In March 2019, Health Canada was voluntarily recalling two lots of combination drugs Losartan/hydrochlorothiazide for containing the impurity N-nitroso-N-methyl-4-aminobutyric acid (NMBA). Long term exposure of NMBA is potentially a human carcinogen agent and may increase the risk of cancer. Health Canada advised that there was no immediate risk to patients who may have been taking the medication; however, patients should be closely monitored for manifestations of cancer. Patients should not abruptly stop taking this medication unless advised by their health care provider ([Government of Canada, 2019](#)).

Dosages

For dosage information on the ARBs, refer to the table on the previous page.

DRUG PROFILES

Losartan potassium

Losartan potassium (Cozaar) is beneficial for patients with hypertension and heart failure. Studies indicate that ARBs are better tolerated and produce a marginally lower mortality rate after myocardial infarction than treatment with ACE inhibitors.

The use of losartan is contraindicated in patients who are hypersensitive to any component of this product. It is to be used with caution in patients with kidney or liver dysfunction and in patients with renal artery stenosis. Breastfeeding women must not take losartan because it can cause serious adverse effects on the nursing infant. For recommended dosages, refer to the table on the previous page.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1 hr	6 hr	6–9 hr	24 hr

CALCIUM CHANNEL BLOCKERS

CCBs are also discussed in detail in the chapters on antidysrhythmic drugs (see [Chapter 26](#)) and antianginal drugs (see [Chapter 24](#)). As a class of medications, they are used for several indications and have many beneficial effects and relatively few adverse effects. CCBs are used primarily for the treatment of hypertension and angina. Their effectiveness in treating hypertension is related to their ability to cause smooth muscle relaxation by blocking the binding of calcium to its receptors. Because of their effectiveness and safety, they are also a first-line drug for the treatment of hypertension. Amlodipine mesylate (Norvasc®) is the CCB most commonly used for hypertension. CCBs are effective antidysrhythmics (see [Chapter 26](#)). One specific CCB, nimodipine, can prevent the cerebral artery spasms that can occur after

a subarachnoid hemorrhage. CCBs are sometimes used in the treatment of Raynaud's disease and migraine headache. Finally, they are also used in combination with other drugs—for example, amlodipine mesylate/atorvastatin calcium (Caduet®), an antihypertensive and cholesterol-lowering drug (see [Chapter 28](#)), and amlodipine mesylate/temisartan (Twynsta®), an antihypertensive and angiotensin II AT₁ receptor blocker.

VASODILATORS

Vasodilators act directly on arterial and venous smooth muscle to cause relaxation. They do not work through adrenergic receptors. Vasodilator drugs include minoxidil (Loniten®), hydralazine (Apresoline®), diazoxide (Proglycem®), and sodium nitroprusside (Nipride®).

Mechanism of Action and Drug Effects

Direct-acting vasodilators are useful as antihypertensive drugs because of their ability to cause peripheral vasodilation. This effect results in a reduction in SVR. In general, the most notable effect of the vasodilators is their hypotensive effect. However, minoxidil (Rogaine®, its topical form) has received attention because of its effectiveness in restoring hair growth. This application is further described in Chapter 56. Diazoxide, hydralazine, and minoxidil work primarily through arteriolar vasodilation, whereas sodium nitroprusside has both arteriolar and venous effects.

Indications

All of the vasodilators can be used to treat hypertension, either alone or in combination with other antihypertensives. Sodium nitroprusside and intravenous diazoxide are reserved for the management of hypertensive emergencies, in which blood pressure is severely elevated.

Contraindications

Contraindications include known drug allergy and may also include hypotension, cerebral edema, head injury, acute myocardial infarction, and coronary artery disease. They may also be contraindicated in cases of heart failure secondary to diastolic dysfunction.

Adverse Effects

Adverse effects of hydralazine include dizziness, headache, anxiety, tachycardia, edema, dyspnea, nausea, vomiting, diarrhea, hepatitis, systemic lupus erythematosus (SLE), vitamin B₆ deficiency, and rash. Minoxidil adverse effects include T-wave electrocardiographic changes, pericardial effusion or tamponade, angina, breast tenderness, rash, and thrombocytopenia. Adverse effects of sodium nitroprusside include bradycardia, decreased platelet aggregation, rash, hypothyroidism, hypotension, methemoglobinemia, and, rarely, cyanide toxicity. Cyanide ions are a by-product of sodium nitroprusside metabolism. Cyanide and thiocyanate toxicity are seen clinically when sodium nitroprusside is used at high dosages for long periods of time or in patients with renal insufficiency. When sodium nitroprusside is combined with sodium thiosulphate, the potential for cyanide toxicity is greatly reduced.

TABLE 23.4 Angiotensin II Receptor Blockers: Drug Interactions

Drug	Mechanism	Result
NSAIDs	Decreased antihypertensive	Decreased effect of ARB and potential to kidney failure
lithium	Inhibits lithium carbonate elimination	Increased lithium concentrations
phenobarbital	Increases metabolism	Decreased ARB effectiveness
potassium supplements and potassium-sparing diuretics	Additive potassium-increasing effects	Possible hyperkalemia

ARB, angiotensin II receptor blocker; NSAIDs, nonsteroidal anti-inflammatory drugs.

Toxicity and Management of Overdose

Hydralazine toxicity or overdose produces hypotension, tachycardia, headache, and generalized skin flushing. Treatment is supportive and symptomatic and includes the administration of intravenous fluids, digitalization if needed, and the administration of beta blockers for the control of tachycardia.

Minoxidil overdose or toxicity can precipitate excessive hypotension. Treatment is supportive and symptomatic and includes the administration of intravenous fluids. Norepinephrine and epinephrine should not be used to reverse the hypotension because of the possibility of excessive cardiac stimulation.

The main symptom of sodium nitroprusside overdose or toxicity is severe hypotension. This drug is normally administered only to patients receiving intensive care. Under these conditions, the infusion rate is usually carefully titrated, yielding immediately visible results on a cardiovascular monitor that provides constant measurements of blood pressure from centrally placed venous or arterial catheters. For this reason, excessive hypotension is usually avoidable. When it does occur, discontinuation of the infusion has an immediate effect because the drug is metabolized rapidly (with a half-life of 10 minutes). Treatment for the hypotension is supportive and symptomatic; if necessary, pressor drugs can be infused to quickly raise blood pressure. The chemical structure of sodium nitroprusside contains cyanide groups, which are released upon its metabolism in the body and can result in cyanide or thiocyanate toxicity. This usually occurs clinically when the drug is used at high dosages for prolonged periods or in patients with kidney failure. If cyanide or thiocyanate toxicity occurs, treatment can be administered using a standard cyanide antidote kit that includes sodium nitrite and sodium thiosulfate for injection and amyl nitrite for inhalation.

Interactions

The incidence of drug interactions is low for the direct-acting vasodilators as a class. Hydralazine can produce additive hypotensive effects when given with adrenergic or other antihypertensive drugs.

Dosages

For dosage information for selected vasodilator drugs, refer to the table on in the next column.

DRUG PROFILES

hydralazine hydrochloride

Hydralazine hydrochloride (Apresoline) is less commonly used now than when it first became available, but it is still effective for selected patients. It can be taken orally for routine cases of essential hypertension. It is also available in injectable form for hypertensive emergencies and is useful for patients who cannot tolerate oral therapy in the hospital. Some hospitals may not require cardiac monitoring when it is given intravenously. Contraindications include drug allergy, coronary artery disease, and mitral valve dysfunction, such as that related to childhood rheumatic fever.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	5–20 min	30–45 min	2–8 hr	1–4 hr
PO	20–30 min	1–2 hr	2–8 hr	8 hr

sodium nitroprusside

Sodium nitroprusside (Nipride), like diazoxide, is normally used in the critical care setting for severe hypertensive emergencies and is titrated to effect by intravenous infusion. Its use is contraindicated in patients with a known hypersensitivity to the drug, severe heart failure, and known inadequate cerebral perfusion (especially during neurosurgical procedures). For recommended dosages refer to the table below.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Less than 2 min	2–5 min	2 min	1–10 min

Dosages

Selected Antihypertensive Drugs: Vasodilators

Drug	Pharmacological Class	Usual Dosage Range	Indications
 hydralazine hydrochloride (Apresoline)	Direct-acting peripheral vasodilator	<i>Adults</i> PO: 10 mg qid for 2–4 days, followed by 25 mg qid for balance of week; second and subsequent weeks 50 mg qid, then adjust to lowest effective dose for maintenance IV: 5–40 mg prn	Hypertension
sodium nitroprusside (Nipride)		<i>Children/Adults</i> IV: 0.5–8 mcg/kg/min	

PO, oral; IV, intravenous.

DRUG PROFILES

Direct Renin Inhibitors

Direct renin inhibitors are the most recent classification of drugs to be used in the treatment of primary hypertension. The sole drug in this class is aliskiren.

aliskiren fumarate

Aliskiren fumarate (Rasilez®) is the only drug in the class of low-molecular-weight direct renin inhibitors. This drug is indicated for the treatment of mild to moderate hypertension. Its use is currently recommended as monotherapy or in combination with other antihypertensive drugs such as thiazide diuretics, ACE inhibitors, or dihydropyridine CCBs because of its synergistic effects.

Aliskiren has a unique mechanism of action: it binds directly to the renin enzyme and blocks the conversion of angiotensinogen to angiotensin I and angiotensin II. This action results in the reduction of plasma renin activity and angiotensin I, angiotensin II, and aldosterone. Use of other antihypertensive drugs that work on the renin–angiotensin–aldosterone system, such as the ACE inhibitors and ARBs, results in a compensatory rise in the plasma renin levels because of their suppression of the negative feedback loop. Because of aliskiren's extended half-life, this compensatory rise in plasma renin does not occur. Antihypertensive effect occurs within 2 weeks after initiating therapy with 150 mg per day, and a maximum effect is reached after 4 weeks.

Its use is contraindicated in those who are hypersensitive to it. Aliskiren is generally well tolerated. The most common adverse effects include headache, dizziness, fatigue, and dose-related GI effects such as diarrhea. The concomitant use of aliskiren with cyclosporine is not recommended. Aliskiren is available for oral use. It is also available in combination with hydrochlorothiazide (Rasilez HCT®). The common adult dosage for this drug is 150 to 300 mg PO, once daily. It is also not recommended for use during pregnancy.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	30 min	1–3 hr	31–41 hr	7 days

DRUG PROFILES

Miscellaneous Antihypertensive Drugs

Four newer medications exemplify some of the antihypertensives most recently made available in Canada. These include eplerenone, bosentan monohydrate, treprostinil sodium, and epoprostenol sodium. All of these drugs are currently indicated for adult use only.

Eplerenone

Eplerenone (Inspra®) is currently the only drug in a new class of antihypertensive drugs called *selective aldosterone blockers*. It reduces blood pressure by blocking the actions of the hormone aldosterone at its corresponding receptors in the kidney, heart, blood vessels, and brain. Eplerenone is indicated for both routine treatment of hypertension and postmyocardial infarction

heart failure. Its use is contraindicated in patients with known drug allergy, elevated serum potassium levels (higher than 5.5 mmol/L), or severe kidney impairment and in those using a medication that inhibits the action of cytochrome P450 enzyme 3A4. Many commonly used medications inhibit the action of this enzyme, including several antibiotic, antifungal, and antiviral drugs. Recommended dosages are given in the table on this page.

bosentan monohydrate

Bosentan monohydrate (Tracleer®) works by blocking the receptors of the hormone endothelin. Normally this hormone acts to stimulate the narrowing of blood vessels by binding to endothelin receptors (ET_A and ET_B) in the endothelial (innermost) lining of blood vessels and in vascular smooth muscle. Bosentan reduces blood pressure by blocking this action. However, currently its use is specifically indicated only for the treatment of pulmonary artery hypertension in patients with moderate to severe heart failure. Its use is contraindicated in patients with known drug allergy, with significant liver impairment, who are pregnant, and who are receiving concurrent drug therapy with cyclosporine or glyburide.

Ambrisentan (Volibris®) is a new drug similar to bosentan. Other drugs used to treat pulmonary hypertension include epoprostenol, and treprostinil. The erectile dysfunction drugs sildenafil citrate and tadalafil are also used (see Chapter 36); both sildenafil citrate and tadalafil have different trade names when used for pulmonary hypertension—sildenafil citrate (commonly known as Viagra®) also has the trade name Revatio®, and tadalafil (commonly known as Cialis®) is Adcirca® when used for pulmonary hypertension.

Dosages

Miscellaneous Antihypertensive Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications
bosentan monohydrate (Tracleer)	Endothelin-receptor antagonist	Adults PO: Initial dose of 62.5 mg bid × 4 wk, then increase as tolerated to maintenance dose of 125 mg bid	Pulmonary artery hypertension in patients with moderate to severe heart failure
eplerenone (Inspra)	Aldosterone receptor antagonist	Adults PO: Initial dose of 50 mg once/day × 4 wk, then increase as tolerated to max dose of 50 mg bid	Hypertension and postmyocardial infarction status (to improve postmyocardial infarction survival in patients with stable heart failure)
treprostinil sodium (Remodulin)	Vasodilator and platelet aggregation inhibitor	Adults Continuous subcutaneous infusion: 0.625–1.25 ng/kg/min	Pulmonary artery hypertension in patients with severe heart failure

PO, oral.

treprostinil sodium

Treprostinil sodium (Remodulin®) and epoprostenol are analogues of prostacyclin, a metabolite of arachidonic acid, a naturally occurring prostaglandin that lowers blood pressure through a combined mechanism of action, by dilating both pulmonary and systemic blood vessels and by inhibiting platelet aggregation. Like bosentan, treprostinil is indicated specifically for long-term management of pulmonary artery hypertension in patients with moderate to severe heart failure. Its only current contraindication is known drug allergy. Both drugs are unique in that they are diluted to the nanogram level for administration. For recommended dosages of treprostinil, refer to the table below.

NURSING PROCESS

Over the last several decades, the diagnosis and treatment of hypertension has changed greatly, from a stepped approach to a medical regimen that is now based on guidelines from Hypertension Canada. These guidelines apply to adults 18 years of age and older and describe evaluation, classification, diagnosis, risk factors, identifiable causes, and blood pressure measurement techniques. A new recommendation is the assessment of global cardiovascular risk using a multifactorial risk assessment model. The Hypertension Canada guidelines identify a high-normal blood pressure, often referred to as *prehypertension*, defined as a systolic blood pressure of 120 to 139 mm Hg or diastolic blood pressure of 80 to 89 mm Hg, or both. The Hypertension Canada guidelines were developed and implemented to encourage the management, both pharmacological and nonpharmacological, of hypertension early in the disease process instead of later when multiple-organ damage may be present. Recommendations for management of high-normal blood pressure are annual follow-up and lifestyle management. The nursing process discussion that follows provides both general and specific information related to the pharmacological and nonpharmacological treatment of all stages of hypertension.

ASSESSMENT

Before any antihypertensive drug is given to a patient, obtain a thorough health history and perform a head-to-toe physical examination. Measure and document blood pressure (including consideration for an orthostatic blood pressure), pulse rate, respirations, and pulse oximetry readings. *Orthostatic hypotension* is defined as a decrease in systolic blood pressure of 20 mm Hg or in diastolic blood pressure of 10 mm Hg within 3 minutes of standing, compared with blood pressure from the sitting or supine position. Monitor laboratory tests, including: (1) serum sodium, potassium, chloride, magnesium, and calcium levels; (2) serum levels of troponin, which is usually elevated within 4 to 6 hours after onset of a myocardial infarction and may be a reliable indicator up to 14 days after a heart attack; (3) kidney function studies, including blood urea nitrogen, serum, and urinary creatinine levels; and (4) liver function studies, including serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST).

Laboratory tests will most likely be complemented by more sophisticated scans and imaging studies. Noninvasive ophthalmoscopic examination of the eye structures (e.g., optic nerve,

optic disc, vessels) by a professional trained to do eye examinations (e.g., nurse practitioner, ophthalmologist, optometrist) allows easy visualization of the structures impacted by hypertension. If hypertensive retinopathy is present, the examination will reveal narrowing of blood vessels in the eye, oozing of fluid from these blood vessels, spots on the retina, swelling of the macula and optic nerve, or bleeding in the back of the eye. These problems may be prevented by controlling blood pressure or treating hypertension with appropriate follow-up once it is diagnosed.

Assess also for conditions, factors, risk factors, or variables that may contribute to a patient's hypertension, such as:

- Addison's disease
- Coarctation of the aorta
- Coronary artery disease
- Culture, race, or ethnicity
- Cushing's disease
- Family history of hypertension
- Nicotine use
- Obesity
- Peripheral vascular disease
- Pheochromocytoma
- Pre-eclampsia of pregnancy
- Renal artery stenosis
- Kidney or liver dysfunction
- Stressful lifestyle

Many of these factors demand cautious use of antihypertensive drugs. Other cautions and contraindications relate to the use of these drugs in older adults and those with chronic illnesses. These individuals are at increased risk for further compromise of their physical condition due to uncontrolled or untreated hypertension or the adverse effects of antihypertensives (e.g., fluid loss, dehydration, electrolyte imbalances, hypotension). For a complete listing of adverse effects and drug interactions associated with antihypertensive drugs, see the pharmacology section in this chapter.

Use of alpha-adrenergic agonists demands close assessment of the patient's blood pressure, pulse rate, and weight before and during treatment because of their strong vasodilating properties and subsequent hypotensive adverse effects. These drugs may also be associated with fluid retention and edema, so assess heart and breath sounds, intake and output, as well as dependent edema. The alpha-adrenergic antagonists need to be used cautiously because of potential for hypotension-induced dizziness and syncope. The use of either of these groups of drugs requires close assessment of all parameters, especially in older adults and other patients with pre-existing dizziness or syncope (or an otherwise debilitated state). With doxazosin mesylate, first-dose orthostatic hypotension may occur within 2 to 6 hours; therefore, carefully assess blood pressures (supine and standing), and measure corresponding pulse rates before the first dose and 2 to 6 hours afterward, as well as with any subsequent increase in the dosage. When any antihypertensive drug is used, measure blood pressures and pulse rates (supine and standing), and assess for cautions, contraindications, and drug interactions. With centrally acting alpha blockers, also assess white blood cell counts, serum potassium and sodium levels, and level of protein in the urine (to identify proteinuria).

Review the beta blockers and their mechanisms of action before administering these drugs to a patient because of the risk of complications in certain patient populations. If a drug is a nonselective beta blocker, it blocks both β_1 and β_2 receptors and will have both heart and respiratory effects, whereas if a drug is a β_1 -blocking drug, the cardiac system will be affected (pulse rate and blood pressure will decrease), but there will be no β_2 effects. This limits any concern regarding respiratory problems. Therefore, if a patient needs a beta blocker but has restrictive airway problems, a β_1 blocker is recommended (to avoid bronchoconstriction). However, if there is no history of respiratory illnesses or concerns, the nonselective beta blockers may be effective as antihypertensives. In addition, for patients with heart failure, understand that beta blockers also have a negative inotropic effect on the heart (decrease contractility); their use would lead to worsening of heart failure, which calls for a completely different type of antihypertensive.

With the use of beta blockers, assess blood pressure and apical pulse rate immediately before each dose. If the systolic blood pressure is less than 90 mm Hg or the pulse rate is less than 60 beats/min, notify the health care provider because of the risk of adverse effects (e.g., hypotension, bradycardia). In such cases, the drug would usually be withheld, as ordered or per protocol. These blood pressure and pulse rate parameters are also applicable to the use of other antihypertensives. Also assess breath sounds and heart sounds before and during drug therapy.

With the use of ACE inhibitors, assess blood pressure, apical pulse rate, and respiratory status (because of the adverse effect of a dry, hacking, chronic cough). Take blood pressure readings immediately before initial and subsequent doses of the drug so that extreme fluctuations may be identified early. Also assess serum potassium, sodium, chloride, and creatinine levels as ordered. Tests of baseline heart functioning will most likely be ordered prior to initiation of therapy. Because of potential adverse effects of neutropenia and other blood disorders, assess complete blood count before and during therapy, as ordered. ARBs are to be used cautiously in older adults and in patients with kidney dysfunction because of their increased sensitivity to the drug's effects and increased risk for more adverse effects. If the serum creatinine increases more than 30% over baseline, the ACE inhibitor should be stopped.

Perform a baseline neurological assessment with the use of vasodilators, with attention to level of consciousness and cognitive ability. Use these drugs with extreme caution with older adults because they are more sensitive to the drugs' blood pressure-lowering effects and may experience more problems with hypotension, dizziness, and syncope.

In summary, many assessment parameters are similar for the various groups of antihypertensives. The difference in the level of assessment depends on the drug's impact on blood pressure as well as the individual's response to the medication and any pre-existing illnesses or conditions. Other factors to be assessed in any patient receiving these drugs, as well as most other drugs, include the patient's cultural background, racial or ethnic group, reading level, learning needs, developmental and cognitive status, financial status, mental health status, support systems, and overall physical health status. Encourage patients to learn how to assess and monitor themselves and their individual responses to drug therapy.

◆ NURSING DIAGNOSES

- Potential for reduced perfusion as a result of the impact of the hypertensive disease process or possible severe hypotensive adverse effects associated with antihypertensive drug therapy
- Potential for sexual dysfunction as a result of adverse effects of some antihypertensive drugs
- Constipation as a result of the adverse effects of antihypertensive drugs
- Potential for nonadherence with therapy as a result of lack of familiarity with or acceptance of the disease process
- Potential risk for injury (e.g., possible falls) as a result of possible antihypertensive drug-induced orthostatic hypotension with dizziness and syncope

◆ PLANNING

Focus nursing goals for antihypertensive therapy on educating patients, family members, and caregivers about the crucial importance of adequate management to prevent end-organ damage. Goals must include making sure patients understand the nature of the disease, its symptoms, and treatment, as well as the importance of adhering to the treatment regimen. Patients must also come to terms with their diagnoses, the fact that there is no cure for the hypertension, and that treatment will be lifelong. Emphasize the influence of chronic illness on daily life and the importance of non-pharmacological therapy, stress reduction, and follow-up care. Plan for ongoing assessment of blood pressure, weight, diet, exercise, smoking habits, alcohol intake, adherence with therapy, and sexual function in patients receiving therapy for hypertension.

◆ Goals

- Patient will regain control of hypertension with return of adequate tissue perfusion.
- Patient will experience minimal changes in sexual functioning while managing adverse drug effects.
- Patient will experience minimal changes in bowel elimination patterns.
- Patient will remain adherent with antihypertensive drug therapy.
- Patient will remain free from injury during drug therapy.

◆ Outcome Criteria

- Patient states the importance of taking antihypertensive drug therapy as prescribed to maintain normal to near-normal blood pressure control.
- Patient regains control of hypertension with a return of blood pressure to a level below the ranges set by Hypertension Canada, that is, below a systolic blood pressure of 120 to 139 mm Hg and a diastolic blood pressure of 80 to 89 mm Hg.
- Patient states the importance of keeping follow-up appointments with health care provider as well as monitoring blood pressure.

- Patient openly discusses any difficulty in sexual functioning during antihypertensive therapy.
 - Patient implements suggestions or interventions as shared by the health care provider to assist in decreasing any problems with sexual function.
 - Patient states the importance of avoiding abrupt discontinuation of drug therapy with antihypertensives while experiencing changes in sexual functioning to avoid rebound hypertension and risk for complications.
- Patient manages constipation with healthy lifestyle and dietary changes.
 - Patient reduces constipation by increasing fluid intake (unless contraindicated), increasing dietary fibre through consuming more fruits and vegetables or by taking health care provider-suggested psyllium-based product for reducing constipation.
- Patient demonstrates an understanding of the importance of taking antihypertensive medication(s) exactly as prescribed.
 - Patient reports to health care provider any adverse effects such as dizziness, syncope, excessive fatigue, constipation, or changes in sexual functioning, while continuing medication regimen.
 - Patient's blood pressure begins to return to an appropriate range as defined by the health care provider and Hypertension Canada.
- Patient follows instructions to maintain safety and minimize dizziness and syncope while on medication regimen.
 - Patient changes position slowly, carefully, and purposefully.
- Patient keeps daily journal with entries about diet, exercise, adverse effects, blood pressure readings, and daily weights.

◆ IMPLEMENTATION

Nursing interventions may help patients achieve stable blood pressure while minimizing adverse effects. Many patients have problems adhering to treatment because the disease is silent, or without symptoms. Because of this, some patients are unaware of their blood pressure or think that if they do not feel ill there is nothing wrong with them, which poses many problems for treatment. Also, the antihypertensives are associated with multiple adverse effects that may impact patients' self-concept and sexual integrity. These adverse effects may lead patients to abruptly stop taking the medication. Inform patients that any abrupt withdrawal is a serious concern because of the risk of developing rebound hypertension, which is a sudden and extremely high elevation of blood pressure. This places the patient at risk for a stroke or other cerebral or cardiac adverse events. It is important to understand that with *all* antihypertensives there is a risk of rebound hypertension (with abrupt withdrawal), and prevention of this through patient education is critical to patient safety. Other interventions related to each major group of drugs are discussed in the following paragraphs. See the Patient Teaching Tips for more information.

Because of the potential for drug-related orthostatic hypotensive effects, patients taking alpha-adrenergic agonists will need to monitor their blood pressure and pulse rate at home or have these parameters measured by a family member who has received instructions or by other qualified medical personnel. The blood pressure machines found in pharmacies and grocery stores do not provide as accurate readings as measurement in the aforementioned ways. The alpha-adrenergic agonists are associated with first-dose syncope, so to avoid injury, advise patients to remain supine for the first dose of the drug. These drugs will often be prescribed to be given at bedtime to allow the patient to sleep through the drug's first-dose syncope. It may take 4 to 6 weeks for the drug to achieve its full therapeutic effects. Educate the patient about this delayed onset of action and bedtime dosing to avoid injury. The patient needs continual monitoring for dizziness, syncope, edema, and other adverse effects (e.g., shortness of breath, exacerbation of pre-existing heart disorders). Diuretics may be ordered as adjunctive therapy to minimize the adverse effects of edema, but they may lead to more dizziness and electrolyte imbalances. Centrally acting alpha blockers require the same type of nursing interventions as other alpha blockers; however, as their name indicates, the mechanism of action of these drugs is central, so adverse effects are often more pronounced (e.g., hypotension, sedation, bradycardia, edema). See the Patient Teaching Tips for more information.

The beta blockers are either nonselective (block both β_1 and β_2 receptors; e.g., propranolol hydrochloride) or cardioselective (block mainly β_1 receptors; e.g., atenolol). With any beta blocker, careful adherence to the drug regimen is crucial to patient safety. Patients taking beta blockers may experience an exacerbation of respiratory diseases such as asthma, bronchospasm, and chronic obstructive pulmonary disease (because of increased bronchoconstriction due to β_2 blocking) or an exacerbation of heart failure (because of the drug's negative inotropic effects, i.e., decreased contractility due to β_1 blocking). Provide clear and concise instructions about reporting adverse effects and instructions for taking blood pressure and pulse rates. If a β_1 blocker causes shortness of breath, it is most likely because of edema or exacerbation of heart failure. Any dizziness, orthostatic hypotension, edema, constipation, or sexual dysfunction needs to be reported to the health care provider immediately. See the Patient Teaching Tips for more information.

ACE inhibitors must also be taken exactly as prescribed. If angioedema occurs, contact the health care provider immediately. If the drug must be discontinued, weaning is recommended (as with all antihypertensives) to avoid rebound hypertension. Monitor serum sodium and potassium levels during therapy. Serum potassium levels increase as an adverse effect of these drugs, resulting in hyperkalemia and possible complications. Impaired taste may occur as an adverse effect and last up to 2 to 3 months after the

drug has been discontinued. It is also important to educate the patient that it takes several weeks to see full therapeutic effects and that potassium supplements are not needed with the ACE inhibitors because of the adverse effect of hyperkalemia.

ARBs must also be taken exactly as prescribed. They are often tolerated best with meals, as with many antihypertensives. The dosage must not be changed and the medication must not be discontinued, except on the order of the health care provider. With ARBs, if the patient has hypovolemia or liver dysfunction, the dosage may need to be reduced. A diuretic such as hydrochlorothiazide may be ordered in combination with an ARB for patients who have hypertension with left ventricular hypertrophy. Most importantly, with ARBs, report any unusual dyspnea, dizziness, or excessive fatigue to the health care provider immediately.

Nursing considerations for vasodilators are similar to those for other antihypertensives; however, the impact of the vasodilators on blood pressure may be more drastic, depending on the specific drug and dosage. Hydralazine given by injection may result in reduced blood pressure within 10 to 80 minutes after administration and requires close monitoring of the patient. With hydralazine, systemic lupus erythematosus (SLE) may be an adverse effect if the patient is taking more than 200 mg orally per day. If signs and symptoms of SLE occur, such as photosensitivity, characteristic skin rashes, CNS changes, or various blood dyscrasias (hemolytic anemia, leukopenia, thrombocytopenia), discontinue the drug, contact the health care provider immediately, and continue to closely monitor the patient. Electrocardiographic changes, cardiovascular inadequacies, and hypotension

may have pronounced effects on the patient's heart status, so *never* give the drug without adequate monitoring and frequent assessment. Always dilute sodium nitroprusside per manufacturer guidelines. Because this drug is a potent vasodilator, it may lead to extreme decreases in the patient's blood pressure. Close monitoring is therefore important for preventing further complications. Severe drops in blood pressure may lead to irreversible ischemic injuries and even death, so close monitoring is needed during drug administration. Remember that sodium nitroprusside should never be infused at the maximum dose rate for more than 10 minutes. If this drug does not control a patient's blood pressure after 10 minutes, it will most likely be discontinued by the health care provider.

Cyanide ions are a by-product of sodium nitroprusside metabolism. Cyanide and thiocyanate toxicity are seen clinically when sodium nitroprusside is used at high dosages for long periods of time or in patients with kidney insufficiency. When sodium nitroprusside is combined with sodium thiosulfate, the potential for cyanide toxicity is greatly reduced. To help prevent complications of cyanide and thiocyanate toxicity, (1) dilute the medication properly and avoid use of any solution that has turned blue, green, or red; (2) infuse only with use of a volumetric infusion pump, not through ordinary intravenous sets; (3) continuously monitor blood pressure during the infusion (often by invasive measures); and (4) when more than 500 mcg/kg of sodium nitroprusside is administered at a rate faster than 2 mcg/kg/min, be aware that this may result in production of cyanide at a more rapid rate than can be eliminated by the patient unaided (see Lab Values Related to Drug Therapy for more information.)

LAB VALUES RELATED TO DRUG THERAPY

Related to Drug Therapy for Sodium Nitroprusside

Laboratory Test	Normal Ranges	Rationale for Assessment
Serum methemoglobin and serum cyanide	Normally there are no detectable amounts with appropriate drug levels of sodium nitroprusside	Use of sodium nitroprusside may be associated with sequestration of hemoglobin as methemoglobin. The appearance of this clinically significant adverse effect of methemoglobinemia is rare (less than 10% of cases). Serum laboratory testing is used to measure the amount of methemoglobin. One significant clinical sign of this adverse effect is impaired oxygen delivery despite adequate cardiac output. When the sequestration is diagnosed, the treatment of choice is 1 to 2 mg/kg of methylene blue given intravenously over several minutes to allow binding of the metabolic by-product of cyanide to methemoglobin as cyanmethemoglobin, but this must be given as ordered and with extreme caution. In addition, sodium nitroprusside may lead to toxic reactions, even with doses that are within recommended dosage ranges. Toxic reactions are evident by extreme hypotension, cyanide toxicity, or thiocyanate toxicity. Cyanide toxicity is manifested by severe hypotension. Cyanide assays are performed to detect if cyanide levels are in body fluids, but the results of this test are difficult to interpret and so it is not the most reliable method of monitoring. Other laboratory tests that may be helpful in diagnosing cyanide toxicity are alterations of acid-base balance and venous oxygen concentrations. Actual cyanide levels in the blood may lag behind peak cyanide levels by an hour or more.

CCBs and related nursing interventions are discussed only briefly here because these drugs are covered in other chapters. Drugs like enalapril are to be taken exactly as prescribed, with the warning to the patient not to puncture, open, or crush the extended-release or sustained-release tablets and capsules. Be aware that CCBs are negative inotropic drugs (decrease cardiac contractility) because this action may induce more signs of heart failure if CCBs are given with drugs that are used to increase heart contractility, such as digoxin. Monitoring of blood pressure and pulse rate before and during therapy will aid in prevention or early detection of any problems related to the negative inotropic effects (decreased contractility), negative chronotropic effects (decreased heart rate), and negative dromotropic effects (decreased conduction).

Remember always to base nursing interventions on a thorough assessment and plan of care that includes consideration of the patient's cultural and ethnic group. Some ethnic groups respond less favourably to certain drugs than to others. As for patients with any disease, patients with hypertension must be treated with respect and with an appreciation for a holistic approach to health care in which all physical, psychosocial, and spiritual needs are taken into consideration. Remember also that patient education is of critical importance and plays an important role in ensuring adherence to the drug regimen and in decreasing the incidence of problems related to these medications.

◆ EVALUATION

Because patients with hypertension are at high risk for cardiovascular injury, it is critical for them to adhere to both their pharmacological and nonpharmacological treatment regimens. Monitoring patients for the adverse effects (e.g., orthostatic hypotension, dizziness, fatigue) and toxic effects of the various types of antihypertensive drugs helps the nurse to identify potentially life-threatening complications. The most important aspect of the evaluation process is collecting data and monitoring patients for evidence of controlled blood pressure. Blood pressure must be maintained at values lower than 140/90 mm Hg or below the levels set by the Hypertension Canada guidelines for high-normal hypertension (prehypertension), namely, below a systolic blood pressure of 120 to 139 mm Hg and a diastolic blood pressure of 80 to 89 mm Hg. If compelling indications are present, such as diabetes mellitus or kidney disease, the blood pressure goal is often 130/80. Blood pressure needs to be monitored at periodic intervals. Patient education about self-monitoring is important to the safe use of antihypertensives. Updated information on hypertension and its diagnosis, treatment, and evaluation is available on Hypertension Canada's website at <http://www.hypertension.ca>.

In addition to measuring blood pressure, the health care provider will examine the fundus of the patient's eye. Because of the changes in the vasculature of the eye caused by high blood pressure, changes in the fundus have been found to be a more reliable indicator of the long-term effectiveness

of treatment than blood pressure readings. Continually monitor the patient for the development of end-organ damage and for the presence of the specific problems that the medication can cause. Counsel and carefully monitor male patients receiving antihypertensives for any sexual dysfunction. This is important because the patient may experience sexual dysfunction and, if he is not expecting it, may not report the problem and decide to stop taking the medication abruptly. Once an antihypertensive drug is stopped abruptly, the patient is placed at high risk for rebound hypertension and possible stroke or other complications. Communication is critical in these situations. Follow-up visits to the health care provider are important for monitoring these and other adverse effects and for confirming patient adherence to the drug regimen.

Therapeutic effects of antihypertensives in general include a return to a normal baseline level of blood pressure with improved energy levels and decreased signs and symptoms of hypertension, such as reduced edema, improved breath sounds, no abnormal heart sounds, capillary refill in less than 5 seconds, and reduced shortness of breath. Monitor for the adverse effects discussed in the pharmacology section of the chapter as well as those described for each group of drugs earlier in the Nursing Process section.

CASE STUDY

Hypertension

Gloria, a 35-year-old lawyer, has been diagnosed with hypertension. Both her mother and sister have hypertension, and both were in their 40s when it was diagnosed. Gloria's most current blood pressure reading is 150/96 mm Hg, and for this reason the nurse practitioner has recommended drug therapy with captopril, light exercise in the form of walking, and relaxation therapy. After 1 month of therapy, Gloria's blood pressure is 145/86 mm

Hg. Stress reduction has been the biggest obstacle in her treatment because of her work at a prominent law firm. She has found that her blood pressure is consistently elevated (160/100 mm Hg) whenever she measures it at work. At this follow-up visit, she is also given a prescription for a diuretic to help with her blood pressure control.

1. What type of diuretic was probably prescribed for Gloria at this time? Explain your answer.
2. What possible adverse effects does Gloria need to be aware of while taking captopril?
3. Gloria tells you that she uses an over-the-counter (OTC) pain reliever for occasional headaches. What potential interaction is of concern?
4. Gloria states that she and her husband are planning to start a family in 1 year. What will you, as her nurse, tell her about pregnancy and therapy with these drugs?
5. What lifestyle changes would you, as her nurse, recommend that she make, and, even more important, what information would you give her to help her change her lifestyle and more effectively reduce the stress in her life?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

PATIENT TEACHING TIPS

Antihypertensives in General

- Patients should be informed that medications are to be taken exactly as ordered; doubling up or omitting doses is to be avoided.
- Stress to patients that successful therapy requires adherence to the medication regimen as well as to any dietary restrictions (e.g., decreasing consumption of fatty foods or high-cholesterol foods as well as dietary salt).
- Patients need to monitor stress levels and use techniques such as biofeedback, imagery, relaxation techniques, or massage, as needed. Exercise, if approved by the health care provider, may also help in the management of hypertension and serve to relieve stress; supervised, prescribed exercise is usually ordered.
- Educate patients about the importance of safety and the need to avoid smoking and excessive alcohol intake as well as excessive exercise, hot climates, saunas, hot tubs, and hot environments. Heat may precipitate vasodilation and lead to worsening of hypotension with the risk of syncope and injury.
- Frequent laboratory tests may be needed for the duration of therapy; emphasize to patients the importance of keeping follow-up appointments.
- All medications must be kept out of the reach of children because of the potential for extreme toxicity.
- Encourage patients to wear a MedicAlert bracelet or necklace and carry medical information, either in written or electronic form, specifying their diagnoses, noting allergies, and listing all medications taken (including prescribed drugs, OTC medications, and natural health products). The same information should be kept in a visible location in the patient's car and in the patient's home on the refrigerator, for the use of emergency medical personnel.
- Emphasize to patients the importance of recording blood pressure readings (including orthostatic blood pressure readings) and daily weights in a journal or on an electronic device. Daily weights are to be done each morning, before breakfast, at the same time, and with the same amount of clothing. The patient must report to the health care provider an increase in weight by 1 kg or more, over a 24-hour period, or 2.3 kg or more in 1 week.
- Assess patients' proficiency and comfort taking their own blood pressures and pulse rates. Monitor to ensure the use of proper techniques.
- Encourage patients to inform all health care providers about their antihypertensive regimens.
- Careful, purposeful, and cautious changing of positions is encouraged because of the possible adverse effect of orthostatic hypotension and associated risk for dizziness, light-headedness, and possible fainting and falls.
- Instruct patients to always keep an adequate supply of hypertensive medications on hand, especially while travelling.
- Eye examinations are recommended every 6 months due to the need to evaluate treatment effectiveness because of the impact of hypertension on the vasculature of the eyes.
- With successful therapy, patients' hypertension will improve; however, patients must understand that they should never abruptly stop taking antihypertensive medications because they are feeling better. Lifelong therapy is usually required.
- If the patient experiences dry mouth, this effect may be alleviated by saliva substitutes, sugar-free hard candy or gum, and frequent fluid intake (unless contraindicated). Increasing fluids and dietary fibre may help with constipation. Instruct patients to contact a health care provider if constipation remains a problem.
- Sexual dysfunction may occur with antihypertensives, so encourage patients to be open in reporting and discussing any problems or concerns. Inform patients that if this adverse effect occurs, options are available to help alleviate the problem, such as combination therapy that allows lower dosages of drugs to be used, or the use of other types of antihypertensives. Always reinforce the fact that these medications are never to be abruptly stopped because of the risk of severe rebound hypertension.
- Inform patients that antihypertensives may lead to depression and to report any changes in mood to the health care provider.

Alpha-Adrenergic Agonists

- First-dose syncope is associated with alpha-adrenergic agonists, so patients need to avoid conditions, situations, and drugs that would exacerbate this.
- Caution patients to be careful at first with driving and other activities requiring alertness. Patients may have to postpone driving and other activities until drug-related drowsiness subsides.
- Instruct patients to report any dizziness, palpitations, and orthostatic hypotension to a health care provider immediately.
- Because centrally acting alpha blockers may also affect patients' sexual functioning (e.g., causing erectile dysfunction or reduced libido), inform patients of these adverse effects and advise them to contact a health care provider if these effects are problematic. Other treatment options may be indicated.

Beta Blockers

- Encourage patients to move and change positions slowly to avoid possible dizziness, syncope, and falls. Instruct patients to report a pulse rate of less than 60 beats per minute, dizziness, or a systolic blood pressure of 90 mm Hg or lower to the health care provider.
- Prolonged sitting or standing and excessive physical exercise may also lead to exacerbation of hypotensive effects, so counsel the patient to avoid these activities or counteract them, such as by pumping the feet up and down while sitting.
- Heat may also exacerbate hypotensive effects of beta blockers. Educate patients to avoid saunas, hot tubs, and excessive heat, or syncope (fainting) may result.

KEY POINTS

- All antihypertensives in some way affect cardiac output, which is the amount of blood ejected from the left ventricle and is measured in litres per minute.
- The major groups of antihypertensives are the diuretics (see [Chapter 29](#)), alpha blockers, centrally active alpha blockers, beta blockers, ACE inhibitors, vasodilators, CCBs, and ARBs. Direct renin inhibitors form a new class of antihypertensive drugs.
- ACE inhibitors work by blocking a critical enzyme system responsible for the production of angiotensin II (a potent vasoconstrictor). They prevent (1) vasoconstriction caused by angiotensin II, (2) aldosterone secretion and therefore sodium and water resorption, and (3) the breakdown of bradykinin (a potent vasodilator) by angiotensin II.
- Angiotensin receptor blockers work by blocking the binding of angiotensin at the receptors; the result is a decrease in blood pressure.
- CCBs may be used to treat angina, dysrhythmias, and hypertension and help to reduce blood pressure by causing relaxation of smooth muscles and dilation of blood vessels. If calcium is not present, the smooth muscle of the blood vessels cannot contract.
- A thorough nursing assessment includes determining whether a patient has any underlying causes of hypertension, such as kidney or liver dysfunction, a stressful lifestyle, Cushing's syndrome, Addison's disease, renal artery stenosis, peripheral vascular disease, or a pheochromocytoma.
- Always assess for the presence of contraindications, cautions, and potential drug interactions before administering any of the antihypertensive drugs. Contraindications include a history of myocardial infarction or chronic kidney disease. Cautious use is recommended in patients with kidney insufficiency or glaucoma. Drugs that interact with antihypertensive drugs include other antihypertensive drugs, anaesthetics, and diuretics.
- Hypertension is managed by both pharmacological and non-pharmacological measures. Patients with hypertension need to consume a diet low in fat, make any other necessary modifications in their diet (such as a decrease in sodium intake and an increase in fibre intake), engage in regular supervised exercise, and reduce the amount of stress in their lives.

EXAMINATION REVIEW QUESTIONS

1. A nurse is administering antihypertensive drugs to older adult patients. What adverse effect would be of most concern to the nurse??
 - a. Dry mouth
 - b. Hypotension
 - c. Restlessness
 - d. Constipation
2. A patient was ordered antihypertensive drugs. What class of drug will the nurse consider when giving the first dose of an antihypertensive drug at bedtime ?
 - a. Alpha blockers such as prazosin (Minipress)
 - b. Diuretics such as furosemide (Lasix®)
 - c. ACE inhibitors such as captopril (Capoten)
 - d. Vasodilators such as hydralazine (Apresoline)
3. A 56-year-old man started antihypertensive drug therapy 3 months ago. He informs the nurse that he is having problems with sexual intercourse. What would be the most appropriate response by the nurse?
 - a. "Not to worry. Tolerance will develop."
 - b. "Your health care provider can work with you on changing the dosage or drugs."
 - c. "Sexual dysfunction happens with this therapy, and you will learn to accept it."
 - d. "This is an unusual occurrence, but it is important to stay on your medications."
4. The nurse is providing medication teaching to a patient about ACE inhibitors. What adverse effect should the nurse mention to the patient?
 - a. Diarrhea
 - b. Nausea
 - c. Dry, nonproductive cough
 - d. Sedation
5. A patient has a new prescription for an ACE inhibitor. During a review of the patient's list of current medications, which would cause concern about a possible interaction with this new prescription? (Select all that apply.)
 - a. A benzodiazepine taken as needed for allergies
 - b. A potassium supplement taken daily
 - c. An oral anticoagulant taken daily
 - d. An opioid used for occasional severe pain
 - e. A nonsteroidal anti-inflammatory drug taken as needed for headaches
6. The order reads: Give hydralazine (Apresoline) 0.75 mg/kg/day. The child weighs 16 pounds. How much hydralazine will be given? Round to hundredths.
7. The nurse is assessing a patient who will be starting antihypertensive therapy with an ACE inhibitor. Which of the following conditions would lead the nurse to exercise caution prior to administering the medication?
 - a. Asthma
 - b. Rheumatoid arthritis
 - c. Hyperthyroidism
 - d. Renal insufficiency

CRITICAL THINKING ACTIVITIES

1. A 53-year-old woman with a history of hypothyroidism and asthma has been diagnosed with primary hypertension. The nurse is reviewing the new orders and notes an order for labetalol (Trandate) as part of the treatment for hypertension. Considering the patient's history, what is the priority action at this time?
2. A 79-year-old woman has been admitted to the emergency department after experiencing severe headaches and "feeling faint." Upon admission, her blood pressure is measured as 286/190 mm Hg. A sodium nitroprusside infusion is started, and the nurse is monitoring the patient closely. After 8 minutes of infusion, the nurse notes that the patient's blood pressure suddenly drops to 100/60. What is the nurse's priority action?
3. During a follow-up appointment, a 58-year-old man is pleased to hear that his blood pressure is 118/64 mm Hg. He says, "I've been hoping to hear this good news! Now I can stop taking these pills, right?" What is the nurse's best answer?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Antianginal Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Briefly describe the pathophysiology of myocardial ischemia and the subsequent occurrence of angina.
2. Describe the various factors that may precipitate angina as well as measures that decrease its occurrence.
3. Contrast the major classes of antianginal drugs (nitrates, calcium channel blockers, and beta blockers) according to their mechanisms of action, dosage forms, routes of administration, cautions, contraindications, drug interactions, adverse effects, patient tolerance, and toxicity.
4. Develop a collaborative plan of care, incorporating all phases of the nursing process, related to the administration of antianginal drugs.

KEY TERMS

Acute coronary syndrome (ACS) A spectrum of clinical presentations compatible with acute myocardial ischemia, ranging from those for ST-segment elevation myocardial infarction (STEMI) to presentations found in non-ST-segment elevation myocardial infarction (NSTEMI) or in unstable angina. (p. 395)

Angina pectoris Chest pain that occurs when the heart's supply of blood carrying oxygen is insufficient to meet the demands of the heart. (p. 394)

Atherosclerosis A common form of arteriosclerosis involving deposits of fatty, cholesterol-containing material (plaques) within arterial walls. (p. 395)

Chronic stable angina Chest pain that is primarily caused by atherosclerosis, which results in long-term but relatively stable levels of obstruction in one or more coronary arteries. (p. 395)

Coronary arteries Arteries that deliver oxygen-carrying blood to the heart muscle. (p. 394)

Coronary artery disease (CAD) Any one of the abnormal conditions that can affect the arteries of the heart and

produce pathological effects, especially a reduced supply of oxygen and nutrients to the myocardium. (p. 395)

Ischemia Poor blood supply to an organ. (p. 394)

Ischemic heart disease Poor blood supply to the heart via the coronary arteries. (p. 394)

Myocardial infarction (MI) Necrosis of the myocardium following interruption of blood supply; almost always caused by atherosclerosis of the coronary arteries. Commonly called a *heart attack*. (p. 395)

Reflex tachycardia A rapid heartbeat caused by a variety of autonomic nervous system effects, such as blood pressure changes, fever, or emotional stress. (p. 397)

Unstable angina Clinical presentation of acute coronary syndrome with cardiac ischemia, without persistent ST-segment elevation on electrocardiogram and with no detectable release of the enzymes and biomarkers of myocardial necrosis. (p. 395)

Vasospastic angina Ischemia-induced myocardial chest pain caused by spasms of the coronary arteries; also referred to as *Prinzmetal's* or *variant angina*. (p. 395)

OVERVIEW

The heart is an efficient organ that pumps blood to all the tissues and organs of the body. It is demanding in an aerobic sense because it requires a large supply of oxygen to meet the extraordinary demands placed on it. The heart's much-needed oxygen supply is delivered to the myocardium through the **coronary arteries**. When the heart's supply of blood carrying oxygen and energy-rich nutrients is insufficient to meet the demands of the heart, the heart muscle (or myocardium) aches. This is called **angina pectoris**, or chest pain. Poor blood supply to an organ is referred to as **ischemia**. When the heart is involved, the condition is called **ischemic heart disease**.

Ischemic heart disease is currently the second most prevalent cause of death in Canada. The primary cause is a disease of the coronary arteries known as **atherosclerosis** (fatty plaque deposits in the arterial walls). When atherosclerotic plaques project from the walls into the lumens of the coronary vessels, the vessels become narrow. The supply of oxygen and energy-rich nutrients needed for the heart to meet its demand is then decreased. This disorder is called **coronary artery disease (CAD)**. An acute result of CAD and of ischemic heart disease is **myocardial infarction (MI)**, or heart attack. An MI occurs when blood flow through the coronary arteries to the myocardium is completely blocked so that part of the myocardium (heart muscle) cannot receive any oxygen or blood-borne nutrients. It is almost always associated with rupture of an atherosclerotic plaque and partial or complete thrombosis of the infarct-related artery. If this process is not reversed immediately, that area of the heart will die and become necrotic (dead or nonfunctioning). Damage to a large enough area of the myocardium can be disabling or fatal.

The rate at which the heart pumps and the strength of each heartbeat (contractility) influence oxygen demands on the heart. There are numerous influences that can increase heart rate and contractility and thus increase oxygen demand. These include caffeine, exercise, and stress, among others, and result in stimulation of the sympathetic nervous system, which leads to increased heart rate and contractility. In a patient with CAD who has an already overburdened heart, this stimulation can worsen the balance between myocardial oxygen supply and demand and result in angina. Some of the drugs used to treat angina are aimed at correcting the imbalance between myocardial oxygen supply and demand by decreasing heart rate and contractility.

The pain of angina is a result of the following process. Under ischemic conditions, when the myocardium is deprived of oxygen, the heart shifts to anaerobic metabolism to meet its energy needs. One of the by-products of anaerobic metabolism is lactic acid. Accumulation of lactic acid and other mediators, such as bradykinin and adenosine, stimulate the pain receptors surrounding the heart, which produces the heart pain known as *angina*. This is the same pathophysiological mechanism responsible for causing the soreness in skeletal muscles after vigorous exercise. The Canadian Cardiovascular Society classifies exertion-induced angina to allow for the gauging of symptom severity according to the amount of physical activity (grade I to grade IV) that patients can tolerate before pain occurs (Christensen, 2014). There are three classic types of chest pain, or angina pectoris. **Chronic stable angina**, also referred to as *classic angina* and *effort angina*, occurs as a result of atherosclerosis. Chronic stable angina can be triggered by either exertion or other stress (e.g., cold, emotions). The nicotine in tobacco, as well as alcohol, caffeine, and other substances that stimulate the sympathetic nervous system, can also exacerbate angina. The pain of chronic stable angina is commonly intense but subsides within 15 minutes of either rest or appropriate antianginal drug therapy. **Unstable angina** is the most dangerous, as it is the clinical presentation of **acute coronary syndrome (ACS)** with cardiac

ischemia without persistent ST-segment elevation on electrocardiogram (ECG) and no detectable release of the enzymes and biomarkers of myocardial necrosis. It often ends in an MI (ST elevation or STEMI) in subsequent years. For this reason, unstable angina is also called *preinfarction angina*. Unstable angina does not follow any predictable pattern and can occur without exertion. Pain increases in severity, as does the frequency of attacks. Unstable angina usually is diagnosed when it meets one or more of the following criteria: (1) angina at rest; (2) recent onset (less than 2 months) of severe angina; and (3) recent (less than 2 months) increase in severity of angina (increased intensity as well as duration, frequency, or both). **Vasospastic angina** results from spasm of the layer of smooth muscle that surrounds the atherosclerotic coronary arteries. In contrast to chronic stable angina, this type of pain often occurs at rest and without any precipitating cause. It does seem to follow a regular pattern, however, usually occurring at the same time of day. This type of angina is also called *Prinzmetal's angina* or *variant angina*. Dysrhythmias and ECG changes often accompany these different types of anginal attacks.

ANTIANGINAL DRUGS

The three main classes of drugs used to treat angina pectoris are the nitrates and nitrites, the beta blockers, and the calcium channel blockers (CCBs). Their various therapeutic effects are summarized and compared in Table 24.1. There are three main therapeutic objectives of antianginal drug therapy: (1) minimize the frequency of attacks and decrease the duration and intensity of the angina pain; (2) improve the patient's functional capacity with as few adverse effects as possible; and (3) prevent or delay the worst possible outcome—MI. The overall goals of antianginal drug therapy are to increase blood flow to the ischemic myocardium, decrease myocardial oxygen demand, or both. Fig. 24.1 illustrates how drug therapy works to alleviate angina. Existing evidence suggests that drug therapy may be at least as effective as angioplasty in treating this condition.

Nitrates

Nitrates have long been the mainstay of both the prophylaxis and treatment for angina and other heart problems. Today, there are several chemical derivatives of the early precursors, all of which are organic nitrate esters. They are available in a wide variety of preparations, including sublingual, chewable, and oral tablets; capsules; ointments; patches; a translingual spray; and intravenous solutions. The following nitrates are the rapid- and long-acting nitrates available for clinical use:

- nitroglycerin (both rapid and long acting)
- isosorbide (both rapid and long acting)
- isosorbide-5-mononitrate (long acting)

Mechanism of Action and Drug Effects

The nitrates dilate all blood vessels. They predominantly affect venous vascular beds; however, they also have a dose-dependent arterial vasodilator effect. These vasodilatory effects are the result of relaxation of the vascular smooth muscle cells that

TABLE 24.1 Antianginal Drugs: Therapeutic Effects

Therapeutic Effect	Nitrates	β-Blockers*	Amlodipine Besylate	Verapamil	Diltiazem
Supply					
Blood flow	↑↑	↑	↑↑↑	↑↑↑	↑↑↑
Duration of diastole	0	↑↑↑	0/↑	↑↑↑	↑↑
Demand

Afterload	↓	0/↓	↓↓↓	↓↓	↓↓
Contractility	0	↓↓↓	↓	↓↓↓	↓↓
Heart rate	0/↑	↓↓↓	0/↓	↓↓	↓↓

*In particular, those that are cardioselective and do not have intrinsic sympathomimetic activity.
↓, Decrease; ↑, increase; 0, little or no effect.
†Preload is pressure in the heart caused by blood volume. The nitrates effectively move part of this blood out of the heart and into blood vessels, thereby decreasing preload or filling pressure.

Fig. 24.1 Benefit of drug therapy for angina through increasing oxygen supply and decreasing oxygen demands.

are part of the wall structure of veins and arteries. Particularly notable, however, is the potent dilating effect of nitrates on the coronary arteries, both large and small. This effect causes redistribution of blood and therefore oxygen to previously ischemic myocardial tissue and a reduction of anginal symptoms. By causing venous dilation, the nitrates reduce venous return and, in turn, reduce the left ventricular end-diastolic volume (or preload). The reduced afterload (pressure that the left ventricle needs to overcome) that nitrates produce is due to its dose-dependent relaxation of arteries in addition to its decreased left ventricular tension. The decreased left

ventricular tension effect is less than the dilation effects. The drug effects of the nitrate drugs listed above as well as others are summarized in Table 24.1.

Coronary arteries that have been narrowed by atherosclerosis can still be dilated as long as there remains smooth muscle surrounding the coronary artery and the atherosclerotic plaque does not completely obstruct the arterial lumen. Exercise-induced spasms in atherosclerotic coronary arteries can also be reversed or prevented by the administration of nitrates, which encourages healthy physical activity.

Indications

Nitrates are used to treat stable, unstable, and vasospastic angina. Long-acting dosage forms are used more for prevention of anginal episodes. Rapid-acting dosage forms, most often sublingual nitroglycerin tablets or spray, or an intravenous drip in the hospital setting, are used to treat acute anginal attacks.

Contraindications

Contraindications to the use of nitrates include known drug allergy as well as severe anemia, closed-angle glaucoma, hypotension, conditions with increased intraocular pressure and severe head injury—the vasodilation effects of nitrates can worsen these conditions. In anemia, a drug-induced hypotensive episode can further compromise already reduced tissue oxygenation. Nitrates are also contraindicated with the use of the erectile dysfunction drugs sildenafil citrate (Revatio®, Viagra®), tadalafil (Adcirca®, Cialis®), and vardenafil hydrochloride (Levitra®, Staxyn®; see Chapter 36) due to the potential risk, when these drugs are combined, of causing a significant drop in blood pressure.

Adverse Effects

Nitrates are well tolerated, and most adverse effects are usually transient and involve the cardiovascular system. The most common undesirable effects are headaches, dizziness, and fatigue, which generally diminish in intensity and frequency soon after the start of therapy. Other cardiovascular effects include tachycardia and orthostatic hypotension. If nitrate-induced vasodilation occurs too rapidly, the cardiovascular system overcompensates and increases the heart

rate, a condition referred to as **reflex tachycardia**. This may occur when significant vasodilation involves the systemic veins. In this situation, there is a large shift in blood volume toward the systemic venous circulation and away from the heart. Pressor sensors (baroreceptors) in the carotid sinus and aortic arch falsely sense that there has been a dramatic loss of blood volume. At this point, the heart begins beating more rapidly to move the apparently smaller volume of blood more quickly throughout the body, especially toward the vital organs (including the heart itself). However, the same baroreceptors soon sense that there has not been a loss of blood volume but that the volume of blood missing in the heart is now in the periphery (e.g., in the venous system), and the heart rate slows back to normal.

Topical nitrate dosage forms can produce various types of contact dermatitis (skin inflammations), but these are actually reactions to the dosage delivery system and not to the nitroglycerin contained within it, thus not a true drug allergy. It is important for the nurse to document the type of allergic reaction so that clinicians do not avoid this important drug class if the reaction is only a contact dermatitis.

Tolerance to the antianginal effects of nitrates can occur surprisingly quickly in some patients, especially in those taking long-acting formulations or taking nitrates around the clock. In addition, cross-tolerance can arise when a patient receives more than one nitrate dosage form. To prevent this, a regular nitrate-free period (usually 12 hours [e.g., on at 0800 hours and off at 2000 hours]) is arranged to allow certain enzymatic pathways to replenish themselves. A common regimen with transdermal patches is to remove them at night for 8 hours and apply a new patch in the morning. This plan has been shown to prevent tolerance to the beneficial effects of nitrates. However, some studies have questioned the advisability of this practice.

