inhibitors: Therapeutic Effects

Body Substance	Effect in Body	ACE Inhibitor Action	Resulting Hemodynamic Effect
aldosterone	Causes sodium and water retention	Prevents its secretion	Diuresis = ↓ plasma volume = ↓ filling pressures or ↓ preload
angiotensin II	Potent vasoconstrictor	Prevents its formation	↓ SVR = ↓ afterload
bradykinin	Potent vasodilator	Prevents its breakdown	↓ SVR = ↓ afterload

ACE, Angiotensin-converting enzyme; ↓, decreased; SVR, systemic vascular resistance.

are contraindicated in women who are lactating, children, and patients with bilateral renal artery stenosis.

Adverse Effects

Major CNS effects of ACE inhibitors include fatigue, dizziness, mood changes, and headaches. A characteristic dry, nonproductive cough may occur that is reversible with discontinuation of the therapy (the ACE inhibitor is usually switched to an ARB). A first-dose hypotensive effect can cause a significant decline in blood pressure. Other adverse effects include loss of taste, hyperkalemia, rash, anemia, neutropenia, thrombocytosis, and agranulocytosis. In patients with severe heart failure whose kidney function may depend on the activity of the renin–angiotensin–aldosterone system, treatment with ACE inhibitors may cause acute kidney failure. ACE inhibitors promote potassium resorption in the kidney, although they promote sodium excretion because of their reduction of aldosterone secretion. For this reason, serum potassium levels must be monitored regularly. This is particularly true when there is concurrent therapy with potassium-sparing diuretics, although many patients tolerate both types of drug therapy with no major problems. One rare, but potentially fatal, adverse effect is angioedema, a strong vascular reaction involving inflammation of submucosal tissues, which can progress to anaphylaxis.

Toxicity and Management of Overdose

The most pronounced symptom of an overdose of an ACE inhibitor is hypotension. Treatment is symptomatic and supportive and includes the administration of intravenous fluids to expand blood volume. Hemodialysis is effective for the removal of captopril and lisinopril.

Interactions

Nonsteroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen, can reduce the antihypertensive effect of ACE inhibitors (see [Chapter 49](#)). The use of NSAIDs and ACE inhibitors may also predispose patients to the development of acute kidney injury. Concurrent use of ACE inhibitors and other antihypertensives or diuretics can have hypotensive effects. Giving lithium carbonate and ACE inhibitors together can result in lithium toxicity. Potassium supplements and potassium-sparing diuretics, when administered with ACE inhibitors, may result in hyperkalemia. The monitoring of serum potassium levels becomes important in these cases. False-positive results on tests for acetone in the urine may occur in patients taking captopril.

Dosages

For dosage information on selected ACE inhibitors, refer to the table on the next page.

DRUG PROFILES

◆ ACE Inhibitors

captopril

Captopril (Capoten) was the first available ACE inhibitor and is considered the prototypical drug for the class. Several large multicentre studies have shown its clinical efficacy in minimizing or preventing the left ventricular dilation and dysfunction (also called *ventricular remodelling*) that can arise in the acute period after a myocardial infarction, and thereby improve the patient's chances of survival. It can also reduce the risk of heart failure in these patients. It has the shortest half-life of all of the currently available ACE inhibitors, and it must be given three or four times a day. For recommended dosages, refer to the table below.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	15 min	1–2 hr	2 hr	2–6 hr

enalapril sodium

Enalapril sodium (Vasotec) is the only ACE inhibitor currently marketed that is available in both oral and parenteral preparations. The parenteral formulation (enalaprilat) is an active drug. It offers the hemodynamic benefit of inhibiting ACE activity in an acutely ill patient who cannot tolerate oral medications. The other benefit to intravenous enalapril is that it does not require cardiac monitoring as the intravenous beta blockers and CCBs do. Although its half-life is slightly longer than that of captopril, it may still have to be given twice a day. The oral form of enalapril differs from captopril in that it is a prodrug, and the patient must have a functioning liver for the drug to be converted into its active form. As with captopril, it has been shown in many large studies to improve a patient's chances of survival after a myocardial infarction and to reduce the incidence of heart failure. For recommended dosages refer to the table below.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1 hr	4–6 hr	2 hr	12–24 hr
IV	15 min	1–4 hr	2 hr	4–6 hr

Dosages

Selected Antihypertensive Drugs: ACE Inhibitors and Angiotensin II Receptor Blockers

Drug	Pharmacological Class	Usual Dosage Range	Indications
 captopril (Capoten)	ACE inhibitor	Adults PO: 25–150 mg bid–tid	Hypertension, heart failure
enalapril sodium (Vasotec)	ACE inhibitor	Children (less than 16 years) PO: 0.08 mg/kg (up to 5 mg) once daily Adults PO: 10–40 mg/day as a single dose or in 2 divided doses PO: 2.5–40 mg/day as a single or divided dose IV: 1.25 mg q6h over a 5-min period	Hypertension Hypertension Heart failure Hypertension
 losartan potassium (Cozaar)	Angiotensin II receptor blocker	Adults PO: 50–100 mg once daily	Hypertension

ACE, Angiotensin-converting enzyme; IV, intravenous; PO, oral.