Interactions

Nitrate antianginal drugs can produce additive hypotensive effects when taken in combination with alcohol, beta blockers, CCBs, phenothiazines, and erectile dysfunction drugs such as sildenafil citrate, tadalafil, and vardenafil hydrochloride. Numerous deaths have been reported due to interactions with erectile dysfunction drugs.

Dosages

The organic nitrates are available in an array of forms and dosages. For more dosage information, refer to the table on the next page.

DRUG PROFILES

isosorbide dinitrate

Isosorbide dinitrate (ISDN[®]) is an organic nitrate. It exerts the same effects as the other nitrates. When isosorbide is metabolized in the liver, it is broken down into two active metabolites, both of which have the same therapeutic actions as isosorbide. Isosorbide is available as rapid-acting sublingual tablets and long-acting oral dosage forms.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	30 min	Unknown	3–5 hr	4–6 hr

isosorbide-5-mononitrate

Isosorbide-5-mononitrate (Imdur[®]) is one of the two active metabolites of isosorbide, but it has no active metabolites itself. Because of these qualities, it produces a more consistent, steady therapeutic response, with less variation in response within the same patient and between patients. It is available in extended-release oral dosage form.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action

nitroglycerin

Nitroglycerin is the prototypical nitrate and is made by many pharmaceutical companies; therefore, it has many different trade names (e.g., Minitrans[®], Nitro-Dur[®], Nitrol[®], Trinipatch[®]). It has traditionally been the most important drug used in the symptomatic treatment of ischemic heart conditions such as angina. When given orally, nitroglycerin is metabolized in the liver before it can become active in the body. During this process, a large amount of the nitroglycerin is removed from the circulation (a large first-pass effect [see Chapter 2]). For this reason, nitroglycerin is administered by many other routes to bypass the first-pass effect. Sublingual tablets or pump sprays are used for the treatment of chest pain or angina of acute onset. They are also used for the prevention of angina when patients find themselves in situations likely to provoke an attack. Use of the sublingual route is advantageous for relieving acute conditions because the area under the tongue and inside the cheek is highly vascular; the nitroglycerin is absorbed quickly and directly into the bloodstream, with its therapeutic effects occurring rapidly. Sublingual nitroglycerin tablets must be stored in their original container because exposure to air and moisture can inactivate the drug.

Nitroglycerin is also available as a metered-dose pump that is sprayed under the tongue. It is available in an intravenous form that is used perioperatively for blood pressure control in patients with hypertension; for the treatment of ischemic pain, heart failure, and pulmonary edema associated with acute MI; and in hypertensive emergency situations. Oral and topical dosage formulations are used for the long-term prophylactic management of angina pectoris. The topical formulations offer the same advantages as the sublingual formulation in that they also bypass the liver and the first-pass effect. This formulation also allows for the continuous slow delivery of the drug, so that patients receive a steady dose of nitroglycerin.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Sublingual	2–3 min	Unknown	1–4 min	0.5–1 hr

Dosages**Selected Antianginal Nitrate Coronary Vasodilators for Angina**

Drug	Usual Dosage Range
 isosorbide dinitrate (ISDN)	<i>Adults</i> PO: 5–30 mg qid
 isosorbide-5-mononitrate (Imdur)	<i>Adults</i> PO (ER): 30–120 mg/day
 nitroglycerin (Minitran, Nitro-Dur, Nitrol, Nitrostat, Trinipatch)	<i>Adults</i> IV (continuous infusion): 5–20 mcg q3–5 min Ointment, 2%: 2.5–5 cm (up to 10–12.5 cm) ribbon q3–8h Spray: 0.4–0.8 mg (1–2 sprays) onto or under the tongue, repeated twice, prn SL: 0.3–0.6 mg q5 min, 3 times Patch: 0.2–0.8 mg applied once daily

ER, Extended-release; IV, intravenous; PO, oral; prn, as needed; SL, sublingual.

BETA BLOCKERS

The beta-adrenergic blockers, more commonly referred to as beta blockers, have become the mainstay in the treatment of several cardiovascular diseases. These include angina, MI, hypertension (Chapter 23), and dysrhythmias (see Chapter 26). Most available beta blockers demonstrate antianginal efficacy, although not all have been approved for this use. Those beta blockers approved as antianginal drugs are atenolol, metoprolol, nadolol, and propranolol hydrochloride (see also Chapter 20).

Mechanism of Action and Drug Effects

The primary effects of beta blockers are related to the cardiovascular system. As discussed in [Chapters 19 and 20](#), the predominant beta-adrenergic receptors in the heart are the beta₁-adrenergic receptors. Beta₁ receptors are located in the heart's conduction system and throughout the myocardium. The beta₁ receptors are normally stimulated by the binding of the neurotransmitters epinephrine and norepinephrine. These catecholamines are released in greater quantities during times of exercise or other stress, to stimulate the heart muscle to contract more strongly. At the normal heart rate of 60 to 100 beats per minute, the heart spends 60 to 70% of its time in diastole. As the heart rate increases during stress or exercise, the heart spends more time in systole and less time in diastole.

In an ischemic heart, the increased oxygen demand from increasing contractility (systole) also leads to increasing degrees of ischemia and chest pain. The physiological act of systole

requires energy in the form of adenosine triphosphate (ATP) and oxygen. Therefore, any decrease in the energy demands on the heart is beneficial for alleviating conditions such as angina. When beta receptors are blocked by beta blockers, the rate at which the pacemaker (sinoatrial [SA] node) fires decreases, and the time it takes for the node to recover increases.

Beta blockers also slow conduction through the atrioventricular (AV) node and reduce myocardial contractility (negative inotropic effect). Both of these effects serve to slow the heart rate (negative chronotropic effect). These effects reduce myocardial oxygen demand, which aids in the treatment of angina by reducing the heart's workload. Slowing the heart rate is also beneficial in patients with ischemic heart disease because the coronary arteries have more diastolic time to fill with oxygen- and nutrient-rich blood and deliver these substances to the myocardial tissues.

Beta blockers also have many therapeutic effects after an MI. Following an MI, there is a high level of circulating catecholamines (norepinephrine and epinephrine). These catecholamines will produce harmful consequences if their actions go unopposed. They cause the heart rate to increase, which leads to a further imbalance in the supply-and-demand ratio, and they irritate the conduction system of the heart, which can result in potentially fatal dysrhythmias. Beta blockers block all of these harmful effects, and their use has been shown to improve the chances for survival after an MI. Unless strongly contraindicated, they are given to all patients in the acute stages after an MI.

Beta blockers also suppress the activity of the hormone renin, which is the first step in the renin–aldosterone–angiotensin system. Renin is a potent vasoconstrictor released by the kidneys when they are not being adequately perfused. When beta blockers inhibit the release of renin, blood vessels to and in the kidney dilate, causing reduced blood pressure (see Chapter 23).

Indications

Beta blockers are most effective in the treatment of exertional angina. This is because the usual physiological effects of an increase in heart rate and systolic blood pressure that occurs during exercise or stress is blunted by beta blockers, thereby decreasing the myocardial oxygen demand. For individuals (often older adults) with significant angina, “exercise” may simply be carrying out activities of daily living such as bathing, dressing, cooking, or housekeeping. Performing such activities with significant angina can become a major stressor for these patients. Beta blockers are also approved for the treatment of MI, hypertension (see Chapter 23), cardiac dysrhythmias (see Chapter 26), and essential tremor. Some uses that are common but are not Health Canada–approved are treatment of migraine headaches and, in low dosages, even treatment of the tachycardia associated with stage fright.

Contraindications

There are a number of contraindications to the use of beta-blockers, including acute stage of decompensated heart failure and serious conduction disturbances because of the effects of beta blockade on heart rate and myocardial contractility. These drugs

should be used with caution in patients with bronchial asthma because any level of blockade of β_2 receptors can promote bronchoconstriction. These contraindications are relative rather than absolute and depend on patient-specific risks and expected benefits of this drug therapy. Other relative contraindications include diabetes mellitus (because of masking of hypoglycemia-induced tachycardia) and peripheral vascular disease (the drug may further compromise cerebral or peripheral blood flow).

Adverse Effects

The adverse effects of beta blockers result from their ability to block beta-adrenergic receptors (β_1 and β_2 receptors) in various areas of the body. Blocking of β_1 receptors can lead to a decrease in heart rate, cardiac output, and cardiac contractility. Blocking of β_2 receptors can result in bronchoconstriction and increased airway resistance in patients with asthma or chronic obstructive pulmonary disease. Beta blockers may lead to cardiac rhythm problems, decreased SA and AV nodal conduction, decrease in systolic and diastolic blood pressures, peripheral receptor blockade, and decreased renin release from the kidneys. Beta blockers can mask the tachycardia associated with hypoglycemia, and patients with diabetes may not be able to tell when their blood sugar falls too low. Fatigue, insomnia, and weakness may occur because of negative effects on the heart and the central nervous system. Beta blockers can also cause both hypoglycemia and hyperglycemia, which is of particular concern in patients with diabetes. Other common beta blocker-related adverse effects are listed in Table 24.2.

Interactions

There are many important drug interactions that involve beta blockers. The more common and important of these interactions are listed in Table 24.3.

Dosages

For information on the dosages of selected beta blockers, refer to the table in the right column.

TABLE 24.2 Beta Blockers: Adverse Effects

Body System	Adverse Effects
Cardiovascular	Bradycardia, hypotension, atrioventricular block
Central nervous	Dizziness, fatigue, depression, lethargy, headaches
Metabolic	Hyperglycemia and hypoglycemia, hyperlipidemia
Other	Wheezing, dyspnea, erectile dysfunction

TABLE 24.3 Beta Blockers: Common Drug Interactions

Interacting Drug	Mechanism	Result
Diuretics and antihypertensives	Additive effects	Hypotension
Calcium channel blockers (diltiazem hydrochloride, verapamil hydrochloride)	Additive atrioventricular node suppression	Hypotension, bradycardia, heart block
Insulin and oral antihyperglycemic drugs	Masking of hypoglycemic effects	Unrecognized hypoglycemia

DRUG PROFILES

Beta blockers are a mainstay in the treatment of a wide range of cardiovascular diseases, primarily hypertension, angina, and the acute stages and postmanagement of MI. The three most commonly used beta blockers are carvedilol, metoprolol, and atenolol. Carvedilol is not indicated for angina but is instead indicated for heart failure, essential hypertension, and left ventricular dysfunction. The newest beta blocker, nebivolol hydrochloride (Bystolic®), is used to treat hypertension. As indicated, atenolol, metoprolol, nadolol, and propranolol hydrochloride all are indicated for angina. The drug profile for carvedilol appears in Chapter 20.

atenolol

Atenolol (Tenorim®) is a cardioselective β_1 -adrenergic receptor blocker and is indicated for the prophylactic treatment of angina pectoris. Use of atenolol after an MI has been shown to decrease mortality. It is available in oral form.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1 hr	2–4 hr	6–7 hr	24 hr

metoprolol tartrate

Metoprolol tartrate (Betaloc®, Lopresor®, Lopresor SR®) is also a cardioselective β_1 -adrenergic receptor blocker that is used for the prophylactic treatment of angina and has many of the same characteristics as atenolol. It has shown similar efficacy in reducing mortality in patients after MI and in treating angina. It is available in both oral (immediate-release and long-acting) and parenteral forms. Intravenous metoprolol is commonly administered to patients who are hospitalized after an MI and is used for treatment of hypertension in patients unable to take oral medicine.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1 hr	2–4 hr	3–8 hr	10–20 hr

Dosages

Selected β_1 -Adrenergic Drugs for Angina

Drug	Pharmacological Class	Usual Dosage Range
atenolol (Tenorim)	β_1 -blocker	Adults PO: 50–200 mg/day as a single dose
metoprolol tartrate (Lopresor, Lopresor SR)	β_1 -blocker	Adults PO: 100–400 mg/day divided bid SR: 100–200 mg taken in the morning

PO, Oral; SR, sustained release.

TABLE 24.4 Classification of Calcium Channel Blockers

Generic Name	Trade Name	Available Routes
Benzothiazepines		
diltiazem hydrochloride	Cardizem®, Tiazac®, others	PO/IV
Dihydropyridines		
amlodipine besylate	Caduet®, Norvasc®, Twynsta®, others	PO
felodipine	Plendil®, Renedil®	PO
nifedipine	Adalat XL®	PO

Phenylalkylamines		
verapamil hydrochloride	Isoptin SR®, Tarka®, Verelan®	PO/IV

IV, Intravenous; PO, oral, SR, sustained release.

CALCIUM CHANNEL BLOCKERS

There are three chemical classes of CCBs: phenylalkylamines, benzothiazepines, and dihydropyridines, commonly represented by verapamil hydrochloride, diltiazem, and amlodipine, respectively (Table 24.4). Although they all block calcium channels, their chemical structures, and thus mechanisms of action, differ slightly. Many CCBs are available. Those used for the treatment of chronic stable angina are diltiazem, amlodipine, nifedipine, and verapamil hydrochloride.

Mechanism of Action and Drug Effects

Calcium plays an important role in the excitation–contraction coupling process that occurs in the heart and vascular smooth muscle cells, as well as in skeletal muscle. Preventing calcium from entering into this process thus prevents muscle contraction and promotes relaxation. Relaxation of the smooth muscles that surround the coronary arteries causes them to dilate. This dilation increases blood flow to the ischemic heart, which in turn increases the oxygen supply and helps shift the supply-and-demand ratio back to normal. Dilation also occurs in the arteries throughout the body, which results in a decrease in the force (systemic vascular resistance) against which the heart has to exert when delivering blood to the body (afterload). Decreasing the afterload reduces the workload of the heart and therefore reduces myocardial oxygen demand. This is the primary beneficial antianginal effect of the dihydropyridine CCBs, such as amlodipine and nifedipine. These drugs have a less negative inotropic effect than verapamil hydrochloride and diltiazem do.

Another cardiovascular effect of the CCBs is depression of the automaticity of and conduction through the SA and AV nodes. For this reason, they are useful in treating cardiac dysrhythmias (Chapter 23). Finally, the CCBs reduce myocardial contractility and peripheral and coronary artery tone. Verapamil and diltiazem also decrease heart rate. Their strongest antianginal properties are secondary to their effects on myocardial contractility and the smooth muscle tone of peripheral and coronary arteries.

Indications

The therapeutic benefits of the CCBs are numerous. Because of their acceptable adverse effect and safety profiles, they are considered first-line drugs for the treatment of angina, hypertension, and supraventricular tachycardia. They are often effective for the treatment of coronary artery spasms (vasospastic or Prinzmetal's angina). However, they may not be as effective as the beta blockers in blunting exercise-induced elevations in heart rate and blood pressure. CCBs are also used for the short-term management of atrial fibrillation and flutter (see Chapter 26), migraine headaches (see Chapter 14), and Raynaud's disease (a type of peripheral vascular disease). The dihydropyridine nimodipine is indicated solely as an adjunct for cerebral artery spasms associated with aneurysm rupture.

Contraindications

Contraindications include known drug allergy, acute MI, second- or third-degree AV block (unless the patient has a pacemaker), and hypotension.

Adverse Effects

The adverse effects of the CCBs are limited and primarily relate to overexpression of their therapeutic effects. The most common adverse effects are listed in Table 24.5.

Interactions

Important drug interactions are listed in Table 24.6. A particular food interaction of note is grapefruit juice, which can increase the bioavailability of CCBs, especially nifedipine. Nifedipine is metabolized by the cytochrome P450 enzyme system, and compounds found in grapefruit juice inhibit the P450 system; hence, the intake of grapefruit juice increases plasma levels of nifedipine and augments its pharmacodynamic effects.

Dosages

For dosage information on selected CCBs, refer to the table on the next page.

DRUG PROFILES

diltiazem hydrochloride

Diltiazem hydrochloride (Cardizem, Tiazac) is the only benzothiazepine CCB. It has a particular affinity for the cardiac conduction system and is effective for the treatment of angina pectoris resulting from coronary insufficiency and hypertension. It is one of the few CCBs that is available in parenteral form, in which it is used for the treatment of atrial fibrillation and flutter along with paroxysmal supraventricular tachycardia (see Chapter 26). Verapamil hydrochloride is another CCB with similar indications. Several sustained-delivery formulations of diltiazem are available and which can be confused with each other. For example, there is Apo-diltiaz®, an immediate-release tablet; Apo-diltiaz SR®, sustained-release capsules that are taken twice a day; and Apo-diltiaz CD®, a controlled-delivery capsule taken once a day. In addition to other brands of these dosage forms, the drug is also available in several strengths of immediate-release tablets as well as in intravenous form.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	0.5–1 hr	2–3 hr	3.5–9 hr	4–12 hr

amlodipine besylate

Amlodipine besylate (Caduet, Norvasc, Twynsta, others) is currently the most popular CCB of the dihydropyridine subclass. It is indicated for both angina and hypertension and is available only for oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action

Other	Dermatitis, dyspnea, rash, flushing, peripheral edema

SUMMARY OF ANTIANGINAL PHARMACOLOGY

In patients with CAD, the clinical symptoms result from a lack of or inadequate delivery of blood carrying oxygen and nutrients to the heart, which results in ischemic heart disease. Antianginal drugs such as nitrates, beta blockers, and CCBs are used to reduce ischemia by increasing the delivery of oxygen- and nutrient-rich blood to cardiac tissues or by reducing oxygen consumption by the coronary vessels. Either of these mechanisms can reduce ischemia and lead to a decrease in anginal pain. Nitrates and nitrites

work primarily by decreasing venous return to the heart (pre-load) and decreasing systemic vascular resistance (afterload). The CCBs decrease calcium influx into the smooth muscle, causing vascular relaxation. This either reverses or prevents the spasms of coronary vessels that cause the anginal pain associated with Prinzmetal's or chronic angina. The beta blockers slow the heart rate and decrease contractility, thereby decreasing oxygen demands. Although these groups of drugs have similar clinical effects, the nursing process required for each is somewhat specific in terms of the characteristics and effects of the drugs and the indications for and contraindications to their use.

PHARMACOKINETIC BRIDGE TO NURSING PRACTICE

Not only are the pharmacokinetic properties of nitrates interesting, but knowledge of these specific properties is critical to safe and accurate nursing care. Moreover, patients' understanding of nitrate pharmacokinetics is also important because the level of a patient's knowledge may strongly influence adherence to the drug regimen and the effectiveness of treatment for angina. The pharmacokinetics differ for the various dosage forms of nitroglycerin and include the following:

- Intravenous infusion: Onset of action 1 to 2 minutes (fastest of all dosage forms), peak action not applicable, duration of action 3 to 5 minutes
- Sublingual tablet: Onset of action 2 to 3 minutes, peak action unknown, duration of action 30 to 60 minutes
- Topical ointment: Onset of action 15 to 60 minutes, peak action within 0.5 to 2 hours, duration of action 3 to 8 hours
- Transdermal patch: Onset of action 30 to 60 minutes, peak action 1 to 3 hours, duration of action 8 to 12 hours.
- Translingual spray: Onset of action 2 minutes, peak action 4 to 10 minutes, duration of action 30 to 60 minutes

If the goal of treatment is to abort or treat a sudden attack of angina, then *rapid* onset of action is needed, so the clinical decision (by the health care provider) would be to order either an intravenous infusion, or a sublingual tablet (or translingual spray, which has a similar onset time). These dosage forms have pharmacokinetics that allow quick entry of the drug into the bloodstream and lead to more rapid vasodilation. This provides more oxygenated blood to the myocardium and aborts acute attacks. If symptoms persist, more drastic medical management would be indicated. The patient may also use the quick-onset nitroglycerin dosage forms 5 to 10 minutes before engaging in activities known to provoke angina, such as increased physical activity, sexual intercourse, or other forms of physical exertion. If the purpose of treatment is maintenance therapy, the nitrate form must have other pharmacokinetic properties, such as a longer duration of action to provide protection against angina; a longer onset of action is acceptable because stopping an attack is not needed in this situation. Use of ointments, transdermal patches, or extended-release preparations would be appropriate in such cases. If an acute episode of angina occurs while the patient is taking maintenance therapy, a dosage form with a rapid onset of action is indicated (as ordered). It is easy to see that thorough knowledge about a drug and its pharmacokinetics allows for safe and sound decisions about drug therapy for patients with angina.

NURSING PROCESS

ASSESSMENT

Before administering antianginal drugs, obtain a thorough nursing history and medication history (including a listing of all prescription drugs, over-the-counter products, and natural health products being taken) and document the findings. Also measure weight, height, and vital signs, with attention to supine, sitting, and standing blood pressures. Report a systolic blood pressure reading of less than 100 mm Hg (or as specified) to the health care provider before administering a dose of any of these drugs. With the use of any drugs affecting blood pressure or pulse rate, such as antianginals, take the apical pulse rate for 1 full minute. If the pulse rate is 60 beats per minute or lower, or 100 beats per minute or greater, contact the health care provider for further instructions. In addition to rate, assess the quality and rhythm of the heartbeat and document prior to administering antianginal drugs. If the patient is experiencing any chest pain, include in your assessment a description of onset, character (e.g., sharp, dull, piercing, squeezing, radiating), intensity, location, duration, precipitating factors (e.g., physical exertion, exercise, eating, stress, sexual intercourse), alleviating factors, and any presence of nausea or vomiting. The health care provider may order an ECG, in which case the nurse must review the results of this test as well. Thoroughly assess for any contraindications, cautions, and drug interactions prior to giving these drugs. Significant interactions can occur with substances such as alcohol, beta blockers, CCBs, phenothiazines, and erectile dysfunction drugs such as sildenafil citrate, tadalafil, and vardenafil hydrochloride. Taking these drugs with nitrates will result in worsening of hypotensive responses, paradoxical bradycardia, and a resultant increase in angina with subsequent significant risk of heart or cerebrovascular complications due to decreased perfusion. Older adult patients often have difficulty with blood pressure control because of the occurrence of normal, age-related orthostatic hypotension, and the use of antianginals may lead to worsening of hypotensive responses. For patients taking nitrates on a long-term basis, it is important to assess continued therapeutic responses because of the development of tolerance to the drug's effects. During assessment and initiation of drug therapy, it is crucial to patient safety to notify the health care provider of any increased angina because another antianginal or vasodilating drug may be needed.

Concerns arise with the use of nonselective beta blockers and beta₂ blockers (as vasodilators) in patients with bronchospastic disease because of the drug-related effects of bronchoconstriction and increased airway resistance, which results in wheezing and dyspnea as adverse effects. Therefore, if asthma or other respiratory problems are present, beta blockers would not be indicated because bronchoconstriction could be exacerbated. In addition, there are also concerns about the use of beta blockers in patients with peripheral vascular disease, hypotension, hyperglycemia or hypoglycemia (see pharmacology discussion), and bradycardia. Nonselective beta blockers may also exacerbate pre-existing heart failure. Assessment for edema is important in patients with cardiac risk factors and a weight gain of 1 kg or more over 24 hours or 2.3 kg or more in 1 week. Weight gain of this nature must be reported to the health care provider immediately. Assess for

TABLE 24.6 Calcium Channel Blockers: Common Drug Interactions

Drug	Mechanism	Result
β-blockers	Additive effects	Bradycardia and atrio-ventricular block
digoxin	Interference with elimination	Possible increased digoxin levels
amiodarone hydrochloride	Decreased metabolism	Bradycardia and decreased cardiac output
Azole antifungals, clarithromycin, erythromycin, HIV drugs	Decreased metabolism	Elevated levels and effects of CCBs
Statins	Inhibited statin metabolism	Increased risk of statin toxicity
cyclosporine	Decreased metabolism of either drug	Possible toxicity of either drug

CCBs, Calcium channel blockers; HIV, human immunodeficiency virus.

significant drug interactions, including the concurrent use of other antihypertensives, CCBs, and oral antihyperglycemic drugs (see Table 24.3 for more information).

In patients taking CCBs, assess for possible drug–food interactions, including grapefruit. Grapefruit juice reduces the metabolism of nifedipine, leading to possible toxicity; grapefruit must therefore be avoided. Another area to be thoroughly assessed is that of the dosage form of nifedipine, which is available in extended- and immediate-release forms. Therefore, follow the orders for administration of nifedipine carefully, and closely monitor the patient (e.g., vital signs). Diltiazem (Cardizem) is available in several sustained-delivery forms; closely assess orders to avoid medication errors. Cautious use is important in patients with a history of hypotension, palpitations, tachycardia or bradycardia, constipation, dyspnea, and edema. Significant drug interactions are included in Table 24.6.

NURSING DIAGNOSES

- Impaired gas exchange and decreased cardiac output as a result of the pathophysiology of CAD
- Reduced knowledge as a result of first-time use of antianginal drugs and a new diagnosis of CAD
- Potential for injury to self, resulting from the possible adverse drug effect of hypotension with subsequent dizziness, syncope, and falls

PLANNING

Goals

- Patient will exhibit therapeutic effects of antianginal drug therapy, such as improved cardiac output, with fewer episodes of chest pain.
- Patient will demonstrate increased knowledge about disease process and drug therapy.
- Patient will remain free from injury while receiving antianginal drug therapy.

◆ Outcome Criteria

- On follow-up with the health care provider, patient states that there are more frequent periods of comfort while carrying out activities of daily living, engaging in supervised exercise, and participating in moderate activity, without recurring angina and without major adverse effects.
 - Patient experiences fewer to no episodes of chest pain (angina).
- Patient states rationale for antianginal drug therapy and the importance of taking medication exactly as prescribed.
 - Patient states adverse effects of antianginal drug therapy, such as orthostatic hypotension, dizziness, and severe headaches, as well as measures to decrease their occurrence.
 - Patient states the appropriate time frame of when to seek out emergency care (e.g., if finding no relief 5 minutes after 1 dose of sublingual nitrates) and call 911.
- Patient states measures to decrease risk for injury, such as changing positions slowly, keeping legs moving when in a still position, increasing fluid intake with medication regimen, and removing rugs or carpets that can cause slips, trips, or falls.

CASE STUDY

Nitroglycerin for Angina

Sherman, a 68-year-old accountant, has been diagnosed with CAD after experiencing chest pain at times when he jogs. After undergoing a thorough physical examination, including cardiac catheterization, he is given a prescription for a low-dose beta blocker, metoprolol 25 mg by mouth, once a day. He

also has a prescription for 0.4-mg sublingual nitroglycerin tablets to take as needed for chest pain.

1. What type of angina is Sherman experiencing, and what are the therapeutic goals of the drug therapy he has received?
2. Sherman asks you, "Why do I have to take two prescription drugs? It doesn't make sense to me!" What is the best answer to his question?
3. Two days after he begins the nitroglycerin, Sherman calls the office and says, "I'm having awful headaches. What is wrong?" What is the best explanation, and what can he do about the headaches?
4. Two months later, Sherman calls and says, "I don't think these drugs are working. I'm having more episodes of chest pain now when I jog." What could be the explanation for this, and what can be done?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

a scale of 1 to 10, before, during, and after therapy. Monitor the patient's response to drug therapy by measuring blood pressure and pulse rate, as well as assessing for the presence of headache, dizziness, or lightheadedness. When the patient is in a supine position, an appropriate dose of a nitrate should produce a clinical response of a fall in blood pressure of about 10 mm Hg or a rise in heart rate of 10 beats per minute. However, the following parameters are alerts that the patient may have a problem and the health care provider should be contacted: a systolic blood pressure of 100 mm Hg or lower (or as specified), a pulse rate of 60 beats per minute or lower, or a pulse rate greater than 100 beats per minute.

2. For oral dosage forms: Counsel the patient that these are to be taken as ordered before meals and with 180 mL of water. Extended-release preparations must not be crushed, chewed, or altered in any way. Acetaminophen may be given if there is a drug-related headache, if not contraindicated.
3. For sublingual forms: Advise the patient to place the tablet under the tongue as directed and *not* to swallow until the drug is completely dissolved. Metered-dose pump sprays are applied onto or under the tongue (see Dosages table). Instruct the patient to keep nitrates in their original packaging or container (e.g., sublingual tablets come in a small, amber-coloured glass container with a metal lid). Exposure to light, plastic, cotton filler, and moisture must be avoided.
4. For ointment: Use the proper dosing paper supplied by the drug company to apply a thin layer on clean, dry, hairless skin of the upper arms or upper body. Avoid areas below the knees and elbows. Do not apply the ointment with the fingers unless using a glove, to avoid contact with the skin and subsequent absorption. A tongue depressor may also be used, but in most situations the ointment may be squeezed directly from the tube onto the proper dosing paper. Once the ointment is in place, do *not* rub it into the skin; cover the area with an occlusive dressing (e.g., plastic wrap). Rotate application sites and remove all residue from the previous dose of ointment gently with soap and water and pat the area dry.
5. For transdermal forms: Apply patches to a clean, residue-free, hairless area, and rotate sites. If cardioversion or use of an automated external defibrillator is required, remove the transdermal patch to avoid burning of the skin and damage to the defibrillator paddles. Before a new patch is applied, locate and remove the old patch and clean the skin of any residual drug. Carefully dispose of used, unneeded, or defective transdermal patches, from any medication, as indicated by hospital policy or per discharge instructions. It is important to follow any packaging insert instructions or facility policy because transdermal patches delivering potent medications need to be folded in half with the sticky sides together and placed in a garbage can that is out of reach of people and pets (see Chapter 2). For more information, visit <http://healthycanadians.gc.ca/drugs-products-medicaments-produits/drugs-medicaments/disposal-defaire-eng.php>.
6. For intravenous forms: Intravenous dosing is for use in emergency situations only and in settings with close automatic monitoring of blood pressure and pulse as well as constant ECG monitoring. Intravenous administration of

◆ IMPLEMENTATION

Always review and record patients' vital signs and descriptions of chest pain for the duration of therapy. Take into account the following considerations associated with the use of the various dosage forms and routes of administration:

1. For any dosage form: Administer the drug while the patient is seated, to avoid falls or injury from drug-induced hypotension. This hypotension may last for up to 30 minutes after dosing of the drug. When administering nitrates, monitor the patient's chest pain, and have the patient rate the pain on

nitrates may lead to sudden and severe hypotension, cardiovascular collapse, and shock. Always check for incompatibilities and the proper diluent. Only give intravenous solutions through an infusion pump and as ordered. Intravenous dosage forms are available as ready-to-use injectable doses and are administered using specific nonpolyvinylchloride (non-PVC) plastic intravenous bags and tubing. Non-PVC infusion kits are used to avoid absorption or uptake of the nitrate by intravenous tubing and bags. This method prevents decomposition of the nitrate with breakdown into cyanide when the drug is exposed to light. Intravenous forms of nitroglycerin are stable for about 96 hours after preparation. If parenteral solutions are not clear and are discoloured, discard the solution.

With isosorbide, tablets are best taken on an empty stomach; however, if the patient reports headache or gastrointestinal upset, the medicine should be taken with meals. Oral tablets of isosorbide can be crushed; however, the sublingual and extended-release forms are *not* to be crushed or chewed. As with sublingual nitroglycerin, instruct patients not to swallow the medication until it is completely dissolved. If dizziness or lightheadedness occurs, assist the patient and encourage slow changing of positions. Closely monitor blood pressure, including orthostatic blood pressures. Document the occurrence of anginal episodes, their character, precipitating factors, severity, and frequency.

Beta blockers need to be given as ordered and may be taken with or without food. Abrupt withdrawal must be avoided. Weights must be measured every day at the same time and with the patient wearing the same amount of clothing. If there is a weight gain of 1 kg or more in 24 hours or 2.3 kg or more in 1 week, contact the health care provider immediately. When these drugs are used, take measures to reduce the incidence of orthostatic hypotension, such as advising the patient to dangle the legs on the side of the bed before standing and to move slowly and purposefully. Instruct the patient to contact the health care provider immediately if any excessive or intolerable dizziness, fatigue, wheezing, or dyspnea occurs (see Chapter 20 for further discussion).

CCBs are to be taken as ordered and without sudden withdrawal. Abrupt withdrawal can precipitate rebound hypertension and worsening of tissue ischemia. Weight needs to be measured daily (see later discussion). Constantly monitor the

patient for edema and shortness of breath. Instruct the patient to move and change positions slowly and cautiously to prevent syncope. Constipation may be prevented by increasing intake of fluids and fibre in the diet. If the patient experiences palpitations, pronounced dizziness, nausea, or dyspnea, contact the health care provider immediately. Intravenous administration of any CCB requires the use of an infusion pump and careful monitoring (see Chapter 26).

Patients taking any of the vasodilators must avoid alcohol, saunas, hot tubs, hot showers, and hot weather or environments. These conditions will exacerbate vasodilation and increase the occurrence of orthostatic hypotension, increasing the risk for dizziness, syncope, and falls. Caution patients that with certain sustained-release forms of medication, the wax matrix may appear in the stool; advise them that this occurs after the drug has been absorbed and that, even though the matrix is visible, it is of no concern. Instruct patients on how to self-monitor blood pressure and pulse rate, as well as how to document these findings in a journal or electronic device so that the information can be shared with health care providers. The journal or electronic device can also keep a record of daily weights, response to the medication regimen, and any adverse effects. See the Patient Teaching Tips for more information.

◆ EVALUATION

Carefully monitor patients taking antianginals for the occurrence of an allergic reaction, which may be manifested by dyspnea, swelling of the face, or hives. Include in your evaluation a review for accomplishments of goals and outcome criteria, such as appropriate decrease in blood pressure, increase in cardiac output and tissue perfusion, decrease in angina, gradual increase in activity level, and improvement in performance of activities of daily living without exacerbation of anginal episodes. In addition, monitor the patient for adverse reactions such as headache, lightheadedness, dizziness, and decreased blood pressure, which may indicate the need to decrease the dosage. If the patient is receiving intravenous nitroglycerin, evaluate for excessive drops in blood pressure, worsening of angina, and significant changes in pulse rate (to less than 60 beats per minute or more than 100 beats per minute), and contact the health care provider immediately if any of these conditions occurs.

PATIENT TEACHING TIPS

- Nitroglycerin
 - Emphasize to patients the importance of keeping a daily journal (in handwritten or electronic form), documenting number of anginal episodes and noting their intensity, frequency, duration, and character, as well as any precipitating and relieving factors. Any evidence of possible tolerance to the medication is important to note and report to the health care provider.
 - Capsules or extended-release dosage forms are never to be chewed, crushed, or altered in any way.
 - Instruct patients taking pump (spray) dosage forms not to shake the canister before lingual spraying and to avoid

inhaling or swallowing until the drug is dispersed. Each metered dose contains 0.4 mg nitroglycerin. With the onset of an acute attack of angina pectoris, 1 or 2 metered doses (0.4 or 0.8 mg of nitroglycerin), as determined by experience, may be administered onto or under the tongue, without inhaling. The optimal dose may be repeated twice, at 5- to 10-minute intervals. With sublingual tablets, the medication must be taken at the first sign of chest pain and not delayed until the pain is severe. The patient needs to sit or lie down and take one sublingual tablet. According to current guidelines, if the chest pain or discomfort is not relieved in 5 minutes, after *one* dose,

the patient (or a family member) must call 911 immediately. The patient can take one more tablet while awaiting emergency care and a third tablet 5 minutes later, but no more than three tablets total. These guidelines reflect the fact that angina pain that does not respond to nitroglycerin may indicate an MI. The sublingual dose is to be placed under the tongue and patients must avoid swallowing until the tablet is dissolved. Instruct patients not to eat or drink until the drug has completely dissolved.

- Educate patients about the best place to store their medication, such as keeping it away from moisture, light, heat, and cotton filler material. The sublingual dosage form of nitroglycerin needs to be kept in its original, amber-coloured glass container with metal lid, to avoid loss of potency from exposure to heat, light, moisture, and cotton filler.
- Patients should know that the potency of the sublingual nitroglycerin can be noted if there is burning or stinging once the medication is placed under the tongue; if the medication does not burn, then the drug has lost its potency, and a new prescription must be obtained.
- It is important to emphasize to patients that the sublingual nitroglycerin is potent for only 3 to 6 months. Remind them to always have a fresh supply of the drug on hand, to plan ahead if travelling, and (no matter what the dosage form) to sit or lie down when taking the medication to avoid falls secondary to a drop in blood pressure.
- With patients taking any form of nitrates, educate about adverse effects such as flushing of the face, dizziness, fainting, brief throbbing headaches, increase in heart rate, and lightheadedness. Headaches associated with nitrates last approximately 20 minutes (with sublingual forms) and may be easily managed with acetaminophen. If headaches are bothersome when taking an oral dosage form, the drug may be taken with meals, and the patient must contact the health care provider if adverse effects continue. Blurred vision, dry mouth, or severe headaches may indicate drug overdose and require immediate medical attention. While taking an antianginal drug, patients must avoid alcohol, hot environmental temperatures, saunas, hot tubs, and excessive exertion; these conditions increase vasodilation, with subsequent worsening of hypotension, which can possibly lead to syncope (fainting) or other cardiac events.
- In many situations, the health care provider specifies that nitroglycerin be taken *before* stressful activities or events that may exacerbate angina, such as emotional situations, consumption of large meals, smoking, or sudden increase in activity (e.g., sexual intercourse). The patient needs to closely follow the health care provider's directions regarding prophylactic dosing.
- With ointment forms, remind patients to use the appropriate dosage paper for application of ointment and not to use the fingers to apply the medicine. The medication can

be pressed evenly and directly from the tube onto the printed dosing line on the paper. Instruct the patient to squeeze a thin line of ointment onto the paper and follow instructions regarding its application, such as measuring and applying 1.3 centimetres of ointment. An occlusive dressing must be used, such as applying a piece of plastic wrap taped around the edges to adhere the dose to the skin. Only clean, nonirritated, and nonhairy areas, free of residual medication, are to be used for these ointments. The use of ointments has been largely replaced by the more effective use of transdermal patches.

- With transdermal nitrate use, patients must apply the patch at the same time each day. Be sure to have only one patch in place at a time, and cleanse all residue off the skin before applying a new patch. Advise patients to avoid skin folds, hairy areas, and any area distal to the knees or elbows as application sites. A transdermal patch must never be applied on irritated or open skin, and if the patch becomes loose, the patient needs to remove it, gently wash off the residue with lukewarm water and soap, *pat* the area dry, and place another patch in another area. Encourage rotation of sites to prevent irritation (with ointments as well). The health care provider may order the removal of the patch for an 8-hour period on specific days to help decrease or prevent drug tolerance, which may develop over time. Provide all instructions both verbally and in written format.
- Isosorbide Dinitrate or Isosorbide-5-Mononitrate
 - Educate patients about the basic differences in oral nitrates (e.g., the mononitrate form is well absorbed after oral dosing; the dinitrate form is poorly absorbed, but its metabolite, isosorbide mononitrate, is active and well absorbed). It is important that patients know that these drugs are *not interchangeable*.
 - Instruct patients to take the medication exactly as ordered, with emphasis on the need to lie down when doses are taken, to avoid injury from a sudden drop in blood pressure, which may lead to dizziness, lightheadedness, and fainting.
 - Isosorbide is generally given three times a day with a 12-hour drug-free interval, such as dosing at 0700 hours, 1300 hours, and 1900 hours. The 12-hour drug-free interval helps prevent the development of tolerance.
 - Oral dosage forms are not to be altered in any way and must be taken with at least 180 to 240 mL of water.
 - Patient must be cautious while taking these drugs and should be encouraged to rise slowly and move the legs around before standing up from a lying or sitting position, to help prevent dizziness, syncope, and falls. The importance of avoiding alcohol, heat, and saunas must be emphasized because these factors exacerbate the hypotensive effects of the drug and may result in injury.
 - Advise patients that these and other antianginals are not to be stopped abruptly.

KEY POINTS

- Angina pectoris (chest pain) occurs because of a mismatch between oxygen supply and oxygen demand, with either too high a demand for oxygen or too little oxygen delivery.
- The heart is an aerobic (oxygen-requiring) muscle; when it does not receive enough oxygen, pain (angina) occurs. When the coronary arteries that deliver oxygen to the heart muscle become blocked, a heart attack or MI occurs.
- CAD is an abnormal condition of the arteries that deliver oxygen to the heart muscle. These arteries may become narrowed, which results in reduced flow of oxygen and nutrients to the myocardium.
- Nitrates, CCBs, and beta blockers may be used to treat the symptoms of angina.
- Nitroglycerin is the prototypical nitrate. Nitrates dilate constricted coronary arteries, helping to increase the supply of oxygen and nutrients to the heart muscle. Nitrates also dilate all other blood vessels. The venous dilation results in a decrease of blood return to the heart (decreased preload), whereas the arterial dilation results in a decrease of peripheral resistance (decreased afterload—that is, the pressure or force against which the left ventricle must pump). Isosorbide dinitrates were the first group of oral drugs used to treat angina; isosorbide-5-mononitrates are new and improved nitrates used for angina therapy; beta blockers are also used to relieve angina, which they do by decreasing the heart rate, reducing the workload on the heart, and decreasing oxygen demands.
- Dosage forms for nitrates include conventional tablets, sublingual spray, controlled-release and sustained-release capsules, transdermal patches, topical ointments, and intravenous injections. It is recommended to use gloves during the application and removal of transdermal patches.
- Quick-onset nitrates are used to treat acute anginal attacks, while longer-onset nitrates are used for prophylaxis. Instruct patients to always keep a fresh supply of sublingual nitroglycerin on their persons and in their homes because the drug is stable for only 3 to 6 months.
- CCBs and beta blockers may be associated with the adverse effects of postural hypotension, dizziness, headache, and edema.
- The nonselective beta blockers may exacerbate heart failure, problems related to respiratory bronchospasm, and hypoglycemia.
- Check the patient's pulse rate before drug administration, and if it is 60 beats per minute or lower, contact the health care provider for further instructions.

EXAMINATION REVIEW QUESTIONS

1. A patient has a new prescription for nitroglycerine tablets to be administered sublingually. The nurse teaches the patient that the tablets are most appropriately used for which purpose?
 - a. To relieve exertional angina
 - b. To prevent palpitations
 - c. To prevent the occurrence of angina
 - d. To stop an episode of angina
2. Which statement about the administration of intravenous nitroglycerin will the nurse recognize as correct?
 - a. The intravenous form is given by intravenous push injection.
 - b. Because the intravenous forms are short-lived, the dosing must be every 2 hours.
 - c. Intravenous nitroglycerin must be protected from exposure to light through use of special tubing.
 - d. Intravenous nitroglycerin can be given via gravity drip infusions.
3. A patient has just been started on the calcium channel blocker diltiazem (Cardizem). Which statement by the patient reflects the need for additional patient education?
 - a. "I can take this drug to stop an attack of angina."
 - b. "I understand that food and antacids can change how well I can absorb this drug when I take it as a pill."
 - c. "When the long-acting forms are taken, the drug cannot be crushed."
 - d. "This drug may cause my blood pressure to drop, so I should be careful when getting up."
4. A patient with angina has been ordered to start beta blocker therapy. What condition will the nurse teach the patient would be a problem with the use of a beta blocker?
 - a. Hypertension
 - b. Essential tremors
 - c. Exertional angina
 - d. Asthma
5. A 68-year-old man has been taking the nitrate isosorbide dinitrate (ISDN) for 2 years for angina. He has recently been experiencing erectile dysfunction and wants a prescription for sildenafil citrate (Viagra). Which response would the nurse most likely hear from the health care provider?
 - a. "He will have to be switched to isosorbide-5-mononitrate if he wants to take sildenafil citrate."
 - b. "Taking sildenafil citrate with the nitrate may result in a contraindication and cause severe hypotension."
 - c. "I'll write a prescription, but if he uses it, he needs to stop taking the isosorbide for one dose."
 - d. "These drugs are compatible with each other, so I'll write a prescription."
6. The nurse is reviewing drug interactions with a male patient who has a prescription for isosorbide (ISDN) as treatment for angina symptoms. Which substances listed below could potentially result in a drug interaction? (Select all that apply.)
 - a. A glass of wine
 - b. Thyroid replacement hormone
 - c. tadalafil (Cialis), an erectile dysfunction drug

- d. metformin hydrochloride (Glucophage®), an antihyperglycemic drug
 - e. carvedilol, a beta blocker
7. The order reads, “Give metoprolol (Lopresor) 300 mg/day PO in 2 divided doses.” The tablets are available in 50-mg strength. How many tablets will the patient receive per dose?
8. A patient with angina has been given a prescription for a calcium channel blocker. The nurse knows that this class of drugs is used to treat which type of angina?
- a. Effort
 - b. Unstable
 - c. Crescendo
 - d. Vasospastic

CRITICAL THINKING ACTIVITIES

1. Your neighbour Angela has been shovelling snow all morning. As you shovel the snow in your yard, you see her suddenly sit down in her driveway. When you go over to check on her, she says that she has nitroglycerin tablets in her jacket pocket, but she has forgotten how to take them. What is your priority action at this time?
 2. Your patient has been switched from oral nitroglycerin capsules to a transdermal form. What are the priorities for patient teaching regarding transdermal nitroglycerin therapy?
 3. Johan has chronic stable angina and has recently been prescribed sublingual nitroglycerin tablets for the relief of his anginal attacks. What teaching instructions does Johan require in order to take the nitroglycerin appropriately?

Heart Failure Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Differentiate between the terms *inotropic*, *chronotropic*, and *dromotropic*.
2. Briefly discuss the pathophysiology of heart failure.
3. Identify the approach to treatment of heart failure.
4. Compare the mechanisms of action, pharmacokinetics, indications, dosages, contraindications, dosage forms, routes of administration, cautions, adverse effects, and toxicity of the drugs used in the treatment of heart failure.
5. Briefly discuss rapid versus slow digitalization as well as the use of the antidote digoxin immune Fab.
6. Identify significant drug–drug, drug–laboratory test, and drug–food interactions associated with digoxin and other heart failure drugs.
7. Develop a collaborative plan of care that includes all phases of the nursing process for patients undergoing treatment for heart failure.

KEY TERMS

Atrial fibrillation A common cardiac dysrhythmia involving atrial contractions that are so rapid that they prevent full repolarization of myocardial fibres between heartbeats. (p. 413)

Automaticity A property of specialized excitable tissue in the heart that allows self-activation through the spontaneous development of an action potential, such as in the pacemaker cells of the heart. (p. 411)

Chronotropic drugs Drugs that influence the rate of the heartbeat. (p. 410)

Dromotropic drugs Drugs that influence the conduction of electrical impulses within tissues. (p. 410)

Ejection fraction The proportion of blood that is ejected during each ventricular contraction compared with the total ventricular filling volume. (p. 409)

Heart failure An abnormal condition in which the heart cannot pump enough blood to keep up with the body's demand. It is often the result of myocardial infarction, ischemic heart disease, or cardiomyopathy. (p. 408)

Inotropic drugs Drugs that affect the force or energy of muscular contractions, particularly contraction of the heart muscle. (p. 410)

Left ventricular end-diastolic volume (LVEDV) The total amount of blood in the ventricle immediately before it contracts, or the preload. (p. 409)

Refractory period The period during which a *pulse generator* (i.e., the sinoatrial node of the heart) is unresponsive to an electrical input signal, and during which it is impossible for the myocardium to respond; during this period, the cardiac cell is readjusting its sodium and potassium levels and cannot be depolarized again. (p. 415)

DRUG PROFILES

digoxin, p. 416

digoxin immune Fab, p. 416

dobutamine, p. 412

hydralazine and isosorbide dinitrate, p. 412

lisinopril, p. 411

milrinone (milrinone lactate)*, p. 413

valsartan, p. 411

Key drug

* Full generic name is given in parentheses. For the purposes of this text, the more common, shortened name is used.

OVERVIEW

Heart failure is not a specific disease per se but rather a clinical syndrome caused by numerous different cardiac disorders. Approximately 600 000 people in Canada live with heart failure and 50 000 new patients are diagnosed each year ([Heart and Stroke Foundation, 2016](#)). It is one of the most common causes for hospitalization in Canada. This is especially true for the patient population over the age of 65. Heart failure also causes more than 5 000 deaths annually in Canada. The findings of one of the largest and most frequently cited studies involving patients with heart failure, the Framingham study, show that the 5-year survival rate in patients with heart failure is approximately 50%. The best way to prevent

heart failure is to control risk factors associated with it, including hypertension, coronary artery disease, obesity, and diabetes.

Heart failure is a pathological condition in which the heart is unable to pump blood in sufficient amounts from the ventricles (i.e., insufficient cardiac output) to meet the body's metabolic needs or can do so only at elevated filling pressures. The signs and symptoms typically associated with this insufficiency make up the syndrome of heart failure. Initially, the patient is asymptomatic. As the disease progresses, so do the symptoms. Failure of the ventricle(s) to eject blood efficiently results in fluid volume overload, chamber dilation, and elevated intracardiac pressure. This syndrome can affect the left ventricle, the right ventricle, or both ventricles simultaneously. Left ventricular or "left-sided" heart failure often leads to pulmonary edema, coughing, shortness of breath, and dyspnea (remember: left equals lung). Right ventricular heart failure typically involves systemic venous congestion, pedal edema, jugular venous distension, ascites, and hepatic congestion. Both syndromes occur due to increased hydrostatic pressure from the ventricles into the pulmonary or systemic circulation. Left-sided failure can be further divided into systolic and diastolic failure. Systolic dysfunction or failure is characterized by a decrease in myocardial contractility and a resulting reduction in the left ventricular ejection fraction (e.g., the left ventricle cannot pump with sufficient force to push blood into the circulation). Diastolic dysfunction or failure refers to cardiac dysfunction in which left ventricular filling is abnormal and is accompanied by elevated filling pressures during diastole. The ventricle is unable to relax as the muscle becomes stiff.

More specifically, heart failure occurs due to a reduced ratio of **ejection fraction** to **left ventricular end-diastolic volume (LVEDV)**. The ejection fraction is the amount of blood ejected with each contraction, whereas the left ventricular end-diastolic volume is the total amount of blood in the ventricle just before contraction. The ejection fraction is an index of left ventricular function, and the normal value is approximately 65% (0.65) of the total volume in the ventricle. According to the 2017 Canadian Cardiovascular Society Guidelines, new terminology is to be used to classify patients living with chronic heart failure. The guidelines describe new classifications of heart failure in relation to function and percentage of left ventricular ejection fractions. According to the new guidelines, patients will be classified in the following ways:

- Heart failure with a preserved ejection fraction (HFpEF) with a left ventricular ejection fraction (LVEF) $\geq 50\%$
- Heart failure with a mid-range ejection fraction (HFmEF) with left ventricular diastolic function (LVDF) 41%–49%
- Heart failure with reduced ejection fraction (HFrEF) with left ventricular ejection fraction (LVEF) of $\leq 40\%$ (Ezekowitz, O'Meara, McDonald, et al., 2017).

When a person has heart failure, the heart cannot meet the increased demands, and the blood supply to certain organs is reduced. The organs that are most dependent on blood supply—the brain and heart—are the last to be deprived of blood. The kidney is relatively less dependent on blood supply, and its blood supply is shunted away from it. Therefore, the filtration of fluids and removal of waste products is impaired. This can lead to acute kidney injury or chronic kidney failure. Reduced blood supply also contributes to conditions such as pulmonary edema (resulting in shortness of breath) and peripheral edema.

BOX 25.1 Myocardial Deficiency and Increased Workload: Common Causes

Myocardial Deficiency

Inadequate Contractility

Coronary artery disease
Myocardial infarction
Cardiomyopathy
Valvular insufficiency

Inadequate Filling

Atrial fibrillation
Infection
Tamponade
Ischemia

Increased Workload

Pressure Overload

Pulmonary hypertension
Systemic hypertension
Outflow obstruction

Volume Overload

Hypervolemia
Congenital abnormalities
Anemia
Thyroid disease
Infection
Diabetes

The physical defects producing heart failure are of two types: (1) a heart defect (myocardial deficiency such as myocardial infarction or valve insufficiency), which leads to inadequate cardiac contractility and ventricular filling, and (2) a defect outside the heart (e.g., systemic defects such as coronary artery disease, pulmonary hypertension, or diabetes), which results in an overload on an otherwise normal heart. Either or both of these defects may be present in a given patient. Common causes of myocardial deficiency and systemic defects are listed in [Box 25.1](#).

The emphasis of this chapter is on systolic dysfunction or inadequate ventricular contractions (systole) during the pumping of the heart. Less common, but still important, is diastolic dysfunction or inadequate ventricular filling during ventricular relaxation (diastole). This condition is most commonly associated with left ventricular hypertrophy secondary to chronic hypertension. However, it may also result from cardiomyopathy (e.g., virus induced), pericardial disease, or diabetes.

Heart failure is stratified into classes, using the New York Heart Association's (NYHA) functional classification with symptom description for patients living with heart failure. Class I describes a patient who is not limited in normal physical activity by symptoms. Class II is said to occur when ordinary physical activity results in fatigue, dyspnea, or other symptoms. Class III is characterized by a marked limitation in normal physical activity. Class IV is defined by symptoms at rest or with any physical activity at all. The American Heart Association (AHA) and American Colleges of Cardiology (ACC) (2020) developed a new classification designed to complement the NYHA classification. The evolution and progression of heart failure is now emphasized via the

Fig. 25.1 Conduction system of the heart. AV, atrioventricular; SA, sinoatrial. (Source: Lewis, S. M., Dirksen, S. R., Heitkemper, M. M., et al. (2014). *Medical-surgical nursing in Canada: Assessment and management of clinical problems* (3rd Canadian ed., M. A. Barry, S. Goldsworthy, & D. Goodridge, Canadian Eds.). Toronto, ON: Mosby. Figure 34-4, p. 845.)

following stages: (1) Stage A includes patients who are at high risk for developing heart failure but have no structural disorder of the heart; (2) Stage B includes patients with structural disorders of the heart who have never had symptoms of heart failure; (3) Stage C includes patients with past or current symptoms of heart failure associated with underlying structural heart disease; and (4) Stage D includes patients with end-stage disease who require specialized treatment strategies, such as mechanical circulatory support, continuous IV inotrope infusions, cardiac transplantation, or hospice care. Drug therapy is individualized based on a patient's class or stage of heart failure.

The Canadian Heart Failure Society interacts with the Canadian Cardiovascular Society to provide a forum for health care professionals to exchange ideas, advance knowledge, and improve the practice and care of patients living with heart failure. The most recent updates from the Canadian Cardiovascular Society guidelines for the management of heart failure were released in 2017. No new updates to the guidelines have been created since that date.

DRUG THERAPY

Drugs that increase the force of myocardial contraction are called positive **inotropic drugs**, and they have a role in the treatment of failing heart muscle. Negative inotropic drugs reduce the force of contraction. Drugs that increase the rate at which the heart beats are called positive **chronotropic drugs**. Negative chronotropic drugs do the opposite. Drugs may also affect how quickly electrical impulses travel through the conduction system of the heart (the sinoatrial [SA] node, atrioventricular [AV] node, bundle of His, and Purkinje fibres) (Figure 25.1). Drugs that accelerate conduction are referred to as positive **dromotropic drugs**. This chapter focuses on the positive inotropic drugs, phosphodiesterase

inhibitors (PDIs), and cardiac glycosides. Although several other drugs are used in the treatment of heart failure, they are discussed in detail in other chapters; for example, angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers (ARBs) are covered in Chapter 23; beta blockers are discussed in Chapters 20, 23, and 24; the vasodilator nitroglycerin, in the form of patches, is used in acute and chronic heart failure, as discussed in Chapter 24, and the mainstays of early treatment—diuretics—are discussed in Chapter 29. These drugs are mentioned in this chapter as well, but for specifics, refer to the indicated chapters.

The treatment of heart failure has changed dramatically over the past decade. The positive inotrope digoxin was once the drug of choice in heart failure treatment, but because of adverse effects and drug interactions, it has been replaced by other drugs. Its usefulness is still debated in the literature; however, it remains an important drug in the symptom management of severe end-stage heart failure and may reduce hospitalizations but not mortality. Inotropes do not improve patient outcomes. According to the 2017 Comprehensive Update of the Canadian Cardiovascular Society Guidelines for the Management of Heart Failure (Ezekowitz et al., 2017), the proper approach to the treatment of chronic heart failure revolves around “the early detection of LV systolic function which will allow for interventions on contributing risk factors and pharmacotherapy to delay or reverse the progression of adverse LV remodeling” (p. 1344). Therefore, the drugs of choice at the start of therapy are the ACE inhibitors (lisinopril, enalapril, captopril, and others) or the ARBs (valsartan, candesartan, losartan, and others), and certain beta blockers (metoprolol or bisoprolol fumarate, cardioselective beta blockers; carvedilol, a nonspecific beta blocker) to preserve LV function and reduce blood pressure throughout the progression of the illness. Loop diuretics (furosemide) are used to reduce the symptoms of heart failure secondary to fluid overload,

and the mineralocorticoid receptor antagonists (spironolactone, eplerenone) are added as the heart failure progresses. Only after these drugs are used is digoxin added. Dobutamine, a positive inotropic drug, has also been used to treat heart failure. A combination of hydralazine and isosorbide dinitrate is recommended specifically for use in patients who are Black.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

ACE inhibitors comprise a class of drugs that, as their name implies, inhibit angiotensin-converting enzyme, which is responsible for converting angiotensin I (formed through the action of renin) to angiotensin II. Angiotensin II is a potent vasoconstrictor and induces aldosterone secretion by the adrenal glands. Aldosterone stimulates sodium and water resorption, which can raise blood pressure. Together, these processes are referred to as the renin–angiotensin–aldosterone system. ACE inhibitors are beneficial in the treatment of heart failure because they prevent sodium and water resorption by inhibiting aldosterone secretion. This action causes diuresis, which decreases blood volume and blood return to the heart. This result in turn decreases preload, or the left ventricular end-diastolic volume, and the work required of the heart. According to the 2017 Comprehensive Update of the Canadian Cardiovascular Society Guidelines for the Management of Heart Failure (Ezekowitz et al., 2017), an ACE inhibitor should be started in the acute setting as soon as safely possible. It is to be continued particularly if the patient is already being treated with chronic ACE inhibitor therapy. The ACE inhibitors (as well as ARBs) are also effective in slowing the progression of ventricular remodeling and hypertrophy.

Numerous ACE inhibitors are available, including lisinopril, enalapril maleate, fosinopril sodium, quinapril hydrochloride, captopril (Chapter 23), ramipril, trandolapril, and perindopril erbumine. These drugs are all similar, and lisinopril will be used as the example for this class of drugs used to treat heart failure.

DRUG PROFILE

lisinopril

Lisinopril (Prinivil®, Zestril®) is a commonly used ACE inhibitor and is available in a generic form. It is used for hypertension, heart failure, and acute myocardial infarction. Like all ACE inhibitors, it can cause injury or fetal death when used in pregnancy. Hyperkalemia may occur with any ACE inhibitor, and potassium supplementation or potassium-sparing diuretics need to be used with caution. Like all ACE inhibitors, lisinopril can cause a dry cough, which is not harmful but can be annoying. The cough is a result of bradykinins, insoluble by-products of the ACE inhibitors, building up in the blood and lodging in the lungs' bronchial tubes. The coughing spells represent the body's attempt to expel the kinins from the lungs. The cough usually resolves in a month, but patients may be switched to an angiotensin II receptor antagonist. Lisinopril (and all ACE inhibitors) may also be associated with a decrease in kidney function. For drug interactions, see Chapter 23.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1 hr	6 hr	11–12 hr	24 hr

ANGIOTENSIN II RECEPTOR BLOCKERS

The therapeutic effects of ARBs in heart failure are related to their potent vasodilating properties. They may be used alone or in combination with other drugs such as diuretics in the treatment of hypertension or heart failure. The beneficial hemodynamic effect of ARBs is their ability to decrease systemic vascular resistance (a measure of afterload). Seven ARBs are currently available: valsartan, candesartan cilexetil, eprosartan mesylate, irbesartan, telmisartan, olmesartan medoximil, and losartan potassium. All of the ARBs are similar in action. Valsartan will be used as the example for this class of drugs used to treat heart failure.

DRUG PROFILE

valsartan

Valsartan (Diovan®) is a commonly used ARB. Like all ARBs, it can cause fetal and neonatal morbidity and death when used during pregnancy. Valsartan shares many of the same adverse effects as lisinopril, profiled earlier. The ARBs are not as likely to cause the cough associated with ACE inhibitors, nor are they as likely to cause hyperkalemia. For drug interactions, see Chapter 23.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	2 hr	Unknown	6 hr	12 hr

BETA BLOCKERS

Beta blockers (also discussed in Chapters 20, 23, and 24) work by reducing or blocking sympathetic nervous system stimulation to the heart and the heart's conduction system. By doing this, beta blockers prevent catecholamine-mediated actions on the heart. This is known as a cardioprotective quality of beta blockers. The resulting cardiovascular effects include reduced heart rate, delayed AV node conduction, reduced myocardial contractility, and decreased myocardial **automaticity**. Three beta blockers have been shown to reduce mortality: bisoprolol, extended-release metoprolol, and carvedilol. Metoprolol tartrate is the beta blocker most commonly used to treat heart failure. It is available as an immediate-release and an extended-release product, as well as an intravenous formulation.

Carvedilol has many effects, including acting as a nonselective beta blocker, an α_1 blocker, and possibly a calcium channel blocker and antioxidant. It is used primarily in the treatment of

heart failure but is also beneficial for hypertension and angina. It has been shown to slow the progression of heart failure and to decrease the frequency of hospitalization in patients with mild to moderate (class II or III) heart failure. Carvedilol is most commonly added to digoxin, furosemide, and ACE inhibitors when used to treat heart failure. It is available only for oral use.

ALDOSTERONE ANTAGONISTS

The aldosterone antagonists spironolactone and eplerenone are useful in severe stages of heart failure. Activation of the renin–angiotensin–aldosterone system causes increased levels of aldosterone, which causes retention of sodium and water, leading to edema that can worsen heart failure. Spironolactone (Aldactone®) is a potassium-sparing diuretic and is discussed in detail in [Chapter 29](#). It also acts as an aldosterone antagonist, which has been shown to reduce the symptoms of heart failure. Eplerenone (Inspra®) is a selective aldosterone blocker, blocking aldosterone at its receptors in the kidney, heart, blood vessels, and brain. It is discussed in detail in [Chapter 23](#).

Miscellaneous Heart Failure Drugs

DRUG PROFILES

hydralazine/isosorbide dinitrate

Hydralazine and isosorbide dinitrate are approved specifically for individuals who are Black. A combination of the two drugs is available in the United States but not in Canada. The individual drugs are discussed in detail in [Chapter 23](#) (hydralazine) and [Chapter 24](#) (isosorbide). Peak plasma levels of hydralazine and isosorbide dinitrate are achieved in 1 hour.

dobutamine hydrochloride

Dobutamine hydrochloride is a β_1 -selective vasoactive adrenergic drug that is structurally similar to the naturally occurring catecholamine dopamine. Through stimulation of the β_1 receptors on heart muscle (myocardium), it increases cardiac output by increasing contractility (positive inotropy), which increases the stroke volume, especially in patients with heart failure. Dobutamine hydrochloride is available only as an intravenous drug and is given by continuous infusion. See [Chapter 18](#) for further discussion of this drug. Dobutamine hydrochloride is recommended for patients who present in acute decompensated heart failure and are hemodynamically unstable ([Tariq & Aronow, 2015](#)).

OMEGA-3 POLYUNSATURATED FATTY ACIDS

The natural health product omega-3 polyunsaturated fatty acids (PUFAs) is included in this chapter because it is recommended by the 2017 Comprehensive Update of the Canadian Cardiovascular Society Guidelines for the Management of Heart Failure ([Ezekowitz et al., 2017](#)), as adjunctive therapy for patients with chronic heart failure. Studies found that mortality is reduced by 21% in patients post-myocardial

infarction who are taking 1 g of omega-3 PUFA (850 to 882 mg of eicosapentaenoic acid [EPA] and docosahexaenoic acid [DHA] as ethyl esters in the ratio of 1:1.2) daily ([McKelvie, Moe, Ezekowitz, et al., 2013](#)). In a nearly 4-year study follow-up, researchers found that there was a 9% relative reduction in all-cause death, and an 8% reduction in death and hospital admissions with the continued use of omega-3 PUFA ([Ezekowitz et al., 2017](#)).

PHOSPHODIESTERASE INHIBITORS

PDIs are a group of inotropic drugs that work by inhibiting the action of an enzyme called phosphodiesterase. These drugs were discovered in the search for positive inotropic drugs with a wider therapeutic window than that of digoxin. Currently, only one drug in this category is available: milrinone.

Mechanism of Action and Drug Effects

The mechanism of action of PDIs differs from that of other inotropic drugs such as digoxin and the catecholamines. PDIs share a similar pharmacological action with methylxanthines, such as theophylline (see [Chapter 38](#)). Both types of drug inhibit the action of phosphodiesterase, which results in an increase in intracellular cyclic adenosine monophosphate (cAMP). However, milrinone is more specific for phosphodiesterase type III, which is commonly found in the heart and vascular smooth muscles.

The beneficial effects of milrinone are from the intracellular increase in cAMP, which results in two beneficial effects in patients with heart failure: a positive inotropic response and vasodilation. For this reason, this class of drugs may also be referred to as *inodilators* (inotropics and dilators). Milrinone has a 10 to 100 times greater affinity for smooth muscle fibres surrounding pulmonary and systemic blood vessels than it does for cardiac muscle. This suggests that the primary beneficial effects of inodilators come from their vasodilating effects, which cause a reduction in the force against which the heart must pump to eject its volume of blood.

Finally, inhibition of phosphodiesterase results in the availability of more calcium for myocardial muscle contraction. This increased availability of calcium leads to an increase in the force of contraction (i.e., positive inotropic action). The increased calcium present in heart muscle is taken back up into its storage sites in the sarcoplasmic reticulum at a much faster rate than normal. As a result, the heart muscle relaxes more than normal and is also more compliant. In summary, PDIs have positive inotropic and vasodilatory effects. They may also increase heart rate in some instances and therefore may have positive chronotropic effects as well.

Indications

PDIs are primarily used in the intensive care unit setting for the short-term management of acute heart failure. The 2017 Comprehensive Update of the Canadian Cardiovascular Society Guidelines for the Management of Heart Failure ([Ezekowitz et al., 2017](#)) does not recommend the use of inotrope therapy for patients with acute heart failure, as research shows an increase in potential harm to patients, leading to higher mortality rates. Patients were previously treated with PDIs to relieve dyspnea symptoms.

Contraindications

Contraindications to the use of PDIs include known drug allergy and may include the presence of severe aortic or pulmonary valvular disease and heart failure resulting from diastolic dysfunction.

Adverse Effects

The primary adverse effect seen with milrinone therapy is dysrhythmia. Milrinone-induced dysrhythmias are mainly ventricular. Ventricular dysrhythmias occur in approximately 12% of patients treated with this drug. Some other adverse effects associated with milrinone therapy are hypotension, angina (chest pain), hypokalemia, tremor, and thrombocytopenia.

Toxicity and Management of Overdose

No specific antidote exists for an overdose of milrinone. Hypotension secondary to vasodilation is the primary effect seen with excessive dosages. The recommendation is to reduce the dosage or temporarily discontinue the drug if excessive hypotension occurs. This is to be done until the patient's condition has stabilized. Initiation of general measures for circulatory support is also recommended.

Interactions

Concurrent administration of diuretics may cause significant hypovolemia and reduced cardiac filling pressure. Appropriately monitor the patient in an intensive care setting to detect and respond to these problems. Additive inotropic effects may be seen with coadministration of digoxin. Furosemide must not be injected into intravenous lines with milrinone because it will precipitate immediately.

Dosages

For dosage information, refer to the table below.

DRUG PROFILE

milrinone lactate

Milrinone lactate is the only currently available PDI after the discontinuation of the production of inamrinone. Milrinone is

also referred to as an *inodilator* because it exerts both a positive inotropic effect and a vasodilatory effect. Milrinone is contraindicated in cases of known drug allergy. Adverse effects include cardiac dysrhythmias, headache, hypokalemia, tremor, thrombocytopenia, and elevated liver enzyme levels. Interacting drugs include diuretics (causing additive hypotensive effects) and digoxin (causing additive inotropic effects). Milrinone is available only in injectable form. Recommended dosages are given in the table below.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	5–15 min	1 hr	2.3 hr	1 to several hr

CARDIAC GLYCOSIDES

Cardiac glycosides comprise one of the oldest groups of cardiac drugs. Not only do they have beneficial effects on the failing heart, but they also help control the ventricular response to **atrial fibrillation**. They were originally obtained from either the *Digitalis purpurea* or the *Digitalis lanata* plant, both commonly known as *foxglove*. For this reason, cardiac glycosides are often referred to as *digitalis glycosides*. Cardiac glycosides were the mainstay of therapy for heart failure for more than 200 years; however, they are no longer used as first-line drugs. ACE inhibitors and diuretics are recommended as the key drugs to offer therapeutic benefit; nevertheless, digoxin may still offer benefit in some patients (see Evidence in Practice: Digoxin Use in Heart Failure box). According to the 2017 Comprehensive Update of the Canadian Cardiovascular Society Guidelines for the Management of Heart Failure (Ezekowitz et al., 2017), digoxin is recommended for HFrEF patients with normal sinus rhythm who continue to have moderate to severe symptoms, despite optimized heart failure therapy to relieve symptoms and reduce hospitalizations. Digoxin is the only cardiac glycoside

Dosages

Selected Drugs for Heart Failure

Drug	Pharmacological Class	Usual Dosage Range	Indications
 digoxin (Lanoxin®)	Digitalis cardiac glycoside	<i>Children</i> Digitalizing dose: IV: 8–50 mcg/kg, divided into 3–4 doses, depending on age, from premature infant to child older than 10 yr PO: 10–60 mcg/kg, divided into 3–4 doses, depending on age, from premature infant to child older than 10 yr Usual maintenance dose: 20–35% of digitalizing dose <i>Adults</i> PO/IV: Usual digitalizing dose: 0.5–0.75 mg followed by 0.125–0.375 mg divided into 3–4 doses; usual oral maintenance dose: 0.125–0.5 mg/day	Heart failure, supraventricular dysrhythmias
 milrinone lactate	Phosphodiesterase inhibitor	<i>Adults</i> IV loading dose: 50 mcg/kg IV continuous infusion dose: 0.375–0.75 mcg/kg/min	Heart failure

IV, Intravenous; PO, oral.

EVIDENCE IN PRACTICE

Digoxin Use in Heart Failure**Background**

Heart failure is a major public health problem in Canada and other developed countries. Digoxin was long established as a positive inotrope in heart failure and for its negative chronotropic activity in atrial fibrillation; however, the use of digoxin has declined, recently, possibly over concerns about safety after the publication of observational studies reporting increased mortality with its use. The Digitalis Investigation Group (DIG) trial, conducted in 2006, was a multicentre randomized, double-blind, placebo-controlled trial conducted in Canada and the United States, that evaluated the effects of digoxin on all-cause mortality and on hospitalization for heart failure in patients with heart failure. The DIG trial study was the largest randomized controlled trial of digoxin in heart failure and showed neutral effects on overall mortality and a reduction in admissions to hospital compared with placebo, as well as a decrease in mortality among those with low serum digoxin concentrations.

Type of Evidence

In order to clarify the concerns over the impact of digoxin on death and clinical outcomes, the authors conducted a systematic review and meta-analysis of observational and controlled trial data. A total of 52 studies published between 1960 and 2014 were reviewed, comprising a total of 621 845 patients.

The researchers assessed the safety and efficacy of digoxin by comprehensively meta-analyzing all available observational and experimental studies. The hypothesis was that study design would have a significant impact on the observed mortality associated with digoxin (Ziff, Lane, & Samra, 2015).

Results of Study

Overall, the researchers established that in studies with sound methodology and low risk of bias, there was a neutral association of digoxin with cardiovascular death. However, for all study types, digoxin led to a small but significant reduction in all-cause hospital admission.

Link of Evidence to Nursing Practice

Heart failure is the most common cause of cardiovascular hospital admission. Digoxin has been available for over 200 years and is widely used. The implementation of evidence-informed therapy for heart failure management is clinically efficacious. However, there is still uncertainty surrounding the appropriateness of its role and its value in treating patients with heart failure. The 2017 Comprehensive Update of the Canadian Cardiovascular Society Guidelines for the Management of Heart Failure (Ezekowitz et al., 2017) strongly recommend the use of digoxin in HFrEF patients in normal sinus rhythm who continue to have moderate to severe symptoms of chronic heart failure, despite optimized heart failure therapy to relieve symptoms and reduce hospitalizations. This recommendation is made with the understanding that the use of digoxin remains controversial in the literature. Nurses should be informed of current evidence to support management of heart failure but also be familiar with potential pitfalls.

SPECIAL POPULATIONS: CHILDREN

Heart Failure

- The causes, symptoms, treatments, and prognoses of heart failure in children vary depending on age. In infants, the cause of heart failure is generally congenital heart defects or other structural problems. In older children, the structure of the heart may be normal, but the heart muscle may be weakened. Symptoms of heart failure differ depending on age and become worse with age because the heart must keep up with increased oxygen demands and energy demands with increased growth.
- Symptoms in infants and young children may include poor growth, difficulty in feeding (reflux, vomiting, feeding refusal), diaphoresis, pallor, and tachypnea; in older children, they include fatigue, inability to tolerate exercise and other activities, the need to rest often, dyspnea with minimal exertion, abdominal pain, orthopnea, nausea, and vomiting.
- Treatment is generally age- and cause-specific. For septal defects, surgery or medication may be indicated. For more complex problems, surgery may be needed within the first few weeks of life.
- Drug therapy may include furosemide (a loop diuretic) and a thiazide diuretic if required, ACE inhibitors, beta blockers, and sometimes digoxin to improve heart pumping efficiency.
- Correct calculation of dosages for any of the medications used is important for safe and cautious nursing care. A one-decimal-point placement error will result in a 10-fold dosage error, which could be fatal.
- Digoxin toxicity is manifested in children by nausea, vomiting, bradycardia, anorexia, and dysrhythmias.
- The health care provider needs to be notified immediately if any of the following develop or worsen: fatigue, sudden weight gain (1 kg or more in 24 hours), palpitations, tachycardia or bradycardia, or respiratory distress.

Source: Kantor, P. F., Loughheed, J., Dancea, A., et al. (2013). Presentation, diagnosis, and medical management of heart failure in children: Canadian Cardiovascular Society Guidelines. *Canadian Journal of Cardiology*, 29(12), 1535–1552. <https://doi.org/10.1016/j.cjca.2013.08.008>

currently available. Although it is a powerful positive inotropic drug, it has not been shown to reduce mortality.

See the Special Populations: Children box for information on the use of cardiac glycosides in children with heart failure.

While the emphasis in this chapter regarding heart failure is on systolic dysfunction or inadequate ventricular contractions (systole) during the pumping of the heart, it is also important to note the less common condition of diastolic dysfunction, or inadequate ventricular filling, during ventricular relaxation (diastole). This condition is most commonly associated with left ventricular hypertrophy secondary to chronic hypertension. However, it may also result from cardiomyopathy (e.g., virus induced), pericardial disease, and diabetes. Unlike with systolic heart failure, inotropic drugs (including digoxin) and vasodilators (see Chapter 23) may not be the drugs of choice for diastolic failure. Diuretic drugs (see Chapter 29), on the other hand, are often used as part of therapy for both conditions.

Mechanism of Action and Drug Effects

The beneficial effect of digoxin is thought to be an increase in myocardial contractility, or a *positive inotropic effect*. This effect occurs secondarily to the inhibition of the sodium–potassium adenosine triphosphatase pump. When the action of this

enzyme complex is inhibited, cellular sodium and calcium concentrations increase. The overall result is enhanced myocardial contractility. Digoxin also augments cholinergic stimulation via the vagus nerve of the parasympathetic nervous system. This effect is more commonly referred to as *vagal tone* and results in increased diastolic filling between heartbeats secondary to reduced heart rate. Vagal tone is also believed to sensitize cardiac baroreceptors, which reduces sympathetic stimulation from the central nervous system (CNS). All of these processes further enhance cardiac efficiency and output.

Digoxin changes the electrical conduction properties of the heart, and this change markedly affects the conduction system and cardiac automaticity. Digoxin decreases the velocity (rate) of electrical conduction and prolongs the **refractory period** in the conduction system. The particular site in the conduction system where this occurs is the area between the atria and the ventricles (SA node to AV node). The cardiac cells remain in a state of depolarization for a longer period and are unable to start another electrical impulse, which also reduces heart rate and improves cardiac efficiency.

The following is a summary of the inotropic, chronotropic, dromotropic, and other effects produced by digoxin:

- A positive inotropic effect—an increase in the force and velocity of myocardial contraction without a corresponding increase in oxygen consumption
- A negative chronotropic effect—reduced heart rate
- A negative dromotropic effect—decreased automaticity at the SA node, decreased AV nodal conduction, reduced conductivity at the bundle of His, and prolongation of the atrial and ventricular refractory periods
- An increase in stroke volume
- A reduction in heart size during diastole
- A decrease in venous blood pressure and vein engorgement
- An increase in coronary circulation
- Promotion of tissue perfusion and diuresis as a result of improved blood circulation
- A decrease in exertional and paroxysmal nocturnal dyspnea, cough, and cyanosis
- Improved symptom control, quality of life, and exercise tolerance, but no apparent reduction in mortality

Indications

Digoxin is primarily used in the treatment of systolic heart failure and atrial fibrillation. However, the latest heart failure treatment guidelines recommend that it be used as an adjunct to drugs of other classes, including beta blockers, diuretics, ACE inhibitors, and ARBs.

Contraindications

Contraindications to the use of digoxin include known drug allergy and may include second- or third-degree heart block, atrial fibrillation, ventricular tachycardia or fibrillation, heart failure resulting from diastolic dysfunction, and subaortic stenosis (obstruction in the left ventricle below the aortic valve), and it should be used with caution in those with reduced kidney function. However, digoxin may be used to treat some of these conditions, if recommended by a cardiologist, depending on the given clinical situation.

TABLE 25.1 Digoxin: Common Adverse Effects

Body System	Adverse Effect
Cardiovascular	Bradycardia, tachycardia, hypotension
Central nervous	Headache*, fatigue, confusion*, convulsions
Visual	Coloured vision (i.e., green, yellow, or purple)*, halo vision*
Gastrointestinal	Anorexia*, nausea*, vomiting*, diarrhea

*These are symptoms of toxicity.

Adverse Effects

The common undesirable effects associated with digoxin use are cardiovascular, CNS, ocular, and gastrointestinal (GI) effects. These are outlined in [Table 25.1](#).

Toxicity and Management of Overdose

Digoxin has a low therapeutic index (see [Chapter 2](#)). Digoxin levels are monitored when the patient first starts taking the drug. However, monitoring of digoxin levels after the drug reaches a steady state is usually necessary only if there is suspicion of toxicity, nonadherence, or deteriorating kidney function. Normal therapeutic levels for digoxin are 0.8 to 2 ng/mL, although lower target levels (0.5–0.9 ng/mL) are recommended by the 2013 Canadian Cardiovascular Society 2017 guidelines ([Ezekowitz et al., 2017](#)) for the management of heart failure. Low potassium or magnesium levels may increase the potential for digoxin toxicity. Therefore, frequent monitoring of serum electrolytes such as potassium and creatinine is important. A decrease in kidney function is also a common cause of digoxin toxicity because digoxin is excreted almost exclusively via the kidneys. Monitor patients during a dehydrating illness for signs of digoxin toxicity. Signs and symptoms of digoxin toxicity include bradycardia, headache, dizziness, confusion, nausea, and visual disturbances (blurred vision or yellow vision). With toxicity, electrocardiogram (ECG) findings may include heart block, atrial tachycardia with block, or ventricular dysrhythmias. Predisposing factors to digoxin toxicity are listed in [Table 25.2](#).

Treatment strategies for digoxin toxicity depend on the severity of the symptoms. These strategies can range from simply withholding the next dose to instituting more aggressive therapies. The steps usually taken in the management of digoxin toxicity are listed in [Table 25.3](#).

When significant toxicity develops as a result of digoxin therapy, the administration of digoxin immune Fab may be indicated. Digoxin immune Fab is an antibody that recognizes digoxin as an antigen and forms an antigen–antibody complex with the drug, thus inactivating the free digoxin. Digoxin immune Fab therapy is not indicated for every patient who is showing signs of digoxin toxicity. The following are the clinical situations in which its use may be indicated:

- Hyperkalemia (a serum potassium level higher than 5 nmol/L) in a patient with digoxin toxicity
- Life-threatening cardiac dysrhythmias, sustained ventricular tachycardia or fibrillation, and severe sinus bradycardia or heart block unresponsive to atropine treatment or cardiac pacing

TABLE 25.2 Conditions Predisposing to Digitalis Toxicity

Condition/Disease	Significance
Use of cardiac pacemaker	A patient with this device may exhibit digoxin toxicity at lower dosages than usual.
Hypokalemia	The patient's risk of serious dysrhythmias is increased, and the patient is more susceptible to digoxin toxicity.
Hypercalcemia	The patient is at higher risk of experiencing sinus bradycardia, dysrhythmias, and heart block.
Atrioventricular block	Heart block may worsen with increasing levels of digoxin.
Dysrhythmias	Dysrhythmias may occur that did not exist before digoxin use and thus could be related to digoxin toxicity.
Hypothyroidism, respiratory disease, or kidney disease	Patients with these disorders require lower dosages because the disorders cause delayed kidney drug excretion.
Advanced age	Because of decreased kidney function and the resultant diminished drug excretion, along with decreased body mass in this patient population, a lower dosage than usual is needed to prevent toxicity. The practice of polypharmacy may also lead to toxicity.
Ventricular fibrillation	Ventricular rate may actually increase with digoxin use.

TABLE 25.3 Digoxin Toxicity: Step-by-Step Management

Step	Instructions
1	Discontinue (hold) administration of the drug, take vital signs, assess for toxicity, and contact the health care provider.
2	Begin continuous electrocardiographic monitoring for cardiac dysrhythmias; administer any appropriate antidysrhythmic drugs, as ordered.
3	Determine serum digoxin and electrolyte levels.
4	Administer potassium supplements for hypokalemia if indicated, as ordered.
5	Institute supportive therapy for GI symptoms (nausea, vomiting, or diarrhea).
6	Administer digoxin antidote (i.e., digoxin immune Fab) if indicated, as ordered.

GI, gastrointestinal.

- Life-threatening digoxin overdose—more than 10 mg of digoxin in adults; more than 4 mg of digoxin in children

Interactions

A wide variety of significant drug interactions are possible with digoxin. Common examples are provided in [Table 25.4](#). The most important drug–drug interactions occurring with digoxin are interactions with amiodarone hydrochloride, quinidine sulfate, and verapamil hydrochloride. These three drugs can increase digoxin levels by 50%. When large amounts of bran are ingested, the absorption of oral digoxin may be decreased. Certain natural health products may interact with digoxin. For example, ginseng may increase digoxin levels, hawthorn may potentiate the effects of digoxin, licorice may increase the risk of cardiac toxicity due to potassium loss, and St. John's wort may reduce digoxin levels. Drugs that lower serum potassium or magnesium levels can predispose patients to digoxin toxicity.

Dosages

For dosage information, refer to the table on p. 413. Also refer to the Preventing Medication Errors: The Importance of Decimal Points box.

DRUG PROFILES

digoxin

Digoxin (Lanoxin) is indicated for the treatment of both heart failure and atrial fibrillation and flutter. Digoxin use is contraindicated in patients who have shown a hypersensitivity to it and in those with ventricular tachycardia or fibrillation. Normal therapeutic drug levels of digoxin should be between 0.5 and 1 ng/mL. Levels higher than 2.4 ng/mL often precipitate manifestations of toxicity. However, levels higher than 0.8–1.5 ng/mL are the target for the treatment of atrial fibrillation. Because of digoxin's long duration of action and half-life, a loading, or *digitalizing*, dose is often given to bring serum levels of the drug up to a desirable therapeutic level more

⚡ PREVENTING MEDICATION ERRORS

The Importance of Decimal Points

Incorrect decimal placement can be lethal when calculating digoxin dosages. According to the Institute for Safe Medication Practices Canada (ISMP Canada), trailing zeros are *not* to be used after decimal points. This is extremely important in the case of digoxin, since when a 1-mg dose is ordered and written as “1.0 mg,” the order could be misread as “10 mg,” and the patient would receive 10 times the ordered dose.

ISMP Canada also recommends that leading zeros be used if a dose is less than a whole number. For example, “.25 mg” can look like “25 mg,” resulting in a dose that is 100 times the ordered dose. Rather, the order should be written as “0.25 mg” to avoid errors.

Of course, such an error hopefully would be caught when the nurse realizes how many 250-mcg digoxin tablets it would take to give a 25-mg dose, or how many millilitres would be needed for an intravenous dose. However, such errors have occurred. Consider what would happen if a digoxin overdose led to digoxin toxicity and the serious effect this would have on the patient.

For more information, visit www.ismp-canada.org/download/caccn/CACCN-Fall05.pdf.

TABLE 25.4 Cardiac Glycosides: Drug Interactions

Interacting Drug	Mechanisms	Result
Antidysrhythmics calcium (parenteral) cholestyramine colestipol sucralfate β -blockers Calcium channel blockers	Increase cardiac irritability Decrease oral absorption Block β -receptors in heart Block calcium channels in myocardium	Increased digoxin toxicity Reduced therapeutic effect Enhanced bradycardic effect of digoxin Enhanced bradycardic and negative inotropic effects of digoxin
quinidine, verapamil, amiodarone, dronedarone ciclosporin Azole antifungals	Decrease clearance	Digoxin levels increased by 50%; digoxin dose should be reduced by 50%

quickly. For recommended digitalizing doses and the daily oral and intravenous adult and pediatric dosages, refer to the table on p. 413.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1–2 hr	2–8 hr	35–48 hr	3–4 days
IV	5–30 min	1–4 hr	35–48 hr	3–4 days

digoxin immune fab

Digoxin immune Fab (Digifab®) is the antidote for severe digoxin overdose and is indicated for the reversal of such life-threatening cardiotoxic effects as severe bradycardia, advanced heart block, ventricular tachycardia or fibrillation, and severe hyperkalemia. It has a unique mechanism of action. Use of digoxin immune Fab is contraindicated in patients who have known hypersensitivity to it. It is available only in parenteral form. It is dosed on the basis of the patient's serum digoxin level in conjunction with the patient's weight. The recommended dosages vary according to the amount of digoxin taken. One vial binds 0.5 mg of digoxin. For recommended dosages, the nurse should consult the manufacturer's latest dosage recommendations. It is important to remember that after digoxin immune Fab is given, all subsequent measures of serum digoxin levels will be elevated for days to weeks. Therefore, after its administration, the clinical signs and symptoms of digoxin toxicity, rather than the serum digoxin levels, should be the primary focus in monitoring for the effectiveness of reversal therapy. Digoxin immune Fab is made from immunoglobulin fragments from sheep immunized with a digoxin derivative. Because papain is used to cleave the antibody into the Fab fragments, individuals who are allergic to papaya, papain, or sheep protein need to be monitored for anaphylactic shock.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Immediate	Immediate	14–20 hr	Days to weeks

NURSING PROCESS**ASSESSMENT**

Before a drug used to treat heart failure is administered, perform a thorough assessment, including the patient's medical history, drug allergies, and family medical history, with emphasis on any history of cardiac, hypertensive, or kidney diseases. The nurse's review may yield findings that either dictate cautious use of the drug or represent contraindications to its use. Assess the following clinical parameters and other data:

- Blood pressure
- Pulse rate—both apical and radial, measured for 1 full minute
- Peripheral pulse location and grading of strength
- Capillary refill
- Presence or absence of edema
- Heart sounds
- Breath sounds
- Weight
- Intake and output amounts
- Serum laboratory values such as potassium, sodium, magnesium, and calcium levels
- Electrocardiogram
- Results of kidney function tests, including urea nitrogen and creatinine levels
- Results of liver function tests, such as levels of aspartate aminotransferase, alanine aminotransferase, creatine phosphokinase, lactate dehydrogenase, and alkaline phosphatase
- Medication history and profile, including all prescription drugs, over-the-counter drugs, and natural health products (e.g., Siberian ginseng may increase digoxin drug levels; consumption of large amounts of bran with digoxin will decrease the drug's absorption)
- Dietary habits and all meals and snacks consumed over the previous 24 hours
- Smoking history
- Alcohol intake

ACE inhibitors, such as lisinopril, require thorough assessment of cautions, contraindications, and drug interactions (see [Chapter 23](#)). Hyperkalemia is an adverse effect; therefore, perform an assessment of serum potassium before giving these drugs

and use caution when administering potassium supplementation or potassium-sparing diuretics. Assess respiratory history, specifically any previous problems of cough. ACE inhibitors may cause a dry cough, which is not harmful but may be annoying. Patients may be switched to an ARB, such as valsartan (see [Chapter 23](#)), if the cough becomes problematic for them.

As mentioned earlier, metoprolol tartrate is the beta blocker most commonly used to treat heart failure. Carvedilol also has many therapeutic effects, as does bisoprolol (see [Chapter 20](#)), and is commonly added to existing regimens of furosemide (loop diuretic) and ACE inhibitors in the management of heart failure. Related assessment information for alpha- and beta-blocking drugs may be found in [Chapter 20](#). Dobutamine hydrochloride, a beta₁-selective adrenergic, is also used to treat heart failure and is discussed further in [Chapter 19](#). The status of the patient's veins is important to assess when this drug is indicated because it is given only intravenously.

Aldosterone antagonists, such as spironolactone and eplerenone, require close assessment of heart and breath sounds as well as assessment for the occurrence of edema, which is a known adverse effect (see [Chapter 23](#) for more information). Hydralazine (discussed further in [Chapter 23](#)) combined with isosorbide dinitrate is used mainly in patients who are Black.

With any medication regimen, it is always important to assess support systems at home because safe and effective therapy depends on close observation, monitoring of appropriate parameters (e.g., daily weight), attention to patient concerns, and evaluation of how the patient is feeling and functioning. With milrinone, a PDI, closely monitor cardiac status, which is crucial to patient safety. Patients who are administered this drug are usually in a critical care setting and require frequent assessment of heart sounds, vital signs, and any evidence of ventricular dysrhythmias on ECG readings. Assess also for any history of angina, hypotension, and hypokalemia, which may all be exacerbated with this drug. Significant drug interactions for which to assess include parenteral furosemide, which will precipitate immediately if milrinone is present in intravenous lines.

Before giving digoxin, closely monitor serum electrolytes. Calcium levels should be checked as calcium is required for cardiac contractility. Specifically, assess potassium levels because low levels or hypokalemia may precipitate digoxin toxicity. Hypokalemia is manifested by muscle weakness, confusion, lethargy, anorexia, nausea, and changes in ECG readings. Low levels of magnesium, or hypomagnesemia, may also precipitate digoxin toxicity. Hypomagnesemia is manifested by agitation, twitching, hyperactive reflexes, nausea, vomiting, and changes in ECG readings. Also closely assess digoxin levels once the drug has been administered because of its narrow therapeutic index (see [Chapter 2](#)). Measure and document baseline weight as well. Perform a careful assessment of the following systems: (1) neurological system—note any history of headaches, fatigue, confusion, or convulsions; assess level of alertness and orientation; (2) GI system—document any changes in appetite (e.g., decrease) or reports of diarrhea, nausea, or vomiting; (3) cardiac system—note any pulse rate lower than 60 beats per minute or greater than 100 beats per minute, hypotension, abnormal heart sounds, abnormal ECG findings (if this test is ordered),

and any history of irregularities; and (4) visual and sensory systems—document baseline vision as well as any changes in vision, such as green, yellow, or purple halos surrounding the peripheral field of vision. See [Table 25.1](#) for more information on adverse effects of digoxin. Also assess for any cautions, contraindications, and drug interactions (see [Table 25.2](#)).

◆ NURSING DIAGNOSES

- Reduced peripheral tissue perfusion as a result of the pathophysiological influence of heart failure
- Inadequate knowledge as a result of lack of information and experience with heart failure as well as first-time use of drugs indicated for heart failure
- Potential for nonadherence with therapy regimen as a result of lack of information about the disease process as well as the drug(s) and adverse effects

◆ PLANNING

◆ Goals

- Patient will exhibit improved cardiac output with improved tissue perfusion once therapy is initiated.
- Patient will state use, action, adverse effects, and toxic effects of therapy.
- Patient will remain adherent to drug therapy regimen.

◆ Outcome Criteria

- Patient experiences improved to strong peripheral pulses; pink, warm extremities; and an improved ability to carry out activities of daily living (ADLs) with minimal dyspnea and increased energy levels.
- Patient demonstrates sufficient knowledge about disease process related to heart failure, stating the importance of the need for lifelong therapy, constant monitoring by the health care provider, energy conservation, and other measures to minimize oxygen demands.
- Patient demonstrates proper technique for measuring radial pulse for 1 full minute before taking medication.
- Patient states the most common adverse effects to expect with digoxin therapy, such as bradycardia or tachycardia (pulse rate lower than 60 beats per minute or greater than 100 beats per minute, as indicated by the health care provider), headache, fatigue, confusion, halo vision, anorexia, nausea, and vomiting.
- Patient states the importance of reporting to the health care provider any symptoms that are indicative of digoxin toxicity, specifically anorexia, nausea, vomiting, and loss of appetite.
- Patient's adherence to therapy results in improved heart function with subsequent heart rate greater than 60 beats per minute and lower than 100 beats per minute, with regular rhythm.
- Patient reports improved ability to perform ADLs with minimal dyspnea and increased energy levels.
- Patient reports taking medication consistently, at the same time every day, and recording daily weights.

- Patient remains free from exacerbations of heart failure and states no severe adverse effects while taking medication exactly as ordered.

◆ IMPLEMENTATION

Nursing interventions associated with the use of ACE inhibitors, ARBs, beta blockers, and adrenergic drugs are discussed further in Chapters 19, 20, and 23. Hydralazine and isosorbide dinitrate must also be used with extreme caution because of associated syncope. If syncope occurs, the drug will most likely be discontinued. Monitor blood pressure and other vital signs, especially with the first few doses of hydralazine and isosorbide dinitrate (because of the risk of syncope). Drug interactions, cautions, and contraindications have been previously discussed.

Always check for compatibility of solutions when giving the PDI milrinone. Record intake and output, heart rate, blood pressure, weight (daily), and respiration rate, as well as heart and breath sounds. Report any evidence of hypokalemia to the prescriber immediately, and monitor the patient's vital signs closely. When heart failure drugs such as digoxin, milrinone, and digoxin immune Fab are administered parenterally, use an infusion pump unless the order is to administer them as an intravenous push.

Before administering any dose of the cardiac glycoside digoxin, check serum potassium and magnesium levels to make sure they are within normal limits, to prevent toxicity. *Always* measure the patient's apical pulse rate (auscultate the apical heart rate, found at the apical impulse located at the left mid-clavicular, fifth intercostal space) for 1 full minute. If the pulse rate is 60 beats per minute or lower, or if it is greater than 100 beats per minute, generally the nurse will withhold the dose and notify the health care provider of the problem immediately. Although withholding the dose is usually indicated, health care facilities and health care providers often have their own protocols that apply to individual patients. In addition, contact the health care provider if a patient experiences any of the following signs and symptoms of digoxin toxicity: headache, dizziness, confusion, nausea, or visual disturbances (blurred vision or yellow-green halo). ECG findings in a patient with digoxin toxicity would show heart block, atrial tachycardia with block, or ventricular dysrhythmias. Remember that most institutions and nursing units follow protocols or policies on digoxin and its administration.

Other nursing interventions include checking the dosage form, prescribed amounts, and the health care provider's order carefully to make sure that the correct drug dosage ordered has been dispensed (e.g., 0.0625, 0.125, or 0.25 mg). Oral digoxin may be administered with meals but not with foods high in fibre (e.g., bran) because the fibre will bind to the digoxin and lead to altered absorption and bioavailability of the drug. If the medication is to be given intravenously, it is critical to patient safety that it be infused undiluted at approximately 0.25 mg per minute, over longer than a 5-minute period, or as per hospital protocol. Digoxin is incompatible with many other medications in solution or syringe; therefore, double-check compatibility before administering parenterally.

Consider the interventions for patients undergoing digitalization separately from those related to other drugs. Digitalization for the management of heart failure is often done in critical care units because cardiac monitoring is required. Rapid digitalization (to achieve faster onset of action) is generally reserved for patients with heart failure who are in acute distress. Such patients are hospitalized because digoxin toxicities can appear quickly in this setting and are directly correlated with the high drug concentrations used. If a patient undergoing rapid digitalization exhibits any of the manifestations of toxicity, contact the health care provider immediately. Continuously observe such patients, taking frequent measurements of vital signs and serum drug and potassium levels. Slow digitalization (rarely used) is generally performed on an outpatient basis in patients with heart failure who are not in acute distress. In such a situation, it takes longer for toxic effects to appear (depending on the drug's half-life) than with rapid digitalization. The main advantages of slow digitalization are that it can be performed on an outpatient basis, oral dosage forms can be used, and it is safer than rapid digitalization. The disadvantages are that it takes longer for therapeutic effects to occur, and the symptoms of toxicity are more gradual in onset and therefore more insidious.

CASE STUDY

Acute Heart Failure

Devon, a 58-year-old retired bus driver, has been in the hospital for 3 days for treatment of heart failure. He had an anterior myocardial infarction 10 years ago and tells the nurse that he "hasn't felt well for weeks." He is currently receiving carvedilol, lisinopril, furosemide, and potassium supplements (all orally), but he has had little improvement.

Today during morning rounds, the nurse notes that Devon is having increased difficulty with breathing, and his heart rate is up to 120 beats per minute. His weight has increased from 72 to 74 kg over the past

2 shifts, and his lower legs and ankles show edema rated as 3+. Crackles are heard over the bases of both lungs, and his pulse oximetry reading is 87% (down from 98% earlier). In addition, Devon is very restless. The nurse notifies the health care provider and the following orders are received:

- Initiate oxygen at 2 litres per minute as per nasal prongs to maintain oxygen saturation > 90%
 - Furosemide 20 mg IV $\times$ 1 dose
 - Increase furosemide to 40 mg PO OD
 - Nitroglycerin patch 0.4 mg per hour q12 hours. On now and remove at night.
1. Describe the drug effects of the medications Devon is receiving for his heart failure.
 2. What laboratory values will you need to monitor while Devon is receiving the medications?
 3. Identify the potential problem.
 4. Are there any additional concerns? What will the nurse need to do at this point?
 5. In addition to being given education regarding his medications, what should Devon be taught to monitor while recovering at home?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

If toxicity occurs and digoxin rises to a life-threatening level, administer the antidote, digoxin immune Fab, as ordered. It is given parenterally over 30 minutes, and in some scenarios as an intravenous bolus (e.g., if cardiac arrest is imminent). All vials of the drug should be refrigerated. The drug is stable for 4 hours after being mixed; use it immediately or discard if it is not used within 4 hours. One vial of digoxin immune Fab binds 0.5 mg of digoxin. Check compatible solutions for dilution prior to infusion of the antidote. Closely monitor blood pressure, apical pulse rate and rhythm, ECG, and serum potassium levels, and record findings. Document baseline data and begin to observe closely for changes in assessment findings, such as changes in muscle strength, occurrences of tremor and muscle cramping, changes in mental health status, and irregular heart rhythms (from hypokalemia), as well as confusion, thirst, and cold clammy skin (from hyponatremia). If the treatment does reduce the toxicity, these problems will decrease considerably, compared with the patient's baseline.

◆ EVALUATION

Monitoring patients after the administration of drugs to improve heart contractility is critical for identifying therapeutic effects and adverse effects. Because positive inotropic drugs increase the force of myocardial contractility; alter electrophysiological properties, leading to a decrease in heart rate (negative chronotropic effect); and decrease AV node conduction properties (negative dromotropic effect), their therapeutic effects include the following:

- Increased urinary output
- Decreased edema
- Decreased dyspnea and crackles
- Decreased fatigue
- Resolution of paroxysmal nocturnal dyspnea
- Improved peripheral pulses, skin colour, and temperature

For patients taking lisinopril, valsartan, metoprolol, dobutamine hydrochloride, or hydralazine and isosorbide dinitrate, therapeutic effects include improvement in symptoms of heart failure and improved cardiac function. During therapy, evaluation must include monitoring for the adverse effects of these medications, which have been discussed previously in the pharmacology section.

Therapeutic effects of milrinone include an improvement in heart function with a corresponding alleviation of the patient's heart failure. Monitor for the adverse effects of hypotension, dysrhythmia, headache, ventricular fibrillation, chest pain, and hypokalemia. Evaluate patients taking milrinone for significant hypotension. If hypotension occurs, contact the health care provider, and discontinue the infusion or decrease the rate while waiting to hear from the health care provider.

While monitoring for the therapeutic effects of digoxin, assess patients for the development of toxicity because of the drug's low therapeutic index. Toxic effects associated with digoxin may include nausea, vomiting, and anorexia. Monitoring laboratory values such as serum creatinine, potassium, calcium, sodium, and chloride levels—as well as watching the serum levels of digoxin (normal levels between 0.8 and 2 ng/mL)—is important to ensure safe and efficacious treatment.

PATIENT TEACHING TIPS

- Hydralazine and isosorbide dinitrate combination may cause syncope; this needs to be explained to patients, along with instructions to change positions carefully.
- Instruct patients to take their radial pulse rate before each dose of digoxin or as indicated. Daily weights are important and need to be measured at the same time every morning and with the same amount of clothing. For older adults and for patients with cognitive impairments or complex physical disabilities, it is important that home health care personnel or a hospital-based heart failure clinic supervise the medication regimen. This is important because these individuals are at risk for adverse effects, toxicity, and drug interactions. If the pulse rate is lower than 60 beats per minute or is erratic; if the pulse rate is 120 beats per minute or greater; or if there is anorexia, nausea, or vomiting, the health care provider must be contacted. Emphasize to patients the importance of reporting any palpitations or feelings that the heart is racing, changes in heart rate or irregular heart rate, the occurrence of dizziness or fainting, any changes in vision, or weight gain (1 kg or more in 24 hours or 2 kg or more in 1 week).
- Advise patients to keep a daily journal with notation of medications, daily weights, dietary intake and appetite, any adverse effects or changes in condition, and a daily rating of how they are feeling.
- Instruct patients to wear a MedicAlert bracelet or necklace, as well as to keep a current medication and medical history that lists allergies, medical diagnoses, and medications (in either written or electronic form) and have it available at all times. This information needs to be updated frequently or with each visit to a health care provider.
- Digoxin is usually taken once a day. Encourage patients to take it at the same time every day. If a dose is missed, they may take the omitted dose if no more than 12 hours have passed from the time the drug was to have been taken. Instruct patients that if more than 12 hours have passed since the missed dose, they should skip that dose, *not* double up on the next digoxin dose, and contact the health care provider immediately for further instructions.
- Instruct patients to *never* abruptly cease taking any of the medications being taken for heart failure. If problems occur, advise patients to always contact their health care provider.
- If potassium-depleting diuretics are being taken as part of therapy, encourage patients to consume foods high in potassium and to report any weakness, fatigue, or lethargy. In addition, any worsening of dizziness or dyspnea, or the occurrence of any unusual problems, should be reported immediately.
- With medication regimens for heart failure, most patients are encouraged to avoid using antacids or eating ice cream, milk products, yogurt, cheese, or bran for 2 hours before or 2 hours after taking medication, to avoid interference with the absorption of the oral dosage forms of these medications.

KEY POINTS

- Inotropic drugs affect the force of myocardial contraction; positive inotropics (e.g., digoxin) increase the force of contractions, and negative inotropics (e.g., beta blockers) decrease myocardial contractility. Chronotropics affect heart rate, with positive chronotropics increasing heart rate and negative chronotropics decreasing heart rate. Dromotropic drugs affect the conduction of electrical impulses through the heart; positive dromotropic drugs increase the speed of electrical impulses through the heart, whereas negative dromotropic drugs have the opposite effect.
- Know the protocol for heart failure management because digoxin, once the cornerstone of treatment for heart failure, is now used only after all other recommended drugs have been tried. The 2017 Comprehensive Update of the Canadian Cardiovascular Society Guidelines for the Management of Heart Failure (Ezekowitz et al., 2017) provides protocol guidelines for treatment of heart failure, including the following: Drugs of choice to initiate treatment are the ACE inhibitors (e.g., lisinopril, enalapril, captopril) or the ARBs (valsartan, candesartan, losartan) and beta blockers (e.g., metoprolol, a cardioselective beta blocker; carvedilol, a nonspecific beta blocker). The loop diuretics (e.g., furosemide) are used to reduce the symptoms of heart failure secondary to fluid overload, and the aldosterone inhibitors (e.g., spironolactone, eplerenone) are added as the heart failure progresses. Only after these drugs are used is digoxin added. Hydralazine and isosorbide dinitrate in combination are approved for use particularly in patients who are Black. Supplementation with omega-3 polyunsaturated fatty acids is also recommended.
- Be aware of important physiological concepts such as ejection fraction. A patient's ejection fraction reflects the contractility of the heart and is approximately 65% (0.65) in a normal heart. This value decreases as heart failure progresses; therefore, patients with heart failure have low ejection fractions because their hearts are failing to pump effectively.
- Recognize that hypotension, dysrhythmias, and thrombocytopenia are major adverse effects of milrinone use.
- Keep informed of the contraindications to the use of digoxin, which include a history of allergy to the digitalis medications, ventricular tachycardia and fibrillations, and AV block.

EXAMINATION REVIEW QUESTIONS

1. The nurse is teaching a patient about the signs and symptoms of cardiac glycoside toxicity. What clinical manifestation should the nurse inform the patient to monitor for when taking cardiac glycosides?
 - a. Visual changes such as photophobia
 - b. Flickering lights or halos around lights
 - c. Dizziness when standing up
 - d. Increased urine output
2. During assessment of a patient who is receiving digoxin, which findings would indicate the possibility of toxicity?
 - a. Apical pulse rate of 62 beats/min
 - b. Digoxin level of 1.5 ng/mL
 - c. Serum potassium level of 2 mmol/L
 - d. Serum calcium level of 4.8 mmol/L
3. When monitoring a patient receiving an intravenous infusion of milrinone, which adverse effect will the nurse closely monitor for?
 - a. Anemia
 - b. Proteinuria
 - c. Thrombocytopenia
 - d. Decreased blood urea nitrogen and creatinine levels
4. A patient is taking a beta blocker as part of the treatment plan for heart failure. The nurse knows that the purpose of the beta blocker for this patient is to do which of the following?
 - a. Increase urine output
 - b. Prevent stimulation of the heart by catecholamines
 - c. Increase the contractility of the heart muscle
 - d. Cause peripheral vasodilation
5. The nurse is assessing a patient who is receiving a milrinone infusion and checks the patient's cardiac rhythm on the heart monitor. What adverse cardiac effect is most likely to occur in a patient who is receiving intravenous milrinone?
 - a. Tachycardia
 - b. Bradycardia
 - c. Atrial fibrillation
 - d. Ventricular dysrhythmia
6. The nurse is administering an intravenous infusion of a phosphodiesterase inhibitor to a patient with heart failure. The nurse will evaluate the patient for which therapeutic effects? (Select all that apply.)
 - a. Positive inotropic effects
 - b. Vasodilation
 - c. Decreased heart rate
 - d. Increased blood pressure
 - e. Positive chronotropic effects
7. The medication order for a 5-year-old child is to: "Give digoxin elixir, 15 mcg/kg, PO now." The child weighs 20 kg. How many milligrams will this child receive?
8. A patient with heart failure will be starting the beta blocker metoprolol (Lopressor). The nurse will monitor for which expected cardiovascular effects? (Select all that apply.)
 - a. Increased heart rate
 - b. Increased myocardial contractility
 - c. Delayed AV node conduction
 - d. Reduced heart rate
 - e. Decreased myocardial automaticity

CRITICAL THINKING ACTIVITIES

1. A nurse administered 125 mg of digoxin instead of 0.125 mg intravenously. The patient has developed a severe heart block dysrhythmia, and the slow heart rate has not responded to administration of atropine and other measures. The nurse stays with the patient while the charge nurse notifies the health care provider. What will be the priority in this situation? What will the nurse expect to give next? How could this situation have been prevented?
2. A nurse is making morning medication rounds. One patient, a 78-year-old man, states that he has been nauseated and without an appetite and has experienced some diarrhea. He has been taking digoxin for the past few weeks for the treatment of recently diagnosed heart failure. What is the nurse's priority action? Explain your answer.
3. A patient is receiving an ACE inhibitor, a diuretic, and a beta blocker as treatment for mild heart failure. He has a history of hypothyroidism—which is controlled by thyroid

replacement hormones—and chronic bronchitis. He states that he stopped smoking a year ago, after smoking two packs of cigarettes a day for 30 years. This morning, he reported a dry cough but said he does not feel short of breath, even when getting up to go to the bathroom. He is unable to produce any sputum. When the nurse listens to his lungs, his breath sounds are clear except for a few scattered rhonchi bilaterally. His weight is the same as the previous morning, and his ankles show only trace edema (2 days ago, he had 2+ edema on the edema scale). His temperature is 36.9°C (98.4°F), his pulse is 88 beats per minute, and his blood pressure is 124/86 mm Hg. He says to the nurse, “This cough is awful! I am so afraid that my heart failure is getting worse or that I’m getting pneumonia!” What is the nurse's priority action?

Antidysrhythmic Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Describe the anatomy and physiology of a normal heart as well as cardiac electrophysiology, including normal conduction patterns, rate, and rhythm.
2. Briefly discuss the various disorders of cardiac electrophysiology and their consequences to the patient.
3. Define the terms *dysrhythmia* and *arrhythmia*.
4. Identify the various causes of abnormal heart rhythms and their impact on the patient's health and activities of daily living.
5. Identify the most commonly encountered dysrhythmias.
6. Compare the various dysrhythmias pertaining to their basic characteristics, impact on the structures of the heart, and related symptoms.
7. Contrast the various classes of antidysrhythmic drugs, citing prototypes in each class and describing their mechanisms of action, indications, routes of administration, dosing, adverse effects, cautions, contraindications, and drug interactions, as well as any toxic reactions or related drug protocols.
8. Develop a collaborative plan of care that includes all phases of the nursing process for patients receiving each class of antidysrhythmic drug.

KEY TERMS

Action potential Electrical activity that consists of polarization and depolarization and that travels across the cell membrane of a nerve fibre during the transmission of a nerve impulse and across the cell membrane of a muscle cell during contraction. (p. 424)

Action potential duration (APD) The interval beginning with baseline (resting) membrane potential, followed by depolarization, and ending with repolarization to baseline membrane potential. (p. 426)

Arrhythmia Technically “without rhythm”—absence of a heart rhythm (i.e., no heartbeat at all). More commonly used in clinical practice to refer to any variation from the normal rhythm of the heart. Also referred to as *dysrhythmia*, which is the primary term used in this chapter and book. (p. 424)

Asystole State of no cardiac electrical activity in the heart or no heartbeat. (p. 424)

Atrial fibrillation Rapid atrial contractions that incompletely pump blood into the ventricles. (p. 427)

Cardiac Arrhythmia Suppression Trial (CAST) A major research study conducted by the National Heart, Lung, and Blood Institute in the United States to investigate the possibility of eliminating sudden cardiac death in patients with asymptomatic ectopy after a myocardial infarction. (p. 434)

Cardioversion A procedure by which an abnormally fast heart rate (tachycardia) or cardiac dysrhythmia is converted to a normal rhythm using electricity or drugs. (p. 427)

Depolarization The movement of positive and negative ions on either side of a cell membrane across the membrane in a direction that brings the net charge to zero. (p. 424)

Dysrhythmia Any disturbance or abnormality in the rhythm of the heartbeat. (p. 424)

Effective refractory period (ERP) The period after the firing of an impulse during which a cell may respond to a stimulus, but the response will not be passed along or continued as another impulse. (p. 426)

Internodal pathways (Bachmann bundle) Special pathways in the atria that carry electrical impulses spontaneously generated by the sinoatrial node. These impulses cause the heart to beat. (p. 427)

Relative refractory period (RRP) The time after generation of an action potential during which a nerve fibre will show a (reduced) response only to a strong stimulus. (p. 426)

Resting membrane potential (RMP) The voltage that exists when the cell membranes of heart muscle (or other muscle or nerve cells) are at rest. (p. 424)

Sodium–potassium adenosine triphosphatase (ATPase) pump A mechanism for transporting sodium and potassium ions across the cell membrane against an opposing concentration gradient. Energy for this transport is obtained from the hydrolysis of adenosine triphosphate (ATP) by means of the enzyme ATPase. (p. 424)

Sudden cardiac death Unexpected, fatal cardiac arrest. (p. 434)

Threshold potential (TP) The critical state of electrical tension required for spontaneous depolarization of a cell membrane. (p. 426)

Torsades de pointes A rare ventricular dysrhythmia that is associated with long QT interval and can degenerate into ventricular fibrillation and sudden death without medical intervention; often simply referred to as *torsades*. (p. 430)

Vaughan Williams classification The system most commonly used to classify antidysrhythmic drugs. (p. 430; see also Table 26.2, p. 430)

Ventricular tachycardia A rapid heartbeat from impulses originating in the ventricles. (p. 430)

DYSRHYTHMIAS AND NORMAL CARDIAC ELECTROPHYSIOLOGY

A **dysrhythmia** is any deviation from the normal rhythm of the heart. Technically, the term **arrhythmia** (meaning “without rhythm”) implies **asystole**, or no heartbeat. Thus, the more accurate term for an irregular heart rhythm is *dysrhythmia*. However, *arrhythmia* is commonly used synonymously with *dysrhythmia* in clinical practice. Dysrhythmias can develop in association with many conditions, such as after a myocardial infarction (MI) or heart surgery, or as the result of coronary artery disease (CAD). Dysrhythmias are usually serious and may require treatment with an antidysrhythmic drug or nonpharmacological therapies; not all dysrhythmias require medical treatment. A cardiologist is usually consulted to make the judgement.

Disturbances in heart rhythm are the result of abnormally functioning cardiac cells. Thus, an understanding of the mechanism responsible for dysrhythmias first requires review of the electrical properties of cardiac cells. Figure 25.1 on p. 410 illustrates the overall anatomy of the conduction system of the heart. Fig. 26.1 illustrates some of the properties of this system based

on a single cardiac cell. Inside a resting cardiac cell, a net negative charge exists relative to the outside of the cell. This difference in the electronegative charge exists in all types of cardiac cells and is referred to as the **resting membrane potential (RMP)**. The RMP results from an uneven distribution of ions (sodium, potassium, and calcium) across the cell membrane, known as *polarization*. Each ion moves through its own specific protein channel that sits across the cell membrane. These proteins work continuously to restore the specific intracellular and extracellular concentrations of each ion. At the RMP, the ionic concentration gradient (distribution) is such that potassium ions are more highly concentrated intracellularly, whereas sodium and calcium ions are more highly concentrated extracellularly.

The polarized distribution of extracellular sodium and calcium ions and intracellular potassium, chloride (Cl^-) and bicarbonate (HCO_3^-) ions is maintained by the **sodium–potassium adenosine triphosphatase (ATPase) pump**, energized by adenosine triphosphate (ATP). Cardiac cells become excited when there is a change in the baseline distribution of ions across their membranes (RMP) that leads to the propagation of an electrical impulse. This change is known as an **action potential**; action potentials occur in a continuous and regular manner in the cells of the heart conduction system (i.e., the sinoatrial [SA] node, atrioventricular [AV] node, and His-Purkinje system). All of these tissues have the property of spontaneous electrical excitability known as *automaticity*, an excited state that creates action potentials that in turn generate electrical impulses that travel through the myocardium, ultimately to create the heartbeat via contraction of cardiac muscle fibres.

An action potential has five phases. Phase 0 is also called the *upstroke* because it appears as an upward line on the graph of an action potential, as shown in Fig. 26.2. Both of these graphs illustrate the cycle of electrical changes that creates an action potential. Note the variation in the shape of the curve of the graph, depending on the relative conduction speed of the specific tissue involved (SA node versus Purkinje fibre). A faster rate of conduction corresponds to a steeper slope on the graph.

During phase 0, the resting cardiac cell membrane suddenly becomes highly permeable to sodium ions, which rush from outside of the cell membrane to inside (influx) through what are known as *fast channels* or *sodium channels*. This disruption of the earlier polarized state of the membrane is known as **depolarization**. Depolarization can be thought of as a temporary equalization of positive and negative charges across the cell membrane. This condition causes the release of electrochemical energy that drives the resulting electrical impulses through adjacent cells. Phase 1 of the action potential begins a rapid period of repolarization that continues through phases 2 and 3 to phase 4, which is the RMP. In phase 1, the sodium channels close and the concentrations of each ion begin to move back toward their ion-specific RMP levels. During phase 2, calcium ion influx occurs through the slow channels or calcium channels. They are called *slow channels*

Fig. 26.1 Phases of the action potential of a cardiac cell. In resting phase (4), the cell membrane is polarized. The cell's interior has a net negative charge, and the membrane is more permeable to potassium ions (K) than to sodium ions (Na). When the cell is stimulated and begins to depolarize (0), sodium ions enter the cell, potassium leaves the cell, calcium (Ca) channels open, and sodium channels close. In its depolarized phase (1), the cell's interior has a net positive charge. In the plateau phase (2), calcium and other positive ions enter the cell and potassium permeability declines, which lengthens the action potential. Then (3) calcium channels close and sodium is pulled from the cell by the sodium-potassium pump. The cell's interior then returns to its polarized, negatively charged state (4). (Source: Monahan, F. D. (2007). *Phipps' medical-surgical nursing: Health and illness perspectives* (8th ed.). St Louis, MO: Mosby.)