ANGIOTENSIN II RECEPTOR BLOCKERS

Angiotensin II receptor blockers (ARBs) are similar to ACE inhibitors. The class includes losartan (Cozaar®), eprosartan mesylate (Teveten®), valsartan (Diovan®), irbesartan, candesartan cilexetil (Atacand®), telmisartan (Micardis®), and azilsartan medoxomil potassium (Edarbi®).

Mechanism of Action and Drug Effects

The ARBs block the binding of angiotensin II to type 1 angiotensin II receptors. These type 1 receptors are thought to mediate the effects of important effectors in controlling blood pressure and volume in the cardiovascular system. The type 1 receptor is activated by angiotensin II with resulting effects that include vasoconstriction and aldosterone synthesis and secretion. The ACE inhibitors such as enalapril block conversion of angiotensin I to angiotensin II, but angiotensin II may be formed by other enzymes that are not blocked by ACE inhibitors. For comparison, recall that ACE inhibitors block the breakdown of bradykinins and substance P, which accumulate and may cause adverse effects such as cough but might also contribute to the drugs' antihypertensive and heart and nephroprotective effects. Bradykinins are potent vasodilators and help to reduce blood pressure by dilating arteries and decreasing SVR.

In contrast to ACE inhibitors, ARBs affect primarily vascular smooth muscle and the adrenal gland. By selectively blocking the binding of angiotensin II to the type 1 angiotensin II

receptors in these tissues, ARBs block vasoconstriction and the secretion of aldosterone. Angiotensin II receptors have been found in other tissues throughout the body, but the effects of ARB blocking of these receptors is unknown.

Clinically, ACE inhibitors and ARBs appear to be equally effective for the treatment of hypertension. Both are well tolerated, but ARBs do not cause cough. There is evidence that ARBs are better tolerated and have lower mortality after myocardial infarction than ACE inhibitors. It is not yet clear whether ARBs are as effective as ACE inhibitors in treating heart failure or in protecting the kidneys, as in diabetes. Both types of drugs are contraindicated for use in the second or third trimester of pregnancy. Whether one or more of these drugs, particularly the newer drugs, could prove to have unique adverse effects with long-term use is unknown at this time.

Indications

The therapeutic effects of ARBs are related to their potent vasodilating properties. They are excellent antihypertensives and adjunctive drugs for the treatment of heart failure. They may be used alone or in combination with other drugs such as diuretics in the treatment of hypertension or heart failure. The beneficial hemodynamic effect of ARBs is their ability to decrease SVR (a measure of afterload). Their use is rapidly growing, and many more studies are verifying their beneficial effects. Currently, these drugs are used primarily in patients who have been intolerant of ACE inhibitors.

Contraindications

Contraindications to the use of ARBs are known drug allergy, pregnancy, and lactation. They need to be used cautiously in older adults and in patients with kidney dysfunction because of increased sensitivity to their effects and risk for more adverse effects in these patients. As with other antihypertensives, blood pressure and apical pulse rate need to be assessed before and during drug therapy.

Adverse Effects

The most common adverse effects of ARBs are upper respiratory infections and headache. Occasionally, dizziness, inability to sleep, diarrhea, dyspnea, heartburn, nasal congestion, back pain, and fatigue can occur. Rarely, anxiety, muscle pain, sinusitis, cough, and insomnia can also occur. Hyperkalemia is much less likely to occur with ARBs than with the ACE inhibitors.

Toxicity and Management of Overdose

Overdose may manifest as hypotension and tachycardia; bradycardia occurs less often. Treatment is symptomatic and supportive and includes the administration of intravenous fluids to expand blood volume.

Interactions

The drugs that interact with ARBs, the mechanisms responsible, and the results of the interactions are summarized in [Table 23.4](#). In addition, as is the case with ACE inhibitors, ARBs can promote hyperkalemia, especially when taken concurrently with potassium supplements (although this occurs much less frequently than with ACE inhibitors). Patients' individual

chemistry varies widely, however, so monitoring of serum potassium level is necessary for all patients. Potassium supplements may still be indicated for those patients with a tendency toward hypokalemia (whether acute or chronic).