Fig. 26.2 Action potentials. RMP, resting membrane potential; SA, sinoatrial; TP, threshold potential.

because the calcium influx occurs relatively more slowly than the earlier sodium influx. Potassium ions then flow from inside the cell to outside (efflux) through specific potassium channels. This is done to offset the elevated positive charge caused by the influx of sodium and calcium ions. In the case of the Purkinje fibres, this causes a partial plateau (flattening on the graph), during which the overall membrane potential changes only slightly, as

seen in Fig. 26.2, B. In phase 3, the ionic flow patterns of phases 0 to 2 are changed by the sodium-potassium ATPase pump (or, more simply, the *sodium pump*), which re-establishes the baseline polarized state by restoring both intracellular and extracellular concentrations of sodium, potassium, and calcium (see Fig. 26.1). As a result, the cell membrane is ultimately repolarized to its baseline level or RMP (phase 4). Note that this entire process

Fig. 26.3 Purkinje fibre action potential.

occurs over approximately 400 milliseconds—that is, four hundred thousandths (less than half) of 1 second.

There is some variation in this period between different parts of the conduction system. As an example, Fig. 26.3 illustrates the pattern of movement of sodium, potassium, and calcium ions into and out of a Purkinje cell during the four phases of the action potential. Note that there are several differences in the action potentials of SA nodal cells and Purkinje cells. The level of the RMP for a given type of cell is an important determinant of the rate of its impulse conduction to other cells. The less negative (i.e., the closer to zero) the RMP is at the onset of phase 0 of the action potential, the slower is the upstroke velocity of phase 0. The slope of phase 0 is directly related to the impulse velocity. An upstroke with a steeper slope indicates faster conduction velocity. Thus, in the Purkinje cells, electrical conduction is relatively fast, and therefore electrical impulses are conducted quickly. These cells are referred to as *fast-response cells*, or *fast-channel cells*, and Purkinje fibres can therefore be thought of as fast-channel tissue. Many antidysrhythmic drugs affect the RMP and sodium channels, and this effect in turn influences the rate of impulse conduction.

In contrast to Purkinje fibres, the cells of the SA node have a slower upstroke velocity, or a slower phase 0. This is illustrated in Fig. 26.2, A, as an upstroke curve that is less steep, which indicates a relatively slower rate of electrical conduction in these cells.

AV nodal cells are comparable to SA nodal cells in this regard. This slower upstroke in the SA and AV nodes is primarily dependent on the entry of calcium ions through the slow channels or calcium channels. This means that nodal action potentials are affected by calcium influx as early as phase 0. The nodes are therefore called *slow-channel tissue*, and conduction in these cells is slower than that in other parts of the conduction system. Drugs that affect calcium ion movement into or out of these cells (e.g., calcium channel blockers) tend to have significant effects on the SA and AV nodal conduction rates.

The interval between phase 0 and phase 4 is called the **action potential duration (APD)**; Fig. 26.4). The period between phase 0 and midway through phase 3 is called the **absolute or effective refractory period (ERP)**. During the ERP, the cardiac cell cannot be stimulated to depolarize and generate another action potential. During the remainder of phase 3 until the return to

Fig. 26.4 Aspects of an action potential. APD, action potential duration; ERP, effective refractory period; RRP, relative refractory period.

the RMP (phase 4), the cardiac cell *can* be depolarized again if it receives a powerful enough impulse (such as one induced by drug therapy or supplied by an electrical pacemaker). This period is referred to as the **relative refractory period (RRP)**. Fig. 26.4 illustrates these aspects of an action potential. Again, the actual shape of the action potential curve varies in different parts of the conduction system.

The RMP of certain cardiac cells gradually decreases (becomes less negative) over time in ongoing cycles. This is due to small changes in the flux of sodium and potassium ions. Depolarization eventually occurs when a certain critical voltage is reached (**threshold potential [TP]**). This process of spontaneous depolarization is referred to as *automaticity*, or *pacemaker activity*. It is normal when it occurs in the SA node (see Chapter 25, Figure 25-1 on p. 410), but when spontaneous depolarizations occur elsewhere, dysrhythmias often result.

The SA node, the AV node, and His-Purkinje cells all possess the property of automaticity. The SA node is the natural pacemaker of the heart because it spontaneously depolarizes the most frequently. The SA node has an intrinsic rate of 60 to 100 depolarizations or beats per minute; that of the AV node is 40 to 60 beats per minute; and that of the ventricular Purkinje fibres is 40 or fewer beats per minute.

As the pacemaker of the heart, the SA node, located near the top of the right atrium, generates an electrical impulse that travels through the atria via specialized **internodal pathways**

Fig. 26.5 The waves and intervals of a normal electrocardiogram. (Source: Goldberger, A. L. (2006). *Clinical electrocardiography: A simplified approach* (7th ed.). St. Louis, MO: Mosby.)

(**Bachmann bundle**). This impulse causes the atrial myocardial fibres to contract, creating the first heart sound. Next, the impulse reaches the AV node, situated near the bottom of the right atrium, which slows this fast-moving electrical impulse to allow the ventricles to fill with blood.

Next, the AV nodal cells generate an electrical impulse that passes into the *bundle of His*, a band of heart muscle fibres located between the right and left ventricles (ventricular septum). The bundle of His distributes the impulse into both ventricles via the right and left bundle branches, which terminate in the Purkinje fibres located in the myocardium. Stimulation of the Purkinje fibres causes ventricular contraction and ejection of blood from the ventricles. Blood from the right ventricle is pumped into the pulmonary circulation, whereas blood from the left ventricle is pumped into the systemic circulation. The bundle of His and Purkinje fibres are often referred to as the His-Purkinje system. Any abnormality in cardiac automaticity or impulse conduction often results in some type of dysrhythmia.

Electrocardiography

The electrophysiological cardiac events described thus far in this chapter correspond more simply to the tracings of an electrocardiogram (ECG; Fig. 26.5). The P wave corresponds to spontaneous impulse generation in the SA node, followed immediately by depolarization of atrial myocardial fibres and their muscular contraction. This sequence normally determines the heart rate. It is affected by the balance between sympathetic and parasympathetic nervous system tone, the intrinsic automaticity of the SA nodal tissue, the mechanical stretch of atrial fibres from incoming blood volume, and heart drugs. The QRS complex (or QRS interval) corresponds to depolarization and contraction of ventricular fibres. The J point marks the start of the ST segment, which corresponds to the beginning of ventricular repolarization. The T wave corresponds to completion of the repolarization of these ventricular fibres. As an analogy, depolarization can be thought of as discharge or contraction of heart muscle fibres, whereas repolarization can be thought of

as a relaxation of just-contracted muscle fibres to prepare for the next contraction (heartbeat). Note that the repolarization of the atrial fibres is obscured on the ECG tracing by the QRS complex and thus has no corresponding deflection in the tracing. The U wave is not always present, and its physiological basis is uncertain. When the U wave occurs, it is generally correlated with electrophysiological events such as repolarization of Purkinje fibres. These events may be a source of dysrhythmias caused by a triggered automaticity. Prominent U waves are often associated with sinus bradycardia, hypokalemia, use of quinidine and other class Ia antidysrhythmics, and hyperthyroidism. Abnormal U waves (inverted) are associated with serious conditions such as MI, acute angina, coronary artery spasms, and ischemic heart disease. The PR and QT intervals and the ST segment are parts of the ECG tracing that are often altered by disease or by the adverse effects of certain types of drug therapy or drug interactions, as discussed in later sections of this chapter.

Common Dysrhythmias

A variety of cardiac dysrhythmias are recognized. Some are easier to treat than others using drug therapy and interventional cardiology procedures, such as pacemaker implantation, catheter ablation, **cardioversion** (a procedure by which an abnormally fast heart rate [tachycardia] or cardiac dysrhythmia is converted to a normal rhythm using electricity or drugs), and implantable cardioverter-defibrillators. Dysrhythmias are subdivided into several broad categories, depending on their anatomical site of origin in the heart. Supraventricular dysrhythmias originate above the ventricles, in the SA or AV node or atrial myocardium. Ventricular dysrhythmias originate below the AV node, in the His-Purkinje system or ventricular myocardium. Dysrhythmias that originate outside the conduction system (i.e., in atrial or ventricular cells) are considered ectopic, and their specific points of origin are called *ectopic foci*. Conduction blocks are dysrhythmias that involve disruption of impulse conduction between the atria and ventricles, through the AV node directly affecting ventricular function. They may also originate in the His-Purkinje system. Less commonly, impulse conduction between the SA and AV node is affected. Several of the most common dysrhythmias are described in Table 26.1, and corresponding ECG tracings are provided. They are also described further in the following text.

Among the supraventricular dysrhythmias, **atrial fibrillation** is a particularly common condition. Atrial fibrillation affects an estimated 350 000 Canadians, with its prevalence increasing with age (**Heart and Stroke Foundation, 2018**). The age of patients with atrial fibrillation has an increase in incidence occurring in patients > 60 years of age (**Laredo, Waldmann, Khairy, et al., 2018**). Atrial fibrillation accounts for one third of hospitalizations for stroke after the age of 60 years of age due to cardiac rhythm disturbances (**Heart and Stroke Foundation, 2018**). Atrial fibrillation is characterized by rapid atrial contractions that incompletely pump blood into the ventricles. Atrial fibrillation is notable in that it predisposes the patient to stroke. This is because the blood tends to stagnate in the incompletely emptied atria and is therefore more likely to clot. If such blood clots manage to make their way into the left ventricle, they may embolize

TABLE 26.1 Common Dysrhythmias

Dysrhythmia	Description	ECG Tracing
Atrial flutter (AF)	Often progresses to atrial fibrillation (F = flutter waves)	
Atrial fibrillation (AF)	Rapid, ineffective atrial contractions (F = fibrillation waves)	
Paroxysmal supraventricular tachycardia (PSVT)	Heart rate of 180–200 beats/min or higher	
Premature ventricular contractions (PVCs)	Contractions generated by impulses arising from ectopic foci within ventricular myocardium	

Nonsustained ventricular tachycardia (NSVT)	Relatively brief period (20 sec or less) in which ventricles contract rapidly on their own as well as in response to AV impulses	
Sustained ventricular tachycardia (SVT)	Same as above but more prolonged	
Torsades de pointes (TdP)	Rapid ventricular tachycardia preceded by QT interval prolongation (often progresses to ventricular fibrillation)	Monitor lead 
Ventricular fibrillation (VF)	Rapid, ineffective ventricular contraction (fatal if not reversed)	

AV, Atrioventricular; ECG, electrocardiogram.

to the brain and result in stroke. Although theoretically there would be a similar risk for pulmonary embolism, this is of less clinical concern with atrial fibrillation than is the risk for stroke. It is estimated that 20% of all strokes are caused by atrial fibrillation (Camm, Lip, De Caterina, et al., 2012). Often, patients with ongoing atrial fibrillation are given warfarin sodium as well as dabigatran, apixaban, or rivaroxaban for anticoagulant therapy (see Chapter 26) to reduce the likelihood of stroke.

AV nodal re-entrant tachycardia is a conduction disorder that often gives rise to a dysrhythmia known as *paroxysmal supraventricular tachycardia*. (The word *paroxysmal* means “sudden recurrence or intensification of symptoms.”) AV nodal re-entrant tachycardia occurs when electrical impulse transmission from the AV node into the His-Purkinje system of the ventricles is disrupted. As a result, some of the impulses circle backward (retrograde impulses) and re-enter the atrial tissues to produce a tachycardic response. In Wolff-Parkinson-White syndrome, ectopic impulses that begin near the AV node actually bypass the AV node and reach the His-Purkinje system before the normal AV-generated impulses. This is one cause of ventricular tachycardia, although it is technically supraventricular in origin.

Varying degrees of AV block (often called *heart block*) involve different levels of disrupted conduction of impulses from the AV node and His-Purkinje system to the ventricles. Although first-degree AV block is often asymptomatic, third-degree block—or complete heart block—often requires use of a cardiac pacemaker to ensure adequate ventricular function. There can also be blocks within the His-Purkinje system of the ventricles, known as *bundle branch blocks*.

Premature ventricular contractions (PVCs) occur when impulses originate from ectopic foci within the ventricles (His-Purkinje system). PVCs probably occur periodically in many people, but they become problematic when they occur frequently enough to compromise systolic blood volume. **Ventricular tachycardia** refers to a rapid heart beat from impulses originating in the ventricles. It can be nonsustained (brief) or sustained, requiring definitive treatment. Worsening ventricular tachycardia can deteriorate into **torsades de pointes**, an intermediate dysrhythmia that often deteriorates into ventricular fibrillation. Ventricular fibrillation is fatal if not reversed, which most often requires electrical defibrillation. Interestingly, torsades de pointes often responds preferentially to intravenous magnesium sulfate.

ANTIDYSRHYTHMIC DRUGS

Numerous drugs are available to treat dysrhythmias. These drugs are categorized according to where and how they affect cardiac cells. Although other classifications are described in the literature, the most commonly used system is the **Vaughan Williams classification**. This system is based on the electrophysiological effect of particular drugs on the action potential. This approach identifies four major classes of drugs: I (including Ia, Ib, and Ic), II, III, and IV. The drugs in these four classes are listed in Table 26.2.

Class I antidysrhythmics are considered membrane-stabilizing drugs. There is currently a gradual trend away from

TABLE 26.2 Vaughan Williams Classification of Antidysrhythmic Drugs

Functional Class	Drugs
Class I: Membrane-stabilizing drugs; fast sodium channel blockers	
Ia: ↑ blockade of sodium channel, delay repolarization, ↑ APD	quinidine sulfate, disopyramide, procainamide
Ib: ↑ blockade of sodium channel, accelerate repolarization, ± APD	lidocaine, phenytoin
Ic: ↑↑ blockade of sodium channel ± on repolarization; also suppress re-entry	flecainide, propafenone
Class II: β-blocking drugs	All β-blockers
Class III: Drugs whose principal effect on cardiac tissue is to ↑ APD	amiodarone, dronedarone, sotalol,* ibutilide
Class IV: Calcium channel blockers	verapamil, diltiazem
Other: Antidysrhythmic drugs that have the properties of several classes and therefore cannot be placed in one particular class	digoxin, adenosine

APD, Action potential duration; ↑, increase; ±, increase or decrease.

*Sotalol also has class II properties.

the use of class Ia drugs. The role of class II drugs (beta blockers) continues to grow in the field of cardiology, including in dysrhythmia management. Class III drugs have emerged as being among the most widely used antidysrhythmics. Class IV drugs (calcium channel blockers) have limited usefulness in tachydysrhythmias (dysrhythmias involving tachycardia), unlike most of the other classes. Digoxin, the cardiac glycoside discussed in Chapter 24, still has a place in dysrhythmia management, especially in the prevention of dangerous ventricular tachydysrhythmias secondary to atrial fibrillation.

Mechanism of Action and Drug Effects

Antidysrhythmic drugs work by correcting abnormal cardiac electrophysiological function. They do this to varying degrees and by various mechanisms. Class I drugs are membrane-stabilizing drugs and exert their actions on sodium (fast) channels. There are some slight differences in the actions of the drugs in this class, so they are divided into three subclasses. These subclasses are Ia, Ib, and Ic drugs and are based on the magnitude of the effects each drug has on phase 0, the APD, and the ERP. Class Ia drugs (quinidine, procainamide, and disopyramide) block the sodium channels; more specifically, they delay repolarization and increase the APD. Class Ib drugs (phenytoin sodium and lidocaine) also block the sodium channels, but unlike class Ia drugs, they accelerate repolarization and decrease the APD. Phenytoin sodium is more commonly used as an antiepileptic (Chapter 15) than as an antidysrhythmic drug. Class Ic drugs (flecainide and propafenone) have a more pronounced effect on the blockade of sodium channels but have little effect on repolarization or the APD.

Class II drugs are the beta-adrenergic blockers (beta blockers, see Chapter 20) and they are commonly used as antihypertensives (see Chapter 23) and antianginal drugs (Chapter 24). They work by

TABLE 26.3 Antidysrhythmic Drugs: Mechanisms of Action

Vaughan Williams Class	Action	Tissue	Effect on Action Potential
I	Blocks sodium channels, affects phase 0	Fast	
II	Decreases spontaneous depolarization, affects phase 4	Slow	
III	Prolongs APD	Fast	
IV	Blocks slow calcium channels	Slow	

APD, action potential duration.

blocking sympathetic nervous system stimulation to the heart and, consequently, the transmission of impulses in the heart's conduction system. This results in depression of phase 4 depolarization. These drugs mostly affect slower-conducting cardiac tissues.

Class III drugs (amiodarone, dronedarone, sotalol, and ibutilide) increase the APD by prolonging repolarization in phase 3. The primary role of potassium channels in cardiac action potentials is cell repolarization; these drugs are also referred to as *calcium channel blockers*. They affect fast tissue and are most commonly used to manage dysrhythmias that are difficult to treat. They are usually reserved for patients for whom other therapies have failed. Sotalol has properties of both class II and class III drugs, and it may be listed as a member of either class.

Class IV drugs (verapamil, diltiazem) are the calcium channel blockers, which, similar to beta blockers, are also used as antianginal drugs (Chapter 24) and antihypertensives (Chapter 23). As their name implies, they act specifically by inhibiting the calcium channels, which reduces the influx of calcium ions during action potentials. This results in depression of phase 4 depolarization.

The mechanisms of action of the major classes of antidysrhythmics are summarized in Table 26.3. The effects of the various classes of drugs are summarized in Box 26.1.

Indications

Antidysrhythmic drugs are effective in treating a variety of cardiac dysrhythmias. The antidysrhythmic drugs and the most common indications for their use are listed in Table 26.4.

Contraindications

As with all drugs, contraindications to the use of antidysrhythmic drugs include known drug allergy to a specific product. Other contraindications may include second- or third-degree AV block, bundle branch block, cardiogenic shock, sick sinus syndrome, or any other major ECG changes, depending on the clinical judgement of a cardiologist. The concurrent use of certain drugs that interact with antidysrhythmics is also considered. The reason for these concerns is that all antidysrhythmic drugs can potentially worsen existing dysrhythmias (also termed *dysrhythmogenic*). The risk is greater in patients with structural heart damage (e.g., after MI). In patients with AV block and bundle branch

BOX 26.1 Effects of Antidysrhythmic Drugs

Class Ia (disopyramide, quinidine, procainamide)

- Depress myocardial excitability
- Prolong the effective refractory period
- Eliminate or reduce ectopic foci stimulation
- Decrease inotropic effect
- Have anticholinergic (vagolytic [has inhibitory effects on the vagus nerve]) activity

Class Ib (lidocaine, mexiletine, phenytoin)

- Decrease myocardial excitability in the ventricles
- Eliminate or reduce ectopic foci stimulation in the ventricles
- Have minimal effect on the SA node and automaticity
- Have minimal effect on the AV node and conduction
- Have minimal anticholinergic (vagolytic) activity

Class Ic (flecainide, propafenone)

- Produce dose-related depression of cardiac conduction, especially in the bundle of the His-Purkinje system
- Have minimal effect on atrial conduction
- Eliminate or reduce ectopic foci stimulation in the ventricles
- Have minimal anticholinergic (vagolytic) activity
- Flecainide use now reserved for the most serious dysrhythmias

Class II (beta blockers [e.g., acebutolol, esmolol, metoprolol])

- Block β -adrenergic heart stimulation
- Reduce SA nodal activity
- Eliminate or reduce atrial ectopic foci stimulation
- Reduce ventricular contraction rate
- Reduce cardiac output and blood pressure

Class III (amiodarone, dronedarone, sotalol*, ibutilide)

- Prolong the effective refractory period
- Prolong the myocardial action potential
- Block both α - and β -adrenergic heart stimulation

Class IV (diltiazem, verapamil)

- Prolong AV nodal effective refractory period
- Reduce AV nodal conduction
- Reduce rapid ventricular conduction caused by atrial flutter

* Sotalol also has class II properties.

AV, Atrioventricular; SA, sinoatrial.

block, there is a danger of drug-induced ventricular failure if a drug further compromises the already existing AV conduction delays. The safe prescribing of antidysrhythmic drugs

TABLE 26.4 Antidysrhythmic Drugs: Indications

Drug	Indications
Class Ia	
disopyramide procainamide hydrochloride quinidine sulfate	Atrial fibrillation, premature atrial contractions, premature ventricular contractions, ventricular tachycardia, Wolff–Parkinson–White syndrome
Class Ib	
lidocaine hydrochloride	Ventricular dysrhythmias only (premature ventricular contractions, ventricular tachycardia, ventricular fibrillation)
Class Ic	
flecainide acetate propafenone hydrochloride	Ventricular tachycardia and supraventricular tachycardia dysrhythmias, atrial fibrillation and flutter; Wolff–Parkinson–White syndrome
Class II	
β -blockers atenolol hydrochloride esmolol hydrochloride metoprolol hydrochloride	Both supraventricular and ventricular dysrhythmias (act as general myocardial depressants)
Class III	
amiodarone hydrochloride	Life-threatening ventricular tachycardia or fibrillation
dronedarone hydrochloride ibutilide fumarate sotalol hydrochloride*	Atrial fibrillation or flutter resistant to other drugs
Class IV	
calcium channel blockers diltiazem hydrochloride verapamil hydrochloride	Paroxysmal supraventricular tachycardia; rate control for atrial fibrillation and flutter

*Sotalol hydrochloride also has class II properties.

is an area that requires strong clinical expertise and careful judgement on a case-by-case basis.

Adverse Effects

Adverse effects common to most antidysrhythmics include hypersensitivity reactions, nausea, vomiting, and diarrhea. Other common effects include dizziness, headache, and blurred vision. In addition, many antidysrhythmic drugs are capable of producing new dysrhythmias (prodyrrhythmic effect). Prolongation of the QT interval is a potentially severe adverse effect shared by many antidysrhythmics. The concern with QT prolongation is the potential for induction of torsades de pointes. As with any drug class, there are also cases of unpredictable or idiosyncratic adverse effects (see [Chapter 2](#)) that are not related to drug concentration in the body. Idiosyncratic reactions are unpredictable; however, it is thought that such effects will eventually be explained by genetic variations. [Table 26.5](#) summarizes the most commonly reported adverse effects by specific drug.

Toxicity and Management of Overdose

The main toxic effects of the antidysrhythmics involve the heart, circulation, and central nervous system (CNS). Specific antidotes are not available.

Interactions

Antidysrhythmics can interact with many different categories of drugs. The most serious drug interactions are those that result in dysrhythmias, hypotension or hypertension, respiratory distress, or excessive therapeutic or toxic drug effects. Drug interactions occur when the presence of one drug strengthens or weakens the pharmacological effects of another. This is most commonly seen when the first drug affects the activity of the enzymes that metabolize the second drug, either speeding or slowing its elimination. One particular interaction common to many antidysrhythmics is the potentiation of anticoagulant activity with warfarin sodium (Coumadin®; see [Chapter 27](#)). Because many patients receiving antidysrhythmic therapy also need warfarin sodium, the international normalized ratio

TABLE 26.5 Antidysrhythmic Drugs: Common Adverse Effects

Class	Drug/Class	Adverse Effects
Ia	procainamide hydrochloride quinidine sulfate	Hypotension, rash, diarrhea, nausea, vomiting, agranulocytosis, SLE-like syndrome Hypotension, QT prolongation, lightheadedness, diarrhea, bitter taste, anorexia, blurred vision, tinnitus, angina
Ib	lidocaine hydrochloride	Bradycardia, dysrhythmia, hypotension, anxiety, metallic taste
Ic	flecainide acetate propafenone hydrochloride	Dizziness, visual disturbances, dyspnea, palpitations, nausea, vomiting, diarrhea, weakness Prodyrrhythmic effect, angina, tachycardia, syncope, AV block, dizziness, fatigue, dyspnea
II	β -blockers	Bradycardia, hypotension, dizziness, fatigue, AV block, heart failure, hyperglycemia, mask the symptoms of hypoglycemia, bronchospasm, wheezing, dry mouth, erectile dysfunction
III	amiodarone hydrochloride	Pulmonary toxicity, thyroid disorders, bradycardia, hypotension, SA node dysfunction, AV block, ataxia, QT prolongation, torsades de pointes, vomiting, constipation, photosensitivity, abnormal liver function test results, jaundice, visual disturbances, hyperglycemia or hypoglycemia, and dermatologic reactions including rash, toxic epidermal necrolysis, vasculitis, blue–grey colouring of the skin (face, arms, neck)
	ibutilide fumarate sotalol hydrochloride*	Nonsustained ventricular tachycardia, ventricular extrasystoles, tachycardia, hypotension, AV block, headache, nausea Bradycardia, chest pain, palpitations, fatigue, dizziness, lightheadedness, weakness, dyspnea
IV	Calcium channel blockers	Constipation, bradycardia, heart block, hypotension, dizziness, dyspnea

AV, atrioventricular; SA, sinoatrial; SLE, systemic lupus erythematosus.

*Sotalol also has class II properties.

(INR) must be monitored and necessary adjustments made to the warfarin sodium dosage. This is especially true with amiodarone. The INR will increase by 50% in almost 100% of patients receiving amiodarone and warfarin sodium. Grapefruit juice can also inhibit the metabolism of several antidysrhythmics, such as amiodarone, disopyramide, and quinidine. Other common interactions are summarized in Table 26.6. To explain the mechanism for each interaction is beyond the scope of this text; readers needing more detailed information are encouraged to consult the appropriate references.

Dosages

For dosage information on selected antidysrhythmic drugs, refer to the table on p. 440.

DRUG PROFILES

The four classes of antidysrhythmics produce a variety of effects on the action potential of the cardiac cell and exert a major effect on cardiac electrophysiological function. The diversity of therapeutic effects and adverse effects presents a special challenge to ensuring the safe and efficacious use of these drugs. Because the nursing process related to the administration of antidysrhythmics differs for each of the four classes of drug, each group is discussed separately.

Class Ia Drugs

Class Ia drugs are considered membrane-stabilizing drugs because they possess local anaesthetic properties. They stabilize the membrane and have depressant effects on phase 0 of the action potential. These drugs include procainamide, quinidine, and disopyramide.

procainamide hydrochloride

The electrophysiological effect of procainamide (Procan SR®) is similar to that of quinidine. Procainamide is useful in the management of atrial and ventricular tachydysrhythmias, although it is not used frequently. Significant adverse effects include ventricular dysrhythmias and blood disorders. It can cause a systemic lupus erythematosus (SLE)-like syndrome, which occurs in approximately 30% of patients on long-term therapy. It can also cause gastrointestinal (GI) effects such as nausea, vomiting, and diarrhea. Other adverse effects include fever, maculopapular rash, flushing, and torsades de pointes resulting from prolongation of the QT interval. For a list of drugs that prolong the QT interval, refer to www.RxFiles.ca. Use of procainamide is contraindicated in patients with a known hypersensitivity to it and in those with heart block or SLE. Procainamide is available in both oral and parenteral forms.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV/IM	10–30 min	10–60 min	3 hr	3 hr
PO	0.5–1 hr	1–2 hr	3 hr	3–8 hr

quinidine sulfate

Quinidine sulfate has both a direct action on the electrical activity of the heart and an indirect (anticholinergic) effect. Significant adverse effects of quinidine include cardiac asystole and ventricular ectopic beats. Quinidine can cause cinchonism; symptoms of mild cinchonism include tinnitus, loss of hearing, slight blurring of vision, and GI upset. Contraindications to the use of the drug include hypersensitivity, thrombocytopenic purpura resulting from previous therapy, AV block, intraventricular conduction defects, Myasthenia Gravis, uncompensated heart failure, digitalis toxicity, and torsades de pointes. Quinidine is available in parenteral form.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Minutes	Immediate	Unknown	Short

Class Ib Drugs

Class Ib drugs share many characteristics with class Ia drugs but act preferentially on ischemic myocardial tissue. They have little effect on conduction velocity in normal tissue. Class Ib drugs have a weak depressive effect on phase 0 depolarization, the APD, and the ERP. They include lidocaine and phenytoin.

lidocaine hydrochloride

Lidocaine hydrochloride (Xylocaine®) is the prototypical class Ib drug. It is one of the most effective drugs for the treatment of ventricular dysrhythmias, but it can only be administered intravenously because it has an extensive first-pass effect (i.e., when taken orally, the liver metabolizes most of it to inactive metabolites). Because of its extensive liver metabolism, dosage reduction by 50% is recommended for patients with liver failure or cirrhosis. Dosage reductions may also be necessary in patients with kidney impairment because of extensive excretion of the drug and its metabolites by the kidney.

Lidocaine exerts its effects on the conduction system of the heart by making it difficult for the ventricles to develop a dysrhythmia. This action is known as *raising the ventricular fibrillation threshold*. It occurs by decreasing the sensitivity of the cardiac cell membrane to impulses and decreasing the cell's ability to depolarize on its own (decreasing automaticity). Many of these effects are accomplished by blocking the fast sodium channels.

Significant adverse effects include CNS toxic effects such as twitching, convulsions, and confusion; respiratory depression or arrest; and the cardiovascular effects of hypotension, bradycardia, and dysrhythmias. Use of the drug is contraindicated in patients who are hypersensitive to it, who have severe SA or AV intraventricular block, or who have Stokes–Adams or Wolff–Parkinson–White syndrome. Lidocaine is available only in parenteral form for intramuscular or intravenous administration. It is commonly used as a local anaesthetic (see Chapter 12); a transdermal form is also available for analgesia (see Chapter 11).

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	2–15 min	5–10 min	8 min	20 min–1.5 hr

Class Ic Drugs

Class Ic drugs (flecainide, propafenone) produce a more pronounced blockade of the sodium channel than class Ia and Ib drugs but have little effect on repolarization or the APD. These drugs significantly slow conduction in the atria, AV node, and ventricles. Because of their marked effect on conduction, class Ic drugs strongly suppress PVCs, reducing or eliminating them.

flecainide acetate

Flecainide acetate (Tambocor®) is a chemical analogue of procainamide. Historically, clinicians have been hesitant to prescribe flecainide because of the findings of a large, multicentre study, the [Cardiac Arrhythmia Suppression Trial \(CAST\)](#). This study showed that mortality and nonfatal cardiac arrest rates in patients treated with this drug were comparable with or higher than those seen in patients who received the placebo. Because of these findings, Health Canada required that the labelling of flecainide be revised to indicate that its use should be limited to the treatment of documented, life-threatening ventricular dysrhythmias. However, since the findings of the CAST were initially published in 1992, there have been numerous studies showing that flecainide is safe and effective for the treatment of atrial fibrillation. According to the most current practice guidelines, flecainide is considered a first-line drug (combined with an AV-blocking drug) in the treatment of atrial fibrillation. It is not to be used in patients with CAD.

Flecainide is better tolerated than quinidine or procainamide. It has a negative inotropic effect and depresses left ventricular function. Less serious but more common, noncardiac adverse effects include dizziness, visual disturbances, and dyspnea. Contraindications to its use include hypersensitivity, cardiogenic shock, second- or third-degree AV block, and non-life-threatening dysrhythmias. Flecainide is available only for oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	3 hr	1.5–3 hr	11–12 hr	12–27 hr

propafenone hydrochloride

Propafenone hydrochloride (Rythmol®) is similar in action to flecainide. It reduces the fast, inward sodium current in Purkinje fibres and to a lesser extent in myocardial fibres. Unlike other class I drugs, propafenone has mild beta-blocking effects. This may contribute to its overall effects on the conduction system. It is also believed to have calcium channel-blocking effects, which may contribute to its mild negative inotropic effects.

Until recently, propafenone's use was limited to the treatment of documented, life-threatening ventricular dysrhythmias such as sustained ventricular tachycardia, as was flecainide. Recent findings suggest that it has benefit in the treatment of atrial fibrillation as well. Treatment is initiated while the patient is in the hospital. Unlike flecainide, however, propafenone can be given to patients with depressed left ventricular function and may be a better drug than disopyramide, procainamide, and quinidine in these patients. However, it should be used with caution in patients with heart failure because it has some beta-blocking properties and dose-dependent negative inotropic effects.

Propafenone is generally well tolerated. The most commonly reported adverse reaction is dizziness. Patients may also report a metallic taste, constipation, and headache, along with nausea and vomiting. These GI adverse effects may be reduced by taking the drug with food. Propafenone use is contraindicated in patients with a known hypersensitivity to it, as well as in patients with bradycardia, bronchial asthma, significant hypotension, uncontrolled heart failure, cardiogenic shock, and various conduction disorders. It is available only for oral use.

PO	2 hr	3–5 hr	2–10 hr	Unknown

Class II Drugs

Class II antidysrhythmics are the beta blockers (see [Chapter 23](#)). They work by blocking sympathetic nervous system stimulation to the heart and the heart's conduction system, and consequently prevent catecholamine-mediated actions on the heart. This action is known as a *cardioprotective quality* of beta blockers. The resulting cardiovascular effects include a reduced heart rate, delayed AV node conduction, reduced myocardial contractility, and decreased myocardial automaticity. The pharmacological effects of the beta blockers are beneficial after an MI. Following an MI, numerous catecholamines are released that make the heart hyperirritable and predisposed to many types of dysrhythmias. Beta blockers offer protection from these potentially dangerous complications. Several studies have demonstrated a significant reduction (on average 25%) in the incidence of [sudden cardiac death](#) after MI, in patients treated with beta blockers on an ongoing basis.

Although there are several beta blockers, only a few are commonly used as antidysrhythmics. Those currently approved by Health Canada are acebutolol hydrochloride, esmolol, metoprolol, propranolol hydrochloride, and sotalol (which has class II and III properties). Selected drugs are described here. The class II drugs are recommended for use during pregnancy only when the benefit outweighs the risk to the fetus.

 atenolol

Atenolol (Tenormin®) is a cardioselective beta blocker. It preferentially blocks the beta₁-adrenergic receptors that are located primarily in the heart. Noncardioselective beta blockers block

not only the β_1 -adrenergic receptors on the heart but also the β_2 -adrenergic receptors in the lungs and can potentially exacerbate pre-existing asthma or chronic obstructive pulmonary disease. In addition to having class II antidysrhythmic properties, atenolol is used in the treatment of hypertension and angina. Its use is contraindicated in patients with severe bradycardia, second- or third-degree heart block, heart failure, cardiogenic shock, or a known hypersensitivity. This drug is available in oral form.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1 hr	2–4 hr	6–7 hr	24 hr

esmolol hydrochloride

Esmolol hydrochloride (Brevibloc®) is an ultra-short-acting beta blocker with pharmacological and electrophysiological effects on the heart's conduction system that are similar to those of atenolol. Esmolol is also a cardioselective beta blocker that preferentially blocks the β_1 -adrenergic receptors in the heart. It is used in the acute treatment of supraventricular tachydysrhythmias or dysrhythmias that originate above the ventricles. It is also used to control hypertension and tachydysrhythmias that develop after an acute MI. Use of esmolol is contraindicated in patients with a known hypersensitivity to it or those with severe bradycardia, second- or third-degree heart block, heart failure, cardiogenic shock, or severe asthma. It is available only in injectable form.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Immediate	6 min	9 min	15–20 min

metoprolol tartrate

Metoprolol tartrate (Lopresor®) is another cardioselective beta blocker commonly given after an MI to reduce the risk of sudden cardiac death. It is also used in the treatment of hypertension and angina. The contraindications to metoprolol use are the same as those to atenolol and esmolol. It is available in both oral and injectable forms.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	1 min	20 min	3–8 hr	5–8 hr
PO	1 hr	2–4 hr	3–8 hr	10–20 hr

Class III Drugs

Class III drugs include amiodarone, dronedarone hydrochloride, sotalol (which also has class II properties), and ibutilide.

Amiodarone controls dysrhythmias by inhibiting repolarization and markedly prolonging refractoriness and the APD. Ibutilide is indicated for conversion of atrial fibrillation or flutter to a normal sinus rhythm. Amiodarone is indicated for the management of life-threatening ventricular tachycardia or ventricular fibrillation that is resistant to other drug therapy. This drug has also been effective in the treatment of sustained ventricular tachycardias. Amiodarone has recently been used more frequently to treat atrial dysrhythmias.

Dronedarone hydrochloride (Multaq®) is the newest antidysrhythmic drug. It is similar to amiodarone and is thought to have less potential for causing the classic amiodarone adverse effects and less potential for drug interactions. However, as with any newly marketed drug, the true incidence of toxicity is not known and won't be until it has been used in numerous patients. In 2011, Sanofi, the manufacturer of dronedarone, worked with Health Canada and issued an advisory regarding the potential for hepatotoxicity related to dronedarone. Later that year, Health Canada also issued a safety communication regarding an increased risk of death and serious cardiovascular events associated with its use.

amiodarone hydrochloride

Amiodarone hydrochloride (Cordarone®) markedly prolongs the APD and the ERP in all cardiac tissues. Besides exerting these dramatic effects, it is also known to block both the α - and β -adrenergic receptors of the sympathetic nervous system. Clinically, it is one of the most effective antidysrhythmic drugs for controlling supraventricular and ventricular dysrhythmias. Amiodarone is indicated for the management of sustained ventricular tachycardia, ventricular fibrillation, and nonsustained ventricular tachycardia. It is reported to be effective in 40 to 60% of all patients with ventricular tachycardia. It is the drug of choice for ventricular dysrhythmias according to the Advanced Cardiac Life Support guidelines. Recently, it has shown promise in the management of atrial dysrhythmias that are difficult to treat with other less toxic drugs.

Amiodarone has many undesirable adverse effects, and these can be attributed to its chemical properties. Amiodarone is *lipophilic*, or “fat loving.” Therefore—because it crosses the phospholipid bilayer of the cell by passive diffusion—once absorbed, it can penetrate and concentrate in the adipose tissue of any organ in the body. For example, it can concentrate in the liver, resulting in hepatic cell injury. It also has iodine in its chemical structure. One organ that sequesters iodine from the diet is the thyroid gland. As a result, amiodarone can cause either hypothyroidism or hyperthyroidism. The package insert for amiodarone lists iodine allergy as a contraindication. However, evidence for avoiding amiodarone in patients with iodine hypersensitivity is extremely limited and does not appear to support its contraindication in patients with severe dysrhythmias.

Adverse reactions occur in approximately 75% of patients treated with this drug, but, with higher dosages (those exceeding 400 mg/day) and prolonged therapy, the incidence is higher and the severity greater. One of the most common adverse effects is corneal microdeposits, which may cause visual halos,

photophobia, and dry eyes. These occur in virtually all adults who take the drug for longer than 6 months. Photosensitivity is also common, reported in 10 to 75% of patients taking amiodarone.

The most serious adverse effect of amiodarone is pulmonary toxicity, which is fatal in about 10% of patients and involves a clinical syndrome of progressive dyspnea and cough accompanied by damage to the alveoli. The result can be pulmonary fibrosis. Another serious complication of amiodarone is that it may not only treat dysrhythmias but also provoke them. Amiodarone has an exceptionally long half-life, approaching many days. As a result, the therapeutic as well as any adverse effects of amiodarone may linger long after the drug has been discontinued. In fact, it may take as long as 2 to 3 months after the drug has been discontinued for some adverse effects to subside. Therapy is usually started in the hospital and is closely monitored until the patient's serum levels are within a therapeutic range.

Amiodarone has two significant drug interactions, namely with digoxin and warfarin sodium. It is reported that digoxin levels will increase by 50% and that the INR will increase by 50% in 100% of patients taking these drugs in combination with amiodarone. When the drug is started in patients who are already taking one of these drugs, it is recommended that the dose of digoxin or warfarin sodium be reduced by 50% at the start of therapy.

Use of amiodarone is contraindicated in patients who have a known hypersensitivity to it and in those with severe sinus bradycardia, or second- or third-degree heart block. Recommended conversions are available for cases in which the patient is maintained on long-term oral amiodarone therapy after intravenous amiodarone administration is discontinued. This drug is marketed in both oral and injectable forms.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1–3 wk	2–10 hr	15–100 days	10–150 days
IV	Minutes (bolus); 1 hr (IV)	10–15 minutes	30–45 minutes	short

ibutilide fumarate

Ibutilide fumarate (Corvert®) is a class III antidysrhythmic drug. Unlike the other two drugs in this class, ibutilide fumarate is indicated for atrial dysrhythmias. Atrial fibrillation and atrial flutter cause irregular contractions of the heart and can lead to serious outcomes, such as decreased cardiac output, heart failure, low blood pressure, and stroke. Although other pharmacological therapies are used to treat atrial fibrillation and flutter, ibutilide is the only drug available for rapid conversion of these two conditions to normal sinus rhythm. The only other treatment that can produce rapid conversion is electrical cardioversion. Although it is effective, electrical cardioversion carries the risk, expense, and inconvenience of both the procedure itself and the anaesthesia it requires.

Ibutilide is dosed based on patient weight. Use of ibutilide is contraindicated in patients who have previously demonstrated hypersensitivity to it. As with other antidysrhythmic drugs, ibutilide is to be used with caution because it can also produce dysrhythmias, most significantly ventricular tachycardia and torsades de pointes. Class Ia antidysrhythmic drugs (e.g., disopyramide, quinidine, and procainamide) and other class III drugs (e.g., amiodarone and sotalol) should not be administered with ibutilide, nor should they be given within 4 hours after infusion of ibutilide because of their potential to prolong refractoriness. Ibutilide is available only in the injectable form.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	10 min	30 min	6 hr	4 hr

sotalol hydrochloride

Sotalol hydrochloride (Rylosol®) is a selective beta blocker that is used to treat dysrhythmias. It is unique in that it possesses antidysrhythmic properties similar to those of the class III drugs (such as amiodarone), while simultaneously exerting beta blocker or class II effects on the conduction system of the heart. In addition, sotalol has prodysrhythmic properties similar to those of the class Ic drugs. This means that while patients are taking sotalol, it can cause serious dysrhythmias, such as torsades de pointes or a new ventricular tachycardia or fibrillation. Like flecainide and propafenone, sotalol was historically reserved for the treatment of documented, life-threatening ventricular dysrhythmias such as sustained ventricular tachycardia. However, recent data indicate it to be safe.

Contraindications to sotalol use include hypersensitivity to it, bronchial asthma, cardiogenic shock, and sinus bradycardia. Sotalol is available only in oral form.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1–2 hr	2.5–4 hr	12 hr	8–16 hr

Class IV Drugs

Class IV antidysrhythmic drugs are the calcium channel blockers. Besides being effective antidysrhythmics, calcium channel blockers are useful in the treatment of hypertension ([Chapter 23](#)) and angina. Verapamil and diltiazem are the two most commonly used calcium channel blockers for (1) treating dysrhythmias, specifically those that arise above the ventricles (paroxysmal supraventricular tachycardia) and (2) controlling the ventricular response to atrial fibrillation and flutter by slowing conduction and prolonging refractoriness of the AV node (i.e., preventing the ventricles from beating as fast as the atria).

These drugs block the slow inward flow of calcium ions into the slow (calcium) channels in cardiac conduction tissue. The

conduction effects of calcium channel blockers are limited to the atria and the AV node, where conduction is prolonged and the tissues are made more refractory to stimulation. These drugs have little effect on ventricular tissues.

diltiazem hydrochloride

Diltiazem hydrochloride (Cardizem®, Tiazac®) is primarily indicated for the temporary control of a rapid ventricular response in patients with atrial fibrillation or flutter and paroxysmal supraventricular tachycardia. Its use is contraindicated in patients with hypersensitivity to it, acute MI, pulmonary congestion, Wolff–Parkinson–White syndrome, severe hypotension, cardiogenic shock, sick sinus syndrome, or second- or third-degree AV block. Diltiazem is available in both oral and parenteral forms.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	0.5–1 hr	2–3 hr	3.5–9 hr	4–12 hr

verapamil hydrochloride

Verapamil hydrochloride (Isoptin SR®) has actions similar to those of diltiazem in that it also inhibits calcium ion influx across the slow calcium channels in cardiac conduction tissue. This results in dramatic effects on the AV node. Verapamil is used to prevent and convert recurrent paroxysmal supraventricular tachycardia and to control ventricular response in atrial flutter or fibrillation. It can also temporarily control a rapid ventricular response to these frequent atrial stimulations, usually decreasing the heart rate by at least 20%. Verapamil is used not only for the management of dysrhythmias, but also to treat angina, hypertension, and hypertrophic cardiomyopathy. The contraindications that apply to diltiazem apply to verapamil as well. It is also available in both oral and parenteral forms.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1–2 hr	3 hr	4.5–12 hr	6–8 hr

Unclassified Antidysrhythmics

adenosine

Adenosine (Adenocard®) is an unclassified antidysrhythmic drug. It slows the electrical conduction time through the AV node and is indicated for the conversion of paroxysmal supraventricular tachycardia to sinus rhythm. It is particularly useful when the paroxysmal supraventricular tachycardia has failed to respond to verapamil or when the patient has coexisting conditions such as heart failure, hypotension, or left ventricular dysfunction that limits the use of verapamil. Its use is contraindicated in patients with second- or third-degree heart block, sick sinus syndrome, atrial flutter or fibrillation, or ventricular tachycardia, as well as in those with a known hypersensitivity to it. It has an extremely short half-life of less than 10 seconds. For

this reason, it is administered only intravenously and only by a fast, direct intravenous injection followed by a fast, direct intravenous saline flush. It commonly causes asystole for a period of seconds. All other adverse effects are minimal because of its short duration of action. Adenosine is available only in parenteral form. This drug would be given only with heart monitoring in a critical care setting.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Immediate	Immediate	Less than 10 sec	Extremely brief

NURSING PROCESS

ASSESSMENT

Before any antidysrhythmic is administered to a patient, conduct a thorough nursing assessment and head-to-toe physical assessment, and complete a medical history and medication profile. Assess for contraindications, cautions, and drug interactions. Review any baseline ECGs and interpret the results, and measure the patient's vital signs, with attention to blood pressure; postural blood pressures; heart sounds; and heart rate, rhythm, and quality. Other signs and symptoms to assess that are related to decreased cardiac functioning (as a result of a dysrhythmia and decreased cardiac output) include apical-radial pulse deficits, jugular vein distention, edema, prolonged capillary refill (longer than 5 seconds), decreased urinary output, activity intolerance, chest pain or pressure, dyspnea, and fatigue. Document any changes in level of alertness, increase in anxiety levels, syncope, or dizziness.

Laboratory studies generally include electrolytes and kidney and liver function tests because abnormal functioning may call for a decrease in the drug dosage by the prescriber to prevent toxicity. Be sure to emphasize to the patient the interaction with grapefruit juice, which inhibits metabolism by cytochrome P450 3A4 hepatic enzymes (see [Chapter 2](#) for a more in-depth discussion of this topic). The interaction of grapefruit juice with amiodarone, disopyramide, and quinidine leads to an increased risk of toxicity and cinchonism. Cinchonism results from an excessive dose of cinchona bark used to manufacture quinine; it is characterized by headache, tinnitus, and vomiting. Other drug interactions with antidysrhythmics are presented in [Table 26.6](#). Altering of dosages is necessary in these situations to help prevent excessive accumulation and toxicity. (See also Evidence in Practice: Antidysrhythmics and Older Adults box).

With the use of lidocaine, assess the cardiovascular system, with attention to heart rate and blood pressure. With amiodarone, assess respiratory, thyroid, liver, dermatological, and hypertensive conditions, due to possible drug-related pulmonary toxicity, exacerbation of thyroid disorders, abnormal liver function tests, and rash. Further assessment for drug interactions (see [Table 26.6](#)) as well as contraindications and cautions is also needed.

TABLE 26.6 Selected Antidysrhythmic Drugs: Common Drug Interactions

Drug (Class)	Interacting Drugs	Effects*
quinidine sulfate (Ia)	amiodarone hydrochloride, dronedarone hydrochloride, amitriptyline hydrochloride, erythromycin, haloperidol, sotalol hydrochloride, moxifloxacin hydrochloride digoxin HMG-CoA reductase inhibitors (statins)	Additive QT prolongation Increase in digoxin levels by 50% Increased statin levels and toxicity
lidocaine hydrochloride (Ib)	amiodarone hydrochloride, azole antifungals, β -blockers, erythromycin, verapamil hydrochloride, cimetidine, tolcapten	Increased serum levels of lidocaine
propafenone hydrochloride (Ic)	cimetidine, quinidine sulfate, pimozone digoxin, warfarin sodium, β -blockers Class Ia and III antidysrhythmics, erythromycin	Increased propafenone levels; use is contraindicated Increase in level of interacting drugs Prolonged QT interval
amiodarone hydrochloride (III)	Azole antifungals, clarithromycin, erythromycin, haloperidol, moxifloxacin, quinidine sulfate, procainamide hydrochloride digoxin, diltiazem hydrochloride, verapamil hydrochloride, β -blockers warfarin sodium, digoxin cyclosporine HMG-CoA reductase inhibitors (statins)	Prolonged QT interval AV block Increase in INR by 50% in almost 100% of patients, increase in digoxin levels by 50% Increased cyclosporine levels and toxicity Increased statin levels and toxicity
sotalol hydrochloride (III) [†]	Calcium channel blockers Class I antidysrhythmics, erythromycin, moxifloxacin, amiodarone hydrochloride Diuretics	Additive effects on AV conduction, bradycardia Prolonged QT interval, bradycardia Promote loss of K in the urine which increases the risk for sotalol toxicity, resulting in dysrhythmia
verapamil hydrochloride, diltiazem hydrochloride (IV)	amiodarone hydrochloride, β -blockers, flecainide acetate, digoxin Azole antifungals, clarithromycin, erythromycin, isoniazid, HIV drugs HMG-CoA reductase inhibitors (statins)	Bradycardia, decreased cardiac output, hypotension Increased verapamil effects Increased statin levels and toxicity

AV, Atrioventricular; HIV, human immunodeficiency virus; HMG-CoA, hydroxymethylglutaryl-coenzyme A; INR, international normalized ratio.

*Note that enhanced activity of any antidysrhythmic drug may reach the level of drug toxicity, including potentially fatal cardiac dysrhythmias.

[†]Sotalol also has class II properties.

◆ PHARMACOKINETIC BRIDGE TO NURSING PRACTICE

◆ Amiodarone

A study of long-term oral amiodarone therapy for the treatment of dysrhythmias provides a different perspective on pharmacokinetics. To aid in evaluating the complex pharmacokinetic properties of amiodarone and developing an optimal dosing schedule for the drug in long-term oral drug therapy, serum concentrations of the drug and its metabolite, desethylamiodarone, were monitored in 345 Japanese patients receiving amiodarone. Serum concentrations of the drug and its metabolite were determined by an analysis called chromatography. In 245 participants who took fixed maintenance dosages of the drug for 6 months, there were small variations in the ratio of the serum level of the actual drug to the serum level of its metabolite. (The concept of metabolism as it relates to pharmacokinetics is discussed in [Chapter 2](#).) Other pharmacokinetic properties of amiodarone included a slightly higher average clearance in women than in men, even though there were no differences between men and women in regard to age, dosage, or duration of action of the dose. Japanese patients showed little variation in the pharmacokinetics of the drug. From this study, one can see how important it is to understand basic pharmacokinetic parameters (e.g., dosing, clearance, drug metabolism, serum concentrations) and to recognize that they are critical components of drug therapy and the

nursing process. It is also important to note that culture, gender, age, and racial or ethnic group have an impact on how each person responds to a drug and how each drug may vary in its action.

◆ NURSING DIAGNOSES

- Decreased cardiac output as a result of the pathology of the dysrhythmia
- Reduced peripheral tissue perfusion as a result of the physiological impact of the dysrhythmia
- Inadequate knowledge as a result of lack of experience with medication therapy

◆ PLANNING

◆ Goals

- Patient will experience improved cardiac output.
- Patient will experience improved peripheral perfusion and circulation.
- Patient will demonstrate adequate knowledge about the medication therapy.

◆ Outcome Criteria

- Patient's symptoms of dysrhythmia and subsequent decreased cardiac output are decreased and alleviated.
- Patient's peripheral pulses are bilaterally equal, strong, and regular; extremities are warm and pink.

EVIDENCE IN PRACTICE

Antidysrhythmics and Older Adults**Background**

A review article presented a thorough examination of research studies and clinical trials investigating the management of dysrhythmia in older adults. As noted in the article, the most interesting and recent application of pacemaker implantation has been for cardiac resynchronization in patients with advanced heart failure. Chronic heart failure is increasing in prevalence. Because older adults are more susceptible to atrial fibrillation, life-threatening ventricular dysrhythmias, and symptomatic bradycardia, it is very important for health care providers to be able to identify abnormal rhythms and initiate appropriate therapies to help prevent stroke and improve quality of life and survival. The article includes a review of the data, but it is the summary of the treatment modalities that is noteworthy.

Type of Evidence

The article provided a review of clinical trials and management of irregularities in heart rate in older adults. It also presented a review of treatment regimens.

Results of Study

Older adults are at increased risk for both atrial and ventricular irregularities even though they may be clinically healthy, and the occurrence of irregularities increases the risk of other problems in these patients. Discussed in this study were the options presented by a new generation of oral anticoagulants and percutaneously implanted devices that may soon play a more expanded role in the management of atrial fibrillation. Data from large clinical trials have shown that the use of automated implanted cardioverter-defibrillators (AICDs) to treat ventricular tachydysrhythmias improves the survival of these patients. Biventricular pacing is also a treatment modality with an identifiable role in reducing morbidity in patients with heart failure. The article also reviews other studies and trials that evaluate the role of treatment modalities in the management of heart irregularities in older adults. The treatment methods examined have provided older adults with the possibility of improved quality of life, decreased morbidity, and longer survival.

Link of Evidence to Nursing Practice

Older adults are subject to a variety of insults to their physiological and psychological status, and even if they are in normal health for their age, the risk for abnormal heart conditions and rhythms is high. Numerous studies reflect that age-related atrial fibrillation is associated with changes in ion-channel function and action potential properties, structural alterations, cardiac remodeling, and changes in the balance of calcium, which promotes cardiac muscle irritability after depolarization and spontaneous atrial activity (Laredo, Waldmann, Khairy, et al., 2018). It is important for nurses to be aware of reliable, valid data, so that they can support patients and families throughout implementation of new treatment plans, including use of antidysrhythmics, anticoagulants, implanted pacemakers, cardioverters and defibrillators, and biventricular pacing (Wenger, Helmy, Patel, et al., 2005). These treatment approaches have remained steadfast options for patients and families living with atrial fibrillation.

Based on: Laredo, M., Waldmann, V., Khairy, P., et al. (2018). Age as a critical determinant of atrial fibrillation: A two-sided relationship. *Canadian Journal of Cardiology*, 35(11), 1396–1406. <https://doi.org/10.1016/j.cjca.2018.08.007>; Wenger, N. K., Helmy, T., Patel, A. D., et al. (2005). Approaching cardiac arrhythmias in the elderly patient. *Medscape General Medicine*, 7(4). Retrieved from <http://www.medscape.com/viewarticle/514471>.

- Patient states rationale for taking medication as prescribed, as well as its therapeutic effects and adverse effects.
- Patient experiences increase in energy and stamina and improved ability to carry out activities of daily living due to positive therapeutic outcomes from drug therapy.

◆ IMPLEMENTATION

When antidysrhythmics are administered, monitor vital signs, especially pulse rate and blood pressure, before administering the drug; if pulse rate is lower than 60 beats per minute, notify the health care provider. During the initiation of therapy, closely monitor the ECG and vital signs because of possible prolongation of the QT interval by more than 50%. The result may be the occurrence of a variety of conduction disturbances. Advise patients that oral dosage forms are better tolerated if taken with food and fluids to help minimize GI upset, unless otherwise ordered. During treatment with quinidine (or with any of the antidysrhythmics), immediately report to the health care provider any patient report of angina, hypotension, lightheadedness, loss of appetite, tinnitus, or diarrhea. An infusion pump is recommended for intravenous dosing of any of the classes of antidysrhythmics, with proper solution and dilution.

With lidocaine, vials of clear solution are labelled as either *for cardiac use* or *not for cardiac use*. This is important to remember when reading the vial's label so that the wrong drug is not given. It is also important to remember that lidocaine solutions need to be used with extreme caution and that it is the plain solution that is used to treat various cardiac conditions. Parenteral solutions of these drugs are usually stable for only 24 hours. Lidocaine is also used as an anaesthetic, so the different concentrations of the drug need to be double-checked, if not triple-checked. In addition, lidocaine comes in a solution with epinephrine, a potent vasoconstrictor. This combined solution is indicated when the surgeon or physician is suturing or repairing wounds, with the lidocaine acting as an anaesthetic and the epinephrine causing vasoconstriction of the local blood vessels and helping to control bleeding of the area, or in dental or oral situations. The solution with epinephrine must *never* be used intravenously, but only as a topical anaesthetic. With lidocaine, document vital signs prior to initiation of and during therapy, and closely monitor the ECG. Often, when patients are receiving this drug, they are in a cardiac step-down unit, telemetry unit, or intensive care setting.

Amiodarone may lead to GI upset, which may be prevented or decreased by taking the drug with a meal or a snack. Photosensitivity (sunburn and other exaggerated skin reactions to the sunlight) and photophobia (light sensitivity) are other concerns with this drug. With photosensitivity, protective clothing, a hat, and sunscreen are needed. Emphasize the importance of eye protection, such as with sunglasses or tinted contact lenses, to patients taking this medication. Encourage consumption of fluids and a high-fibre diet to minimize the constipation that is a common adverse effect of antidysrhythmic drugs. When beta blockers are used with an antidysrhythmic, any shortness of breath, weight gain, changes in baseline blood glucose levels, or excessive fatigue (see Chapters 23 and 33) must be reported to the health care provider immediately.

Dosages

Selected Antidysrhythmic Drugs

Drug Name	Pharmacological Class	Usual Dosage Range
Class I		
quinidine sulfate	Class Ia antidysrhythmic	Adults IV: 200–750 mg infused at up to 10 mg/min
 lidocaine hydrochloride (Xylocaine)	Class Ib antidysrhythmic	Children IV: bolus dose, 1 mg/kg; usual maintenance infusion rate, 20–50 mcg/kg/min Adults IV: Bolus dose 50–100 mg; may be repeated in 5 min; do not exceed 200–300 mg over 1 hr; usual maintenance infusion rate 1–4 mg/min
propafenone hydrochloride (Rythmol)	Class Ic antidysrhythmic	Adults PO: Start with 150 mg q8h and increase q3–4 days; usual range, 450–900 mg/day divided
Class II		
metoprolol tartrate (Lopresor)	β_1 -blocker (class II antidysrhythmic)	Adults IV/PO: 3 bolus injections of 5 mg at 2-min intervals followed by 50 mg PO PO: q6h for 48h, thereafter 50–100 mg bid PO: 50–100 mg bid
Class III		
 amiodarone hydrochloride (Cordarone)	Class III antidysrhythmic	Adults IV: 150 mg over 10 min, then 60 mg/h for 6 h, then 30 mg/h as maintenance dose PO: 800–1 600 mg/day for 1–3 wk, reduced to 400–800 mg/day for 5 wk; usual maintenance dose 200–400 mg/day
ibutilide fumarate (Corvert)	Class III antidysrhythmic	Adults IV: 1-mg infusion over 10 min (if patient weighs less than 60 kg, then 0.1 mL/kg)
 sotalol hydrochloride* (Rylosol)	Class III antidysrhythmic	Adults PO: 160–320 mg/day divided into 2–3 doses
Class IV		
 diltiazem hydrochloride (Cardizem)	Calcium channel blocker (class IV antidysrhythmic)	Adults IV: Bolus dose 0.25 mg/kg over 2 min, second dose 0.35 mg/kg over 2 min after 15 min as needed, then 5–10 mg/h by continuous infusion PO: 120–360 mg daily
 verapamil hydrochloride (Isoptin)	Calcium channel blocker (class IV antidysrhythmic)	Children IV: 0–1 yr: 0.1–0.2 mg/kg bolus over 2 min; 0.1–0.2 mg/kg; repeat dose after 30 min 1–15 yr: 0.1–0.3 mg/kg bolus over 2 min; do not exceed 5-mg dose; repeat dose, not exceeding 10 mg, may be given after 30 min Adults PO: Start with 80 mg tid–qid; daily range 240–480 mg IV: 5–10 mg bolus over 2 min; repeat dose of 10 mg may be given after 30 min
Unclassified		
adenosine (Adenocard)	Unclassified antidysrhythmic	Adults IV: 6-mg bolus over 1–2 sec; second rapid bolus of 12 mg as needed, which may be repeated a second time as needed

IM, Intramuscular; IV, intravenous; PO, oral.

*Sotalol also has class II properties.

Beta blockers, diltiazem, and verapamil may all be used to manage abnormal rhythms and are to be given only after checking and documenting pulse rates and blood pressures. Contact the health care provider and withhold the drug—if supported by facility policy and the health care provider's guidelines—if the pulse rate is 60 beats per minute or lower or 100 beats per minute or higher or if the systolic blood pressure is 90 mm Hg or lower.

◆ EVALUATION

It is important to monitor patients receiving all classes of antidysrhythmics to confirm the therapeutic effects as well as

identify the adverse and toxic effects. Class I through class IV antidysrhythmic drugs have many overlapping therapeutic effects, adverse effects, and toxicities.

Therapeutic effects, in general, include improved cardiac output; decreased chest discomfort; decreased fatigue; improved vital signs, skin colour, and urinary output; and conversion of irregularities to normal rhythm. Adverse effects for the class I antidysrhythmics include hypotension, rash, diarrhea, drug-induced SLE-like syndrome characterized by joint and muscle pain, fatigue, pericarditis, and pleuritis (with use of procainamide); ECG changes, bitter taste, anorexia, blurred vision, and tinnitus (with use of

CASE STUDY

Antidysrhythmic Medications

Vijay, a 46-year-old patient, is admitted to the emergency room after going to the hospital reporting chest pain. He is diagnosed with CAD with a partial block of one of his coronary arteries and is awaiting an angioplasty procedure. He has a history of alcoholism but states that he has not had a drink for 2 years, thanks to Alcoholics Anonymous. In the coronary care unit, Vijay's heart monitor indicates increased episodes of PVCs when a 20-second run of ventricular tachycardia is noted. The patient is assessed and found to be short of breath and light-headed from the run of ventricular

tachycardia. The nurse contacts the health care provider and an amiodarone hydrochloride infusion is ordered. The order reads: "For episodes of ventricular

tachycardia, give a loading dose of 150 mg amiodarone intravenous (IV) push; then initiate infusion at 1 mg/min IV."

1. What factors will the nurse consider before beginning the amiodarone infusion?
2. What will the nurse monitor while Vijay is receiving this infusion? Three days later, Vijay is ready for discharge. He has had the angioplasty procedure, which was deemed a success, and the amiodarone infusion was discontinued the previous day. He has been started on oral amiodarone. Vijay asks the nurse, "What are the possible side effects of this drug? It seems that all drugs have bad side effects."
3. What is the nurse's best answer to this question?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

quinidine); and gingival hyperplasia and decrease in blood pressure and pulse rate (with use of phenytoin sodium). Class II beta blockers may cause bradycardia, AV block, heart failure, bronchospasm, and changes in blood glucose levels. Amiodarone, a class III drug, may lead to pulmonary

toxicity, thyroid disorders, decrease in blood pressure and pulse rate, photosensitivity, and abnormal liver function. Calcium channel blockers, or class IV drugs, are associated with heart block, hypotension, constipation, dizziness, and dyspnea (see Table 26.6).

PATIENT TEACHING TIPS

- Instruct patients not to crush or chew any oral dosage form that is identified as sustained-release or extended-release and not to alter the original dosage form of the drug in any way.
- Some dosage forms are delivered in a sustained-released tablet or capsule that may be composed of a wax matrix, and this matrix may be visible in the patient's stool. This extended-release dosage form provides for a slow release of the medicine, and the wax substance may then be passed out of the body through the stool. Advise patients that the passing of the matrix through the stool occurs after the drug has been absorbed, and although the matrix is often visible to the naked eye, its presence in the stool is of no major concern.
- If the use of an oral preparation is associated with continual and moderate or severe GI distress, tell the patient to take the drug with food and to contact the health care provider if nausea and vomiting worsen.
- If an antacid is needed, inform the patient that it must be taken either 2 hours before or 2 hours after the antidysrhythmic drug to avoid interference with drug absorption.
- Recommend a well-balanced diet and encourage an increase in fluid intake of up to 3 L of water a day, unless contraindicated.
- Educate the patient to limit or avoid caffeine and grapefruit intake. Caffeine-containing foods and beverages include coffee (decaffeinated coffee contains 2 to 4 mg caffeine per 240 mL, while caffeinated coffee contains 65 to 120 mg per 240 mL), tea, some soft drinks, chocolate, and energy drinks. Grapefruit can increase drug absorption and potential adverse effects.
- Instruct the patient to take medications exactly as prescribed, without doubling up or omitting doses. If the patient forgets a dose or is ill and cannot take a dose, contact the health care provider for further instructions.
- Provide written and verbal instructions and demonstrations for measuring pulse and blood pressure.
- Advise the patient to use journaling to document how the patient feels each day. Recommend recording in the journal any worsening or improvement of symptoms, adverse effects, daily weights, activity tolerance, blood pressure readings, and pulse rate. (Daily weights need to be measured at the same time every day and with the same amount of clothing.)
- Tell the patient to contact the health care provider immediately if there is a weight gain of 1 kg or more in 24 hours or 2.3 kg or more in 1 week.
- Inform the patient that changing positions purposefully and with caution is important because of the common adverse effect of orthostatic hypotension—moving too quickly may lead to dizziness, syncope, and subsequent injury or falls.
- At the beginning of therapy and after any dosage increase, encourage the patient to avoid driving and other hazardous activities until sedating adverse effects have resolved.
- Dry mouth may be helped by carrying out frequent mouth care, drinking fluids, chewing on sugarless gum, sucking on sugarless candy, and eating ice chips. Artificial saliva and special toothpaste made specifically for dry mouth and its management are available over the counter. Encourage frequent dental visits.
- Counsel the patient to avoid exertion, hot temperatures, saunas, and hot tubs because of heat-induced vasodilation, leading to orthostatic hypotension with dizziness or syncope and a subsequent risk for falls or injury. Alcohol intake may also lead to vasodilation and subsequent dizziness and syncope.

- Emphasize the need to wear a MedicAlert bracelet or necklace identifying the patient's specific medical diagnosis and provide a list of all medications and allergies. The patient needs to understand the importance of carrying this information (in either written or electronic form), having it available at all times, and updating it regularly and whenever there are major changes in the diagnosis and treatment regimen.
- Instruct the patient to report immediately to the health care provider any dizziness, shortness of breath, chest pain, worsening of symptoms, or occurrence of new symptoms.
- The patient must *never* stop taking these medications without specific instructions to do so; an abrupt discontinuation of these drugs may lead to severe or life-threatening complications.
- With amiodarone, photosensitivity is an adverse effect; advise the patient to avoid sun exposure and to wear sun-protective clothing and dark glasses when outside. Sunblocks that block ultraviolet B light are recommended, such as those containing zinc or titanium chloride.
- With amiodarone, instruct the patient to immediately report any blue-grey discoloration of the skin (often after 1 year, and especially on the face, neck, and arms) as well as any jaundice, unusual rashes or skin reactions, nausea, vomiting, or dizziness.

KEY POINTS

- The SA node, AV node, and bundle of His-Purkinje cells are all areas in which there is automaticity (i.e., cells can depolarize spontaneously). The SA node is the pacemaker because it can spontaneously depolarize more easily and quickly than the other areas can.
- Any disturbance or abnormality in the pattern of the heart-beat and pulse rate is termed a *dysrhythmia*.
- Antidysrhythmic drugs are used to correct dysrhythmias; however, they may also cause dysrhythmias, and for this reason are said to be *prodysrhythmic*. The Vaughan Williams classification system is most commonly used to classify antidysrhythmic drugs. It classifies groups of drugs according to where and how they affect cardiac cells and what their mechanism of action is:
 - *Class I*: membrane-stabilizing drugs (e.g., class Ia: quinidine; class Ib: lidocaine; class Ic: flecainide)
 - *Class II*: beta-adrenergic blockers that depress phase 4 depolarization (e.g., atenolol)
 - *Class III*: drugs that prolong repolarization in phase 3 (e.g., amiodarone, ibutilide)
 - *Class IV*: calcium channel blockers that depress phase 4 depolarization (e.g., verapamil)
- Nursing actions for the antidysrhythmic drugs include skillful nursing assessment and close monitoring of heart rate, blood pressure, heart rhythms, general well-being, skin colour, temperature, and heart and breath sounds. Some of the antidysrhythmics are administered in specialty areas (e.g., Critical Care Units, coronary care units, emergency departments), depending on the route (e.g., by IV) and the institution policy.
- Therapeutic responses to antidysrhythmics include a decrease in blood pressure in patients with hypertension, a decrease in edema, and restoration of a regular pulse rate without major irregularities or with improved regularity compared to before therapy.

EXAMINATION REVIEW QUESTIONS

1. A patient with a rapid, irregular heart rhythm is being treated with adenosine in the emergency department. During administration of this drug, the nurse will be prepared to monitor for which effect?
 - a. Nausea and vomiting
 - b. Transitory asystole
 - c. Muscle tetany
 - d. Hypertension
2. When assessing a patient who has been taking amiodarone for 6 months, the nurse monitors for which potential adverse effect?
 - a. Hyperglycemia
 - b. Dysphagia
 - c. Photophobia
 - d. Urticaria
3. The nurse is assessing a patient who has been on quinidine and asks about adverse effects. Which of the following is an adverse effect associated with the use of this drug?
 - a. Muscle pain
 - b. Tinnitus
 - c. Chest pain
 - d. Excessive thirst
4. A patient calls the family medicine clinic to report that he saw his pills in his stools when he had a bowel movement. What will the nurse respond?
 - a. "The pills are not being digested properly. You should be taking them on an empty stomach."
 - b. "The pills are not being digested properly. You should be taking them with food."
 - c. "What you are seeing is the waxy matrix that contained the medication, but the drug has been absorbed."
 - d. "This indicates that you are not tolerating this medication and will need to switch to a different form."
5. The nurse is administering lidocaine and considers which condition, if present in the patient, a caution for the use of this drug?
 - a. Tachycardia
 - b. Hypertension
 - c. Ventricular dysrhythmias
 - d. Kidney dysfunction

6. When the nurse is teaching a patient about taking an anti-dysrhythmic drug, which statements by the nurse are correct? (Select all that apply.)
 - a. “Take the medication with an antacid if stomach upset occurs.”
 - b. “Do not chew sustained-release capsules.”
 - c. “If you have a weight gain of 2.3 kg within 1 week, notify your health care provider at the next office visit.”
 - d. “If you experience severe adverse effects, stop the drug and notify your physician.”
 - e. “You may take the medication with food if stomach upset occurs.”
7. A patient is in the emergency department with new-onset rapid-rate atrial fibrillation. The nurse is about to add a continuous infusion of diltiazem at 5 mg/hr but must first give a bolus of 0.25 mg/kg over 2 minutes. The patient weighs 220 pounds. The medication comes in a vial of 5 mg/mL. How many milligrams will the patient receive, and how many millilitres will the nurse draw up for this dose?
8. A patient is in the clinic for a follow-up visit. He has been taking amiodarone (Cordarone) for almost 1 year, and today he tells the nurse, “I am noticing some blue colour around my face, neck, and upper arms. Is that normal?” Which is the nurse’s correct response?
 - a. “This is an expected side effect and should go away soon.”
 - b. “This is a harmless effect. As long as the medication is working, we’ll just monitor your skin.”
 - c. “This can happen with amiodarone. I will let your doctor know about it right away.”
 - d. “How much sun exposure have you had recently?”

CRITICAL THINKING ACTIVITIES

1. A patient who was admitted to the hospital for treatment of atrial fibrillation is about to go home with a new prescription for diltiazem (Cardizem). As the nurse goes over the patient’s medication list, the patient reports, “I’m feeling very tired. And when I stand up, I can hardly walk because I’m so dizzy.” What is the nurse’s priority action?
 2. A patient will be discharged from the hospital with a prescription for amiodarone (Cordarone). He has been ill for some time and tells the nurse, “I cannot wait to get to my beach house and relax outside by the ocean. I’m sure the fresh air will be good for me.” What is the priority for patient teaching at this time?
 3. A patient has been admitted to the emergency department and is experiencing paroxysmal supraventricular tachycardia that has not responded to treatment with calcium channel blockers. Immediately after the patient receives a dose of adenosine by intravenous push, the monitor shows asystole. What is the nurse’s priority action in response to the asystole?
- For answers, see** <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Coagulation Modifier Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Briefly review the coagulation process and the impact of coagulation modifiers such as anticoagulants, antiplatelets, thrombolytics, and antifibrinolytics.
2. Compare the mechanisms of action, indications, cautions, contraindications, drug interactions, adverse effects, routes of administration, and dosages of the various anticoagulants, antiplatelets, thrombolytics, and antifibrinolytics.
3. Discuss the administration procedures and techniques as well as related standards of care for the various coagulation modifiers.
4. Identify any available antidotes for the coagulation modifiers.
5. Compare the laboratory tests used in conjunction with treatment with the various coagulation modifiers and their implications for therapeutic use of these drugs and monitoring for adverse reactions.
6. Develop a collaborative plan of care that includes all phases of the nursing process for patients receiving anticoagulants, antiplatelet drugs, thrombolytics, and antifibrinolytics.

KEY TERMS

Anticoagulants Substances that prevent or delay coagulation of the blood. (p. 447)

Antifibrinolytic drugs Drugs that prevent the lysis of fibrin and in doing so promote clot formation. (p. 447)

Antiplatelet drugs Substances that prevent platelet plugs from forming. (p. 447)

Antithrombin III (AT-III) A substance that inactivates three major activating factors of the clotting cascade: activated II (thrombin), activated factor X, and activated factor IX. (p. 447)

Clot Insoluble solid elements of blood (e.g., cells, fibrin threads) that have chemically separated from the liquid (plasma) component of the blood. (p. 445)

Coagulation The process of blood clotting; more specifically, the sequential process by which the multiple coagulation factors of the blood interact in the coagulation cascade (see below), ultimately forming an insoluble fibrin clot. (p. 445)

Coagulation cascade The series of steps beginning with the intrinsic or extrinsic pathways of coagulation and proceeding through the formation of a fibrin clot. (p. 445)

Deep vein thrombosis (DVT) The formation of a thrombus in one of the deep veins of the body; most commonly occurs in the iliac and femoral veins. (p. 447)

Embolus A blood clot (thrombus) that has been dislodged from the wall of a blood vessel and travels through the bloodstream; emboli that lodge in critical blood vessels can result in ischemic injury to a vital organ (e.g., heart, lung, brain) and result in disability or death. (p. 447)

Enzyme A protein molecule that catalyzes chemical reactions of other substances without being altered or destroyed in the process. (p. 450)

Fibrin A stringy, insoluble protein produced by the action of thrombin on fibrinogen during the clotting process; a major component of blood clots or thrombi (see thrombus). (p. 445)

Fibrin-specificity The property of some thrombolytic drugs of activating the conversion of plasminogen to plasmin, only in the presence of established clots having fibrin threads, rather than inducing systemic plasminogen activation throughout the body. (p. 457)

Fibrinogen A plasma protein that is converted into fibrin by thrombin in the presence of calcium ions. (p. 455)

Fibrinolysis The continual process of fibrin decomposition produced by the actions of the enzymatic protein fibrinolysin; the normal mechanism for removing small fibrin clots, stimulated by anoxia, inflammatory reactions, and other kinds of stress. (p. 445)

Fibrinolytic system An area of the circulatory system undergoing fibrinolysis. (p. 445)

Hemophilia A rare, inherited blood disorder in which the blood does not clot normally. (p. 445)

Hemorheological drugs Drugs that alter the function of platelets without compromising their blood-clotting properties. (p. 447)

Hemostasis The arrest of bleeding, either by the physiological properties of vasoconstriction and coagulation or by mechanical, surgical, or pharmacological means. (p. 445)

Hemostatic Referring to any procedure, device, or substance that arrests the flow of blood. (p. 447)

Plasmin The enzymatic protein that breaks down fibrin into fibrin degradation products; derived from plasminogen. (p. 445)

Plasminogen A plasma protein that is converted to plasmin. (p. 445)

Pulmonary embolus (PE) The blockage of a pulmonary artery by foreign matter such as fat, air, tumour cells, or a thrombus that has typically arisen from a peripheral vein. (p. 447)

Stroke Occlusion of the blood vessels of the brain by an embolus, thrombus, or cerebrovascular hemorrhage, resulting in ischemia to brain tissue (may be referred to as a *cerebrovascular accident*). (p. 447)

Thromboembolic events Events in which a blood vessel is blocked by an embolus carried in the bloodstream from the site of its formation; the tissue supplied by an obstructed artery may tingle and become cold, numb, cyanotic, and eventually necrotic (dead). (p. 447)

Thrombolytic drugs Drugs that dissolve thrombi by functioning similarly to tissue plasminogen activator (see below). (p. 447)

Thrombus blood clot (plural thrombi); an aggregation of platelets, fibrin, clotting factors, and the cellular elements of the blood that is attached to the interior wall of a vein or artery, sometimes occluding the lumen of the vessel. (p. 445)

Tissue plasminogen activator A naturally occurring plasminogen activator secreted by vascular endothelial cells in the walls of the blood vessels. Thrombolytic drugs are based on this blood component. (p. 445)

HEMOSTASIS AND COAGULATION

Hemostasis is a general term for any process that stops bleeding. This can be accomplished by mechanical means (e.g., compression to the bleeding site) or by surgical means (e.g., surgical clamping or cauterization of a blood vessel). When hemostasis occurs because of physiological clotting of blood, it is called **coagulation**, which is the process of blood clot formation. The technical term for a blood clot is **thrombus**. A thrombus that is not stationary but moves through blood vessels is an **embolus**. Normal hemostasis involves a complex interaction of substances that promote **clot** formation and substances that either inhibit coagulation or dissolve the formed clot. Substances that promote coagulation include platelets, von Willebrand factor, activated

clotting factors, and tissue thromboplastin. Substances that inhibit coagulation include prostacyclin, antithrombin III, and proteins C and S. In addition, **tissue plasminogen activator** is a natural substance that dissolves clots that are already formed.

The coagulation system is illustrated in Figs 27.1 and 27.2. It is called a *cascade* (or **coagulation cascade**) because each activated clotting factor serves as a catalyst that amplifies the next reaction. The result is a large concentration of a clot-forming substance called **fibrin**. The coagulation cascade is typically divided into the intrinsic and extrinsic pathways, and these pathways are activated by different types of injury. When blood vessels are damaged by penetration from the outside (e.g., a knife or bullet wound), thromboplastin—a substance contained in the walls of blood vessels—is released. This release initiates the extrinsic pathway by activating factors VII and X (see Fig 27.1). The components of the intrinsic pathway are present in the blood in their inactive forms (see Fig 27.2). This pathway is activated when factor XII comes in contact with exposed collagen on the inside of damaged blood vessels. Figs 27.1 and 27.2 illustrate the steps that occur in the extrinsic and intrinsic pathways, respectively, and the factors involved. They also illustrate the sites of action of two commonly used anticoagulant drugs: warfarin and heparin.

Once a clot is formed and fibrin is present, the **fibrinolytic system** is activated. This system initiates the breakdown of clots and serves to balance the clotting process. **Fibrinolysis** is the reverse of the clotting process. It is the mechanism by which formed thrombi are lysed (broken down) to prevent excessive clot formation and blood vessel blockage. Fibrin in the clot binds to a circulating protein known as **plasminogen**. This binding converts plasminogen to plasmin. **Plasmin** is the enzymatic protein that eventually breaks down the fibrin thrombus into fibrin degradation products. This action keeps the thrombus localized, to prevent it from becoming an embolus that can travel and obstruct a major blood vessel in the lungs, heart, or brain. Fig 27.3 illustrates the fibrinolytic system.

Hemophilia is a rare genetic disorder in which the previously mentioned natural coagulation and hemostasis factors are limited or absent. Hemophilia is categorized into two main types, depending on which of the coagulation factors is absent (factor VII, factor VIII, or factor IX). Patients with hemophilia can bleed to death if coagulation factors are not given.

Fig. 27.1 Coagulation pathway and factors: extrinsic pathway. plt, platelets.

Fig. 27.2 Coagulation pathway and factors: intrinsic pathway. HMWK, high-molecular-weight kinogen; plt, platelets.

Fig. 27.3 The fibrinolytic system.

COAGULATION MODIFIER DRUGS

Drugs that affect coagulation are some of the most dangerous drugs used today, and numerous factors can affect their action. These drugs are among those most commonly associated with adverse drug reactions. The drugs discussed in this chapter aid the body in reversing or achieving hemostasis, and they can be broken down into several main categories based on their actions. **Anticoagulants** inhibit the action or formation of clotting factors, thereby preventing clots from forming. **Antiplatelet drugs** prevent platelet plugs from forming by inhibiting platelet aggregation, which can be beneficial in preventing heart attacks and strokes. **Hemorheological drugs** alter platelet function without preventing the platelets from working. Sometimes clots form and totally block a blood vessel. When this happens in one of the coronary arteries, a heart attack occurs, and the clot must be lysed to prevent or minimize damage to myocardial muscle. **Thrombolytic drugs** lyse clots, or *thrombi*, that have already formed. This characteristic creates an important distinction between thrombolytics and anticoagulants, which can only prevent the formation of a clot. **Antifibrinolytic drugs**, also known as **hemostatic drugs**, have the opposite effect of these other classes of drugs—they actually promote blood coagulation and are helpful in the management of conditions in which excessive bleeding would be harmful. The various drugs in each category of coagulation modifiers are listed in Table 27.1. Understanding the individual coagulation modifiers and their mechanisms of action requires a basic working knowledge of the coagulation pathway and coagulation factors, which are described in the next section.

Anticoagulants

Drugs that prevent the formation of a clot by inhibiting certain clotting factors are called *anticoagulants*. These drugs have no direct effect on a blood clot that has already formed. They

prevent intravascular thrombosis by decreasing blood coagulability. Their uses vary from preventing clot formation to preventing the extension of an established clot.

Once a clot forms on the wall of a blood vessel, it may dislodge and travel through the bloodstream. A dislodged clot is referred to as an *embolus*. If it lodges in a coronary artery, it causes a myocardial infarction (MI); if it obstructs a brain vessel, it causes a **stroke** (cerebrovascular accident [CVA]); if it travels to the lungs, it is a **pulmonary embolus (PE)**; and if it travels to a vein in the leg, it is a **deep vein thrombosis (DVT)**. Collectively, these complications are called **thromboembolic events** because they involve a thrombus that becomes an embolus and causes an adverse cardiovascular “event.” Anticoagulants can prevent these events from occurring if used in the correct manner. Both orally and parenterally administered anticoagulants are available, and each drug has a slightly different mechanism of action and indications. All of them have their own risks, mainly the risk of causing bleeding. The mechanisms of action of the anticoagulants vary depending on the drug. Drug classes of anticoagulants include older drugs such as unfractionated heparin and warfarin. There are also several newer drug classes, including low-molecular-weight heparins (LMWHs), direct thrombin inhibitors, and a selective factor Xa inhibitor. For dosage information, refer to the table on p. 452.

Mechanism of Action and Drug Effects

Anticoagulants are also called *antithrombotic drugs* because they work to prevent the formation of a clot or thrombus, a condition known as *thrombosis*. All anticoagulants work in the clotting cascade but do so at different points. As shown in Figs 27.1 and 27.2, heparin *inhibits* circulating clotting factors. It binds to a substance called **antithrombin III (AT-III)**, which turns off three main activating factors: activated factor II (also called thrombin), activated factor X, and activated factor IX.

TABLE 27.1 Coagulation Modifiers: Comparison of Drug Subclasses

Type of Coagulation Modifier and Mechanism of Action	Drug Class	Individual Drugs
Prevent Clot Formation Anticoagulants		
Inhibit clotting factors IIa (thrombin) and Xa	Heparins	Unfractionated heparin (heparin sodium) and low-molecular-weight heparins (enoxaparin sodium [Lovenox®], dalteparin sodium [Fragmin®], nadroparin calcium [Fraxiparine®], tinzaparin sodium [Innohep®])
Inhibit vitamin K–dependent clotting factors II, VII, IX, and X	Coumadins	warfarin sodium (Coumadin®)
Inhibit clotting factors IIa and Xa	Glycosaminoglycans	danaparoid sodium (Orgaran®)
Inhibit thrombin (factor IIa)	Direct thrombin inhibitors	Human antithrombin III (Thrombate III®), argatroban, bivalirudin (Angiomax®), dabigatran etexilate mesylate (Pradaxa®)
Inhibit factor Xa	Selective factor Xa inhibitor	fondaparinux (Arixtra®), rivaroxaban (Xarelto®), apixaban (Eliquis®)
Antiplatelet Drugs		
Interfere with platelet function	P2Y ₁₂ inhibitors Aggregation inhibitors/vasodilators Glycoprotein IIb/IIIa inhibitors Miscellaneous	clopidogrel bisulphate (Plavix®), prasugrel (Effient®), ticagrelor (Brilinta®) treprostinil (Remodulin®) abciximab (ReoPro®), eptifibatide (Integrilin®), tirofiban (Aggrastat®) anagrelide hydrochloride (Agrylin®), dipyridamole (Aggrenox®, Persantine®)
Lyse Preformed Clots Thrombolytics		
Dissolve thrombi	Tissue plasminogen activators	alteplase (Activase RT-PA®, Cathflo), tenecteplase (TNKase®)
Promote Clot Formation Antifibrinolytics		
Prevent lysis of fibrin	Systemic hemostats	tranexamic acid (Cyklokapron®), aprotinin (Trasylol®)
Reduce blood viscosity	Hemorheological	pentoxifylline (Trental®)
Reversal Drugs		
	Heparin sodium antagonist Warfarin sodium antagonist	protamine sulphate vitamin K

(Factors XI and XII are also inactivated but do not play as important a role as the other three factors.) Of these, thrombin is the most sensitive to the actions of heparin. AT-III is the major natural inhibitor of thrombin in the blood. The overall effect of heparin is that it turns off the coagulation pathway and prevents clots from forming. However, it cannot lyse a clot. The drug name *heparin* usually refers to unfractionated heparin, which is a relatively large molecule and is derived from porcine intestine. In contrast, LMWHs are synthetic and have a smaller molecular structure. They include enoxaparin (Lovenox), dalteparin (Fragmin), nadroparin calcium (Fraxiparine), and tinzaparin sodium (Innohep). They all work similarly to heparin. Heparin binds primarily to activated factors II, X, and IX, whereas the LMWHs are much more specific for activated factor X (Xa) than for activated factor II (IIa, or thrombin). This property gives LMWHs a much more predictable anticoagulant response. As a result, frequent laboratory monitoring of bleeding times using tests such as activated partial thromboplastin time (aPTT), which is imperative with unfractionated heparin, is not required with LMWHs. When heparin is used for flushing catheters (10–100 units/mL), no monitoring is needed.

Warfarin (Coumadin) inhibits clotting factor synthesis. It works by inhibiting vitamin K synthesis by bacteria in the gastrointestinal (GI) tract. This action, in turn, inhibits production of clotting factors II, VII, IX, and X. These four factors are normally synthesized in the liver and are known as *vitamin K–dependent clotting factors*. As with heparin, the final effect is the prevention of clot formation. [Figs 27.1 and 27.2](#) show where in the clotting cascade this occurs.

Fondaparinux (Arixtra) inhibits thrombosis by its action against factor Xa alone. Rivaroxaban (Xarelto) and apixaban (Eliquis) are two oral, direct-acting factor Xa inhibitors, approved for prophylaxis and treatment of DVT; venous thromboembolism (VTE) in adult patients after undergoing elective knee or hip surgery; stroke and systemic embolism in patients with atrial fibrillation; and treatment of DVT and PE and prevention of recurrent DVT and PE. There are also currently five antithrombin drugs that inhibit thrombin molecules directly, one natural and four synthetic. The natural drug is human antithrombin III (Thrombate), which is isolated from the plasma of human donors. The synthetic drugs are argatroban (Argatroban®), bivalirudin (Angiomax), and dabigatran (Pradaxa). Dabigatran is a new oral direct thrombin inhibitor.

TABLE 27.2 Anticoagulants: Common Adverse Effects

Drug Subclass	Adverse Effects
Heparins (unfractionated heparin, low-molecular-weight heparin)	Bleeding, hematoma, nausea, anemia, thrombocytopenia, fever, edema
Direct thrombin inhibitors (argatroban, bivalirudin, dabigatran etexilate mesylate)	Bleeding, dizziness, shortness of breath, fever, urticaria
Selective factor Xa inhibitors (fondaparinux, rivaroxaban)	Bleeding, hematoma, dizziness, rash, GI distress, anemia
warfarin sodium (Coumadin)	Bleeding, lethargy, muscle pain, purple toes

All of these drugs work similarly to inhibit thrombus formation by inhibiting thrombin. Newer oral anticoagulants such as dabigatran, rivaroxaban, and apixaban may also be called novel oral anticoagulants (NOAC).

Indications

The ability of anticoagulants to prevent clot formation is of benefit in certain conditions where there is a high likelihood of clot formation. These include MI, unstable angina, atrial fibrillation, presence of indwelling devices such as mechanical heart valves, and conditions in which blood flow may be slowed and blood may pool, such as major orthopedic surgery, prolonged periods of immobility, or even long plane rides. The ultimate consequence of a clot can be a stroke, an MI, a DVT, or a pulmonary embolism; therefore, the ultimate benefit of these drugs is the prevention of these serious events. Warfarin is indicated for *prevention* of any of these events, whereas unfractionated heparins, LMWHs, direct thrombin inhibitors, and the factor Xa inhibitor are used for both prevention and treatment. Patients at risk for clots are given DVT prophylaxis while in the hospital and after major surgery. LMWHs are also routinely used as anticoagulant bridge therapy in situations in which a patient must stop warfarin for surgery or other invasive medical procedures. LMWH may also be contraindicated in patients with significant kidney disease; heparin would be preferred in this case. The term *bridge therapy* refers to the fact that heparins (unfractionated or LMWHs) act as a bridge to provide anticoagulation while the patient must be off of warfarin therapy. The remainder of the antithrombotic drugs have similar but more restricted indications, which are listed in the Dosages table on p. 452.

Contraindications

Contraindications to the use of anticoagulants are generally similar for all of the different drugs within this class. They include known drug allergy to a specific product and usually include any acute bleeding, as well as thrombocytopenia. Warfarin is strongly contraindicated in pregnancy, whereas the other anticoagulants are rated in lower pregnancy categories, where benefits of taking the drug during pregnancy may override potential risks. LMWHs are contraindicated in patients with an indwelling epidural catheter; they can be given 2 hours after the epidural is removed. This is important to remember because giving an LMWH with an epidural has been associated with epidural hematoma.

Adverse Effects

Bleeding is the main complication of anticoagulation therapy, and the risk increases with increasing dosages. Such bleeding

may be localized (e.g., hematoma at the site of injection) or systemic. It also depends on the nature of the patient's underlying clinical disorder and is increased in patients taking high doses of aspirin or other drugs that impair platelet function. One particularly notable common adverse effect of heparin is heparin-induced thrombocytopenia (HIT), which is also called *heparin-associated thrombocytopenia* (HAT). There are two types of HIT. Type I is characterized by a gradual reduction in platelets. In this type, heparin therapy can generally be continued. In contrast, in type II HIT, there is an acute fall in the number of platelets (more than 50% reduction from baseline). Heparin therapy must be discontinued in patients with type II HIT. Thrombosis that occurs in the presence of HIT can be fatal. The greatest risk to the patient with HIT is the paradoxical occurrence of thrombosis, something that heparin normally prevents or alleviates. The incidence of this disorder ranges from 5 to 15% of patients and is higher with bovine (cow-derived) than with porcine (pig-derived) heparins. The use of bovine- or porcine-derived products may conflict with cultural and religious beliefs specific to individuals who identify as Sikh, Hindu, or Muslim. The direct thrombin inhibitors argatroban and bivalirudin, as well as danaparoid sodium (Orgaran, an anticoagulant/antithrombotic mixture), and fondaparinux are indicated for treating HIT. Warfarin can cause skin necrosis and "purple toes" syndrome. Other adverse effects are listed in Table 27.2.

Toxicity and Management of Overdose. Treatment of the toxic effects of anticoagulants is aimed at reversing the underlying cause. Although the toxic effects of heparin, LMWH, and warfarin are hemorrhagic in nature, the management is different for each drug. Symptoms that may be attributed to toxicity or an overdose of anticoagulants are hematuria, melena (blood in the stool), petechiae, ecchymoses, and gum or mucous membrane bleeding. In the event of heparin or warfarin toxicity, the drug is to be stopped immediately. In the case of heparin, simply stopping the drug may be enough to reverse the toxic effects because of the drug's short half-life (1 to 2 hours). In severe cases or when large doses have been given intentionally (i.e., during cardiopulmonary bypass for heart surgery), intravenous (IV) injection of protamine sulphate is indicated. This drug is a specific heparin antidote and forms a complex with heparin, completely reversing its anticoagulant properties. This occurs in as few as 5 minutes. In general, 1 mg of protamine sulphate can reverse the effects of 100 units of heparin. Protamine sulphate may also be used to reverse the effects of LMWHs. A 1-mg dose of protamine sulphate is administered for each milligram of LMWH given (e.g., 1 mg protamine sulphate for 1 mg enoxaparin). If the heparin overdose has resulted in a large

volume of blood loss, replacement with packed red blood cells may be necessary.

In the event of warfarin toxicity or overdose, the first step is to discontinue the warfarin. As with heparin, the toxicity associated with warfarin is an extension of its therapeutic effects on the clotting cascade. However, because warfarin inactivates the vitamin K–dependent clotting factors, and because these clotting factors are synthesized in the liver, it may take 36 to 42 hours before the liver can resynthesize enough clotting factors to reverse the warfarin's effects. Giving vitamin K₁ (phytonadione) can hasten the return to normal coagulation. The dose and route of administration of the vitamin K depend on the clinical situation and its acuity (i.e., how quickly the warfarin-induced effects must be reversed and whether the patient is having significant bleeding). High doses of vitamin K (10 mg) given intravenously will reverse the anticoagulation within 6 hours. Current recommendations are to use the lowest amount of vitamin K possible, based on the clinical situation. This is because once vitamin K is given, warfarin resistance will occur for up to 7 days; thus, the patient cannot be anticoagulated by warfarin during this period. Warfarin requires 5 to 7 days to reach full antithrombotic effect after this medication is initiated orally, and the patient will not be sufficiently anticoagulated during this time. In such cases, either heparin or an LMWH may need to be added to provide adequate anticoagulation. In acute situations in which bleeding is severe, and the time it would take for the vitamin K to take effect is too long, it may be necessary to administer transfusions of human plasma or clotting factor concentrates. Depending on the clinical situation, oral vitamin K is usually the preferred route. However, when the international normalized ratio (INR) is extremely elevated or the patient is bleeding, vitamin K is given intravenously. There is a risk of anaphylaxis when it is given by this route; the risk is diminished by diluting it and giving it over 30 minutes. Some institutions allow it to be given via IV push. Vitamin K is available in 5-mg tablets and in 10-mg and 1-mg injections. It is common to give the injectable form orally.

Transfusions may be indicated for overdoses of direct thrombin inhibitors and the selective factor Xa inhibitor fondaparinux, which both lack specific antidotes. These drugs may also be removed with hemodialysis.

Interactions

Drug interactions involving the oral anticoagulants are profound and complicated. The drugs and the results of an interaction are given in [Table 27.3](#). The main interaction mechanisms responsible for increasing anticoagulant activity include the following:

- **Enzyme** inhibition of metabolism
- Displacement of the drug from inactive protein-binding sites
- Decrease in vitamin K absorption or synthesis by the bacterial flora of the large intestine
- Alteration in the platelet count or activity

The drugs that interact with warfarin and heparin are listed in [Table 27.3](#). More specifics on significant drug interactions are discussed under the drug profiles. Although both aspirin

and warfarin increase the risk of bleeding when given with heparin, they are commonly given together in clinical practice. In fact, when a patient is placed on IV heparin, it is recommended that warfarin be started at the same time. Heparin is continued until the warfarin effect is therapeutic, for at least 2 days.

Dosages

For dosage information on selected anticoagulants, refer to the table on p. 452.

DRUG PROFILES

Of the anticoagulants, warfarin, dabigatran etexilate mesylate, and rivaroxaban are used orally. The rest are given by IV or subcutaneous injection only. Intramuscular (IM) injection of these drugs is contraindicated because of their propensity to cause large hematomas at the site of injection.

warfarin sodium

Warfarin sodium (Coumadin) is a pharmaceutical derivative of the natural plant anticoagulant known as *coumarin*. Warfarin is the most commonly prescribed oral anticoagulant and is used exclusively in the oral form. Use of this drug requires careful monitoring of the prothrombin time (PT) and INR, which are standardized measures of the degree to which a patient's blood coagulability has been reduced by the drug. The PT and INR evaluate the extrinsic pathway of coagulation. The INR provides a standardized unit to report the results of the PT. A normal INR (without warfarin) is 0.8 to 1.2, whereas a therapeutic INR (with warfarin) ranges from 2 to 3.5, depending on the indication for use of the drug (e.g., atrial fibrillation, thromboprevention, prosthetic heart valve). Patients older than 65 years of age may have a lower INR threshold for bleeding complications and may need to be monitored accordingly. Older adult patients should be started on lower dosages initially. Recently, it has been shown that about one third of patients receiving warfarin metabolize it differently from the expected way, based on variations in certain genes, *CYP2C9* and *VKORC1*. Genetic testing for these genes is helpful in determining the appropriate initial dosage of warfarin. The maintenance dosage is still determined by the INR.

Warfarin has significant interactions with many drugs, including amiodarone hydrochloride, fluconazole, erythromycin, metronidazole, sulfonamide antibiotics, and cimetidine. Although many more drugs can interact with warfarin, the aforementioned are by far the most common. Combining warfarin and amiodarone hydrochloride will lead to a 50% increase in a patient's INR. When amiodarone hydrochloride is added to warfarin therapy, it is recommended that the warfarin dose be cut in half.

Because warfarin inhibits vitamin K–dependent clotting factors, foods that are high in vitamin K may reduce warfarin's ability to prevent clots. Common foods rich in vitamin K include leafy green vegetables (e.g., kale, spinach, collard

greens). The most important aspect of these food–drug interactions is consistency in diet. Educate patients to maintain consistency in their intake of leafy green vegetables. Many patients are under the misconception that they must avoid all leafy green vegetables; however, this is not true. Once their maintenance warfarin dose is established, patients may still eat green vegetables, but they need to be consistent in their intake because increasing or decreasing it can affect their INR. Natural health products that interact with warfarin and result in increased risk of bleeding include dong quai, garlic, ginkgo, and St. John's wort.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	24–72 hr	4 hr	0.5–3 days	2–5 days

enoxaparin sodium

Enoxaparin sodium (Lovenox) is the prototypical LMWH and is obtained by enzymatically cleaving large unfractionated heparin molecules into small fragments. These fragments of heparin have a greater affinity for factor Xa than for factor IIa and have a higher degree of bioavailability and a longer elimination half-life than unfractionated heparin. Laboratory monitoring, as is done with heparin therapy, is not necessary when enoxaparin is given because of its greater affinity for factor Xa. It is available only in injectable form. Other anticoagulants with comparable pharmacology and indications include danaparoid sodium and dalteparin sodium. Enoxaparin is a commonly used LMWH given for both prophylaxis and treatment. Dalteparin prefilled syringes are increasingly being used for the thromboprophylaxis in conjunction with surgery, and higher doses of the drug are used in the treatment of DVT and pulmonary embolism. All LMWHs have a distinct advantage over heparin in that they do not require any laboratory monitoring and can be given at home for the treatment of DVT or pulmonary embolism. This factor allows patients to be discharged from the hospital sooner. These drugs may also be used at home after major orthopedic surgery.

A potentially deadly medication error is to give heparin in combination with enoxaparin (or any LMWH, dabigatran sodium, or rivaroxaban). Always double-check that enoxaparin and heparin are never given to the same patient.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Subcut	3–5 hr	4–5 hr	4–5 hr	12 hr

heparin sodium

Heparin sodium is a natural mucopolysaccharide anticoagulant obtained from porcine intestinal mucosa. Heparin Leo® is a brand name that refers only to small vials of aqueous heparin IV flush solutions used to maintain patency of heparin lock IV

insertion sites. Because of the risk for the development of HIT, however, most institutions routinely use 0.9% normal saline as a flush for heparin-lock IV ports and have moved away from using heparin flush solutions for this purpose. Heparin flushes (100 units/mL) are still used for central catheters. When used for flushing purposes, there is no need for monitoring.

Heparin is commonly used for DVT prophylaxis in a dose of 5 000 units, two or three times a day, given subcutaneously, and it does not need to be monitored when used for prophylaxis. When heparin is used therapeutically, it is given by continuous IV infusion or, rarely, by subcutaneous injection. Most hospitals have weight-based protocols for heparin administration. Because the dosage is based on the patient's weight in kilograms, ensure that the appropriate weight is recorded and that only kilograms are used, not pounds. A potential double-dose medication error can occur if pounds and kilograms are mixed. This is also true for enoxaparin because it is also dosed on body weight when used therapeutically. When heparin is given by IV infusion, monitoring by frequent measurement of aPTT (usually every 6 hours until therapeutic effects are seen) is necessary. Because the required monitoring is time-consuming, many institutions now use enoxaparin in place of heparin.

Other drugs that affect the coagulation cascade can have additive effects with heparin, which may lead to bleeding.

Heparin is available only in injectable form, in multiple strengths ranging from 10 to 10 000 units/mL. The vials of different strengths of heparin are similar and look alike. Indeed, they are available in strengths of 10, 100, 1 000, and 10 000 units/mL, so it is easy to mix up the vials. In fact, several newborns have died when a vial of more concentrated heparin was mistaken for a more dilute solution. Take great care in checking and double-checking the concentration of heparin before administering it.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Immediate	Immediate	1–2 hr	Dependent on infusion duration
Subcut	20–30 min	2–4 hr	1–2 hr	8–12 hr

dabigatran etexilate mesylate

Dabigatran etexilate mesylate (Pradaxa) is the first oral direct thrombin inhibitor approved for prevention of strokes and thrombosis in patients with nonvalvular atrial fibrillation. Dabigatran etexilate mesylate is a prodrug that becomes activated in the liver. It specifically and reversibly binds to both free and clot-bound thrombin. Dabigatran etexilate mesylate is excreted extensively in the kidneys, and the dose is dependent upon kidney function. The normal dose is 150 mg twice daily, but it must be reduced to 75 mg twice daily if creatinine clearance is less than 30 mL per minute. There is no antidote to

dabigatran etexilate mesylate, and the most common and serious adverse effect is bleeding. No coagulation monitoring is required for dabigatran etexilate mesylate. Drug interactions include phenytoin (causing decreased effect) and amiodarone hydrochloride (causing increased effect). Information about storage and handling is discussed in the Nursing Process section later in the chapter.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	2–3 hr	2 hr	12–17 hr	12 hr

fondaparinux sodium

Fondaparinux sodium (Arixtra) is a selective inhibitor of factor Xa, which is indicated for prophylaxis or treatment of DVT or PE. It is contraindicated with known allergy or in patients with a creatinine clearance less than 30 mL per minute or a body weight of less than 50 kg. Bleeding is the most common and serious adverse reaction. Thrombocytopenia has also been reported, and therapy should be stopped if platelet count falls below 100 000 platelets per microlitre. It should not be given for at least 6 to 8 hours after surgery and should be used with caution in conjunction with warfarin or other anticoagulants.

Other adverse effects include anemia, increased wound drainage, postoperative hemorrhage, hematoma, confusion, urinary tract infection, hypotension, dizziness, and hypokalemia. There is no antidote for fondaparinux sodium, and its effect cannot be measured by standard anticoagulant tests. Fondaparinux sodium is given only by subcutaneous injection. The dose for prophylaxis is 2.5 mg daily. The dose for acute DVT or PE treatment is 5 to 10 mg daily, depending on body weight.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Subcut	2 hr	2–3 hr	17–21 hr	24 hr

argatroban

Argatroban, which has the same trade name, is a synthetic direct thrombin inhibitor that is derived from the amino acid L-arginine. It is indicated both for treatment of active HIT (rather than heparin) and for percutaneous coronary intervention procedures in patients at risk for HIT (i.e., those with a history of the disorder). It is given only by the IV route. A lower dosage must be used in patients with severe liver dysfunction.

Dosages

Selected Anticoagulant Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications/Uses
argatroban	Synthetic thrombin inhibitor	<i>Adults</i> IV: 2–10 mcg/kg/min until aPTT 1.5 to 3 times baseline	Thromboprevention and treatment of HIT and with PCI in patients at risk for HIT
 enoxaparin sodium (Lovenox)	LMWH	<i>Adults</i> Subcut: 30–40 mg every 12 hr for prophylaxis or 1 mg/kg every 12 hr for treatment	Prevention and treatment of thromboembolic and ischemic processes in unstable angina and in pre- and post-MI situations
heparin sodium	Natural anticoagulant	<i>Children</i> IV: Initial 75–100 units/kg, then 25–30 units/kg/hr; adjust to maintain aPTT of 60 to 85 seconds <i>Adults</i> Subcut: 333 units/kg followed by 250 units/kg every 12 hr IV: 10 000 units followed by 5 000–10 000 units every 4–6 hr IV infusion: 5 000 units followed by 20 000–40 000 units/day aPTT determines maintenance dose	Thrombosis/embolism, coagulopathies (e.g., DIC), DVT, and PE prophylaxis, clotting prevention (e.g., open heart surgery, dialysis)
dabigatran etexilate mesylate (Pradaxa)	Synthetic direct thrombin inhibitor	<i>Adults</i> PO: 110 mg bid (depending on kidney function)	Prevention of strokes and thrombosis in patients with nonvalvular atrial fibrillation; VTE prevention
fondaparinux (Arixtra)	Factor Xa inhibitor	Prophylaxis: 2.5 mg subcut daily Treatment: less than 50 kg: 5 mg daily; 50–100 kg: 7.5 mg daily; over 100 kg: 10 mg daily	Prevention and treatment of DVT and PE
 warfarin sodium (Coumadin)	anticoagulant	<i>Adults</i> INR determines maintenance dose, usually 2–10 mg/day	Thromboprevention and treatment in DVT, PE, atrial fibrillation, post-MI

aPTT, Activated partial thromboplastin time; DIC, disseminated intravascular coagulation; DVT, deep vein thrombosis; HIT, heparin-induced thrombocytopenia; INR, international normalized ratio; IV, intravenous; LMWH, low-molecular-weight heparin; MI, myocardial infarction; PCI, percutaneous coronary intervention; PE, pulmonary embolus; PO, oral; subcut, subcutaneous; VTE, venous thromboembolism.

TABLE 27.3 Anticoagulants: Drug Interactions

Drug	Mechanism	Result
Warfarin Sodium		
acetaminophen (high doses) amiodarone hydrochloride bumetanide furosemide	Displacement from inactive protein-binding sites	Increased anticoagulant effect
aspirin/other NSAIDs Broad-spectrum antibiotics Barbiturates Carbamazepine rifampin phenytoin		
amiodarone hydrochloride cimetidine ciprofloxacin erythromycin ketoconazole metronidazole omeprazole Sulfonamides Macrolides	Enzyme induction	Decreased anticoagulant effect
amiodarone hydrochloride cimetidine ciprofloxacin erythromycin ketoconazole metronidazole omeprazole Sulfonamides Macrolides	Enzyme inhibition	Increased anticoagulant effect
HMG-CoA reductase inhibitors (statins) Cholestyramine sucralfate	Impaired warfarin sodium absorption	Decreased anticoagulant effect
Natural health products: Dong quai Garlic Ginkgo	Unknown; case reports of increased INR	Increased bleeding risk from warfarin sodium
St. John's wort ginseng (alone and in Cold-FX)	Decreases INR	Increased risk of clotting
Heparin Sodium		
aspirin/other NSAIDs Oral anticoagulants Thrombolytics	Decreased platelet activity Additive	Increased bleeding risk Increased anticoagulant effect
Antiplatelets		
aspirin, other NSAIDS	Decreased platelet activity	Increased bleeding risk
warfarin sodium, heparin sodium, thrombolytics rifampin	Additive	Increased bleeding risk
Natural health products: Garlic Ginkgo Kava	Increased effects	Increased bleeding risk

HMG-CoA, hydroxymethylglutaryl-coenzyme A; INR, international normalized ratio; NSAIDs, nonsteroidal anti-inflammatory drugs.

Antiplatelet Drugs

Another class of coagulation modifiers that prevent clot formation is the antiplatelet drugs. The anticoagulants work in the clotting cascade; in contrast, antiplatelet drugs act to prevent platelet adhesion at the site of blood vessel injury, which occurs before the clotting cascade.

Platelets normally flow through blood vessels without adhering to their surfaces. Blood vessels can be injured by

Fig. 27.4 Relationship between platelets and the clotting cascade. ADP, adenosine diphosphate; 5-HT, serotonin; PF4, platelet factor 4; TXA₂, thromboxane A₂.

Fig. 27.5 Cyclooxygenase pathway. PG, prostaglandin; TXA₂, thromboxane A₂.

a disruption of blood flow, trauma, or the rupture of plaque from a vessel wall. When such events occur, substances such as collagen and fibronectin, which are present in the walls of blood vessels, become exposed. Collagen is a potent stimulator of platelet adhesion, as it is a prevalent component of the platelet membranes called *glycoprotein IIb/IIIa* (GP IIb/IIIa). Once platelet adhesion occurs, stimulators (compounds such as adenosine diphosphate [ADP], thrombin, thromboxane A_2 [TXA_2], and prostaglandin H_2) are released from the activated platelets. These cause the platelets to aggregate (accumulate) at the site of injury. Once at the site of vessel injury, the platelets change shape and release their contents, which include ADP, serotonin, and platelet factor IV. The hemostatic function of these substances is twofold. First, they function as platelet recruiters, attracting additional platelets to the site of injury; second, they are potent vasoconstrictors. Vasoconstriction limits blood flow to the damaged blood vessel to reduce blood loss.

A platelet plug that has formed at a site of vessel injury is not stable and can be dislodged. The clotting cascade is therefore stimulated to form a more permanent fibrin plug (blood clot). The role of platelets and their relationship to the clotting cascade are illustrated in [Fig 27.4](#).

Mechanism of Action and Drug Effects

Many of the antiplatelet drugs affect the cyclooxygenase pathway, which is one of the common final enzymatic pathways in the complex arachidonic acid pathway that operates within platelets and on blood vessel walls. This pathway as it functions in both platelets and blood vessel walls is illustrated in [Fig 27.5](#).

Aspirin is widely used for its analgesic, anti-inflammatory, and antipyretic properties (see Chapter 49). It also has antiplatelet effects. Aspirin acetylates and inhibits cyclooxygenase in the platelet irreversibly so that the platelet cannot regenerate this enzyme. Therefore, the effects of aspirin last the lifespan of a platelet, or 7 days. This irreversible inhibition of cyclooxygenase within the platelet prevents the formation of TXA_2 , a substance that causes blood vessels to constrict and platelets to aggregate. By preventing TXA_2 formation, aspirin prevents these actions, which results in dilation of blood vessels and prevention of platelets from aggregating or forming a clot.

Dipyridamole, another antiplatelet drug, also acts to inhibit platelet aggregation, by preventing the release of ADP, platelet factor IV, and TXA_2 , all substances that stimulate platelets to aggregate or form a clot. [Fig 27.4](#) shows how these substances accomplish this. Dipyridamole may also directly stimulate the release of prostacyclin and inhibit the formation of TXA_2 (see [Fig 27.5](#)).

Clopidogrel is a drug that belongs to the class of antiplatelet drugs called the *ADP inhibitors*. Its use has largely superseded that of the original ADP inhibitor ticlopidine hydrochloride. Clopidogrel's mechanism of action is entirely different from that of aspirin, as it inhibits platelet aggregation by altering the platelet membrane so that it can no longer receive the signal to aggregate and form a clot. This signal is in the form of **fibrinogen** molecules, which attach to glycoprotein receptors GP IIb/IIIa, on the surface of the platelet. Clopidogrel inhibits the activation of this receptor. Clopidogrel has been shown to

be somewhat better than aspirin at reducing the number of MIs, strokes, and vascular deaths in at-risk patients. The combination of aspirin and clopidogrel has been shown to be effective in patients with known cardiovascular disease but not in patients who have only risk factors. Prasugrel hydrochloride (Effient) is a newer antiplatelet drug, similar to clopidogrel, that is used primarily after interventional cardiac procedures and in patients who do not respond to clopidogrel. The newest antiplatelet drug is ticagrelor (BRILINTA). It is indicated for patients with acute coronary syndrome. It must be avoided in patients taking more than 100 mg of aspirin daily.

Pentoxifylline, another antiplatelet drug, is a methylxanthine derivative with properties similar to those of other methylxanthines, such as caffeine and theophylline (see Chapter 38). It was one of the earliest antiplatelet drugs but is now much less commonly used. It reduces the viscosity of blood by increasing the flexibility of red blood cells and reducing the aggregation of platelets. It is sometimes referred to as a *hemorheological drug*, or a drug that alters the fluid dynamics of the blood. The antiplatelet effects of pentoxifylline are attributed to its inhibition of ADP, serotonin, and platelet factor IV (see [Fig 27.4](#)). Pentoxifylline also stimulates the synthesis and release of prostacyclin (a natural occurring prostaglandin synthesized from arachidonic acid and a vasodilator) from blood vessels (see [Fig 27.5](#)). In addition, it may have effects on the fibrinolytic system by raising the plasma concentrations of tissue plasminogen activator (see [Fig 27.3](#)).

Another class of antiplatelet drugs is the GP IIb/IIIa inhibitors. They act by blocking the receptor protein by the same name that occurs in the platelet wall membranes. This protein plays a role in promoting the aggregation of platelets in preparation for fibrin clot formation. There are currently three available drugs in this class: tirofiban hydrochloride (Aggrastat), eptifibatide (Integrilin), and abciximab (ReoPro). The GP IIb/IIIa inhibitors are available only for IV infusion.

Indications

The therapeutic effects of antiplatelet drugs depend on the particular drug. Common indications for dual antiplatelet therapy (aspirin and P2Y₁₂ inhibitors) include postangioplasty and placement of a stent and 1 year post-MI). Aspirin has multiple therapeutic effects, but many of them vary depending on the dosage. Aspirin is recommended for stroke prevention in daily doses of 75 to 160 mg. (However, in clinical practice, dosages may vary.) Clopidogrel is also used for reducing the risk for fatal and nonfatal thrombotic stroke, for prophylaxis against transient ischemic attacks (TIAs), as well for post-MI prevention of thrombosis. Dipyridamole is used as an adjunct to warfarin in the prevention of postoperative thromboembolic complications. It is also used to decrease platelet aggregation in other thromboembolic disorders. GP IIb/IIIa inhibitors are used to treat acute unstable angina and MI and are also given during the endovascular procedure, coronary angioplasty. Their purpose is to prevent the formation of thrombi. This process is known as *thromboprevention*. This treatment approach is based on the fact that prevention of thrombus formation is easier and less risky overall, from a pharmacological standpoint, than is lysing a formed thrombus. Pentoxifylline is indicated for peripheral vascular disease.

Contraindications

Contraindications to the use of antiplatelet drugs include known drug allergy to a specific product, thrombocytopenia, active bleeding, leukemia, traumatic injury, GI ulcer, vitamin K deficiency, and recent stroke.

Adverse Effects

The potential adverse effects of the various antiplatelet drugs can be serious, and they all pose a risk for inducing a serious bleeding episode. The most common adverse effects are listed in Table 27.4.

Interactions

Some potentially dangerous drug interactions can occur with antiplatelet drugs. The use of dipyridamole with clopidogrel, aspirin, or nonsteroidal anti-inflammatory drugs (NSAIDs) produces additive antiplatelet activity and increased bleeding potential. The combined use of steroids or nonaspirin NSAIDs with aspirin can increase the ulcerogenic effects of aspirin. The

rectal forms. A combination form of aspirin and dipyridamole (Aggrenox) is used for antiplatelet purposes.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	15–30 min	0.25–2 hr	2–3 hr	4–6 hr

clonidogrel bisulphate

Clopidogrel bisulphate (Plavix) is currently the most widely used ADP inhibitor. It has superseded ticlopidine hydrochloride because of the serious adverse reactions associated with the latter drug, including life-threatening neutropenia and agranulocytosis. It was initially believed that clopidogrel might be free from such adverse effects. However, some case reports of clopidogrel-associated hematological adverse effects are emerging. It is available only in oral form. Prasugrel hydrochloride (Effient) and ticagrelor (BRILINTA) are similar to clopidogrel.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1–2 hr	1 hr	8 hr	7–10 days

DRUG PROFILES

Antiplatelet drugs are extremely useful in the management of thromboembolic disorders. Each has unique pharmacological properties, and therefore they all are somewhat different from one another.

aspirin

Aspirin is available in many combinations with other prescription and nonprescription drugs and has numerous product names. One unique contraindication for aspirin is its use in children and adolescents with flulike symptoms—its use in such situations is associated with the occurrence of Reye's syndrome, a rare, acute, and sometimes fatal condition involving liver and central nervous system (CNS) damage (see Chapter 49). The use of aspirin for adults 18 years and older is acceptable. There is also allergic cross-reactivity between aspirin and other NSAIDs. Patients with documented aspirin allergy must not receive NSAIDs. Aspirin is available in both oral and

eptifibatide

Eptifibatide (Integrilin) is a GP IIb/IIIa inhibitor, along with tirofiban hydrochloride (Aggrastat) and abciximab (ReoPro). These drugs are usually administered in critical care or cardiac catheterization laboratory settings where continuous cardiovascular monitoring is the norm. All are available only for IV use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	1 hr	Unknown	2–2.5 hr	4 hr

Dosages

Selected Antiplatelet Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications/Uses
 aspirin	Salicylate antiplatelet	<i>Adults</i> PO: 81–325 mg/day	MI prophylaxis TIA prophylaxis
 clopidogrel bisulphate (Plavix)	ADP inhibitor	<i>Adults</i> PO: 75 mg daily; 300 mg may be given as a one-time loading dose for patients with unstable angina, non-ST segment elevation	Reduction of atherosclerotic events; acute coronary syndrome without ST segment elevation
 eptifibatide (Integrilin)	GP IIb/IIIa inhibitor	<i>Adults Only</i> IV: Single bolus of 180 mcg/kg followed by continuous infusion of 2 mcg/kg/min; specific doses based on weight*	Unstable angina; non-ST segment elevation MI coronary angioplasty

ADP, Adenosine diphosphate; GP, glycoprotein; IV, intravenous; MI, myocardial infarction; PO, oral; TIA, transient ischemic attack.

*See manufacturer's directions for specific dose.

TABLE 27.4 Antiplatelet Drugs: Adverse Effects

Body System	Adverse Effects
Aspirin	
Central nervous	Drowsiness, dizziness, confusion, flushing
Gastrointestinal	Nausea, vomiting, GI bleeding, diarrhea
Hematological	Thrombocytopenia, agranulocytosis, leukopenia, neutropenia, hemolytic anemia, bleeding
Clopidogrel	
Cardiovascular	Chest pain, edema
Central nervous	Flulike symptoms, headache, dizziness, fatigue
Gastrointestinal	Abdominal pain, diarrhea, nausea
Miscellaneous	Epistaxis, rash, pruritus
Ticagrelor	
Respiratory	Dyspnea (on initiation)
Miscellaneous	Elevated uric acid levels
GP IIb/IIIa Inhibitors	
Cardiovascular	Bradycardia, hypotension, edema
Central nervous	Dizziness
Hematological	Bleeding, thrombocytopenia

combined use of aspirin and heparin with GP IIb/IIIa inhibitors also further enhances antiplatelet activity and increases the likelihood of a serious bleeding episode. In spite of all of these potentially harmful interactions, it is not uncommon to see patients on daily maintenance doses of aspirin for thrombopreventive purposes, sometimes in combination with other antiplatelet drugs. The most commonly used dose in this situation is the “baby aspirin” dose of 81 mg (the standard adult dose is 325 mg). Even though GP IIb/IIIa and heparin have additive therapeutic effects when given concurrently, and are listed as interacting drugs, it is common to see both used together. However, the therapeutic goal of heparin treatment, and thus the dose, is lower when used with a GP IIb/IIIa inhibitor.

Dosages

For dosage information on selected antiplatelet drugs, refer to the table on p. 456.

Thrombolytic Drugs

Thrombolytics are coagulation modifiers that lyse thrombi in the coronary arteries. This action re-establishes blood flow to the blood-starved heart muscle. If the blood flow is re-established early, the heart muscle and left ventricular function can be preserved. If blood flow is not re-established early, the affected area of the heart muscle becomes ischemic and eventually necrotic and nonfunctional.

Thrombolytic therapy made its debut in 1933, when a substance that broke down fibrin clots was isolated from a patient's blood. This substance was determined to be produced by certain bacteria growing in the patient's blood. The bacteria were found to be *beta-hemolytic streptococci* (group A), and the substance was eventually called *streptokinase* (SK).

SK was first used in a patient in 1947 to dissolve a clotted hemothorax, but it was not until 1958 that it was given to a patient

with an acute MI. In 1960, a naturally occurring human plasminogen activator called *urokinase* became available. Urokinase was found to exert fibrinolytic effects on pulmonary emboli. However, the results of the early thrombolytic trials conducted during the 1960s and 1970s involving patients who had had an acute MI were not taken seriously by the medical community. In the 1980s, the underlying cause of acute MI was determined to be due to coronary artery occlusion. This marked the start of rapid growth in the use of thrombolytic drugs for the early treatment of acute MI.

Since that time, several new thrombolytics have become available for this and other clinical uses. Tissue plasminogen activator (t-PA) and anisoylated plasminogen streptokinase activator complex (APSAC) are two of these drugs. Following the advent of these new thrombolytics came the results of several large, landmark thrombolytic research studies. These studies demonstrated that early thrombolytic therapy could produce a 50% reduction in mortality, a reduction in the infarct size, an improvement in left ventricular function, and a reduction in the incidence and severity of heart failure. These findings and developments, along with a better understanding of the pathogenesis of acute MI, have led the way to the advancements made in the treatment of acute MI. However, the use of thrombolytics has been almost completely replaced by interventional cardiology procedures, such as percutaneous coronary intervention. Thrombolytics are still a viable option in hospitals that do not offer percutaneous coronary intervention. Currently available thrombolytic drugs include t-PAs (alteplase [Activase] and tenecteplase [TNKase]). For dosage information on thrombolytics, see the table on p. 458.

Mechanism of Action and Drug Effects

There is a fine balance between the formation and dissolution of a clot. The coagulation system is responsible for forming clots, whereas the fibrinolytic system is responsible for dissolving clots. The natural fibrinolytic system within the blood takes several days to break down a thrombus. This is of little value in the case of a clotted blood vessel that supplies blood to the heart muscle. Necrosis of the myocardium would not be prevented by these natural means, but thrombolytic drug therapy activates the fibrinolytic system to break down the thrombus in the blood vessel quickly so that the delivery of blood to the heart muscle via the coronary arteries is quickly re-established. This action prevents myocardial tissue (heart muscle) and heart function from being destroyed. Thrombolytics accomplish this by activating the conversion of plasminogen to plasmin, which breaks down, or lyses, the thrombus (see Fig 27.3). Plasmin is a proteolytic enzyme, which means that it breaks down proteins. It is a relatively non-specific serine protease that is capable of degrading proteins such as fibrin, fibrinogen, and other procoagulant proteins such as factors V, VIII, and XII. In other words, the substances that form clots are destroyed by plasmin. Essentially, thrombolytic drugs work by mimicking the body's own process of clot destruction. Although the individual thrombolytic drugs are somewhat diverse in their actions, they all have this common result.

SK, the original thrombolytic enzyme, and the naturally occurring urokinase have been removed from the market, primarily because of their adverse effects—due to the fact that they are not fibrin specific. The newer thrombolytics have chemical specificity for fibrin threads (**fibrin-specificity**) and work

Dosages

Selected Thrombolytic Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications/Uses
 alteplase (Activase)	t-PA	Adults IV: 0.9 mg/kg (total dose not to exceed 90 mg) over 60 min; 10% given as an IV bolus over 1 min; must be given within 3 hr of onset of symptoms	Acute ischemic stroke, pulmonary embolism, myocardial infarction (STEMI)
Tenecteplase (TNKase)	t-PA	Adults IV: 30–50 mg (based on patient weight) bolus over 5 min	Myocardial infarction

IV, Intravenous; t-PA, tissue plasminogen activator.

primarily at the site of a clot. They still carry some bleeding risk but much less than that of the thrombolytic enzymes.

t-PA is a naturally occurring plasminogen activator secreted by vascular endothelial cells (the walls of blood vessels). However, the amount secreted naturally is not sufficient to dissolve a coronary thrombus quickly enough to restore circulation to the heart and brain and reduce the severity of a myocardial infarction or ischemic stroke. Recombinant deoxyribonucleic acid (rDNA) techniques are now used to produce t-PA, and thus it can be administered in quantities sufficient to dissolve a thrombus quickly. It is fibrin specific (clot specific); that is, only the fibrin clot stimulates t-PA to convert plasminogen to plasmin. Therefore, it has a lower propensity to induce a systemic thrombolytic state, compared to the thrombolytic enzymes.

Indications

The purpose of the thrombolytic drugs is to activate the conversion of plasminogen to plasmin, the enzyme that breaks down a thrombus. The presence of a thrombus that interferes significantly with normal blood flow on either the venous or the arterial side of the circulation is an indication for the use of thrombolytic therapy. An exception may be a thrombus that has formed in blood vessels that connect directly with the CNS. The indications for thrombolytic therapy include acute MI, arterial thrombosis, DVT, occlusion of shunts or catheters, pulmonary embolism, and acute ischemic stroke.

Contraindications

Contraindications to the use of thrombolytic drugs include known drug allergy to the specific product and any preservatives, as well as concurrent use of other drugs that alter clotting. Any history of recent major surgery, trauma, or bleeding (e.g., hemorrhagic stroke) are also contraindications to their use.

Adverse Effects

The most common undesirable effect of thrombolytic therapy is internal, intracranial, and superficial bleeding. Other problems

DRUG PROFILES

All thrombolytic drugs exert their effects by activating plasminogen and converting it to plasmin, which is capable of digesting fibrin, a major component of clots.

alteplase

Alteplase (Activase) is a pharmaceutically available recombinant t-PA (rt-PA) made through recombinant DNA techniques. It is fibrin specific and therefore does not produce a systemic lytic state. Tenecteplase (TNKase) is a newer form of alteplase that is given by IV push after MI. Because rt-PA is present in the human body in a natural state, its administration for therapeutic use does not induce an antigen–antibody reaction. The drug rt-PA has a short half-life of 5 minutes. It is believed to open the clogged artery rapidly, but its action is short-lived. Therefore, it is given with heparin to prevent reocclusion of the affected blood vessel. Alteplase is available only in parenteral form. There is also a smaller dosage form of alteplase, Cathflo® Activase, that is used to flush clogged IV or arterial lines. Alteplase is used specifically in ischemic stroke, and tenecteplase is used specifically for lysis of suspected occlusive coronary artery thrombi associated with evolving transmural MI.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	immediate	60 min	5 min	Dependent on infusion duration

include hypersensitivity, anaphylactoid reactions, nausea, vomiting, and hypotension. These drugs can also induce cardiac dysrhythmias.

Toxicity and Management of Overdose. Acute toxicity primarily causes an extension of the adverse effects of the thrombolytic drug. Treatment is symptomatic and supportive, as thrombolytic drugs have a relatively short half-life and no specific antidotes.

Interactions

The most common effect of drug interactions is an increased bleeding tendency resulting from the concurrent use of anticoagulants, antiplatelets, or other drugs that affect platelet function.

A laboratory test interaction that can occur with thrombolytic drugs is a reduction in plasminogen and fibrinogen levels.

Dosages

For dosage information on alteplase, refer to the table above.

Antifibrinolytic Drugs

Individual antifibrinolytic drugs have varying mechanisms of action, but all prevent the lysis of fibrin. Fibrin is the substance that helps make a platelet plug insoluble and anchors the clot to the damaged blood vessel (see Figs 27.1 and 27.2). The term

TABLE 27.5 Antifibrinolytics: Mechanisms of Action

Antifibrinolytic Drug	Mechanism of Action
Synthetic drug: tranexamic acid (Cyklokapron)	Forms a reversible complex with plasminogen and plasmin. By binding to the lysine binding site of plasminogen, tranexamic acid displaces plasminogen from the surface of fibrin. This prevents plasmin from lysing the fibrin clot. Therefore, the drug can work only if a clot has formed.
Natural drug: aprotinin (Artiss®, Trasylol)	Inhibits the proteolytic enzymes trypsin, plasmin, and kallikrein, which lyse proteins that destroy fibrin clots. By inhibiting these enzymes, aprotinin prevents the degradation of the fibrin clot. It is also thought to inhibit the action of the complement system.
Other: desmopressin acetate (DDAVP)	Works by increasing von Willebrand factor, which anchors platelets to damaged vessels via the GP IIb platelet receptor. It appears that desmopressin acts as a general endothelial stimulant, stimulating factor VIII, prostaglandin I ₂ , and plasminogen-activated release.

GP, glycoprotein.

antifibrinolytic refers to what these drugs do, which is to prevent the lysis of fibrin; in doing so, these drugs promote clot formation. For this reason, they are also called *hemostatic* drugs. Their effects are opposite to those of anticoagulant and antiplatelet drugs, which *prevent* clot formation. Two synthetic antifibrinolytics are available—tranexamic acid and desmopressin—as well as one natural antifibrinolytic drug, aprotinin. Dosages, indications, and other information for desmopressin appear in the associated Dosages table on p. 460. There are also hemostatic drugs that are used topically (on the skin or tissue surface) in surgical settings to stop excessive bleeding. These include topical thrombin, microfibrillar collagen, absorbable gelatin, and oxidized cellulose.

Although not technically antifibrinolytic drugs, there are three drugs used for the treatment of hemophilia. These are produced by recombinant DNA technology, which eliminates the risk associated with obtaining them from human blood. Products currently available include rVII, rVIII, and rIX. As mentioned earlier, factors VII, VIII, and IX are important in the coagulation pathway. Warfarin also inhibits these factors. These products are used in patients with hemophilia and are also used in patients with severe bleeding due to warfarin therapy.

Mechanism of Action and Drug Effects

Antifibrinolytic drugs vary in several ways. The various antifibrinolytic drugs and their proposed mechanisms of action are described in [Table 27.5](#).

The drug effects of antifibrinolytics are specific and limited. They do not have many effects outside of their hematological ones. Tranexamic acid and aprotinin inhibit the breakdown of fibrin, which prevents the destruction of formed platelet clots. Desmopressin causes a dose-dependent increase in the concentration of plasma factor VIII (von Willebrand factor), along with an increase in the plasma concentration of rt-PA. The overall effect is increased platelet aggregation and clot formation. This drug is also an analogue of antidiuretic hormone and is discussed further in Chapter 31.

Indications

Antifibrinolytics are useful in both the prevention and treatment of excessive bleeding resulting from systemic hyperfibrinolysis or surgical complications. They have also proved successful

TABLE 27.6 Antifibrinolytics: Adverse Effects

Body System	Adverse Effects
Cardiovascular	Dysrhythmias, orthostatic hypotension, bradycardia
Central nervous	Headache, dizziness, fatigue, hallucinations, convulsions
Gastrointestinal	Nausea, vomiting, abdominal cramps, diarrhea

in arresting excessive oozing from surgical sites such as chest tubes, as well as in reducing total blood loss and the duration of bleeding in the postoperative period.

Desmopressin may also be used in patients who have hemophilia A or type I von Willebrand disease. As stated earlier, recombinant factors VII, VIII, and IX are used to treat hemophilia or to stop bleeding caused by excessive warfarin therapy.

Contraindications

Contraindications to the use of antifibrinolytic drugs include known drug allergy to a specific product and disseminated intravascular coagulation, which could be worsened by these drugs.

DRUG PROFILES

desmopressin acetate

Desmopressin acetate (DDAVP®) is a synthetic polypeptide. It is structurally similar to vasopressin, or antidiuretic hormone, the natural human posterior pituitary hormone (see [Chapter 31](#)). Because of these physical characteristics, it is most often used to increase the resorption of water by the collecting ducts in the kidneys to prevent or control polydipsia, polyuria, and dehydration in patients with diabetes insipidus due to a deficiency of endogenous posterior pituitary vasopressin or in patients with polyuria and polydipsia resulting from trauma or surgery in the pituitary region.

Desmopressin also causes a dose-dependent increase in plasma factor VIII (von Willebrand factor), along with an increase in t-PA, which results in increased platelet aggregation and clot formation; thus, it is often used to stop bleeding. Desmopressin is contraindicated in patients with a known hypersensitivity to it and in those with nephrogenic diabetes insipidus. It is available in both injectable and

intranasal dosage forms as well as oral disintegrating tablets. Desmopressin nasal spray and tablets are used for primary nocturnal enuresis.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	15–30 min	1–2 hr	2 hr	Unknown

Adverse Effects

The adverse effects of antifibrinolytic drugs are infrequent and mild. However, there have been rare reports of these drugs causing thrombotic events, such as acute cerebrovascular thrombosis and acute MI. The common adverse effects of antifibrinolytics are listed in Table 27.6.

Interactions

When drugs such as estrogens or oral contraceptives are used concurrently with tranexamic acid or aprotinin, additive effects may occur, resulting in increased coagulation. Few specific interactions have been reported for desmopressin, although caution should be used when giving it to patients receiving lithium carbonate, heparin, patients who have consumed alcohol or those receiving large doses of epinephrine. Drugs such as chlorpropamide and fludrocortisone-21-acetate may potentiate the antidiuretic response, which may lead to edema.

Dosages

For dosage information on desmopressin, refer to the table below.

NURSING PROCESS

Coagulation modifiers have a variety of uses, including the following: (1) prevention or elimination of clotting in a peripherally inserted catheter (PIC) (or peripherally inserted central catheter [PICC]), (2) maintenance of patency (without clotting) of a central venous catheter, (3) clot prevention in coronary artery bypass grafting, (4) prevention of clotting after major vessel injury, (5) treatment of thrombophlebitis to prevent venous or arterial thromboembolism, and (6) prevention of clotting with the use of prosthetics (e.g., heart valve replacements) and in atrial fibrillation. The drugs that are used for these different conditions are varied in their mechanisms of action, and the related general and specific nursing process issues will be discussed.

ASSESSMENT

Begin the nursing assessment associated with the use of all coagulation modifier drugs by taking a thorough patient health history, including the following: any drug or food allergies, current medical problems, underlying systemic disease processes, past and present medical history, family health history, dietary habits, changes in body weight over time, ability to perform activities of daily living, level of exercise or degree of sedentary lifestyle, employment activities, success of previous treatment regimens, blood pressure, pulse rate, respirations, body weight, height, recent dietary intake, and fluid intake. A medication history is also needed and should include a listing of all drugs the patient takes on a daily basis such as prescription drugs, over-the-counter medications, and natural health products, as well as any intake of nicotine, alcohol, or other substances.

Perform a thorough patient assessment to identify the presence of the following risk factors: immobility, history of limited activity or prolonged bedrest (i.e., generally for longer than 3 to 5 days); dehydration; obesity; smoking; heart failure; mitral or aortic stenosis; coronary artery disease with documented atherosclerosis or arteriosclerosis; peripheral vascular disease; pelvic, gynecological, genitourinary (GU), abdominal, orthopedic, or major vascular surgery; history of thrombophlebitis, DVT, thromboembolism including pulmonary embolism, MI, or atrial fibrillation; peripheral edema; trauma to the lower extremities; use of oral contraceptives; and recent extended airline travel time. If the patient has a history of clotting disorders or thromboembolism, assess and document the following: presenting signs and symptoms of thrombophlebitis of the leg such as calf edema; pain, warmth, or redness directly over the vessel (more indicative of a superficial clot); increased diameter measurement of the calf of the affected leg; pain in the calf with dorsiflexion (often called Homans sign; however, asking the patient to dorsiflex is a controversial method of assessment and is now discouraged, as the test may dislodge the clot) or pain upon gentle passive compression of the calf muscle against the tibia; and presenting signs and symptoms of pulmonary embolism such as chest pain, cough, dyspnea, tachypnea, drop in oxygen saturation (by oximetry or blood gas measurement), hemoptysis, tachycardia, drop in blood pressure, and possible shock. All contraindications, cautions, and drug interactions also need to be assessed (see pharmacology discussion) and documented.

Because of the effects of anticoagulants, it is also important to assess the skin, oral mucous membranes, gums, urine, and stool

Dosages

Selected Antifibrinolytic Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications/Uses
desmopressin acetate (DDAVP)	Synthetic posterior pituitary hormone	<i>Children and Adults</i> IV: 0.3 mcg/kg infused over 20–30 min; preoperative use: drug is administered 30 min before surgery	Surgical and postoperative hemostasis and management of bleeding in patients with hemophilia A or type I von Willebrand disease

IV, Intravenous.

LAB VALUES RELATED TO DRUG THERAPY

ANTICOAGULANTS

Laboratory Test	Normal Ranges	Rationale for Assessment
Activated partial thromboplastin time (aPTT), partial thromboplastin time (PTT)	With heparin therapy, aPTT values must fall between 1.5 and 2.5 times the control or baseline value. Normal control values are 25 to 35 seconds. Target therapeutic level of anticoagulation is between 45 and 70 seconds.	Therapeutic levels of aPTT indicate decreased levels of clotting factors and subsequent clotting activity; aPTT is the more sensitive part of PTT (and often replaces it). It is used to determine whether there are deficiencies in the patient's intrinsic coagulation pathway and to monitor heparin sodium therapy. aPTT is sensitive to changes in blood clotting factors, except for factor VII. Therefore, it is used to assess normal blood coagulation. With continuous IV infusions of heparin, aPTT levels can be drawn at any time, but with intermittent infusions the aPTT should be drawn approximately 1 hour before a dose of heparin is scheduled to be given. Monitoring of aPTT is not done for prophylactic doses (i.e., 5 000 units every 12 hours subcut).
Prothrombin time (PT)	The normal control PT value ranges from 11 to 13 seconds; target therapeutic level of anticoagulation aimed at 1.5 times the control or about 18 seconds.	Prothrombin is a vitamin K-dependent protein and a major component of the clotting process. It reflects clotting activity and is used to monitor effectiveness of warfarin therapy. PT values vary for each laboratory centre and are based on the specifics of the testing procedure.
International normalized ratio (INR)	Target levels of INR range from 2 to 3 or an average of 2.5. For individuals taking warfarin for treatment of recurring systemic clots or emboli and those with mechanical heart valves, the target INR may be 2.5 to 3.5, with a middle value of 3.	INR determination is a routine test, based on a calculation of the PT, to evaluate coagulation while patients are taking warfarin. When the therapy is initiated, the INR and PT are measured daily until a stable daily dose is reached (i.e., the dose maintains the PT and INR within therapeutic ranges and does not cause bleeding). INR results actually reflect a dose of warfarin given 36 to 72 hours prior to the testing. Advantages of INR testing include the fact that there is more consistency among laboratories and a more consistent warfarin dosage. Some laboratories report INR and PT together.

for any evidence of bleeding. Assess patients for any blood in the urine or stool, easy bruising, excessive bleeding from toothbrushing or shaving, or unexplained epistaxis while receiving these medications, and report any such findings. Laboratory tests performed before and during therapy with these drugs usually include, but are not limited to, baseline complete blood counts, hemoglobin level, hematocrit, lipoprotein fractionation, triglyceride and cholesterol levels, various clotting studies, and liver function tests. The serum laboratory tests that are usually ordered with anticoagulant therapy are presented in the Lab Values Related to Drug Therapy table.

With heparin and LMWHs, it is critical to patient safety to continuously assess the skin to identify potential subcutaneous injection sites. For these injection sites, avoid any area within 5 centimetres of the umbilicus, open wounds, scars, open or abraded areas, incisions, drainage tubes, stomas, or areas of bruising or oozing. These sites would be at higher risk for further tissue damage with injection of the anticoagulant. Appropriate sites for injection of subcutaneous heparin and LMWHs include the upper, outer area of the arms; the thigh; and the subcutaneous fatty area across the lower abdomen and between the iliac crests (see Chapter 10 for more information).

With use of the parenteral anticoagulant heparin, to ensure patient safety and prevent injury, assess for allergies, contraindications, cautions, and drug interactions (see pharmacology discussion). Severe hypertension, peptic ulcer disease, ulcerative colitis, aneurysms, malignant hypertension, alcoholism, and traumatic brain injury are all conditions in which a bleed is potential and could be precipitated by parenteral

anticoagulation. An important caution for heparin use is pregnancy or lactation; however, if there is a need for an anticoagulant during pregnancy, heparin is the drug of choice, not warfarin. Other information is shown in [Table 27.1](#).

It is crucial to patient safety to remember that heparin is *not* interchangeable unit for unit with drugs in another class of anticoagulants, the LMWHs. Although the use of LMWHs leads to fewer adverse reactions in some patients, they are still associated with specific contraindications, cautions, and drug interactions (see previous discussion). When assessing the medication profile, remember that a potentially deadly medication error is to give heparin in combination with enoxaparin (or any LMWH). Always double-check that enoxaparin and heparin are never given to the same patient. The same assessment parameters discussed earlier for heparin are also appropriate for LMWHs. In addition, LMWHs contain sulphites and benzyl alcohol, and so assess patients for allergies to these substances. It is important to note again that the LMWHs differ from standard heparin and also from each other and, for this reason, they are not interchangeable. LMWHs may be used for outpatient anticoagulant therapy because these drugs usually require less close monitoring than standard heparin use. Assess the results of clotting studies prior to therapy.

The oral anticoagulant warfarin and its related contraindications, cautions, and drug interactions were discussed earlier in this chapter. All of the previously mentioned assessment parameters are applicable to warfarin. Because of the drug's action, withhold warfarin (as with all drugs altering bleeding or clotting), as ordered, before the patient undergoes any dental procedures or if

there is any evidence of tissue necrosis, gangrene, diarrhea, intestinal flora imbalances, or steatorrhea. It is important to emphasize that this drug is indicated for prophylaxis and long-term treatment of a variety of thromboembolic disorders (see previous pharmacology discussion); constant and skillful assessment of the patient and clotting results is required. Most health care providers use standard protocols for warfarin to assist in dosing the drug based on PT and INR values. The most common starting dose for warfarin is 5 mg daily. However, the dose can range from 1 to 10 mg and may occasionally be even higher (e.g., 12 mg), depending on individual patient response. In most situations, dosage for adults is between 1 and 5 mg orally, every day. In addition, it is important to understand the pharmacokinetics of warfarin because it takes about 3 days for the drug to reach a steady state. Patients taking heparin may receive warfarin before discontinuation of heparin for anticoagulation.

Dabigatran etexilate mesylate (Pradaxa), although an anticoagulant, is the first oral direct thrombin inhibitor. Additional assessment parameters include kidney function studies. No coagulation monitoring is needed for this drug. Assess for drug interactions with phenytoin and amiodarone. With fondaparinux sodium (Arixtra), carefully assess kidney function. As with dabigatran etexilate mesylate, its effect cannot be measured by standard anticoagulant tests.

With antiplatelet drugs, obtain a thorough nursing history and medication history, as well as a physical assessment, before beginning drug therapy. Possible drug interactions, cautions, and contraindications have been discussed, but close assessment of any bleeding is extremely important to patient safety. Because aspirin, other NSAIDs, and other antiplatelet drugs alter bleeding times,

withhold these drugs as ordered for 5 to 7 days before the patient undergoes surgical procedures. Specific guidelines are generally given by the health care provider to avoid the concurrent use of other anticoagulants, antiplatelets, and fibrinolytics. See Chapter 49 for more information on aspirin. Perform a baseline cardiovascular assessment before beginning clopidogrel, and document any pre-existing chest pain, edema, headache, dizziness, epistaxis, or flu-like symptoms. Laboratory values usually include complete blood count, hemoglobin level and hematocrit, platelet counts, and PT and INR values. These laboratory values provide baseline levels with which therapy values can be compared. If platelet counts are at or fall below $80 \times 10^9/L$, notify the health care provider; antiplatelet therapy will most likely not be initiated (or will be discontinued).

In addition, it is important to patient safety to re-emphasize that aspirin must not be used in children and adolescents, patients with any bleeding disorder, pregnant or lactating women, or patients with vitamin K deficiency or peptic ulcer disease. Major consequences could occur if aspirin were used by such patients—for example, Reye's syndrome in children and adolescents, teratogenic effects in pregnant women, and ulcers or bleeding tendencies in patients with vitamin K deficiency or peptic ulcer disease. Know how each of the coagulation modifier drugs acts in the body to establish a sound knowledge base, to support critical thinking and decision making; for example, such understanding would inform the decision to call the health care provider and not to administer two antiplatelets at the same time or the decision not to give a thrombolytic with heparin, warfarin, or aspirin or other NSAIDs. This type of critical drug information is important to ensure that patients receive the safest and most appropriate care during all phases of the nursing process.

The GP IIb/IIIa inhibitors (e.g., eptifibatide, tirofiban, and abciximab) require the same baseline assessment information (i.e., vital signs, medical history, history of chest pain and heart disease, complete blood cell counts, hemoglobin level, hematocrit, kidney function tests, and platelet counts) as well as assessment for any edema, bradycardia, or leg pain. Before or during therapy, should platelet counts fall below $90 \times 10^9/L$, contact the health care provider for further orders.

Thrombolytics require similar assessments, including attention to baseline complete blood counts and results of clotting studies. Additional concerns include a history of hypotension and cardiac dysrhythmias. The use of alteplase and other thrombolytics always carries the possibility of major concerns, cautions, contraindications, and drug interactions (see previous pharmacology discussion). Constantly assess any arterial punctures, venous cut-down sites, PICC sites, central infusion ports, or other possible sites for bleeding. Do not use IM injections in any situation, as they pose problems with bleeding. As with any drugs that alter clotting and platelet activity, the thrombolytics are associated with the risk of bleeding from wounds or from the GI, GU, or respiratory tract, so assess any drainage, urine, stool, emesis, sputum, and secretions for the presence of blood.

Antifibrinolytics require the same skillful assessment of baseline parameters and laboratory testing listed above; however, there are additional concerns for patients with dysrhythmias, hypotension, bradycardia, convulsive disorders, nausea, vomiting, abdominal pain, or diarrhea. These are possible adverse

CASE STUDY

Heparin Therapy

In the past 2 years, Maciej, a 56-year-old lawyer, has had three episodes of DVT. All occurred without complications, and all were treated successfully with anticoagulant therapy and bedrest. He has now arrived at the emergency department because of increased pain and swelling in his left calf that has

lasted for the past 3 days. Initially, he is given 5 000 units subcutaneous of heparin and admitted to a unit for observation.

1. What nursing actions should be implemented to ensure the accuracy and safety of the continuous heparin infusion?
2. What patient findings would indicate a therapeutic response to the heparin therapy?

Maciej suddenly reports numbness and tingling in his lower extremities with accompanying changes in muscle strength and sensation, 12 hours after the initiation and continuation of heparin therapy.

3. What would be the most appropriate nursing actions to implement?

Maciej developed shortness of breath, a drop in blood pressure, and tachycardia while in hospital. The physician ordered anticoagulant therapy, and Maciej was started on a continuous infusion of 25 000 units of heparin in 500 mL of 0.9% sodium chloride (prefilled bag).

1. What was the expected new diagnosis for the patient?
2. Explain how the heparin infusion was a warranted medication for the new diagnosis.

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

DVT, deep vein thrombosis.

BOX 27.1 Anticoagulation Therapy and Related Nursing Considerations**Subcutaneous Heparin and Low-Molecular-Weight Heparin Injections**

- After thoroughly checking the health care provider's order, assess the patient for any allergies, contraindications, cautions, or drug interactions.
- Always begin by performing hand hygiene, and maintain standard precautions. Gloves must be worn. Prefilled syringes are available. When the medication is not available in a prefilled or premeasured syringe, use a 1.5 to 2 cm, 25- to 28-gauge needle. Check the site for bleeding or bruising and do not massage or rub the site before or after the injection. *Do not aspirate* before injecting to prevent hematoma formation. See Chapter 10 for more information on the technique associated with heparin and LMWH injections.
- Make sure the patient is comfortable; then remove your gloves and wash your hands. Document the medication given on the medication record, and monitor the patient for a therapeutic response as well as for adverse reactions.

Intravenous Heparin Administration

- Always double-check the specific health care provider's order for dosage and rate of infusion before beginning therapy. Always follow the "rights" of medication administration to prevent overdosing or erroneous dosing. Make sure the proper diluent is used. Check the compatibility of solutions or other drugs before beginning the infusion.
- For continuous IV administration of heparin sodium, an IV pump must be used to ensure a precise rate of infusion.
- Continuous dosing is preferred over intermittent dosing because continuous dosing helps to maintain blood levels of the drug and because intermittent IV dosing is associated with a higher risk for bleeding abnormalities than continuous dosing.
- Treatment by continuous IV infusion generally begins with a loading dose and is followed by a maintenance dose. Be aware that dosage adjustments must be made exactly as ordered. The patient's activated partial thromboplastin time (aPTT) or results of other related clotting studies are used as parameters for dosing of standard heparin.
- In the past, for intermittent infusions, a heparin lock was used. Heparin locks are now referred to as *intermittent infusion locks* or *saline locks* (because the

locks are flushed with isotonic saline and not heparin). The exception is with PICC lines and central lines, in which heparin is still used as a flush.

- Intermittent infusions of heparin sodium are usually ordered to be given every 4 to 6 hours because of heparin's short half-life. Needleless systems are used for intermittent infusions and all other types of IV infusions.
- Regardless of the type of IV infusion (i.e., intermittent or continuous), it is crucial to check the site to determine whether infiltration has occurred, to prevent hematoma formation. If infiltration is suspected, remove the lock and replace it at a new site before the next scheduled infusion. Document appropriately.
- The therapeutic dosage of heparin is guided by aPTT, with a targeted level of 1.5 to 2.5 times the control (normal) value. The aPTT is measured within 24 hours of beginning therapy, 24 to 48 hours after therapy starts, and 1 to 2 times weekly for about 3 to 4 weeks, on average. With long-term therapy, aPTT is monitored 1 to 2 times per month.

Oral Anticoagulant Administration

- It is important to recheck the health care provider's orders and the patient's medication and medical history before administering any coagulation modifier drug. Always check to make sure the patient has no known hypersensitivity to the drug.
- Scored tablets may be crushed and may be given with or without food.
- Many more drugs can interact with oral anticoagulants than with heparin, especially those that are highly protein bound (see [Table 27.3](#)). Always check the patient's medication list before initiating therapy with warfarin.
- Dosages of warfarin are calculated based on INR blood values. The INR is also used to monitor the effectiveness of therapy. Remember, however, that dosing is highly individualized. Warfarin therapy overlaps with heparin therapy (for about 5 days) until the INR is within therapeutic range for at least 24 hours, at which time the heparin is discontinued. This is referred to as *bridge therapy*.
- Oral anticoagulants are to be administered at the same time every day to maintain steady blood levels.
- Document the dose, time of administration, and any other pertinent facts with these and all other medications.

effects; thus, in these situations, the health care provider may need to decrease the dosage of medication.

- Patient will remain free from injury resulting from either the disease or the medication being taken.

◆ NURSING DIAGNOSES

- Inadequate knowledge as a result of new medication regimen and the need for altered lifestyle
- Potential risk for ineffective cerebral tissue perfusion as a result of the clotting disorder, such as thrombus and subsequent embolus formation
- Potential risk for injury as a result of possible adverse reactions to drugs altering blood clotting

◆ PLANNING**◆ Goals**

- Patient will demonstrate adequate knowledge regarding medication therapy and its potential adverse effects, as well as the need for lifestyle changes.
- Patient will exhibit improved blood flow and tissue perfusion as a result of the therapeutic effects of the anticoagulant.

◆ Expected Patient Outcomes

- Patient states the adverse effects of the drug therapy, ways to monitor for complications of the anticoagulants, the importance of scheduling follow-up appointments with the health care provider and of frequent laboratory studies, and the circumstances under which to contact the health care provider to prevent complications such as hemorrhage.
 - Patient states the nature of and rationale for the lifestyle changes needed, such as improved diet, exercise, and avoidance of smoking.
- Patient shows evidence of improved cerebral circulation while maintaining alertness, orientation, and stable neurological status.
 - Patient remains free of evidence of peripheral clotting, with maintenance of pink, warm extremities with strong pedal pulses, or experiences a return to predisease state of maximal tissue perfusion.

- Due to safe medication use, patient is free from bruising, bleeding problems, and any other injury to self.

◆ IMPLEMENTATION

Routinely monitor vital signs, heart sounds, peripheral pulses, and neurological status in all patients, during and immediately after anticoagulant therapy. The various laboratory values to be monitored are presented in Laboratory Values Related to Drug Therapy on p. 461. If there is any change in pulse rate or rhythm, blood pressure, or level of consciousness, or unexplained restlessness occurs, contact the health care provider immediately. These changes may indicate bleeding or hemorrhage.

Knowledge of the proper techniques of administration is crucial for safe and effective use of heparin and the LMWHs (see [Box 27.1](#) for other dosing and route information). Heparin is given by the subcutaneous or IV routes but not intramuscularly. Inadvertent IM injection can be easily avoided if only subcutaneous syringes that include a 1.5 cm, 25- to 28-gauge needle are used. No major harm would result if a subcutaneous dose was inadvertently administered intravenously. If rapid anticoagulation is needed, IV heparin, by continuous or intermittent infusion, may be prescribed. Whether the drug is given by IV infusion or subcutaneous injection, monitor daily clotting study results, and perform these studies as ordered for therapeutic doses (monitoring is not done for prophylactic treatment). The drug effects of heparin can be reversed with the IV administration of protamine sulphate. With subcutaneous heparin, several doses of protamine sulphate may be needed to reverse the anticoagulant effect because of the variable rates of absorption of this dosage form. See [Box 27.1](#) for the procedure for the intermittent or continuous IV administration of heparin.

Administer LMWHs by subcutaneous injection deep into the injection site (see previous discussion), using the same techniques as for heparin. The abdomen is the preferred site. Rotate sites frequently. Avoid aspiration with subcutaneous injections to prevent hematoma formation and tissue injury. To avoid bruising, do not massage the site after the injection. Prefilled syringes of LMWHs are available for inpatient use and for at-home treatment. Solutions may be clear to pale yellow. The usual length of therapy is approximately 5 to 10 days, and it is important to be constantly aware of any bleeding problems while the patient is taking this or any other clot-altering drugs. Complete blood counts, platelet counts, and stool tests for occult blood will probably be performed during therapy, for monitoring purposes. Tests for occult blood in the stool can be done if occult blood test paper and developer are available. Blood in the stool may occur as an adverse effect with LMWHs or any clot-altering drugs.

When the oral anticoagulant warfarin is prescribed, therapy is often initiated while the patient is still receiving heparin. This bridging or cross-over dosing is done purposely to allow time for the blood levels of warfarin to rise, so that when the heparin is eventually discontinued, therapeutic anticoagulation levels of warfarin will have been achieved. The full therapeutic effect of warfarin does not occur until 4 to 5 days after the first dose. Monitoring of the results of the various clotting studies is still of

utmost priority, as is watching for any clotting or bleeding problems. The administration procedures for warfarin are outlined in [Box 27.1](#).

For conversion from heparin to an oral anticoagulant such as warfarin, the dose of the oral drug is the usual initial dosage amount, with the health care provider using the PT and INR levels to determine the next appropriate dosage of warfarin. Once there is continuous therapeutic anticoagulation coverage and warfarin has reached therapeutic levels, the heparin or LMWH may then be discontinued without tapering. If uncontrolled bleeding occurs with any of these medications, take action to control bleeding, institute emergency measures to stabilize the patient's condition, and contact the health care provider immediately.

The anticoagulant dabigatran etexilate mesylate (Pradaxa) is given orally. It is packaged in aluminum blister strips and bottles. Dabigatran etexilate mesylate is to be stored in and dispensed from its original container (e.g., blister pack or bottle). It is important to keep the bottle cap closed tightly after each use and keep the bottle away from excessive moisture, heat, or cold. If not stored properly and with the desiccant (drying agent to absorb moisture) in the packaging cap, the substance in the drug is easily broken down and potency is lost. This would result in less therapeutic effectiveness. This storage information is not widely disseminated and so it is important to be aware of these precautions. The drug can maintain its potency for up to 4 months if kept in the original bottle or blister package, not stored or placed in any other type of container, opened one bottle at a time, and closed tightly after the capsule is removed. The blister package is opened at time of use and the blister is not to be punctured prior to the use of the drug. Fondaparinux sodium (Arixtra) is given subcutaneously and, as with dabigatran etexilate mesylate, has no standard anticoagulant tests for monitoring.

Of benefit to counter the toxic effects of anticoagulants is the use of antidotes. The antidote to hemorrhage or uncontrolled bleeding resulting from heparin or LMWH therapy is protamine sulphate. For heparin, 1 mg of protamine sulphate given intravenously neutralizes 100 units of heparin. For the LMWHs, 1 mg of protamine sulphate neutralizes each 1 mg of LMWH given. It is important to note that too-rapid infusion may lead to acute hypotensive episodes, bradycardia, dyspnea, and transient feelings of warmth and flushing. If the heparin overdose has resulted in a large blood loss, replacement with packed red blood cells may be necessary.

The aPTT ranges and hematocrit levels are generally used as ordered to monitor bleeding, clotting, and risk for bleeding. Always monitor patients receiving anticoagulant therapy, especially for any changes in blood pressure and pulse rate. The antidote to oral anticoagulant (warfarin) therapy is vitamin K. See the pharmacology section for more discussion on dosing and the impact of vitamin K on the effects of warfarin. When given intravenously, vitamin K may lead to anaphylaxis with resultant dyspnea, dizziness, rapid or weak pulse, chest pain, and hypotension, which may progress to shock and cardiac arrest. Always check facility policy and the health care provider's order for the specific dosage and route of administration. It is important to

continuously monitor the patient's vital signs, heart parameters, bleeding times, and clotting study results.

Constantly monitor the patient being treated with antiplatelet drugs (or any clot-altering drug) for signs and symptoms of bleeding during and after their use, including epistaxis, hematuria, hematemesis, easy or excessive bruising, blood in the stools, and bleeding of the gums. If invasive procedures must be performed or injections given, apply appropriate pressure to bleeding sites, and closely watch all areas of venous or arterial catheter insertion for bleeding. Advise patients to take extended-release dosage forms in their entirety and without chewing or crushing. Enteric-coated aspirin is best taken with 180 to 240 mL of water and with food to help reduce GI upset. To avoid irritation to the esophagus, after each dose of aspirin, instruct the patient to remain upright and not lie down for up to 30 minutes. If aspirin has a strong, vinegar-like odour, discard the drug. Interventions with clopidogrel therapy are similar to those with aspirin. Advise the patient to report the following if they occur: aches in the joints, back pain, dizziness, severe headache, dyspepsia, flulike signs and symptoms, and epigastric pain.

Antiplatelet drugs are often discontinued for 7 days prior to surgery, as ordered. However, some surgical procedures (e.g., cardiovascular surgery) may warrant that the patient remain in an anticoagulated state intraoperatively. Oral forms of dipyridamole are recommended to be taken on an empty stomach; however, if this is not tolerated, the patient can take the drug with food. If nausea occurs, a carbonated beverage, unsalted crackers, or dry toast may help to alleviate this adverse effect. In addition, it may take up to 2 to 3 months of continuous therapy for the drug to reach therapeutic levels. Encourage patients to change positions slowly and take their time going from lying to sitting to standing because of the adverse effects of dizziness and orthostatic hypotension with antiplatelets.

Nursing considerations associated with GP IIb/IIIa inhibitors such as abciximab, eptifibatide, and tirofiban hydrochloride include some similar, yet different, nursing actions to antiplatelet drugs. Close monitoring of all vital signs, electrocardiogram readings, peripheral pulses, heart sounds, skin colour, and temperature are an important part of nursing care during and after the use of these drugs. Because GP IIb/IIIa inhibitors are used in combination with heparin to treat patients suspected of having acute coronary syndrome or those undergoing percutaneous transluminal coronary angioplasty (PTCA), there is always concern for the stability of the patient as well as a high risk for serious bleeding and extension of an acute MI. The patient in this situation is at risk for other medical complications, and this risk may be intensified by the drug. Avoid further invasive procedures while the patient is taking GP IIb/IIIa inhibitors to help prevent bleeding. If invasive procedures are required, continuously monitor for bleeding, and measure all vital parameters before, during, and after the procedure.

Protect IV tirofiban from light. Discard any unused solutions 24 hours after an infusion has been started. Do NOT give any other drugs with this drug except for heparin, which may be administered through the same IV line. For PTCA, abciximab, in particular, can be given by bolus or by continuous infusion; closely monitor infusion rates. Manufacturer guidelines call for the use of a sterile, nonpyrogenic, low protein-binding 0.2-

0.22-micron filter, and while the vascular shield is in position, keep the patient on complete bedrest, with the head of the bed elevated at 30 degrees. Maintain the affected extremity in a straight position, and constantly monitor peripheral pulses and the colour and temperature of the distal extremities. Once the sheath is removed, apply pressure to the femoral artery for at least 30 minutes, either by manual or mechanical pressure. Apply a pressure dressing once bleeding has stopped. Closely monitor the site for any oozing or bleeding.

If serious bleeding occurs, discontinue the GP IIb/IIIa inhibitor and heparin (the usual protocol for PTCA) immediately, monitor the patient closely, and notify the health care provider immediately for initiation of emergency treatment. Always move and handle these patients with caution and avoid unnecessary trauma because of the risk for hematoma formation or bleeding. Do *not* take blood pressures in the lower extremities, but keep a close and constant watch on the patient's blood pressure (for hypotension) and pulse rate (for tachycardia). Also closely monitor the patient for any reports of abdominal or back pain, severe headache, and any other signs or symptoms of hemorrhage. When adhesive or sticky tape is removed, take care to avoid tearing or ripping the skin, which would lead to tissue trauma and further risk for bleeding. Monitor aPTT levels after the procedure and observe for bleeding, with attention to IM injection sites, arterial or venous puncture sites, and nasogastric tubes and urinary catheters. Avoid invasive procedures, if at all possible, during or immediately after the angioplasty.

Nursing considerations related to thrombolytics are quite similar to those for the other drugs already discussed. Specifically, carry out the preparation for their IV administration per manufacturer guidelines and per protocol. Avoid invasive procedures during the use of these drugs. Avoid simultaneous use of anticoagulants or antiplatelets. Frequently monitor IV infusion sites for bleeding, redness, and pain. IM injections of other drugs are contraindicated to prevent tissue damage and bleeding. Report any bleeding from gums or mucous membranes or the occurrence of epistaxis or increased pulse (higher than 100 beats per minute) to the health care provider immediately, and frequently monitor all vital signs. Other nursing considerations include monitoring for hypotension, restlessness, and a decrease in hemoglobin level or hematocrit, which are to be reported to the health care provider immediately (as they indicate possible shock). Advise patients to report pink, red, or cloudy urine; black, tarry stools or frank red blood in the stools; abdominal or chest pain; dizziness; or severe headache.

Thrombolytics require reconstitution for IV dosing with sodium chloride or 5% dextrose in water. Gently roll, don't shake, the solutions to mix and maintain a stable solution. Continually monitor the INR, aPTT, platelet counts, and fibrinogen levels, beginning no later than 2 to 3 hours after the administration of thrombolytics. Measure the patient's fibrinogen level to check for the occurrence of fibrinolysis. With the breakdown of fibrin (or fibrinolysis), INR will increase and aPTT will be prolonged. If bleeding occurs, the health care provider will most likely discontinue the drug and replace fibrinogen through infusions of whole blood plasma or cryoprecipitate. The antifibrinolytics aminocaproic acid or tranexamic acid may also be given. See Patient Teaching Tips.

With antifibrinolytics, it is important to understand the reasons for the use of these drugs, such as to stop bleeding from overdoses of thrombolytic drugs or to control bleeding during heart surgery. Tranexamic acid is usually given intravenously until bleeding is controlled. Because of the possibility of drug-induced internal, intracranial, and superficial bleeding, closely monitor the patient, and if there is any change in motor strength or level of consciousness, notify the health care provider immediately. Nurses must apply their knowledge of certain adverse effects of drugs like these to prevent complications, maintain safety, and return patients to a healthier state. It is also important to monitor heart rate and blood pressure, with attention to quality and strength of peripheral pulses. For patients with hemophilia, tranexamic acid may be used to help decrease bleeding from dental extractions.

◆ EVALUATION

Monitoring for the therapeutic and adverse effects of coagulation modifier drugs is crucial for their safe use. Because these drugs are used for a variety of purposes, therapeutic responses vary. Some of the therapeutic effects include decreases in chest pain, dizziness, and other neurological symptoms. Adverse effects of anticoagulants include bleeding and hematoma formation (heparin); thrombocytopenia (heparin and LMWHs); bleeding, dizziness, shortness of breath, and fever (direct thrombin inhibitors); bleeding, hematoma, dizziness, and GI distress (selective factor Xa inhibitors); and bleeding, lethargy, and muscle pain (warfarin). Early signs of drug overdose of any of the anticoagulant drugs include bleeding of the gums while brushing the teeth, unexplained nosebleeds or bruising, and heavier-than-usual menstrual bleeding. Abdominal pain, back pain, bloody or tarry stools, bloody urine, constipation, blood in the sputum, severe or continuous headaches, and vomiting of frank red blood or a coffee ground–like substance, indicating old blood, are all possible indications of internal bleeding.

Therapeutic effects of clopidogrel and other antiplatelet drugs include a decrease in the occurrence of clotting events

such as TIAs and strokes. The adverse effects of aspirin, as an antiplatelet drug, include dizziness, confusion, nausea, vomiting, GI bleeding, diarrhea, thrombocytopenia, agranulocytosis, leukopenia, and neutropenia. Adverse effects of clopidogrel include chest pain, flulike symptoms, headache, dizziness, fatigue, abdominal pain, diarrhea, and epistaxis. Therapeutic levels of anticoagulants and other clot-altering drugs or coagulation modifier drugs are also monitored by laboratory studies such as aPTT, PT, and INR, described in Lab Values Related to Drug Therapy, on p. 461. Remember, however, that aPTT levels are measured with heparin, whereas PT and INR are measured with warfarin. Once the level of the particular drug stabilizes and maintenance therapy is ongoing, the clotting studies may be performed at 1- to 4-week intervals, depending on the specific drug, the patient's responses, and the patient's overall physical condition. If a heparin or LMWH overdose occurs, the antidote is protamine sulphate, whereas vitamin K, or phytonadione, is the antidote to oral anticoagulant overdose.

Continuous monitoring of patients for signs and symptoms of internal or external bleeding is crucial during both the initiation and maintenance of therapy. Therapeutic effects of thrombolytics include improvement in cardiac status during an acute MI, improved blood flow from resolution of DVT, and improved neurological status. Adverse effects include bleeding, hypotension, and cardiac dysrhythmias. Therapeutic effects of antifibrinolytics include the arrest of oozing of blood from a surgical site or a decrease in blood loss. Adverse effects for which to monitor with the antifibrinolytics include orthostatic hypotension, dysrhythmias, headache, dizziness, fatigue, convulsions, nausea, vomiting, abdominal cramps, and diarrhea. Because of the complexity and life-threatening nature of the conditions for which these drugs are used, continuously monitor and re-evaluate the patient's response to the treatment, document this response accordingly, and always keep goals and outcome criteria in the plan of care to serve as benchmarks. Following the evaluation phase, the patient will hopefully emerge experiencing full therapeutic effects and minimal adverse and toxic effects related to drug therapy.

PATIENT TEACHING TIPS

- Coagulation modifier drugs are used in patients with heart valve replacements and to prevent serious complications related to clotting, such as strokes, MIs, clot formation (DVT of the legs), and TIAs. Their use necessitates frequent and close monitoring. Educate patients that a healthy lifestyle is an important part of therapy and includes eating the right foods, reducing weight if needed, ceasing smoking, controlling blood pressure, and reducing stress. Advise patients to provide a listing of all medications to all possible health care providers (e.g., dentists).
- Direct patients to take all of a clot-altering drug exactly as prescribed because too little of the drug may lead to clot formation and too much of the drug may lead to bleeding. Regular follow-up appointments are an important part of patient care, with frequent blood tests to monitor therapeutic effects and

adverse effects of the medication. The results of blood tests will help health care providers determine proper dosage.

- At all times, patients must carry an identification card or wear a MedicAlert bracelet or necklace indicating allergies, medical diagnoses, drugs being taken, health care providers' names and telephone numbers, and an emergency contact name and number.
- Home heparin therapy may require that patients receive injections for a period of time, and LMWHs are generally used. If there is a switch from heparin to warfarin, there may be an overlap period of approximately 3 to 5 days, during which both drugs are taken to allow therapeutic levels of the oral warfarin to be reached before the heparin is discontinued. Provide complete and thorough instructions to patients, and use return demonstrations to evaluate learning (see Chapter 7).

- Advise patients to report any unusual bleeding from anywhere on the body, including nosebleeds or excessive vaginal or menstrual bleeding, or any occurrence of blurred vision, severe headache, vomiting of blood, dizziness, fainting, fever, muscle or limb weakness, or rash.
- With dabigatran etexilate mesylate (Pradaxa), educate patients to protect the original bottle from moisture. Once a bottle is opened, it must be used within 4 months; this needs to be written on the bottle with the date of expiration. Instruct the patient to remove only 1 capsule from the opened bottle at the time of use and to immediately and tightly close the bottle. These capsules are *not* to be repackaged or placed in other pillboxes or organizers. Encourage patients to take the medication with food if dyspepsia occurs.
- To ensure safe, effective treatment, patients should be encouraged to keep a journal with daily notation of how they are feeling as well as how they are tolerating the medication and any adverse effects.
- To reduce risk factors for cardiovascular disease, the health care provider may recommend consumption of a low-fat, low-cholesterol diet; cholesterol-lowering drug therapy; weight reduction; control of blood pressure if hypertension is present; avoidance of smoking; management of stress; and regular exercise.
- Teach the patient about clot prevention measures to minimize sluggish circulation (e.g., avoid tight-fitting clothing and socks, minimize sitting for prolonged periods of time, avoid crossing the legs at the knees, avoid prolonged bed-rest, make stops during long trips every 1 to 2 hours to walk around, and keep well hydrated).
- When patients are taking any of the anticoagulants (oral drugs, heparin, or LMWHs) or clot-altering drugs, encourage them to avoid brushing the teeth with a hard-bristled toothbrush, shaving with a straight razor (instead, use an electric shaver), and engaging in any activity that would increase their risk of tissue injury. Always caution patients to be careful when shaving, trimming nails, gardening, or participating in rough or contact sports.
- Instruct patients to avoid ingesting large amounts of foods high in vitamin K (e.g., broccoli, Brussels sprouts, collard greens, kale, lettuce, mustard greens, tomatoes) while taking an anticoagulant, to minimize food–drug interactions. Also advise against fad diets as these can alter INR results. Instruct patients to avoid beverages that are high in vitamin K such as green tea, cranberry juice, and alcohol.
- Capsicum (hot red pepper), feverfew, garlic, ginger, ginkgo, ginseng, and St. John's wort are some natural health products that have potential interactions with coagulation modifier drugs, especially with warfarin. Educate patients about these and other interactions.
- Patients should immediately report to their health care providers any decrease in urine output; constant ringing in the ears (tinnitus); swelling of the feet, ankles, or legs; dark urine; clay-coloured stools; abdominal pain; rash (medication use needs to be discontinued as ordered if rash occurs); or blurred vision.
- If patients omit doses of medications, advise them to contact their health care providers for further instructions.
- Patients should be aware that oral dosage forms of any coagulation modifier medications are to be taken with at least 240 mL of water and with food, to help minimize stomach upset.
- Patients should keep all medication containers out of the reach of children and use childproof caps. All syringes, needles, and other equipment must be kept out of the reach of children and other individuals.

KEY POINTS

- Coagulation modifiers act by preventing or promoting clot formation, lysing a preformed clot, or reversing the action of anticoagulants. Coagulation modifiers include anticoagulants, antiplatelets, thrombolytics, antifibrinolytics, and reversal drugs.
- Warfarin prevents clot formation by inhibiting vitamin K–dependent clotting factors (II, VII, IX, and X) and is used prophylactically to prevent clots from forming; it cannot lyse preformed clots.
- The degree of anticoagulation (for any of the medications) is monitored by the PT.
- Heparin, given intravenously or subcutaneously, prevents clot formation by binding to AT-III, which turns off certain activating factors. The overall effect is to inactivate the coagulation pathway and prevent clots from forming. Heparin does not lyse (break down) a clot. Antiplatelet drugs prevent clot formation by preventing platelet involvement in clot formation.
- Thrombolytic drugs are able to lyse preformed clots in blood vessels such as those that supply the heart with blood. Therapeutic effects for which to monitor include improved tissue perfusion, decreased chest pain, and prevention of further myocardial damage. Before giving these drugs, a thorough physical assessment should be performed, and pertinent laboratory values (e.g., INR, aPTT, PT) should be checked.
- Antifibrinolytics prevent the lysis of fibrin, thus promoting clot formation, and have an effect opposite to that of the anticoagulants. Nursing care is individualized and is based on the characteristics of the patient, thorough assessment data, existing medical conditions, and the specific drug.

EXAMINATION REVIEW QUESTIONS

1. The nurse is monitoring a patient who is receiving anti-thrombolytic therapy in the emergency room because of a possible myocardial infarction. Which adverse effect would be of the greatest concern for the nurse?
 - a. Dizziness
 - b. Blood pressure of 130/98 mm Hg
 - c. Slight bloody oozing from the IV insertion site
 - d. Irregular heart rhythm
2. A patient is receiving instructions for warfarin therapy and asks the nurse about what medications she can take for headaches. What medication will the nurse instruct the patient to avoid?
 - a. Opioids
 - b. Acetaminophen (Tylenol®)
 - c. NSAIDs
 - d. There are no restrictions while taking warfarin
3. The nurse is teaching a patient about self-administration of enoxaparin (Lovenox). Which statement by the nurse should be included for appropriate patient education?
 - a. "We will need to teach a family member how to give this drug in your arm."
 - b. "This drug is given in the folds of your abdomen, but at least 5 centimetres away from your navel."
 - c. "This drug needs to be taken at the same time every day with a full glass of water."
 - d. "Be sure to massage the injection site thoroughly after receiving the drug."
4. A patient is receiving dabigatran etexilate mesylate (Pradaxa), 150 mg by mouth, twice daily, as part of treatment for atrial fibrillation. Which condition, if present, would be a concern for a patient receiving this dose?
 - a. Asthma
 - b. Kidney impairment
 - c. History of myocardial infarction
 - d. Elevated liver enzymes
5. A patient has received a double dose of heparin during surgery and is bleeding through the incision site. The surgeons attempt to stop the bleeding at the incision site. What would be the anticipated order to be given by the health care provider for the nurse?
 - a. Give IV vitamin K as an antidote
 - b. Give IV protamine sulphate as an antidote
 - c. Call the blood bank for an immediate platelet transfusion
 - d. Obtain an order for packed red blood cells
6. A patient is starting warfarin (Coumadin) therapy as part of treatment for atrial fibrillation. The nurse will follow what principles of warfarin therapy? (Select all that apply).
 - a. Teach proper subcutaneous administration
 - b. Administer the oral dose at the same time every day
 - c. Assess carefully for excessive bruising or unusual bleeding
 - d. Monitor laboratory results for a target INR of 2 to 3
 - e. Monitor laboratory results for a therapeutic aPTT value of 1.5 to 2.5 times the control value
7. The order for enoxaparin (Lovenox) reads: "Give 1 mg/kg subcut every 12 hours." The patient weighs 242 lb, and the medication is available in an injection form of 120 mg/0.8 mL. How many milligrams will this patient receive? How many millilitres will the nurse draw up for the injection? (Round to hundredths.)

CRITICAL THINKING ACTIVITIES

1. After a patient undergoes total hip replacement, the nurse reviews the new postoperative orders and notes an order for dalteparin sodium (Fragmin) 2 500 international units subcutaneously 6 hours after surgery, then 5 000 international units daily for 7 days. When assessing the patient before administering the drug, the nurse sees that the patient has an epidural catheter for administration of pain medication. What is the nurse's priority action regarding the administration of the dalteparin sodium?
 2. A patient is going home from hospital and will be taking warfarin (Coumadin). While discussing his medications just before his discharge, the patient says, "I want to get back to taking my vitamins with ginkgo. They really help my memory." What is the priority as the nurse answers the patient's question?
 3. A patient who has been receiving a heparin infusion for DVT has a new order for warfarin (Coumadin). When the nurse explains that the warfarin is another drug to prevent blood clot formation, the patient asks if it is safe to be taking "two blood thinners at the same time." What is the nurse's best response to this patient's question?

Antilipemic Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Explain the pathophysiology of primary and secondary dyslipidemia, including causes and risk factors.
2. Discuss the different types of lipoproteins and their role in cardiovascular diseases and in dyslipidemia.
3. List the drug classes with specific drugs that are used to treat dyslipidemia.
4. Compare the drugs used to treat dyslipidemia, including the rationale for their use in treatment as well as their indications, mechanisms of action, dosages, routes of administration, adverse effects, toxicity, cautions, contraindications, and associated drug interactions.
5. Develop a collaborative plan of care that includes all phases of the nursing process for patients receiving antilipemic drugs.

KEY TERMS

Antilipemic drugs Drugs that reduce lipid levels. (p. 469)

Apolipoproteins The protein components of lipoproteins. (p. 470)

Cholesterol A fat-soluble steroid alcohol found in animal fats, oils, and egg yolks and widely distributed in the body, especially in the bile, blood, brain tissue, liver, kidneys, adrenal glands, and myelin sheaths of nerve fibres. (p. 469)

Chylomicrons Microscopic droplets made up of fat and protein that are produced by cells in the small intestine and released into the bloodstream. Their main purpose is to carry fats to tissues throughout the body, primarily the liver. Chylomicrons consist of about 90% triglycerides and small amounts of cholesterol, phospholipids, and proteins. (p. 470)

Exogenous lipids Lipids originating outside the body or an organ (e.g., dietary fats). (p. 470)

Foam cells The characteristic initial lesions of atherosclerosis, also known as *fatty streaks*. (p. 471)

Hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors A class of cholesterol-lowering drugs

that act by inhibiting the rate-limiting step in cholesterol synthesis; also commonly referred to as *statins*. (p. 473)

Hypercholesterolemia A condition in which higher than normal amounts of cholesterol are present in the blood. High levels of cholesterol and other lipids may lead to the development of atherosclerosis and serious illnesses such as coronary artery disease. (p. 470)

Lipoprotein A conjugated protein synthesized in the liver that contains varying amounts of triglycerides, cholesterol, phospholipids, and protein; classified according to its composition and density. (p. 470)

Statins A class of cholesterol-lowering drugs more formally known as *HMG-CoA reductase inhibitors*. (p. 473)

Triglycerides Compounds that consist of fatty acids and a type of alcohol known as *glycerol*. Triglycerides make up most animal and vegetable fats and are the principal lipids in the blood, where they circulate bound to a protein, forming high-density and low-density lipoproteins (HDLs and LDLs). (p. 469)

DRUG PROFILES

-  atorvastatin (atorvastatin calcium)*, p. 475
-  cholestyramine, p. 477
-  ezetimibe, p. 479
-  gemfibrozil, p. 478
-  nicotinic acid, p. 478
-  rosuvastatin, p. 476
-  Key drug

* Full generic name is given in parentheses. For the purposes of this text, the more common, shortened name is used.

OVERVIEW

Key to understanding the use of **antilipemic drugs** is a working knowledge of the pathophysiology of lipid abnormalities and their contribution to coronary artery disease (CAD). It is also important to understand, at the cellular level, the transport and use of **cholesterol** and **triglycerides** in the human body. Lipoproteins, apolipoproteins, receptors, and enzyme systems are all integral parts of these processes. Armed with this knowledge, clinicians can develop and implement a rational approach to treatment using both nonpharmacological and pharmacological interventions. See the **Natural Health**

Products boxes on p. 472 and below for information on some common dietary products patients may use to control dyslipidemia.

NATURAL HEALTH PRODUCTS

Garlic (*Allium sativum*)

Overview

Garlic obtains its pharmacological effects from the active ingredient allicin.

Common Uses

Antispasmodic, antiseptic, antibacterial and antiviral, antihypertensive, antiplatelet, lipid reducer

Adverse Effects

Dermatitis, vomiting, diarrhea, anorexia, flatulence, antiplatelet activity

Potential Drug Interactions

May inhibit iodine uptake. May interact with warfarin, diazepam, and protease inhibitors. Use with nonsteroidal anti-inflammatory drugs may enhance bleeding.

Contraindications

Contraindicated in patients who will undergo surgery within 2 weeks and in patients with human immunodeficiency virus (HIV) infection or diabetes.

Follow manufacturer directions on container for use of specific preparations.

Flax (*Linum usitatissimum*)

Overview

Flax is a flowering annual found in the Europe and North America. Both the seed and the oil of the plant are used medicinally.

Common Uses

Treatment of atherosclerosis, hypercholesterolemia, hyper-triglyceridemia, gastrointestinal distress (especially constipation), menopausal symptoms, bladder inflammation; among other uses

Adverse Effects

Diarrhea, allergic reactions

Potential Drug Interactions

Antihyperglycemic drugs: Theoretically can potentiate hypoglycemic effects

Anticoagulant drugs: Theoretically can potentiate anticoagulant effects by reducing platelet aggregation and prolonging bleeding time

Contraindications

Pregnancy (more information needed); use with caution in diabetes and cardiovascular disease

Follow manufacturer directions on container for use of specific preparations.

LIPIDS AND LIPID ABNORMALITIES

Primary Forms of Lipids

Triglycerides and cholesterol are the two primary forms of lipids in the blood. Triglycerides function as an energy source and are stored in adipose tissue. Cholesterol is primarily used to make steroid hormones, cell membranes, and bile acids. Triglycerides and cholesterol are both water-insoluble fats that must be bound to specialized lipid-carrying proteins called **apolipoproteins**. This combination of triglycerides and cholesterol with an apolipoprotein is referred to as a **lipoprotein**. Lipoproteins

TABLE 28.1 Lipoprotein Classification

Classification	Lipid Content	Protein Content
Chylomicron	Most	Least
VLDL	↑ Least	↓ Most
LDL		
IDL		
HDL	Least	Most

HDL, high-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; VLDL, very-low-density lipoprotein.

transport lipids via the blood. They are made up of a lipid core of triglycerides, cholesterol esters, or both, which is surrounded by a thin layer of phospholipids, apolipoproteins, and cholesterol. The various types of lipoproteins are classified according to their density and the type of apolipoproteins they contain. The lipoproteins and their classifications are presented in **Table 28.1**.

Cholesterol Homeostasis

Cholesterol homeostasis involves a complex array of biochemical factors. **Fig. 28.1** summarizes the major concepts. Fats are taken into the body through the diet and are broken down in the small intestine to form triglycerides. These triglycerides are then incorporated into **chylomicrons** in the cells of the intestinal wall and are absorbed into the lymphatic system. The primary purpose of chylomicrons is to transport lipids obtained from dietary sources (**exogenous lipids**) from the intestines to the liver, to be used to make steroid hormones, lipid structural components for peripheral body cells, and bile acids.

The liver is the major organ where lipid metabolism occurs. The liver produces very-low-density lipoprotein (VLDL) from both endogenous and exogenous sources. The major role of VLDL is the transport of endogenous lipids to peripheral cells. Once VLDL is circulating, it is enzymatically cleaved by lipoprotein lipase and loses triglycerides. This creates intermediate-density lipoprotein (IDL), which is soon also cleaved by lipoprotein lipase to create low-density lipoprotein (LDL). Cholesterol is almost all that is left in LDL after this process. Any tissues that require LDL, such as endocrine cells, have LDL receptors. LDL and about half of IDL are reabsorbed from the circulation into the liver by means of LDL receptors on the liver.

High-density lipoprotein cholesterol (HDL-C) is produced in the liver and intestines and is also formed when chylomicrons are broken down. Lipids that are not used by peripheral cells are transferred as cholesterol esters to high-density lipoprotein (HDL). HDL then transfers the cholesterol esters to IDL to be returned to the liver. HDL is responsible for the “recycling” of cholesterol. HDL is sometimes referred to as the *good lipid* (or *good cholesterol*) because it is believed to be cardioprotective.

If the liver has an excess amount of cholesterol, the number of LDL receptors on the liver decreases, resulting in an accumulation of LDL in the blood. One explanation for **hypercholesterolemia** (high levels of cholesterol in the blood), therefore, is down-regulation (reduced production) of liver LDL receptors. A major function

Fig. 28.1 Cholesterol homeostasis. *CE*, cholesterol ester; *HDL*, high-density lipoprotein; *HMG-CoA*, hydroxymethylglutaryl-coenzyme A; *IDL*, intermediate-density lipoprotein; *LCAT*, lecithin cholesterol acetyltransferase; *LDL*, low-density lipoprotein; *TG*, triglyceride; *VLDL*, very-low-density lipoprotein.

of the liver is to manufacture cholesterol, a process that requires acetyl coenzyme A (CoA) reductase. Inhibition of this enzyme thus results in decreased cholesterol production by the liver.

ATHEROSCLEROTIC PLAQUE FORMATION

Lipids and lipoproteins participate in the formation of atherosclerotic plaque, which subsequently leads to the development of CAD. The primary event that causes atherosclerosis appears to be repeated, subtle injury to the artery's wall through various mechanisms, including smoking, elevated blood pressure, diabetes, and elevated cholesterol. An ongoing inflammatory response plays a central role in all stages of the formation of an atherosclerotic plaque, also referred to as *atherogenesis*. When serum cholesterol levels are elevated, LDLs are oxidized by reactive oxygen-free radicals produced by endothelial cells. In response to the injury, circulating monocytes adhere to the smooth endothelial surface of the coronary vasculature. These monocytes burrow into the next layer of the blood vessel (sub-endothelial tissue) and differentiate into macrophage cells, which then absorb the oxidized LDLs and slowly become large **foam cells**, the characteristic precursor lesion of atherosclerosis, also known as the *fatty streak*. Once this process is established, it is usually present throughout the coronary and systemic circulation. There is also smooth muscle proliferation and migration from the tunica media (middle layer of the artery) to the intima (inner layer of the artery) in response to cytokines secreted by damaged endothelial cells. This process eventually forms a fibrous capsule covering the fatty streak.

CHOLESTEROL AND CORONARY ARTERY DISEASE

Numerous epidemiological trials have shown that as blood cholesterol levels increase, the incidence of death and disability related to CAD also increases. The risk for CAD in patients with cholesterol levels of 5.2 mmol/L is three to four times greater than that for patients with levels lower than 4 mmol/L. The incidence of CAD is lower in premenopausal women. This lower incidence is thought to be secondary to the effects of estrogen because the risk of CAD climbs considerably in post-menopausal women. However, there is controversy in regard to this longstanding belief because two major trials of estrogen replacement therapy (ERT) did not demonstrate prevention of cardiovascular events in women receiving ERT. Other experimental studies that looked for any benefits of low-dose estrogen therapy in male patients also failed to demonstrate significant cardioprotective efficacy.

Heart disease is one of the leading causes of death in Canada, with an estimated 51 000 related deaths occurring yearly, divided almost equally between men and women ([Government of Canada, 2018](#)). Thus, there are two goals of treatment: primary prevention in patients with risk factors, and secondary prevention of subsequent cardiac events in individuals who have CAD or have experienced a coronary event (e.g., myocardial infarction [MI]). The benefits of cholesterol reduction, specifically elevated low-density lipoprotein cholesterol (LDL-C) reduction, have been illustrated in a variety of trials. Results of some of the larger investigations support the view that, in patients with

known risk factors for CAD, therapy with an antilipemic drug can reduce an individual's relative risk for CAD by 25 to 35%. Drug therapy can also reduce the incidence of first-time MIs and death caused by heart disease. Benefits of cholesterol reduction for secondary prevention have been illustrated in a variety of trials as well. In patients with documented CAD, treatment with a cholesterol-lowering drug has many positive outcomes: decreased coronary events, regression of coronary atherosclerotic lesions, reduced inflammation, and prolonged survival.

Measures taken early in life to reduce and maintain cholesterol levels within a desirable range can have dramatic effects in preventing CAD. These include lifestyle modifications in diet, weight, and activity level. [The Heart and Stroke Foundation of Canada \(2018\)](#) recommends four specific diets to reduce the risk of CAD: the DASH diet, vegetarian diet, Mediterranean diet, and the MIND diet. Diets lower in saturated fat and higher in fibre and plant chemicals known as *sterols* and *stanols*, and possibly the substitution of soy-based proteins for animal proteins, appear to promote healthier lipid profiles. The consumption of fatty fish or dietary supplements containing omega-3 fatty acids appears to have beneficial effects on triglyceride and HDL-C levels. Even modest weight reduction and exercise can have substantial therapeutic benefits in both the improvement of lipid profiles and reduction of the likelihood of heart disease.

NATURAL HEALTH PRODUCTS

Omega-3 Fatty Acids (Fish Oil)

Overview

Omega-3 fatty acids are essential fatty acids, most commonly supplied as fish oil products. Several over-the-counter (OTC) products are available.

Common Uses

Cholesterol reduction

Adverse Effects

Rash, burping, allergic reactions, possible increase in total cholesterol or LDL levels in those patients with dyslipidemia combined with weight gain

Potential Drug Interactions

Anticoagulant drugs: May prolong bleeding time. There is a theoretical risk of increased bleeding when omega-3 fatty acids are taken with anticoagulant drugs, but studies to date are inconclusive.

Contraindications

Pregnancy (more information is needed), allergy to fish oil

Follow manufacturer directions on the bottle or box for use of specific preparations.

DYSLIPIDEMIAS AND TREATMENT GUIDELINES

The decision to prescribe antilipemic drugs as an adjunct to diet therapy in patients with an elevated cholesterol level is based on the patient's clinical profile. This includes the patient's age, sex, menopausal status for women, family history, and response to dietary treatment, as well as the presence of risk factors (other than dyslipidemia) for premature CAD and the cause, duration, and phenotypic pattern of the patient's dyslipidemia.

BOX 28.1 Coronary Artery Disease

Risk Factors

- Age: males over 40 years; females over 50 years or post-menopausal*
- Family history: History of premature CAD (e.g., MI or sudden death before 55 years of age in father or other male, first-degree relative; before menopause in mother or other female, first-degree relative)
- Current cigarette smoker
- Hypertension: greater than 140/90 mm Hg or currently receiving antihypertensive drug therapy
- Low-density lipoprotein level: greater than 2 mmol/L; high-density lipoprotein level: lower than 1 mmol/L (men) or 1.3 mmol/L (women); cholesterol greater than 5 mmol/L; triglycerides: greater than 1.7 mmol/L; total cholesterol-to-HDL-C ratio: greater than 4.5 mmol/L
- Diabetes

*There are discrepancies in the literature regarding the ages for risk. CAD, Coronary artery disease; HDL, high-density lipoprotein; MI, myocardial infarction.

A major source of guidance for antilipemic treatment in Canada has been the 2016 Canadian Cardiovascular Society Guidelines for the Management of Dyslipidemia for the Prevention of Cardiovascular Disease in the Adult ([Anderson, Grégoire, Pearson, et al., 2016](#)). These recommendations are developed by a panel of multidisciplinary Canadian experts, based on current evidence and practical experience. The focus of the most recent update continues to be cardiovascular risk assessment using the Framingham Risk Score (FRS; see <http://www.palmedpage.com/Framingham/CCSFramingham.html> for a risk calculator) and the Cardiovascular Life Expectancy Model (CLEM), based on conventional risk factors, to identify patients who will most benefit from primary prevention strategies. It is important to note that the FRS and the CLEM are validated resources for Canadian individuals; however, they cannot validate risk of CAD for Canadians who are South Asian, First Nations, or new refugees, which is where new recommendations were suggested. Recommendations from the committee suggested “that a CV risk assessment be completed every 5 years for men and women aged 40 to 75 years using the modified FRS or CLEM to guide therapy to reduce major CV events. A risk assessment might also be completed whenever a patient's expected risk status changes” (Anderson et al., 2018, p. 1265). Health behaviour recommendations emphasize appropriate dietary intake of total cholesterol and saturated fat, weight control, physical activity, smoking cessation, and the control of other lifestyle risk factors such as stress. The other focus of the guidelines is on the management of individual patients who are at increased risk for CAD. LDL-C levels are the primary target in the guidelines.

The selection of diet and drug therapy options is determined by the presence of certain risk factors. The 2016 Canadian guidelines include CAD risk equivalents (low, intermediate, and high) and have been statistically calculated to equate 10-year risk for a major coronary event (e.g., MI) for patients who do not currently have CAD but may have other diseases such as diabetes. These risk factors are listed in [Box 28.1](#).

When the decision to institute drug therapy has been made, the choice of drug should then be determined by the specific lipid profile of the patient. Five patterns or phenotypes of

TABLE 28.2 Types of Dyslipidemia

Phenotype	LIPID COMPOSITION		
	Lipoprotein Elevated	Cholesterol (mmol/L)	Triglyceride (mmol/L)
I	Chylomicrons	Greater than 7.8	Greater than 34.2
IIa	LDL	Greater than 7.8	Normal equal to or about 1.7
IIb	LDL, VLDL	Greater than 7.8	Normal equal to or about 1.7
III	IDL	Greater than 10.6	Greater than 6.8 (1–3 times higher than cholesterol)
IV	VLDL	Normal or mildly elevated; approximately equal to 6.5	Greater than 4.6
V	VLDL, chylomicrons	Greater than 7.8	Greater than 22.8

IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; VLDL, very-low-density lipoprotein.

TABLE 28.3 Target Lipid Levels Risk Categories and Target Lipid Levels

Risk Level	Initiate Therapy If	Primary Target LDL-C	Alternate Target
High FRS equal to or greater than 20%	Consider treatment for all	Equal to or less than 2 mmol/L or a greater than 50% reduction in LDL-C	- Apo B less than or equal to 0.8 mg/L - Non-HDL-C less than or equal to 2.6 mmol/L
Intermediate FRS 10–19%	- LDL-C equal to or greater than 3.5 mmol/L - For LDL-C less than 3.5 mmol/L, consider if: Apo B greater than or equal to 1.2 g/L or non-HDL-C is greater than or equal to 4.3 mmol/L	Equal to or less than 2 mmol/L or a greater than 50% reduction in LDL-C	- Apo B less than or equal to 0.8 mg/L - Non-HDL-C less than or equal to 2.6 mmol/L
Low FRS under 10%	- LDL-C greater than or equal to 5 mmol/L - Familial hypercholesterolemia	Less than or 50% reduction in LDL-C	

Apo B, apolipoprotein B; C, cholesterol; FRS, Framingham Risk Scale; HDL, high-density lipoprotein; LDL, low-density lipoprotein; non-HDL-C, total cholesterol minus HDL-C.

Adapted from Anderson, T. J., Grégoire, J., Hegele, R. A., et al. (2013). 2012 update of the Canadian Cardiovascular Society guidelines for the diagnosis and treatment of dyslipidemia for the prevention of cardiovascular disease in the adult. *Canadian Journal of Cardiology*, 29(2), 151–167. doi:10.1016/j.cjca.2012.11.032

dyslipidemia have been identified, and these are determined by the nature of the plasma (serum) concentrations of total cholesterol, triglycerides, and lipoprotein fractions (i.e., HDL-C, LDL-C, IDL-C, and VLDL-C). The various types of dyslipidemia are listed in Table 28.2. The process of characterizing a patient's specific lipid profile in this way is referred to as *phenotyping*.

The Canadian Cardiovascular Society Guidelines' focus is on cardiovascular risk assessment (Anderson et al., 2016). Very low-risk patients require no further testing and no treatment with statins. A more liberal use of statins regardless of LDL-C is recommended for patients of intermediate risk. Statin treatment is indicated for all patients of high risk. One of the basic tenets of the Canadian guidelines is that health behaviour management is the cornerstone of all treatment, involving an approach that includes zero cigarette smoking, five daily servings of fruits and vegetables, and at least 150 minutes of moderate- to vigorous-intensity aerobic physical activity per week, in bouts of 10 minutes or more. A change in cardiovascular risk can encourage a patient when the positive benefits of a healthy diet, weight reduction, exercise, and smoking cessation are seen. Drug therapy for dyslipidemias entails a long-term commitment to the therapy.

Treatment decisions made based on the Framingham Risk Score and modified by family history, HDL-C and LDL-C levels are listed in Table 28.3. There is new information on the impact of unhealthy behaviours such as abdominal obesity, lack of regular exercise; diabetes; chronic kidney disease; and *metabolic syndrome*. Features of metabolic syndrome are listed in Box 28.2.

There are currently four established classes of drugs used to treat dyslipidemia: hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (**statins**), bile acid sequestrants, the B vitamin nicotinic acid (vitamin B₃, also known as niacin), and the fibric acid derivatives (fibrates). In addition, a cholesterol absorption inhibitor, ezetimibe (Ezetrol®), is also available.

HYDROXYMETHYLGLUTARYL-COENZYME A REDUCTASE INHIBITORS

The rate-limiting enzyme in cholesterol synthesis is known as HMG-CoA reductase. Drugs in the class of medications that competitively inhibit this enzyme, the **hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors**, are the most potent ones available for reducing plasma concentrations of LDL-C.

BOX 28.2 Cardiometabolic Syndrome

Identifying Features

- Waist circumference greater than 102 cm in men or 88 cm in women (North American descent); greater than 94 cm in men or 80 cm in women (European, Middle Eastern, sub-Saharan African, or Mediterranean descent); greater than 90 cm in men or 80 cm in women (Asian, Japanese, South and Central American descent)
- Serum triglyceride level of 1.7 mmol/L or higher
- HDL-C level of less than 1 mmol/L in men or less than 1.3 mmol/L in women
- Blood pressure of 130/85 mm Hg or higher
- Fasting serum glucose level higher than 5.6 mmol/L

Lovastatin was the first drug in this class to be approved for use. Since then, five other HMG-CoA reductase inhibitors have become available on the Canadian market: pravastatin sodium, simvastatin, atorvastatin, fluvastatin sodium, and rosuvastatin calcium. Because of the shared suffix of their generic names, these drugs are often collectively referred to as *statins*. Lipid levels may not be lowered until 6 to 8 weeks after the start of therapy. Few direct comparisons of the statins have been published. The following doses of drugs are considered “therapeutically equivalent,” meaning they produce the same therapeutic effect: simvastatin, 20 mg; pravastatin sodium, 40 mg; lovastatin, 40 mg; atorvastatin, 10 mg; fluvastatin sodium, 80 mg; and rosuvastatin calcium, 5 mg.

Mechanism of Action and Drug Effects

Statins lower blood cholesterol level by decreasing the rate of cholesterol production. To produce cholesterol, the liver requires HMG-CoA reductase, which is the rate-limiting enzyme in the reactions. The statins inhibit this enzyme, thereby decreasing cholesterol production. When less cholesterol is produced, the liver increases the number of LDL receptors to recycle LDL-C from the circulation back into the liver, where it is needed for the synthesis of other needed substances such as steroids, bile acids, and cell membranes. Lovastatin and simvastatin are administered as inactive drugs or prodrugs that must be biotransformed into their active metabolites in the liver. In contrast, pravastatin sodium is administered in its active form.

Indications

The statins are recommended as first-line drug therapy for hypercholesterolemia (elevated LDL-C), the most common and dangerous form of dyslipidemia. More specifically, they are indicated for the treatment of type IIa and IIb dyslipidemia and have been shown to reduce the plasma concentrations of LDL-C. Their cholesterol-lowering properties are dose dependent; 5–80 mg/day of simvastatin lowers the LDL-C by 26 to 47%, while 5–40 mg/day of rosuvastatin lowers the LDL-C by 45–63%. A 10 to 30% decrease in the concentrations of plasma triglycerides has also been observed in patients receiving these drugs. Another important therapeutic effect of the statins is an overall tendency for the HDL-C level to increase by 2 to 15%, a known beneficial factor that reduces the risk for cardiovascular disease.

These drugs appear to be equally effective in their ability to reduce LDL-C concentrations. However, rosuvastatin is more

TABLE 28.4 HMG-CoA Reductase Inhibitors: Adverse Effects

Body System	Adverse Effects
Central nervous	Headache, dizziness, blurred vision, fatigue, insomnia
Gastrointestinal	Constipation, diarrhea, nausea
Miscellaneous	Myopathy, skin rashes, myalgia

HMG-CoA, hydroxymethylglutaryl-coenzyme A.

potent on a per-milligram basis. Atorvastatin appears to be more effective at lowering triglycerides than other HMG-CoA reductase inhibitors. The statins are rarely combined with nicotinic acid or fibrates because of the statins’ superior efficacy and the risk of adverse drug effects (see Adverse Effects). It should also be noted that rosuvastatin is often used to replace atorvastatin because of the associated adverse effects of the latter drug. Rosuvastatin is thought to have fewer adverse effects and may improve the lipid profile compared to atorvastatin (Folse, Sternhufvud, Schuetz, et al., 2014).

Contraindications

Contraindications to the use of HMG-CoA reductase inhibitors (statins) include known drug allergy and pregnancy. Other contraindications may include liver disease or elevation of liver enzymes, previous serious myopathy, or rhabdomyolysis.

Adverse Effects

HMG-CoA reductase inhibitors are generally well tolerated, and significant adverse effects are fairly uncommon. However, mild and transient gastrointestinal (GI) disturbances, rash, and headache are the most common problems and tend to be under-reported in clinical trials. These and other less common adverse effects are listed in Table 28.4. Elevations in liver enzyme levels may also occur, and patients need to be monitored for excessive elevations, which may indicate the need for alternative drug therapy. Dose-dependent elevations in liver enzyme activity to values greater than three times the upper limit of normal have been noted in approximately 0.4% to 1.9% of patients taking HMG-CoA reductase inhibitors. The serum creatine phosphokinase concentrations may be increased by more than 10 times the normal level in patients receiving these drugs. Most of these patients have remained asymptomatic, however.

A clinically important adverse effect is myopathy, characterized by muscle pain, which may progress to a serious condition known as *rhabdomyolysis* (Ward, Watts, & Eckel, 2019). Health Canada (2013) has issued public health advisories regarding reports of myopathy and rhabdomyolysis cases associated with use of statins. Rhabdomyolysis is the breakdown of muscle protein accompanied by *myoglobinuria*, which is the urinary elimination of the muscle protein myoglobin. This abnormal urinary excretion of protein can place a severe strain on the kidneys, possibly leading to acute kidney injury and even death. It appears to be dose dependent. Advise patients receiving statin therapy to immediately report to the health care provider any unexplained muscular pain or discomfort. When recognized reasonably early, rhabdomyolysis is usually reversible with discontinuation

TABLE 28.5 HMG-CoA Reductase Inhibitors: Drug Interactions

Drug/Food	Mechanism	Effect
warfarin sodium	Inhibit warfarin sodium metabolism	Increased risk of bleeding
erythromycin, azole antifungals, quinidine sulphate, verapamil hydrochloride, amiodarone hydrochloride, grapefruit juice, HIV and hepatitis C protease inhibitors, cyclosporin, clarithromycin, diltiazem hydrochloride, amlodipine besylate	Inhibit statin metabolism	Increased risk of myopathy
gemfibrozil	Potentiation	Increased risk of myopathy

of the statin drug. Risk factors for myopathy include: age older than 65 years, hypothyroidism, renal insufficiency, and concurrent use of the antifungal drug gemfibrozil, the immunosuppressant cyclosporin, or macrolide antibiotics. In addition, the use of amiodarone hydrochloride, diltiazem hydrochloride, and amlodipine besylate is associated with an increased risk for myopathy. Patients of Asian descent (those of Filipino, Chinese, Japanese, Korean, Vietnamese, or South Asian origin) may be at greater risk of developing rhabdomyolysis. Although these adverse effects are relatively uncommon, and much benefit is often derived from statin use, health care providers are advised to use minimal effective doses, along with baseline laboratory blood monitoring to include: liver function tests, lipid profile, creatine kinase (CK) and kidney function with repeat laboratory tests only if non-adherence, myopathy, or manifestations of liver injury are suspected. Alternate day administration can be useful to reduce adverse effects and increase adherence. Educate patients about possible serious adverse drug effects, and instruct them to immediately report signs of toxicity, including muscle soreness, changes in urine colour (e.g., tea-coloured because of the presence of myoglobin), fever, malaise, nausea, or vomiting. In 2012, Health Canada imposed new restrictions on simvastatin, which are discussed in detail in its Drug Profile. In 2013, Health Canada issued a label update for all statins, regarding the increased risk for elevated blood glucose levels with their use and a small elevated risk for the development of diabetes in patients with pre-existing risk factors. Health Canada also reaffirmed the position that the benefits of taking statins to reduce cholesterol levels outweigh associated risks. In 2012 (updated in 2015), the United States Food and Drug Administration (FDA) advised consumers and health care providers of information about statins, including the adverse effects of memory loss, forgetfulness, and confusion; an increased risk of elevated blood glucose levels and the development of type 2 diabetes; and potential drug interaction with lovastatin resulting in myopathy. The FDA also advised that routine liver enzyme monitoring is no longer necessary.

Toxicity and Management of Overdose

Limited data are available on the nature of toxicity and overdose in patients taking HMG-CoA reductase inhibitors. Treatment, if needed, is supportive and based on the presenting symptoms.

Interactions

Drug interactions with the HMG-CoA reductase inhibitors are listed in Table 28.5. They are to be used cautiously in patients taking oral anticoagulants. In addition, the coadministration of the statins with drugs that are metabolized by cytochrome P450 enzyme 3A4

(CYP3A4; see Chapter 2) may lead to the development of rhabdomyolysis (see the section on adverse effects for the drugs). Patients taking statins are advised to limit their intake of grapefruit juice and grapefruit. Components in grapefruit juice inactivate CYP3A4 in both the liver and intestines. This enzyme plays a key role in statin metabolism. The presence of grapefruit juice in the body results in sustained levels of unmetabolized statin drug, which increases the risk for major drug toxicity (e.g., rhabdomyolysis). Pravastatin sodium and fluvastatin sodium inhibit CYP3A4 to a much lesser degree than the other statins, whereas lovastatin and simvastatin are the most potent inhibitors of this enzyme.

Laboratory Test Interactions

Laboratory tests may be altered with the use of statins. Altered results may include increases in alanine transaminase (ALT) levels and activated clotting time, thrombocytopenia, and transient eosinophilia.

Dosages

For dosage information on atorvastatin, refer to the table on p. 479.

DRUG PROFILES

The HMG-CoA reductase inhibitors are all potent inhibitors of the enzyme that catalyzes the rate-limiting step in the synthesis of cholesterol. Six statins are currently available in Canada: atorvastatin (Lipitor®), fluvastatin sodium (Lescol®), lovastatin, pravastatin sodium, rosuvastatin calcium (Crestor®), and simvastatin (Zocor®). There are some minor differences between drugs in this class of antilipemics; the most dramatic difference is that of potency. All six drugs are prescription only and are contraindicated in pregnant or lactating women and in those with active liver dysfunction or with elevated serum transaminase levels of unknown cause or who consume large quantities of alcohol. There have also been reports of elevations in fasting glucose and HbA1c levels. There is little evidence to recommend one drug over another, although simvastatin is used less frequently because of its significant adverse effect profile, drug interactions, and lower potency when compared with atorvastatin or rosuvastatin.

atorvastatin calcium

Atorvastatin calcium (Lipitor) has become one of the most commonly used drugs in this class of cholesterol-lowering drugs. It is used to lower total and LDL-C levels as well as triglyceride levels. Atorvastatin has also been shown to raise levels of “good” cholesterol, the HDL component. All statins are administered

once daily, usually with the evening meal or at bedtime. One particular advantage of atorvastatin is that it can be dosed at any time of day. However, bedtime dosing provides peak drug levels in a time frame that correlates better with the natural diurnal (daytime) rhythm of cholesterol production in the body. Atorvastatin is available only in tablet form, in strengths of 10, 20, 40, and 80 mg.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	0.5 hr	1–2 hr	7–14 hr	Unknown

rosuvastatin calcium

Rosuvastatin (Crestor) has also become a more popular statin and as with all statins, it is used primarily to lower total and LDL-C levels as well as triglyceride levels. It can also modestly raise levels of HDL, the “good” cholesterol. It is available only in tablet form, in strengths of 5, 10, 20, and 40 mg. The use of the 40-mg dose of rosuvastatin is contraindicated in the Asian population or in patients who have pre-disposing risk factors for myopathy/rhabdomyolysis. Rosuvastatin should not be taken concomitantly with cyclosporin and fusidic acid. In patients taking the protease inhibitors atazanavir/ritonavir or simeprevir, the dose of rosuvastatin is not to exceed 10 mg daily. In patients taking the protease inhibitors lopinavir/ritonavir, darunavir/ritonavir or tipranavir/ritonavir; gemfibrozil, clopidogrel; eltrombopag; or dronedarone, the dose is not to exceed 20 mg. Decreased oral contraceptive efficacy is observed in doses greater than 40 mg.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	3 days	3–5 hr	19 hr	Unknown

BILE ACID SEQUESTRANTS

Bile acid sequestrants, also called the *bile acid-binding resins* and *ion-exchange resins*, include cholestyramine resin, colestipol hydrochloride, and colesvelam. The first two of these drugs have been widely used for more than 20 years and have been evaluated extensively in well-controlled clinical trials. They have proven efficacy. The powdered form of cholestyramine resin is somewhat messy to use. Colestipol hydrochloride is available in granules and a tablet form. Colesvelam has a similar mechanism of action and is available only in tablet form. These drugs are considered second-line drugs after the more potent statins. They are suitable alternatives for patients intolerant of the statins. Generally, bile acid sequestrants lower the plasma concentrations of LDL-C by 15 to 30%. They also increase the HDL-C level by 3 to 8% and increase liver triglyceride and VLDL production, which may result in a 10 to 50% increase in triglyceride levels.

TABLE 28.6 Bile Acid Sequestrants: Adverse Effects

Body System	Adverse Effects
Gastrointestinal	Constipation, nausea, belching, bloating
Other	Headache, tinnitus, burnt odour of urine

Mechanism of Action and Drug Effects

Bile acid sequestrants bind bile and prevent the resorption of bile acids from the small intestine. An insoluble bile acid and resin (drug) complex is formed and then excreted in the bowel movement. Bile acids are necessary for the absorption of cholesterol from the small intestine and are also synthesized from cholesterol by the liver. This is one natural way that the liver excretes cholesterol from the body. The more that bile acids are excreted in the feces, the more the liver converts cholesterol to bile acids. This reduces the level of cholesterol in the liver and thus in the circulation as well. The liver then attempts to compensate for the loss of cholesterol by increasing the number of LDL receptors on its surface. Circulating LDL molecules bind to these receptors to be taken up into the liver, which has the benefit of reducing circulating LDL in the bloodstream.

Indications

Bile acid sequestrants may be used as primary or adjunct drug therapy in the management of type II hyperlipoproteinemia. A common strategy is to use them along with statins for an additive drug effect in reducing LDL-C levels. In addition, cholestyramine resin is also used to relieve the pruritus associated with partial biliary obstruction. Colesvelam may be better tolerated by higher-risk patients who are intolerant of other antilipemic therapy, including organ transplant recipients and those with serious liver or kidney disease. They may also be used in pregnant women if required for cholesterol control.

Contraindications

Contraindications to the use of bile acid sequestrants include known drug allergy, biliary or bowel obstruction, and phenylketonuria (PKU).

Adverse Effects

The adverse effects of colestipol hydrochloride, cholestyramine resin, and colesvelam are similar; however, colesvelam is reported to have fewer GI adverse effects and drug interactions. Constipation is a common problem and may be accompanied by heartburn, nausea, belching, and bloating. These adverse effects tend to disappear over time. Many patients require additional education and support to help them manage GI effects and adhere to their medication regimens. It is important that therapy be initiated with low doses and that patients be instructed to take the drugs with meals to reduce adverse effects. Patients may relieve constipation and bloating by increasing dietary fibre intake or taking a fibre supplement such as psyllium (e.g., Metamucil® or others), as well as increasing fluid intake. These drugs may cause mild increases in triglyceride levels. The most common adverse effects of the bile acid sequestrants are listed in [Table 28.6](#).

Toxicity and Management of Overdose

Because bile acid sequestrants are not absorbed, an overdose can cause obstruction of the GI tract. Therefore, treatment of an overdose involves restoring gut motility.

Interactions

The significant drug interactions associated with the use of bile acid sequestrants are limited to effects on the absorption of concurrently administered drugs. All drugs should be taken at least 1 hour before or 4 to 6 hours after the administration of bile acid sequestrants. In addition, high doses of a bile acid sequestrant will decrease the absorption of fat-soluble vitamins (A, D, E, and K).

Dosages

For dosage information on a selected bile acid sequestrant, refer to the table on p. 479.

DRUG PROFILE

Bile Acid Sequestrants

The bile acid sequestrants cholestyramine resin, colestipol hydrochloride, and colesevelam are indicated for the treatment of type IIa and IIb dyslipidemia. They lower levels of cholesterol, particularly the LDL-C level, by increasing the destruction of LDL. However, their use may result in increases in the VLDL-C level. Because of the high incidence of GI adverse effects, adherence to prescribed dosage schedules is often poor. However, educating patients about the purpose and expected adverse effects of therapy can foster improved adherence. Warn patients not to take bile acid sequestrants concurrently with other drugs because of the consequence of reduced absorption. Other drugs must be taken at least 1 hour before or 4 to 6 hours after the bile sequestrant at other times of the day. This requirement cannot be overemphasized.

cholestyramine resin

Cholestyramine resin (Olestr®) is a prescription-only drug that is contraindicated in patients with a known hypersensitivity to it and in those who have complete biliary obstruction or PKU. It may interfere with the distribution of proper amounts of fat-soluble vitamins to fetuses of pregnant women or to nursing infants of nursing women taking the drug. Cholestyramine resin is now being used for its constipating effect, often given as needed for loose bowel movements.

NICOTINIC ACID

Nicotinic acid (niacin, Niaspan®) is not only a unique lipid-lowering drug, it is also a vitamin. Much larger doses of nicotinic acid are required for its lipid-lowering effects than are commonly given when it is used as a vitamin. Nicotinic acid is a B vitamin, specifically vitamin B₃. It is an effective and inexpensive medication that exerts favourable effects on plasma concentrations of all lipoproteins. Nicotinic acid is often given in combination with other antilipemic drugs to enhance their lipid-lowering effects.

TABLE 28.7 Nicotinic Acid: Potential Adverse Effects

Body System	Adverse Effects
Gastrointestinal	Abdominal discomfort
Integumentary	Cutaneous flushing, pruritus
Other	Blurred vision, glucose intolerance, hepatotoxicity

Mechanism of Action and Drug Effects

Although the exact mechanism of action of nicotinic acid is unknown, its beneficial effects are believed to be related to its ability to inhibit lipolysis in adipose tissue, decrease esterification of triglycerides in the liver, and increase the activity of lipoprotein lipase. The drug's effects are primarily limited to reduction of the metabolism or catabolism of cholesterol and triglycerides. Nicotinic acid decreases LDL levels moderately (10 to 20%), decreases triglyceride levels (20 to 35%), decreases apolipoprotein B (Apo B), and increases HDL levels moderately (20 to 35%). Nicotinic acid is also a vitamin needed for many bodily processes. In large doses, it may produce vasodilation that is limited to the cutaneous vessels. This effect seems to be induced by prostaglandins. Nicotinic acid also causes the release of histamine, which results in an increase in gastric motility and acid secretion. Nicotinic acid may also stimulate the fibrinolytic system to break down fibrin clots.

Indications

Nicotinic acid has been shown to be effective in lowering lipid levels, including triglyceride, total serum cholesterol, apolipoprotein B, and LDL-C levels. It also increases HDL cholesterol levels. Nicotinic acid may also lower the lipoprotein(a) level, except in patients with severe hypertriglyceridemia. It has been shown to be effective in the treatment of types IIa, IIb, III, IV, and V dyslipidemia. Nicotinic acid's effects on triglyceride levels begin to be noticed after 1 to 4 days of therapy, with the maximum decrease seen after 3 to 5 weeks of continuous therapy.

Contraindications

Contraindications to the use of nicotinic acid include known drug allergy and may include liver disease, hypertension, peptic ulcer, and any active hemorrhagic process.

Adverse Effects

Nicotinic acid can cause flushing, pruritus, and GI distress. These undesirable effects can be minimized by starting patients on a low initial dosage and increasing it gradually, and by having patients take the drug with meals. Small doses of aspirin or non-steroidal anti-inflammatory drugs (NSAIDs) may be taken 30 minutes before nicotinic acid to minimize cutaneous flushing. The most common adverse effects and those associated with nicotinic acid are listed in [Table 28.7](#).

Interactions

Drug interactions associated with nicotinic acid are minimal. However, when nicotinic acid is taken with an HMG-CoA reductase inhibitor, the likelihood of myopathy development

is greatly increased, although it is not uncommon to see these drugs used together.

Dosages

For dosage information on nicotinic acid, refer to the table on p. 479.

DRUG PROFILES

nicotinic acid

Used alone or in combination with other lipid-lowering drugs, nicotinic acid (niacin, vitamin B₃; Niaspan) is an effective, inexpensive medication that has beneficial effects on LDL-C, triglyceride, and HDL-C levels. Drug therapy is usually initiated at a small daily dose taken with or after meals, to minimize the adverse effects. Liver dysfunction has been observed in individuals taking nicotinic acid. Niacin is contraindicated in patients who have shown a hypersensitivity to it; in those with peptic ulcer, liver disease, hemorrhage, or severe hypotension; and in lactating women. It is also not recommended for patients with gout.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Rapid	30–60 min	45 min	Unknown

FIBRIC ACID DERIVATIVES

Current fibric acid derivatives include bezafibrate, gemfibrozil and fenofibrate. These drugs primarily affect triglyceride levels but may also lower total cholesterol and LDL-C levels and raise HDL-C levels. They are often collectively referred to as *fibrates*.

Mechanism of Action and Drug Effects

Fibric acid drugs are believed to work by activating lipoprotein lipase, an enzyme responsible for the breakdown of cholesterol. This enzyme usually cleaves off a triglyceride molecule from VLDL or LDL, leaving behind lipoproteins. Fibric acid derivatives also suppress the release of free fatty acid from adipose tissue, inhibit the synthesis of triglycerides in the liver, and increase the secretion of cholesterol into bile. They have been shown to reduce triglyceride levels and serum VLDL and LDL concentrations. Independent of their lipid-lowering actions, fibric acid derivatives can also induce changes in blood coagulation; this involves a tendency toward a decrease in platelet adhesion. They can also increase plasma fibrinolysis, the process that causes fibrin, and therefore clots, to be broken down.

Indications

The fibric acid derivatives bezafibrate, gemfibrozil, and fenofibrate decrease triglyceride levels and increase HDL-C levels by as much as 25%. They decrease LDL concentrations in patients with type IIa and IIb dyslipidemias but increase LDL levels in patients with type IV and V dyslipidemias. They are indicated

TABLE 28.8 Fibric Acid Derivatives: Potential Adverse Effects

Body System	Adverse Effects
Gastrointestinal	Nausea, vomiting, diarrhea, gallstones
Genitourinary	Impotence, decreased urine output, hematuria
Other	Drowsiness, dizziness, rash, pruritus, vertigo

for the treatment of type III, IV, and V dyslipidemias and, in some cases, the type IIb form, although other classes of antilipemics are usually attempted first.

Contraindications

Contraindications to the use of fibrates include known drug allergy and may include severe liver or kidney disease, cirrhosis, or gallbladder disease.

Adverse Effects

The most common adverse effects of fibric acid derivatives are abdominal discomfort, diarrhea, nausea, headache, blurred vision, increased risk for gallstones, and prolonged prothrombin time. Liver function tests may also show increased enzyme levels. The more common adverse effects are listed in [Table 28.8](#).

Toxicity and Management of Overdose

The management of fibrate overdose, which is uncommon, is supportive care based on presenting symptoms.

Interactions

Gemfibrozil can enhance the action of oral anticoagulants; thus, careful adjustment of the dosage of warfarin is required. The risk for myositis, myalgia, and rhabdomyolysis is increased when either bezafibrate, gemfibrozil, or fenofibrate is given with a statin. Laboratory test interactions that can occur in patients taking gemfibrozil include a decrease in hemoglobin level, hematocrit value, and white blood cell count. In addition, aspartate aminotransferase (AST), activated clotting time, lactate dehydrogenase, and bilirubin levels can be increased. Fenofibrate may raise the blood level of ezetimibe if the two are taken concurrently.

Dosage

For dosage information on gemfibrozil, refer to the table on p. 479.

DRUG PROFILES

Fibric Acid Derivatives (Fibrates)

The fibric acid derivatives bezafibrate, gemfibrozil, and fenofibrate are prescription-only drugs. They are contraindicated in patients with hypersensitivity, pre-existing gallbladder disease, significant liver or kidney dysfunction, and primary biliary cirrhosis. Women of childbearing age must use birth control measures; in women who become pregnant, the drugs must be discontinued. Fibrates decrease triglyceride levels and increase HDL levels by as much as 25%. They are effective for the treatment of mixed dyslipidemia.

gemfibrozil

Gemfibrozil is a fibric acid derivative that decreases the synthesis of Apo B and lowers the VLDL level. It can also increase the HDL level. In addition, it is highly effective for lowering plasma triglyceride levels. In a landmark study known as the Helsinki study, reported in 1987 in the *New England Journal of Medicine*, the triglyceride levels of the group receiving gemfibrozil were reduced by as much as 43% compared with those in the control group. Total cholesterol and LDL-C levels were reduced by 11% and 10%, respectively, and the HDL level was increased by 10%. Gemfibrozil is indicated for the treatment of type IV and V dyslipidemias and, in some cases, the type IIb form.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Several days	1–2 hr	1.3–1.5 hr	Unknown

DRUG PROFILES

Cholesterol Absorption Inhibitor

ezetimibe

Ezetimibe (Ezetrol) is currently the only cholesterol absorption inhibitor. Ezetimibe has a novel mechanism of action in that it selectively inhibits absorption of cholesterol and related sterols in the small intestine. The result is a reduction in several blood lipid parameters: total cholesterol, LDL-C, Apo B, and triglyceride level. Serum levels of HDL-C have been shown to increase with the use of ezetimibe. Beneficial effects of ezetimibe appear to be further enhanced when it is taken with a statin drug. Ezetimibe may be used as monotherapy. Recent studies have shown that, although the combination of ezetimibe and a statin is effective in reducing LDL, the rate of atherosclerotic progression is no different from when a statin is given alone. Use of ezetimibe and simvastatin is effective in reducing the risk of vascular events in patients with advanced chronic kidney disease.

Ezetimibe levels are increased by the fibric acid derivatives (fibrates). It is not known whether this is harmful, but concurrent use of ezetimibe and fibrates is not recommended. The use of ezetimibe with bile acid sequestrants has been shown to reduce the serum level of ezetimibe by 55% and 80%, in two small studies. Ezetimibe is contraindicated in those with a known hypersensitivity to it and in those with active liver disease or unexplained elevations in serum liver enzymes. It may be taken with or without food, and for patient convenience, it may be dosed at the same time as a statin drug, if prescribed.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Unknown	4–12 hr	22 hr	Unknown

Dosages

Selected Antilipemic Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications
 atorvastatin calcium (Lipitor)	HMG-CoA reductase inhibitor	Adults PO: 10–80 mg/day	Dyslipidemia
 cholestyramine resin (Olestryl)	Bile acid sequestrant	Adults PO: Powder, 4–24 g/day	
ezetimibe (Ezetrol)	Cholesterol absorption inhibitor	Adults PO: 10 mg 1 ×/day	
gemfibrozil	Fibric acid derivative	Adults PO: 600 mg bid 30 min before meals in a.m. and p.m.	
 nicotinic acid (Niacin, Niaspan)	B vitamin	Adults PO: 1–2 g/day at bedtime	
simvastatin (Zocor)	HMG-CoA reductase inhibitor	Adults PO: 5–40 mg/day	

HMG-CoA, hydromethylglutaryl-coenzyme A; PO, oral.

NURSING PROCESS

ASSESSMENT

Before initiating therapy with any antilipemic drug, obtain a thorough health and medication history, with a listing of allergies and any prescription drugs, OTC drugs, and natural health products the patient is taking. Assess the patient's dietary patterns, stress levels, exercise program and frequency, weight, height, and vital signs, and document these parameters, especially food intake, over time, such as for several weeks. Also document the patient's use of tobacco, alcohol, and social drugs, along with information about frequency, amount, and duration of use. Some lipid disorders are hereditary; therefore, perform a thorough assessment of family history. Positive risk factors for CAD for which the patient needs to be assessed include the following: (1) males 40 years or older; females 50 years or older or postmenopausal ([Anderson et al., 2016](#)); (2) family history, including history of premature CAD (e.g., MI or sudden death before 55 years of age in father or other male, first-degree relative, or before menopause in mother or other female, first-degree relative); (3) cigarette smoking; (4) hypertension with a blood pressure higher than 140/90 mm Hg or current antihypertensive drug therapy; (5) low HDL cholesterol level (lower than 1 mmol/L in men or lower than 1.3 mmol/L in women); and (6) diabetes.

Perform an assessment to identify any cautions, contraindications, and potential drug interactions before initiating use of any of the antilipemics. Also assess serum lipid values and lipoprotein levels (see Lab Values Related to Drug Therapy, p.480). With the use of cholestyramine resin, which contains aspartame, a history of PKU is of particular interest. Patients with PKU cannot properly process the amino acid phenylalanine, a component of

LAB VALUES RELATED TO DRUG THERAPY

Coronary Artery Disease

Laboratory Test	Normal Ranges	Rationale for Assessment
Lipid panel with serum cholesterol, triglycerides, and lipids	Serum cholesterol levels less than 5 mmol/L Triglyceride levels less than 1.7 mmol/L Low-density lipoprotein (LDL) cholesterol levels less than 2.0 mmol/L and less than 1.8 mmol/L for recent ACS patients High-density lipoprotein (HDL) cholesterol levels 1 mmol/L or greater for men; 1.3 mmol/L or greater for women Very-low-density lipoprotein (VLDL) cholesterol levels less than 3.4 mmol/L	A lipid panel is a serum test that measures lipids, fats, and fatty substances used as a source of energy in the body. Lipids include cholesterol, triglycerides, HDL, and LDL. When a lipid panel is ordered, the levels include all of the following: total cholesterol, triglycerides, HDL, LDL, VLDL, ratio of total cholesterol to HDL, and ratio of LDL to HDL. Lipid levels are important to health status and are indicators of health; if there are abnormalities (e.g., high cholesterol, triglycerides, HDL, VLDL and LDL levels), the individual is at increased risk for heart disease and stroke. Dietary and other lifestyle changes may be implemented to help decrease “bad” cholesterol levels (LDL and VLDL) and elevate “good” cholesterol levels (HDL). Medical treatment protocols may also be implemented to help prevent MI and stroke.

ACS, Acute coronary syndrome.

Based on Anderson, T. J., Grégoire, J., Pearson, G. J. R. A., et al. (2016). 2016 Canadian Cardiovascular Society guidelines for the management of dyslipidemia for the prevention of cardiovascular disease in the adult. *Canadian Journal of Cardiology*, 32(11), 1264–1282. doi:10.1016/j.cjca.2016.07.510

protein. High levels of phenylalanine lead to behavioural, cognitive, and learning dysfunction as early as 3 weeks of age in such patients; dietary restrictions must continue throughout their lives. Adult patients with PKU require monthly testing of phenylalanine levels. Because of the aspartame in cholestyramine resin, another class of antilipemics would be indicated, as ordered, to prevent further complications from this disorder.

HMG–CoA reductase inhibitors (the statins) are not to be used in patients who have liver disease or increased liver enzymes. Other contraindications, cautions, and drug interactions were previously discussed in the pharmacology section of this chapter. With the use of the statins and all antilipemics, assess patients' intake of alcohol, including the amount consumed and the period of time that alcohol has been used because of the potential for liver dysfunction associated with the majority of lipid-lowering drugs. The statins may have additional adverse effects on an already damaged liver. Monitor levels of liver enzymes that are indicative of liver function, AST, CPK, and ALT. Review lipid and lipoprotein levels before, during, and after drug therapy with statins, as well as with other antilipemic drugs. Assess patients for any musculoskeletal problems or concerns due to the possible adverse effect of myopathy. If AST or ALT blood levels increase or signs and symptoms of myopathy or rhabdomyolysis occur (i.e., muscle soreness, changes in urine colour, fever, malaise, nausea, or vomiting), the drug will most likely be discontinued by the health care provider. It is always important to determine if patients' cultural practices or beliefs will impact their adherence to dietary restrictions. Cultural practices may also include the use of natural health products that may constitute contraindications to the use of statins or other antilipemics.

Use of bile acid sequestrants requires careful assessment of possible contraindications such as a history of biliary or bowel obstructions and PKU. Drug interactions are numerous (see previous discussion) because of the decreased absorption of drugs caused by bile acid sequestrants. With nicotinic acid, patient assessment includes noting contraindications such as liver disease, peptic ulcer disease, gout, hypertension, and any active bleeding. Liver function studies are usually ordered for baseline and comparative levels, with the majority of antilipemics. Fibrin acid derivatives are not used in patients with liver, kidney, or

gallbladder disease, and so assessment for these disorders is critical to patient safety. With ezetimibe, assess for liver disease and liver enzyme elevation before initiation of therapy.

◆ NURSING DIAGNOSES

- Modified nutrition, more than body requirements, as a result of poor dietary habits including high fat intake
- Inadequate knowledge as a result of a lack of knowledge about the disease, related complications, and drug therapy
- Potential risk for impaired liver function as a result of potential adverse and toxic effects of drug therapy

◆ PLANNING

◆ Goals

- Patient will maintain healthy nutritional intake with appropriate restrictions.
- Patient will demonstrate adequate knowledge of disease process and its associated drug therapeutic regimens.
- Patient will maintain baseline liver function during drug therapy.

◆ Expected Patient Outcomes

- Patient states the importance of dietary restrictions, with emphasis on a low-fat, low-cholesterol, high-fibre, and low-calorie (if appropriate) diet, as prescribed.
- Patient engages in a nutritional consultation to support implementation of changes in lifestyle and diet to help decrease cholesterol and triglyceride levels.
- Patient follows guidelines from the [Heart and Stroke Foundation of Canada \(2018\)](#), which recommends four specific diets to reduce the risk of CAD: the DASH diet, vegetarian diet, Mediterranean diet, and the MIND diet. From Canada's Food Guide, patients are encouraged to incorporate recommendations such as decreasing saturated and trans fat intake, boosting intake of polyunsaturated and monounsaturated fats, increasing fruit and vegetable intake to a minimum of five servings per day, and consuming a low-carbohydrate or low-fat diet.

CASE STUDY

Antilipemic Drug Therapy

Sophie, a 49-year-old mayor, lives a busy life but manages to exercise regularly and tries to maintain a healthy lifestyle, including watching her diet. She is a nonsmoker and is not overweight. Recently, Sophie had a medical checkup and, to her surprise, was told that her lipid levels are

elevated. She has no history of diabetes, and her blood pressure is within normal limits. Her nurse practitioner has recommended that she start the HMG-CoA reductase inhibitor (statin) drug atorvastatin (Lipitor), at a dosage of 20 mg every evening.

1. Sophie says, "Isn't there something else I can do instead of taking this medicine? I really don't like taking pills." What alternatives may be available to her?
2. After 4 months, Sophie's lipid levels have not improved. The nurse practitioner discusses Sophie's risk factors, including the fact that her father died at 54 years of age of an MI. What other risk factors need to be considered?
3. Sophie agrees to take the medication and schedules a follow-up appointment in 3 months. Two months later, she wakes up with pain in her legs and feeling extremely tired. She thinks she is suffering the effects of a new workout program that she started the previous day. But when she goes to work, the pain gets worse, and she calls the nurse to describe her symptoms. What could be happening?
4. Sophie asks whether she will just be switched to another "statin" drug. How will the nurse respond?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

- Patient implements regular aerobic exercise for at least 150 minutes per week of moderate-vigorous intensity, aerobic physical activity, as prescribed.
- Patient demonstrates adequate knowledge about disease processes and the need for lifelong treatment with drug therapy.
 - Patient states the rationale for antilipemic drug therapy (decrease in lipid levels).
 - Patient states the importance of taking the medication exactly as prescribed.
 - Patient states the various adverse effects, such as GI upset, changes in liver function tests, and belching, related to the specific drug prescribed.
- Patient returns for follow-up care for monitoring of lipid levels and for adverse effects.
- Patient demonstrates knowledge of the risk for liver dysfunction associated with antilipemic therapy.
 - Patient states potential adverse effects to report to the health care provider, such as jaundice and abdominal pain.
 - Patient states the importance of follow-up care with the health care provider to monitor for changes in liver function and monitoring of liver function tests.

GI problems such as constipation. Appropriate actions need to be taken to avoid or minimize constipation, such as increasing intake of fibre and fluids. Monitoring the results of blood studies per the health care provider's instructions often includes noting levels of serum transaminases and results of other tests of liver function.

With the HMG-CoA reductase inhibitors, or statin drugs, serum levels of ALT, AST, and CK are often measured for baseline. These may be repeated if non-adherence is suspected (repeat lipid profile), if the patient experiences myopathy (repeat CK), or if the patient has manifestations of hepatic injury (repeat liver function tests). If a lipid profile is ordered, instruct the patient to fast for 12 to 14 hours before the blood sample is drawn. Also, inform patients of the desired laboratory levels to be achieved (see Table 28.3). Because severe cardiovascular disease and strokes are associated with high cholesterol levels, it is critical to the maintenance of health and the prevention of complications that the patient continue with any prescribed nonpharmacological and pharmacological therapies, regardless of the specific antilipemic used. Another aspect to consider when administering these medications, specifically simvastatin (Zocor), is dosage amount. See the pharmacology discussion for prescribing restrictions on 80-mg dosage forms of simvastatin. There are additional concerns about simvastatin and other medications that were discussed in the pharmacology section of this chapter.

Bile acid sequestrants often come in powder form and should be mixed thoroughly with food or fluids (at least 120 to 180 mL of fluid). The powder may not mix completely at first, but patients need to be sure to mix the dose as much as possible and then dilute any undissolved portion with additional fluid. The powder should be dissolved for at least 1 full minute. Powder and granule dosage forms are *never* to be taken in dry form. It is important that bile acid sequestrants such as colestipol hydrochloride be taken 1 hour before or 4 to 6 hours after any other oral medication or meals because of the high risk for drug–drug or drug–food interactions. Bile acid sequestrants interfere with the absorption of other medications. Colestipol hydrochloride is also available in tablet form. Cholestyramine is to be taken just before meals or with meals, and it must never be given to a patient with PKU because it contains aspartame (see previous discussion). Constipation may be prevented with high fibre and increased fluid intake.

With nicotinic acid, flushing of the face may occur; educate patients regarding this adverse effect. To minimize GI upset, advise patients to take this medication with meals. Of the different dosage forms available, the extended-release dosage forms—which dissolve more slowly than the immediate-release forms but faster than the sustained-release forms—appear to be associated with less flushing of the skin. Other actions that may help to minimize flushing of the skin include titrating the drug dosage or taking a small dose of aspirin or an NSAID 30 minutes before the nicotinic acid, but only as ordered or recommended by the health care provider. Educate patients that fibric acid derivatives are to be taken as prescribed. Frequently monitor liver and kidney function tests and prothrombin times with these drugs. The cholesterol absorption inhibitor ezetimibe may be taken with or without food and may be taken with statin drugs.

◆ IMPLEMENTATION

Patients who are taking antilipemics for a long period may have altered levels of the fat-soluble vitamins and may then require supplementation of vitamins A, D, and K. Antilipemics may also cause problems with the liver and biliary systems and may cause

◆ EVALUATION

Begin with evaluation of goals and outcome criteria when trying to evaluate the therapeutic versus adverse effects of these medications. In addition, cholesterol and triglyceride levels are used to monitor the patient's response to the medication regimen, and specific targets are listed in [Table 28.3](#). While taking antilipemics, patients should remain on a low-fat, low-cholesterol diet as an integrated part of a change in lifestyle. Monitor patients receiving antilipemic drugs for therapeutic and adverse effects during their therapy. The therapeutic effects of both

nonpharmacological and pharmacological measures are evidenced by a decrease in cholesterol and triglyceride levels to within normal levels (see previous serum laboratory values). Nonpharmacological measures include consumption of a low-fat, low-cholesterol diet; supervised, moderate exercise; weight loss; cessation of smoking and drinking; and relaxation therapy.

Adverse effects for which to monitor include GI upset, increased liver enzyme levels, hepatomegaly, myalgias, and other effects mentioned earlier in the chapter. Closely monitor patients' kidney and liver function before and throughout treatment to detect the development of liver or kidney dysfunction.

PATIENT TEACHING TIPS

- Advise patients to notify their health care providers if there are any new or troublesome symptoms or if there is persistent GI upset, constipation, gas, bloating, heartburn, nausea, vomiting, abnormal or unusual bleeding, muscle pain, or yellow discoloration of the skin.
- Advise patients to keep antilipemics and all medications out of the reach of children and protected with childproof lids.
- Encourage patients to maintain a diet that is rich in raw vegetables, fruit, and bran. Also encourage the consumption of fluids (up to 3 000 mL/day unless contraindicated) to help prevent the constipation associated with antilipemics.
- Advise patients to inform all health care providers about all medications being taken, including antilipemics. These drugs are highly protein-bound and are therefore associated with many drug interactions, including with drugs that a dentist might prescribe. In addition, antilipemics may alter clotting if taken on a long-term basis, so bleeding may occur during dental work.
- Educate patients that exercise is to be done in moderation and may require supervision, as indicated.
- Alert patients taking simvastatin to concerns regarding the use of 80-mg doses.
- Inform patients that when taking an HMG-CoA reductase inhibitor or statin drug, it is best to take the medication with at least 120 to 180 mL of water or with meals to help minimize GI upset. It takes several weeks before therapeutic results are seen. Monitor liver and kidney function laboratory studies every 3 to 6 months, upon initiation of therapy, then routine monitoring for patients who are symptomatic or at high risk for adverse events.
- Patients should be aware that drug and food interactions associated with statin drugs necessitate the avoidance of oral anticoagulants, erythromycin, verapamil hydrochloride, some antifungal drugs, and grapefruit products.
- Patients taking HMG-CoA reductase inhibitors need to know to report any muscle soreness, change in colour of the urine, fever, nausea, vomiting, or malaise to their health care providers, immediately.
- Advise patients taking a bile acid sequestrant that the medication should be taken with meals to decrease GI upset. Other drugs must be taken 1 hour before or 4 to 6 hours after taking a bile acid sequestrant.
- Nicotinic acid is contraindicated in patients with liver disease, peptic ulcer disease, gout, hypertension, or active bleeding. Instruct patients to take nicotinic acid with meals, to decrease GI upset.

KEY POINTS

- There are two primary forms of lipids: triglycerides and cholesterol. Triglycerides function as an energy source and are stored in adipose tissue. Cholesterol is primarily used to make steroid hormones, cell membranes, and bile acids.
- Lipids and lipoproteins participate in the formation of atherosclerotic plaque, which leads to CAD, and it is important to understand the pathophysiology of this disease process so that appropriate patient education can be delivered.
- When plaque forms in the blood vessels that supply the heart with needed oxygen and nutrients, the lumens of these blood vessels will eventually decrease in size and the amount of oxygen and nutrients that can reach the heart (and major organs) will be reduced.
- Antilipemic drugs are used to lower high levels of lipids (triglycerides and cholesterol) in the blood.
- The major classes of antilipemics include HMG-CoA reductase inhibitors, bile acid sequestrants, nicotinic acid, fibric acid derivatives, and cholesterol absorption inhibitors, with each having its own mechanism of action.
- While taking a history, it is important to assess patients for any possible cautions, contraindications, and drug interactions.
- Fat-soluble vitamins may need to be prescribed for patients taking antilipemics for long periods because these medications have long-term effects on the liver's production of these vitamins.
- When using the powder or granule, oral-based forms of these drugs, they must be mixed with noncarbonated liquids and *never* taken dry.
- Monitoring for adverse effects of antilipemics includes periodic liver and kidney function studies.
- Statins have gained much attention for their adverse effects of muscle aches and pain due to breakdown of muscle tissue. Some patients experience irreversible kidney damage and severe pain and may have to have dosages altered or drugs changed, as ordered by the health care provider.

EXAMINATION REVIEW QUESTIONS

- Which nursing action would help to reduce adverse effects when administering nicotinic acid?
 - Give the medication with grapefruit juice.
 - Administer a small dose of aspirin or an NSAID 30 minutes before the niacin dose.
 - Administer the medication on an empty stomach.
 - Have the patient increase dietary fibre intake.
- When administering nicotinic acid, the nurse needs to monitor for which adverse effect?
 - Cutaneous flushing
 - Muscle pain
 - Headache
 - Constipation
- A nurse is providing teaching to a patient who was newly ordered an antilipemic. Which point will the nurse emphasize to a patient who is taking an antilipemic drug in the “statin” class?
 - The drug needs to be taken on an empty stomach before meals.
 - A low-fat diet is not necessary while taking these medications.
 - It is important to report muscle pain immediately.
 - Improved cholesterol levels should be evident within 2 weeks.
- A patient is being assessed before a newly ordered antilipemic medication is given. Which condition would alert the nurse as a potential contraindication prior to administration?
 - Diabetes insipidus
 - Pulmonary fibrosis
 - Liver cirrhosis
 - Myocardial infarction
- A patient is currently taking a statin. The nurse considers that the patient may have a higher risk of developing rhabdomyolysis when also taking which product?
 - NSAIDs
 - A fibric acid derivative
 - Orange juice
 - Fat-soluble vitamins
- The nurse is administering cholestyramine resin, a bile acid sequestrant. Which nursing interventions are appropriate? (Select all that apply.)
 - Administering the drug on an empty stomach
 - Administering the drug with meals
 - Instructing the patient to follow a low-fibre diet while taking this drug
 - Instructing the patient to take a fibre supplement while taking this drug
 - Increasing fluid intake
 - Not administering this drug at the same time as other drugs
- The medication order reads: nicotinic acid, 1 g PO, every evening. The medication is available in 500-mg tablets. How many tablets will the patient receive per dose?
- A patient has been taking simvastatin (Zocor) for 6 months. Today he received a call that he needs to come to the office for a “laboratory check.” The nurse expects which of the following laboratory studies to be ordered at this time? (Select all that apply.)
 - PT/INR
 - Total cholesterol
 - Triglycerides
 - Liver function studies
 - Complete blood count
 - HDL and LDL levels

CRITICAL THINKING ACTIVITIES

- A patient has started taking nicotinic acid as part of treatment for high cholesterol levels. After the first dose, he tells the nurse that he feels “hot” and that his face and neck are flushed. He says that he thinks he is having an allergic reaction. What is the nurse’s priority action at this time?
- While reviewing instructions for newly prescribed antilipemic medications, a patient informs the nurse that he “hates

to mix powdered medicines” and plans to take his cholestyramine resin powder dry. What is the nurse’s best response to this patient’s comment?

Diuretic Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Describe the normal anatomy and physiology of the kidney.
2. Briefly discuss the impact of the kidney on blood pressure regulation.
3. Describe how diuretics work in the kidney and how they lower blood pressure.
4. Distinguish among the different classes of diuretics in regard to mechanisms of action, indications, dosages, routes of administration, adverse effects, toxicities, cautions, contraindications, and drug interactions.
5. Develop a collaborative plan of care that includes all phases of the nursing process for patients receiving diuretics.

KEY TERMS

Afferent arterioles The small blood vessels approaching the glomerulus (proximal part of the nephron). (p. 486)

Aldosterone A mineralocorticoid steroid hormone produced by the adrenal cortex that regulates sodium and potassium balance. (p. 486)

Ascites Intraperitoneal accumulation of fluid (defined as a volume of 500 mL or more) containing large amounts of protein and electrolytes. (p. 492)

Collecting duct The most distal part of the nephron, between the distal convoluted tubule and the ureters, which lead to the urinary bladder. (p. 486)

Distal convoluted tubule The part of the nephron immediately distal to the ascending loop of Henle and proximal to the collecting duct. (p. 486)

Diuretics Drugs or other substances that tend to promote the formation and excretion of urine. (p. 486)

Efferent arterioles The small blood vessels exiting the glomerulus; at this point, blood has completed its filtration in the glomerulus. (p. 486)

Filtrate The material that passes through a filter; in the case of the kidney, the filter is the glomerulus, and the filtrate is the material extracted from the blood (normally liquid) that becomes urine. (p. 486)

Glomerular capsule The open, rounded, and most proximal part of the proximal convoluted tubule that surrounds the glomerulus and receives the filtrate from the blood. (p. 486)

Glomerular filtration rate (GFR) An estimate of the volume of blood that passes through the glomeruli of the kidney per minute. (p. 486)

Glomerulus The cluster of kidney capillaries that marks the beginning of the nephron and is immediately proximal to the proximal convoluted tubule. (p. 486)

Loop of Henle The part of the nephron that is immediately distal to the proximal convoluted tubules. (p. 486)

Nephron The functional filtration unit of the kidney, consisting of (in anatomical order from proximal to distal) the glomerulus, proximal convoluted tubule, loop of Henle, distal convoluted tubule, and collecting duct, which empties urine into the ureters. There are approximately 1 million nephrons in each kidney. (p. 486)

Open-angle glaucoma A condition in which pressure is elevated in the eye because of obstruction of the outflow of aqueous humour. (p. 487)

Proximal convoluted (twisted) tubule The part of the nephron that is immediately distal to the glomerulus and proximal to the loop of Henle. (p. 486)

DRUG PROFILE

* Full generic name is given in parentheses. For the purposes of this text, the more common, shortened name is used.

OVERVIEW

Diuretics are drugs that accelerate the rate of urine formation through a variety of mechanisms. The result is the removal of sodium and water from the body. Diuretics were discovered accidentally when it was noticed that a mercury-based antibiotic had a potent diuretic effect. All the major classes of diuretic drugs in use today were developed between 1950 and 1970, and they remain among the most commonly prescribed drugs in the world.

Hypertension Canada 2018 Guidelines (Nerenberg, Zarnke, Leung, et al., 2018) recommends diuretics, especially the thiazides, as one option for first-line drug treatment of hypertension. The hypotensive activity of diuretics is due to many different mechanisms. They cause direct arteriolar dilation, which decreases peripheral vascular resistance. They also reduce extracellular fluid volume, plasma volume, and cardiac output, which may account for the decrease in blood pressure. They have long been the mainstay of therapy for not only hypertension, but also heart failure. Two of their advantages are their relatively low cost and their favourable safety profile. The primary disadvantage with their use is the metabolic adverse effects that can result from excessive fluid and electrolyte loss. These effects are usually dose related and are therefore controllable with dosage titration (careful adjustment).

This chapter reviews the essential properties and actions of the following important classes of diuretic drugs: carbonic anhydrase inhibitors, loop diuretics, osmotic diuretics, potassium-sparing diuretics, and thiazide and thiazide-like diuretics. Each class of diuretic acts on a different site (primarily within the kidney tubules) in the kidney.

The kidney plays an important role in the day-to-day functioning or homeostasis of the body. It filters out toxic waste products from the blood while simultaneously conserving essential substances. This delicate balance between elimination of toxins and retention of essential chemicals is maintained by the **nephron**. The nephron is the main structural unit in the kidney, and each kidney contains approximately 1 million nephrons. Diuretics exert their effect in the nephron. The initial filtering of the blood takes place in the **glomerulus**, a cluster of capillaries surrounded by the **glomerular capsule**. The rate at which this filtering occurs is referred to as the **glomerular filtration rate (GFR)**, and it is used as a gauge of how well the

kidneys are functioning as filters. The GFR can be estimated mathematically by calculating creatinine clearance. A GFR below 60 for 3 months or more, or a GFR above 60 with kidney damage (marked by high levels of albumin in the urine), comprises the gold standard for determining chronic kidney disease. The GFR is used to determine necessary adjustment of drugs based on the patient's kidney function.

The GFR, which can also be thought of as the rate at which blood flows into and out of the glomerulus, is regulated by the small blood vessels entering the glomerulus (**afferent arterioles**) and exiting the glomerulus (**efferent arterioles**). Normally, about 180 L of blood is filtered through the nephrons every day. (A mnemonic [memory aid] that may help one to remember which arteriole is which is “A for *approach* and *afferent*” and “E for *exit* and *efferent*.”) Alterations in blood flow such as those that occur in a patient in shock can therefore have a dramatic effect on kidney function. Diuretics may have diminished effects in situations of low blood flow, because the kidney receives less blood, and therefore less diuretic reaches the site of action.

The **proximal convoluted (twisted) tubule**, or, more simply, the **proximal tubule**, follows the glomerulus anatomically and returns 60 to 70% of the sodium and water from the filtered fluid back into the bloodstream. Blood vessels surround the nephrons and allow substances to be directly reabsorbed from or secreted into the bloodstream. This process is one of active transport that requires energy in the form of adenosine triphosphate (ATP) molecules. The active transport of sodium and potassium ions back into the blood causes the passive reabsorption of chloride and water. The chloride ions (Cl⁻) and water passively follow the sodium ions (Na⁺) and, to a lesser extent, potassium ions (K⁺) by osmosis. Another 20 to 25% of sodium is resorbed back into the bloodstream in the ascending **loop of Henle**. Chloride is actively resorbed in the loop of Henle, and sodium passively follows.

The remaining 5 to 10% of sodium resorption takes place in the **distal convoluted tubule**, often called the **distal tubule**, which anatomically follows the ascending loop of Henle. In the distal tubule, sodium is actively filtered in exchange for potassium or hydrogen ions, a process regulated by the hormone **aldosterone**. The **collecting duct** is the final common pathway for the **filtrate** that started in the glomerulus. It is here that antidiuretic hormone acts to increase the absorption of water back into the bloodstream, thereby preventing it from being lost in the urine. The entire nephron, along with the sites of action of the different classes of diuretics, is shown in Fig. 29.1.

DIURETIC DRUGS

The various diuretics are classified according to their sites of action within the nephron, their chemical structure, and their diuretic potency. The sites of action of diuretics are determined by the way in which they affect the solute (electrolyte) and water transport systems located along the nephron (see Fig. 29.1). The commonly used classes of drugs and individual drugs in these classes are listed in Table 29.1. The most potent diuretics are the loop diuretics, followed by mannitol (an osmotic diuretic), metolazone (a thiazide-like diuretic), the thiazides, and the potassium-sparing diuretics. The potency of these diuretics is a function of where they

Fig. 29.1 The nephron and diuretic sites of action. ADH, antidiuretic hormone.

TABLE 29.1 Classification of Diuretics

Class	Drugs
Carbonic anhydrase inhibitors	acetazolamide, methazolamide
Loop diuretics	bumetanide, ethacrynic acid, furosemide
Osmotic diuretics	mannitol
Potassium-sparing diuretics	amiloride, eplerenone, spironolactone, triamterene (available only in combination with hydrochlorothiazide)
Thiazide and thiazide-like diuretics	chlorthalidone, hydrochlorothiazide, indapamide, metolazone

act in the nephron to inhibit sodium and water resorption. The more sodium and water they inhibit from resorption, the greater the diuresis and, consequently, the greater the potency.

CARBONIC ANHYDRASE INHIBITORS

Carbonic anhydrase inhibitors (CAIs) are chemical derivatives of sulfonamide antibiotics. As their name implies, CAIs inhibit the activity of the enzyme carbonic anhydrase, which is found in the kidneys, eyes, and other parts of the body. The CAIs act at the location of the carbonic anhydrase enzyme system along the nephron, primarily in the proximal tubule. Acetazolamide is the most commonly used CAI today.

Mechanism of Action and Drug Effects

The carbonic anhydrase system in the kidney is located just distal to the glomerulus in the proximal tubules, where

approximately two thirds of all sodium and water are resorbed into the blood. In the proximal tubules, there is an active transport system that exchanges sodium for hydrogen ions. For sodium and water to be resorbed back into the blood, hydrogen must be exchanged for it. Without hydrogen, this process cannot occur, and the sodium and water will be eliminated with the urine. Carbonic anhydrase makes hydrogen ions for this exchange. When its actions are inhibited by a CAI, such as acetazolamide, little sodium and water can be resorbed into the blood, and they are eliminated with the urine. CAIs reduce the formation of hydrogen (H^+) and bicarbonate (HCO_3^-) ions from carbon dioxide and water through the noncompetitive, reversible inhibition of carbonic anhydrase activity. This action results in a reduction in the availability of the ions, primarily hydrogen, for use by active transport systems.

The reduction of the formation of bicarbonate and hydrogen ions can have effects on other parts of the body. CAIs can induce respiratory and metabolic acidosis, both of which can increase oxygenation during hypoxia by increasing ventilation and cerebral blood flow, and by the dissociation of oxygen from oxyhemoglobin, all of which are usually beneficial to the patient. An undesirable effect of CAIs is elevation of blood glucose levels, which causes glycosuria in patients with diabetes. This may be due in part to CAI-enhanced potassium loss through the urine.

Indications

Therapeutic applications of CAIs include the treatment of glaucoma, edema, epilepsy, and high-altitude sickness. CAIs are used as adjunct drugs in the long-term management of acute **open-angle**

glaucoma that cannot be controlled by topical miotic drugs or epinephrine derivatives alone (see Chapter 57). Glaucoma is caused by the obstruction of the outflow of aqueous humour. When CAIs are given, an increase in the outflow of the aqueous humour results. They are also used short term in conjunction with miotics to lower intraocular pressure in preparation for ocular surgery and as an adjunct in the treatment of secondary glaucoma.

Acetazolamide is also used to manage edema secondary to heart failure that has become resistant to other diuretics. However, as a class, CAIs are much less potent diuretics than loop diuretics or thiazides, and the metabolic acidosis they induce diminishes their diuretic effect in 2 to 4 days.

Acetazolamide is also effective in both the prevention and treatment of the symptoms of high-altitude sickness. These symptoms include headache, nausea, shortness of breath, dizziness, drowsiness, and fatigue.

Contraindications

Contraindications to the use of CAIs include known drug allergy, hyponatremia, hypokalemia, severe kidney or liver dysfunction, adrenal gland insufficiency, and cirrhosis.

Adverse Effects

Common undesirable effects of CAIs are metabolic abnormalities such as acidosis and hypokalemia. Drowsiness, dizziness, depression, anorexia, paresthesias, hematuria, urticaria, photosensitivity, and melena (blood in the stool) can also occur.

Interactions

Because CAIs can cause hypokalemia, an increase in digoxin toxicity may occur when they are combined with digoxin. Use with corticosteroids may also cause hypokalemia. The effects of amphetamines, carbamazepine, cyclosporin, phenytoin, and quinidine sulphate may be increased when these drugs are taken concurrently with CAIs.

Dosages

The usual dose of acetazolamide is 250 to 500 mg per day, which may be given orally or intravenously.

DRUG PROFILE

acetazolamide

Use of acetazolamide (Acetazolam®) is contraindicated in patients who have a known hypersensitivity to it as well as in those with significant liver or kidney dysfunction, low serum potassium or sodium levels, acidosis, or adrenal gland failure. It is available in oral and parenteral forms. Potential benefits may warrant use of acetazolamide in pregnant women despite potential risks to the fetus.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1 hr	2–4 hr	10–15 hr	8–12 hr

LOOP DIURETICS

Loop diuretics (bumetanide, ethacrynic acid, and furosemide) are potent diuretics. Bumetanide and furosemide are chemically related to the sulfonamide antibiotics. They are therefore often listed as contraindicated in sulfa-allergic patients. However, analysis of the literature indicates that cross-reaction is unlikely to occur. Loop diuretics are commonly given to patients with sulfa allergy with no problems; however, always be aware of the possibility of allergy.

Mechanism of Action and Drug Effects

Loop diuretics have kidney, cardiovascular, and metabolic effects. These drugs act primarily along the thick ascending limb of the loop of Henle, blocking chloride and, secondarily, sodium resorption. They are also thought to activate kidney prostaglandins, which results in dilation of the blood vessels of the kidneys, the lungs, and the rest of the body (i.e., causing a reduction in kidney, pulmonary, and systemic vascular resistance). The hemodynamic effects of loop diuretics are a reduction in both the preload and central venous pressures (which are the filling pressures of the ventricles). These actions make them useful in the treatment of edema associated with heart failure, liver cirrhosis, and kidney disease.

Because of their rapid onset of action, loop diuretics are particularly useful when rapid diuresis is needed. The diuretic effect lasts at least 2 hours. Loop diuretics have a distinct advantage over thiazide diuretics in that their diuretic action continues even when the creatinine clearance decreases below 25 mL/min. This means that even when kidney function diminishes, loop diuretics can still work. However, higher doses, administered by IV, may be required to achieve diuresis because of the decline in kidney function. Because of their potent diuretic effect and their duration of action, loop diuretics are usually effective when given in a single daily dose. This allows the kidney tubule time to partially compensate for the potassium depletion and other electrolyte derangements that often accompany around-the-clock diuretic therapy. Despite this, the major adverse effect of loop diuretics is electrolyte disturbance. Prolonged administration of high dosages can also result in hearing loss stemming from ototoxicity, although this is rare.

SUMMARY OF MAJOR DRUG EFFECTS OF LOOP DIURETICS

Loop diuretics produce a potent diuresis and subsequent loss of fluid. The resulting decreased fluid volume leads to a decreased return of blood to the heart, or decreased filling pressures. This has the following cardiovascular effects:

- Reduces blood pressure
- Reduces pulmonary vascular resistance
- Reduces systemic vascular resistance
- Reduces central venous pressure
- Reduces left ventricular end-diastolic pressure

The metabolic effects of loop diuretics are secondary to electrolyte losses resulting from potent diuresis. Major electrolyte

TABLE 29.2 Loop Diuretics: Common Adverse Effects

Body System	Adverse Effects
Central nervous	Dizziness, headache, tinnitus, blurred vision
Cardiovascular	dehydration/hypovolemia
Gastrointestinal	Nausea, vomiting, diarrhea
Hematological	Agranulocytosis, thrombocytopenia, neutropenia
Metabolic	Hypokalemia, hyperglycemia, hyperuricemia, hyponatremia, hypochloremia, hypocalcemia, hypomagnesemia, metabolic alkalosis in severe cases

losses include loss of sodium and potassium and, to a lesser extent, calcium. Changes in the plasma levels of insulin, glucagon, and growth hormone have been observed in association with loop diuretic therapy.

Indications

Loop diuretics are used to manage edema associated with heart failure and liver or kidney disease, to manage hypertension, and to increase the kidney excretion of calcium in patients with hypercalcemia. As with certain other classes of diuretics, they may also be indicated in cases of heart failure resulting from diastolic dysfunction.

Contraindications

Contraindications to the use of loop diuretics include known drug allergy, hepatic coma, and severe electrolyte loss. Although allergy to sulfonamide antibiotics is listed as a contraindication, analysis of the literature indicates that cross-reaction with the loop diuretics is unlikely to occur. Loop diuretics are commonly given to such patients in clinical practice.

Adverse Effects

Common undesirable effects of loop diuretics are listed in [Table 29.2](#). Hypokalemia is of serious clinical importance. To prevent hypokalemia, patients often receive potassium supplements along with furosemide. Furosemide can produce erythema multiforme, exfoliative dermatitis, photosensitivity, and, in rare cases, aplastic anemia.

Toxicity and Management of Overdose

Electrolyte loss and dehydration, which can result in circulatory failure, are the main toxic effects of loop diuretics that require attention. Treatment involves electrolyte and fluid replacement.

Interactions

Loop diuretics exhibit both neurotoxic and nephrotoxic properties, and they produce additive effects when given in combination with drugs that have similar toxicities. Related drug interactions are summarized in [Table 29.3](#).

Loop diuretics also affect certain laboratory results. They cause increases in serum levels of uric acid, glucose, alanine aminotransferase, and aspartate aminotransferase. Their combined use with a thiazide (particularly metolazone) results in the blockade of sodium and water resorption at multiple sites in the

nephron, a property referred to as *sequential nephron blockade*, which increases their effects. Nonsteroidal anti-inflammatory drugs (NSAIDs) may diminish the reduction of vascular resistance induced by loop diuretics because these two drug classes have opposite effects on prostaglandin activity.

Dosages

For dosage information on loop diuretics, refer to the table on p. 491.

DRUG PROFILE

The currently available loop diuretics are bumetanide, ethacrynic acid, and furosemide. Ethacrynic acid is rarely used clinically. As a class, they are potent diuretics, but the potency of each drug within this class varies. The equipotent doses for these drugs are as follows:

PHARMACOKINETICS

bumetanide	ethacrynic acid	furosemide
1mg	50 mg	40 mg

furosemide

Furosemide (Lasix®) is by far the most commonly used loop diuretic in clinical practice and the prototypical drug in this class. The trade name Lasix was derived from the fact that the duration of action is 6 hours. It has all the therapeutic and adverse characteristics of the loop diuretics mentioned earlier. It is used in the management of pulmonary edema and the edema associated with heart failure, liver disease, nephrotic syndrome, and ascites. It has also been used in the treatment of hypertension, usually that caused by heart failure.

Furosemide use is contraindicated in patients who have shown a hypersensitivity to it or to the sulfonamides (see previous discussion in regard to sulfonamide allergy) and in patients with anuria, hypovolemia, and electrolyte depletion. It is available in oral form—as a solution and as tablets—and in parenteral form. Potential benefits may warrant use of the drug in pregnant women despite potential risks to the fetus.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	5 min	15 min	1–2 hr	2 hr
PO	30–60 min	1–2 hr	1–2 hr	6–8 hr

OSMOTIC DIURETICS

The osmotic diuretics include mannitol, urea, organic acids, and glucose. Mannitol, a nonabsorbable solute, is the most commonly used.

Mechanism of Action and Drug Effects

Mannitol works along the entire nephron. Its major site of action, however, is the proximal tubule and descending limb of

TABLE 29.3 Loop Diuretics: Common Drug Interactions

Interacting Drug	Mechanism	Results
Aminoglycosides, vancomycin	Additive effect	Increased neurotoxicity, especially ototoxicity
Corticosteroids, Digoxin, Lithium carbonate NSAIDs	Hypokalemia Decrease in kidney excretion Inhibition of kidney prostaglandins	Additive hypokalemia, increased digoxin toxicity Increased lithium toxicity Decreased diuretic activity

NSAIDs, Nonsteroidal anti-inflammatory drugs.

the loop of Henle. Because it is nonabsorbable, it increases osmotic pressure in the glomerular filtrate, which in turn pulls fluid, primarily water, into the renal tubules from the surrounding tissues. This process also inhibits the tubular reabsorption of water and solutes, which produces a rapid diuresis. Ultimately, this action reduces cellular edema and increases urine production, causing diuresis; however, it produces only a slight loss of electrolytes, especially sodium. Therefore, mannitol is not indicated for patients with peripheral edema because it does not promote sufficient sodium excretion.

Mannitol may induce vasodilation and, when it does so, it increases both glomerular filtration and kidney plasma flow. This makes it an excellent drug for preventing kidney damage during acute kidney injury. It is also often used to reduce intracranial pressure and cerebral edema resulting from head trauma. In addition, mannitol treatment may be tried when elevated intraocular pressure is unresponsive to other drug therapies.

Indications

Mannitol is the osmotic diuretic of choice. It is commonly used in the treatment of patients in the early, oliguric phase of acute kidney injury. For it to be effective in this situation, however, enough blood flow to the kidney and glomerular filtration must still remain to enable the drug to reach the kidney tubules. Increased kidney blood flow resulting from the dilation of blood vessels supplying blood to the kidneys is another therapeutic benefit of mannitol therapy in such patients. It can also be used to promote the excretion of toxic substances, reduce intracranial pressure, and treat cerebral edema. In addition, it can be used as a genitourinary irrigant in the preparation of patients for transurethral surgical procedures and as supportive treatment in patients with edema induced by other conditions.

Contraindications

Contraindications to the use of mannitol include known drug allergy, severe kidney disease, pulmonary edema (in which case loop diuretics are used instead), and active intracranial bleeding.

Adverse Effects

Significant undesirable effects of mannitol include convulsions, thrombophlebitis, and pulmonary congestion. Other less significant effects are headaches, chest pain, tachycardia, blurred vision, chills, and fever.

Interactions

There are no drugs that interact significantly with mannitol.

Dosages

For the recommended dosages of mannitol, refer to the table on the next page.

DRUG PROFILES

mannitol

Mannitol (Osmitol®) is the prototypical osmotic diuretic. Its use is contraindicated in patients with hypersensitivity to it as well as in those with anuria, severe dehydration, pulmonary congestion, or cerebral hemorrhage. Treatment should be terminated if severe heart or kidney impairment develops after the initiation of therapy. It is available only in parenteral form as 5%, 10%, 20%, and 25% solutions for intravenous (IV) injection. The volume infused differs based on the concentration of mannitol provided. Calculations may need to be performed to determine the volume to be used. Mannitol may crystallize when exposed to low temperatures. This is more likely to occur when concentrations exceed 15%. For this reason, mannitol should always be administered intravenously through a filter, and vials of the drug are often stored in a warmer. The use of mannitol may have adverse effects on a fetus, but potential benefits may warrant use of the drug in pregnant women despite potential risks.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	0.5–1 hr	0.25–2 hr	1.5 hr	6–8 hr

POTASSIUM-SPARING DIURETICS

The currently available potassium-sparing diuretics are amiloride, eplerenone, spironolactone, and triamterene. In Canada, triamterene is available only in combination with hydrochlorothiazide. These diuretics are also referred to as *aldosterone-inhibiting diuretics* because they block aldosterone receptors. Spironolactone is a competitive antagonist of aldosterone, and for this reason it causes sodium and water to be excreted and potassium retained. It is the most commonly used of the three drugs.

Dosages

Selected Loop Diuretics and Osmotic Diuretics

Drug	Pharmacological Class	Usual Dosage Range	Indications
 furosemide (Lasix)	Loop diuretic	<i>Children</i> IM/IV: 0.5–1 mg/kg; max 1 mg/kg/day PO: 0.5–1 mg/kg q4h; max 2 mg/kg/day divided <i>Adults</i> IM/IV: 20–40 mg/dose; max 100 mg/day: administer high-dose IV therapy as a controlled infusion at a rate not exceeding 4 mg/min or less (always refer to agency policy prior to administration) PO: 20–80 mg/day as a single dose; max 200 mg/day	Heart failure, hypertension, kidney failure, pulmonary edema, cirrhosis
 mannitol (Osmitol)	Osmotic diuretic	<i>Adults</i> IV infusion: 50–200 g/day 1.5–2 g/kg over 30–60 min 50–200 g IV given at a rate to induce urine output of 100–500 mL/hr	Kidney failure; high intraocular and intracranial pressure; drug intoxication (to induce diuresis)

IM, Intramuscular; IV, intravenous; PO, oral.

Mechanism of Action and Drug Effects

Potassium-sparing diuretics act in the collecting ducts and distal convoluted tubules, where they interfere with sodium–potassium exchange. Spironolactone competitively binds to aldosterone receptors and therefore blocks the resorption of sodium and water that is induced by aldosterone secretion. These receptors are found primarily in the distal tubule. Amiloride and triamterene do not bind to aldosterone receptors; however, they inhibit both aldosterone-induced and basal sodium reabsorption, working in the distal tubule as well as the collecting ducts. They are often prescribed for children with heart failure because pediatric heart problems are frequently accompanied by an excess secretion of aldosterone, and the loop and thiazide diuretics are often ineffective in their management (see also the Special Populations: Children box, on use of diuretics in children).

The potassium-sparing diuretics are relatively weak compared with the thiazide and loop diuretics. When diuresis is needed, they are generally used as adjuncts to thiazide treatment. This combination is beneficial in two respects. First, the drugs have synergistic diuretic effects; second, the two drugs counteract each other's adverse metabolic effects. Thiazide diuretics cause potassium, magnesium, and chloride to be lost in the urine, and the potassium-sparing diuretics counteract this effect by elevating potassium and chloride levels.

Indications

Therapeutic applications of potassium-sparing diuretics vary depending on the particular drug. Spironolactone and triamterene are used to treat hyperaldosteronism and hypertension and to reverse the potassium loss caused by the potassium-wasting (i.e., loop and thiazide) diuretics. One common feature of heart failure is a hyperactive renin–angiotensin–aldosterone system. Research has identified this hyperactivity as a causative

SPECIAL POPULATIONS: CHILDREN

Diuretics

- Calculate pediatric dosages of diuretic medications carefully, regardless of whether the patient is in the hospital or in the home setting. Weight should be measured and recorded daily at the same time every day so that both therapeutic effects and adverse effects of diuretics can be assessed. Because children are at greater risk for adverse effects and toxicity, they require closer and more cautious daily assessment in order to avoid consequences such as excess fluid volume, electrolyte loss, hypotension, and shock.
- The half-life of furosemide is increased in neonates, so the interval between doses may need to be lengthened, as ordered by the health care provider.
- Oral forms of diuretics may be taken with food or milk and are to be taken early in the day and at the same time every day.
- Children taking diuretics should avoid lengthy exposure to either heat or sun because it may precipitate heat stroke, exhaustion, and fluid volume loss.
- Thiazide diuretics cross the placenta and pass through to the fetus. Small amounts are distributed in breast milk; thus, breastfeeding is not advised for mothers who are taking these drugs.
- Laboratory test results that may be altered by diuretics include serum levels of calcium, glucose, and uric acid, which may be increased.
- Loop diuretics may also interfere with urea nitrogen, chloride, magnesium, potassium, and sodium levels; therefore, perform frequent monitoring.

factor in permanent ventricular myocardial wall damage, known as *remodelling*, following myocardial infarction. Clinical drug trials have demonstrated a cardioprotective benefit of spironolactone in preventing this remodelling process, due to its aldosterone-inhibiting activity. The uses for amiloride are similar to those for spironolactone and triamterene, but amiloride is less effective in the long term. It may be more effective than spironolactone or triamterene in the treatment of metabolic alkalosis. It is used primarily in the management of heart failure. As

TABLE 29.4 Potassium-Sparing Diuretics: Common Adverse Effects

Body System	Adverse Effects
Central nervous	Dizziness, headache
Gastrointestinal	Cramps, nausea, vomiting, diarrhea
Other	Urinary frequency, weakness, hyperkalemia

with certain other classes of diuretics, potassium-sparing diuretics may also be indicated in cases of heart failure due to diastolic dysfunction.

Contraindications

Contraindications to the use of potassium-sparing diuretics include known drug allergy, hyperkalemia (i.e., serum potassium level greater than 5.5 mmol/L), and severe kidney failure or anuria. Triamterene may also be contraindicated in cases of severe liver failure.

Adverse Effects

Potassium-sparing diuretics have several common undesirable effects, which are listed in Table 29.4. There are also some significant adverse effects specific to individual drugs. Spironolactone can cause gynecomastia, amenorrhea, irregular menses, and postmenopausal bleeding. Triamterene may reduce folic acid levels and cause the formation of kidney stones and urinary casts. It may also precipitate megaloblastic anemia. However, adverse effects from triamterene are rare. Hyperkalemia may occur when potassium-sparing diuretics are used in combination with each other or with other potassium-sparing drugs such as angiotensin-converting enzyme (ACE) inhibitors (see Chapter 23, as well as the Interactions section that follows).

Interactions

Concurrent use of potassium-sparing diuretics and lithium, ACE inhibitors, or potassium supplements can result in significant drug interactions. The administration of ACE inhibitors or potassium supplements in combination with potassium-sparing diuretics can result in hyperkalemia, which can result in fatal cardiac dysrhythmias if not identified and treated promptly. When lithium and potassium-sparing diuretics are given together, lithium toxicity can result. NSAIDs can inhibit kidney prostaglandins, which decreases blood flow to the kidneys and therefore decreases the delivery of diuretic drugs to this site of action. This action, in turn, can lead to a diminished diuretic response.

Dosages

For the recommended dosages of potassium-sparing diuretics, refer to the table on the next page.

DRUG PROFILES

amiloride hydrochloride

Amiloride hydrochloride (Midamor®) is generally used in combination with a thiazide or loop diuretic in the treatment of

heart failure. Hyperkalemia may occur in approximately 10% of the patients who take amiloride alone. It should be used with caution in older adults and in patients with kidney impairment or diabetes mellitus. It has weak antihypertensive properties. Amiloride is available only in oral form. It is also available in combination with hydrochlorothiazide (Novamilor®).

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	2 hr	6–10 hr	6–9 hr	24 hr

spironolactone

Spironolactone (Aldactone®) is a synthetic steroid that blocks aldosterone receptors. It is used in high dosages for the treatment of ascites, a condition commonly associated with cirrhosis of the liver. Monitor serum potassium levels frequently in patients taking spironolactone who have impaired kidney function or who are currently taking potassium supplements because hyperkalemia is a common complication of spironolactone therapy. It is the potassium-sparing diuretic most commonly prescribed for children who have heart failure. Recently, spironolactone has been shown to reduce morbidity and mortality rates in patients with severe heart failure when added to standard therapy. Of the three commonly used potassium-sparing diuretics, spironolactone has the greatest antihypertensive activity. It is available only in oral form. It is also available in combination with hydrochlorothiazide (Aldactazide®). There is positive evidence of human fetal risk with the use of spironolactone, but potential benefits may warrant use of the drug in pregnant women despite potential risks.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1–3 days	2–3 days	13–24 hr	2–3 days

triamterene

The pharmacological properties of triamterene are similar to those of amiloride. Like amiloride, triamterene acts directly on the distal renal tubule of the nephron to depress the resorption of sodium and the excretion of potassium and hydrogen. It has little or no antihypertensive effect. It is available only in combination with hydrochlorothiazide. There is positive evidence of human fetal risk with the use of triamterene, but potential benefits may warrant use of the drug in pregnant women despite potential risks.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	2–3 hr	6–8 hr	2–3 hr	12–16 hr

Dosages

Selected Potassium-Sparing Diuretic Drugs

Drug	Usual Dosage Range	Indications
amiloride hydrochloride (Midamor)	<i>Adults</i> PO: 5–20 mg/day	Edema, heart failure (as an adjunct to loop diuretics)
eplerenone (Inspar)	<i>Adults</i> PO: 25–50 mg/day	Heart failure, hypertension
 spironolactone (Aldactone)	<i>Children</i> PO: 3 mg/kg/day single or divided; 1–2 mg/kg maintenance <i>Adults</i> PO: 25–200 mg/day	Edema, hypertension, heart failure, ascites
triamterene 50 mg/hydrochlorothiazide 25 mg	<i>Adults</i> PO: 1–4 tablets daily after meals	Edema, hypertension, heart failure, ascites

PO, oral.

THIAZIDES AND THIAZIDE-LIKE DIURETICS

Thiazide and thiazide-like diuretics are generally considered equivalent in their effects. Thiazide diuretics, like several of the loop diuretics, are benzothiadiazines, chemical derivatives of sulfonamide antibiotics. Thiazide diuretics include hydrochlorothiazide and trichlormethiazide; hydrochlorothiazide is the most commonly prescribed and the least expensive. Hydrochlorothiazide is included in numerous combination products with antihypertensive drugs. The thiazide-like diuretics are similar in action to the thiazides and include chlorthalidone, indapamide, and metolazone. Metolazone may be more effective than other drugs in this class in the treatment of patients with kidney dysfunction.

Mechanism of Action and Drug Effects

The primary site of action of thiazide and thiazide-like diuretics is the distal convoluted tubule, where they inhibit the resorption of sodium, potassium, and chloride. This action results in osmotic water loss. Thiazides also cause direct relaxation of the arterioles, which reduces peripheral vascular resistance, or afterload. Decreased preload and afterload are their beneficial hemodynamic effects; these make them effective for the treatment of both heart failure and hypertension.

As kidney function decreases, the efficacy of thiazides diminishes because delivery of the drug to the site of activity is impaired. Thiazides are not to be used if creatinine clearance is less than 30 to 50 mL/min. Normal creatinine clearance is 125 mL/min, depending on the age of the patient. However, metolazone remains effective to a creatinine clearance of 10 mL/min and is used for edema accompanying kidney failure, including nephrotic syndrome, and states of diminished kidney function. It is also used for the treatment of edema associated with heart failure. The major adverse effects of these drugs stem from the electrolyte disturbances they produce. They are noted for precipitating hypokalemia and hypercalcemia, as well as metabolic disturbances such as dyslipidemia, hyperglycemia, and hyperuricemia.

TABLE 29.5 Thiazide and Thiazide-Like Diuretics: Potential Adverse Effects

Body System/Process	Adverse Effects
Central nervous	Dizziness, headache, blurred vision
Gastrointestinal	Anorexia, nausea, vomiting, diarrhea
Genitourinary	Erectile dysfunction
Hematological	Jaundice, leukopenia, agranulocytosis
Integumentary	Urticaria, photosensitivity
Metabolic	Hypokalemia, glycosuria, hyperglycemia, hyperuricemia, hypochloremic alkalosis

Indications

The thiazide and thiazide-like diuretics are used in the treatment of edema of various origins, idiopathic hypercalciuria, and diabetes insipidus, in addition to hypertension. Any of these drugs can be used either as monotherapy or in combination with other drugs. As with certain other classes of diuretics, they may be indicated in cases of heart failure due to diastolic dysfunction.

Contraindications

Contraindications to the use of thiazides and thiazide-like diuretics include known drug allergy, hepatic coma (for metolazone), anuria, and severe kidney failure.

Adverse Effects

Major adverse effects of thiazide and thiazide-like diuretics relate to the electrolyte and metabolic disturbances they cause, primarily reduced potassium levels and elevated levels of calcium, lipids, glucose, and uric acid. Other effects, such as gastrointestinal disturbances, skin rashes, photosensitivity, thrombocytopenia, pancreatitis, and cholecystitis are less common. Dizziness and vertigo are common adverse effects of metolazone therapy and are attributed to sudden shifts in the plasma volume brought about by the drug. Headache, erectile dysfunction, and reduced libido are other adverse effects of these drugs that are important to know. Thiazide diuretics are associated with a higher risk of falls in older adults, with the highest risk in the first 3 weeks after a prescription is given (Gribben, Hubbard, Gladman, et al., 2010; Makam, Boscardin, Miao, et al., 2014). Many of these adverse effects are dose related and are seen at higher doses, especially those above 25 mg. For example, the metabolic adverse effect of hyperglycemia is dose dependent. Thiazide doses (e.g., hydrochlorothiazide) should be kept less than or equal to 25 mg daily as doses 50 mg or greater produce metabolic adverse effects. Prolonged use of hydrochlorothiazide has a potential risk to patients of causing development of non-melanoma skin cancer and should be monitored as needed (Health Canada, 2019). The more common adverse effects of thiazide and thiazide-like diuretics are listed in Table 29.5.

Toxicity and Management of Overdose

An overdose of these drugs can lead to an electrolyte imbalance resulting from hypokalemia. Symptoms include anorexia, nausea, lethargy, muscle weakness, mental confusion, and hypotension. Treatment involves electrolyte replacement.

Interactions

Thiazides and related drugs interact with corticosteroids, diazoxide, digoxin, and oral hypoglycemics. The mechanisms and results of these interactions are summarized in [Table 29.6](#). Excessive consumption of licorice can lead to an additive hypokalemia in patients taking thiazides.

Dosages

For recommended dosages for thiazide and thiazide-like diuretics, refer to the table on the next page.

DRUG PROFILES

hydrochlorothiazide

Hydrochlorothiazide (Urozide®) is a safe and effective diuretic. Hydrochlorothiazide is used in combination with many other drugs, including amiloride, angiotensin II receptor antagonists, the direct renin inhibitor aliskiren fumarate, spironolactone, ACE inhibitors, and beta blockers. Dosages exceeding 50 mg/day rarely produce additional clinical results and may only increase drug toxicity. This property is known as the *ceiling effect*. However, doses up to 100 mg/day are not uncommon. Hydrochlorothiazide is available only in oral form. Use in pregnancy poses no risk to the fetus.

PHARMACOKINETICS (HYDROCHLOROTHIAZIDE)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	2 hr	4–6 hr	5–15 hr	6–12 hr

metolazone

Metolazone (Zaroxolyn®) is a thiazide-like diuretic that appears to be more potent than the thiazide diuretics. This greater potency becomes important in patients with kidney dysfunction. It remains effective to a creatinine clearance as low as 10 mL/min. It may also be given in combination with loop diuretics to obtain a potent diuresis in patients with severe symptoms of heart failure. Its peak effect occurs much later than the effect of intravenous furosemide. Metolazone is available only in oral form. The administration of metolazone during pregnancy requires that the potential benefits of the drug be weighed against its possible hazards to the fetus.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1 hr	1–2 hr	6–20 hr	24 hr

NURSING PROCESS

ASSESSMENT

Before giving a patient any type of diuretic, obtain a complete patient history and thorough medication history. Perform a physical assessment and document all findings, with emphasis on the body systems affected by the disease process or the indication for the diuretic, as well as on potential drug-related adverse effects. This would include assessing baseline breath sounds, heart sounds, and neurological status, as well as checking skin turgor and for pitting edema; moisture levels of mucous membranes and capillary refill are also important to assess with diuretic therapy. Because fluid volume levels and electrolyte concentrations are affected by diuretics, assess and document the patient's baseline fluid volume status (as indicated by vital signs, weight, and intake–output measurements). Assess postural blood pressures (e.g., lying, sitting, standing) before and during drug therapy because of diuretic-induced fluid volume loss, which may lead to orthostatic hypotension (a drop in blood pressure of 20 mm Hg or more upon standing).

TABLE 29.6 Thiazide and Thiazide-Like Diuretics: Common Drug Interactions

Drug	Mechanism	Result
Oral antihyperglycemic drugs	Antagonism	Reduced therapeutic hypoglycemic effect
Corticosteroids	Additive effect	Hypokalemia
Digoxin	Hypokalemia	Increased digoxin toxicity
Lithium	Decreased clearance	Increased lithium toxicity
NSAIDs	Inhibition of kidney prostaglandins	Decreased diuretic activity

NSAIDs, Nonsteroidal anti-inflammatory drugs.

Dosages

Thiazide and Selected Thiazide-Like Diuretic Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications
 hydrochlorothiazide (Urozide)	Thiazide diuretic	<i>Neonates and infants under 6 mo</i> PO: 1.5 mg/kg/day divided bid <i>Infants over 6 mo and children under 2 yr</i> PO: 12.5–37.5 mg/day divided bid <i>Children 2–12 yr</i> PO: 37.5–100 mg/day divided bid <i>Adults</i> PO: 25–200 mg/day, usually divided	Edema, heart failure as an adjunct to loop diuretics
metolazone (Zaroxolyn)	Thiazide-like diuretic	<i>Adults</i> PO: 5–20 mg/day	

PO, oral.

In addition, assess specific laboratory values associated with renal and hepatic functioning; for example, BUN level (normal range, 8 to 16.4 mmol/L) and creatinine level (normal range, 50 to 100 μ mol/L) for kidney function, and ALP (normal range, 13 to 39 units/L), AST (normal range, 8 to 46 units/L in males; 7 to 34 units/L in females), and LDH (normal range, 45 to 90 units/L) for liver function. It is important to note, however, that normal ranges of these laboratory values may vary somewhat from facility to facility. Serum electrolyte levels are also crucial to assess before and during diuretic therapy because of the subsequent loss of electrolytes through the urine and their relationship to fluid volume status. Specifically, obtain and document serum potassium, sodium, chloride, magnesium, calcium, uric acid, and creatinine levels, as ordered. Arterial blood gas levels may also be ordered.

The use of CAIs requires close assessment of sodium and potassium levels. These drugs are not to be used in patients with a history of kidney or liver dysfunction. As with any diuretic that results in loss of potassium (excluding potassium-sparing diuretics), if these drugs are given concurrently with digoxin, there is increased risk for digoxin toxicity (because of hypokalemia).

Loop diuretics are more potent than thiazide diuretics, combination products, and potassium-sparing diuretics. These drugs may pose more problems for older adult patients or those with severe electrolyte loss and liver failure. An additional and significant concern for patients taking loop diuretics is their interaction with other medications that are neurotoxic or ototoxic (see Table 29.3). Cross-sensitivity has been documented in patients who are allergic to sulfonamide antibiotics. Loop diuretics may also cause severe skin reactions (e.g., exfoliative dermatitis with furosemide), so a thorough assessment of the patient's skin prior to administration is important. Additionally, with loop diuretics, potential drug-laboratory value interactions include increased serum uric acid and glucose levels. Cases of tinnitus and reversible deafness have been reported with the use of IV furosemide.

With potassium-sparing diuretics, hyperkalemia may be an adverse effect; therefore, assess the patient's serum levels of potassium. Additionally, because of the potassium-sparing effect, contraindications include drugs or conditions that may result in hyperkalemia. Thus, potassium supplements, ACE inhibitors, and severe kidney failure are contraindications. Lithium toxicity may occur if given with these diuretics because of resultant hyperkalemia. See the previous discussion of additional cautions, contraindications, and drug interactions associated with diuretic use.

◆ NURSING DIAGNOSES

- Reduced cardiac output as a result of drug effects and adverse effects of diuretics (e.g., fluid and electrolyte loss)
- Inadequate fluid volume as a result of drug effects and adverse effects of diuretics
- Potential risk for injury as a result of orthostatic hypotension and dizziness

◆ PLANNING

◆ Goals

- Patient will regain and maintain balanced cardiac output.

CASE STUDY

Hydrochlorothiazide Therapy

Glenda, a 62-year-old university professor, has been diagnosed with primary hypertension and will be taking 50 mg of hydrochlorothiazide (Urozide) daily. There is no evidence of renal insufficiency or cardiac damage at this time, nor is there evidence of retinopathy or other signs or symptoms of end-organ disease. She is anxious because the fall semester is starting and she has a heavy teaching load, but she is willing to take the steps needed for better health.

At her 1-month follow-up appointment, Glenda reports "feeling so tired" and asks whether the medication causes sleepiness. When questioned, she says that she takes the hydrochlorothiazide at dinnertime because she is afraid it will "interfere with her classes."

1. What do you suspect is happening with Glenda, and what would you recommend?
2. During this follow-up appointment, you ask Glenda if she is eating foods high in potassium. She looks embarrassed and answers, "I lost that pamphlet about the foods with potassium, but I try to drink orange juice every day." What foods should she eat for their potassium content?
3. The report on Glenda's potassium levels comes back from the laboratory, and the results are 3.4 mmol/L. She asks, "Am I going to be put on a potassium pill, too?" What is your answer?
4. Six months later, Glenda is diagnosed with type 2 diabetes mellitus and is started on oral antihyperglycemic therapy. What will you teach her about managing her diabetes while taking the hydrochlorothiazide?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

- Patient will regain and maintain balanced fluid volume status.
- Patient will remain free from injury.

◆ Expected Patient Outcomes

- Patient continues to show normal cardiac output while receiving diuretic therapy, as evidenced by vital signs, adequate intake, and output within normal limits (pulse between 60 and 100 beats per minute; blood pressure 120/80 mm Hg or within normal parameters for the patient; urine output 30 mL/hr or higher).
 - Patient has strong pedal pulses and warm, pink extremities with rapid capillary refill.
- Patient regains balanced fluid volume status without dehydration or overhydration.
 - Patient's skin is pliable and with firm turgor.
 - Patient's laboratory values return within normal limits for urine specific gravity, serum sodium, chloride, and potassium.
- Patient takes diuretic therapy as directed and with adequate fluid intake, avoiding hypotensive episodes.
 - Patient changes positions slowly and with purpose while on diuretic therapy.
 - Patient reports any excessive dizziness, lightheadedness, palpitations, tingling of fingers and toes, confusion, disorientation, or fainting episodes.

◆ IMPLEMENTATION

Measure and record blood pressure, pulse rate, intake and output, and daily weights during diuretic therapy. Changes from the initial assessment data that alert the nurse to potential problems with the drug therapy include the presence of dizziness, fainting, or lightheadedness on standing or changing positions; weakness; fatigue; tremor; muscle cramping; changes in mental health status; or cold clammy skin. Diuretic therapy may also precipitate heart irregularities or palpitations; therefore, continue to monitor heart rate and rhythm. Fluid loss from the action of the diuretic may lead to the adverse effect of constipation, so preventive measures are needed, such as increased intake of fluids and fibre (unless contraindicated). If

constipation continues, the health care provider may need to provide alternatives such as psyllium-based, bulk-forming laxatives. Always give diuretics exactly as directed but with consideration of the patient's age and related needs. Appropriate dosing and timing of the drugs are often important to enhance therapeutic effects and minimize adverse effects. Because diuretics taken late in the afternoon or evening may lead to nocturia and subsequent loss of sleep, these medications are usually scheduled for morning dosing. Safety concerns exist with nocturia, especially with older adults, because possible confusion and dizziness associated with getting up in the middle of the night may create the potential for falls and injury (see also [Special Populations: Older Adults: Diuretic Therapy](#) box).

SPECIAL POPULATIONS: OLDER ADULTS

Diuretic Therapy

- Before and during diuretic drug therapy, measure the patient's height, weight, intake and output, blood pressure, pulse rate, respiratory rate, and temperature. Assess breath and heart sounds and edematous areas. Monitor serum sodium, potassium, and chloride levels.
- Emphasize to older adult patients that diuretics need to be taken at the same time every day. These drugs are generally ordered to be taken in the morning to help prevent nocturia, which can result in lack of sleep. More importantly, nocturia can lead to injury if the individual needs to get out of bed to void and subsequently becomes dizzy or confused and falls. A bedside commode may be used to decrease the risk of injury.
- If an older adult patient is living alone and has minimal or no assistance with the medication regimen, visits from a home health provider or other health care provider may help ensure safety, efficacy, and adherence, not only in taking the medication but also in following all aspects of the therapeutic regimen.
- Exercise caution in administering diuretics to older adults because they are more sensitive to the therapeutic effects of these drugs (often reacting to smaller dosages of medication than are required by other patients) and may experience adverse effects such as dehydration, electrolyte loss, dizziness, and syncope.
- Encourage patients to change positions slowly because of the risk of orthostatic hypotension and subsequent falls and injury. Emphasize the importance of recording daily weights, blood pressures, and overall well-being.
- Advise patients that carrying a card or electronic device containing a brief medical history, blood pressure readings, names and telephone numbers for contact persons, and a list of medications is important to ensure safety and minimize complications. Many older adults are adept at using electronic devices, and information can be easily stored on a smartphone, tablet, or computer and changed as necessary. If a patient is not comfortable using a device, a physical card can be formatted to fit in a wallet, with a copy placed on the refrigerator door or in another visible location so that it will be easily available to emergency personnel should they need to visit the home. Such a card can be easily made using standard card stock or an index card. Information can be entered using a pen or pencil. Copies of the card should be given

to caregivers, family members, significant others, health care providers, and dentists. The card then needs to be updated at regular intervals by the patient or another individual or health care provider involved in the patient's care. The following sample shows the headings and content for such a card (or the information to be made available on an electronic device):

1. **Name:** _____
2. **Age:** _____
3. **Allergies (drug/food):** _____
4. **Medical history** (place an X to the left of all that apply; write in any not listed):

☐ Anemia	☐ Depression	☐ Nerve problems
☐ Asthma	☐ Diabetes	☐ Pacemaker or defibrillator device
☐ Bleeding problems	☐ Difficulty swallowing	☐ Recent weight gain
☐ Blood clots	☐ Heart problems	☐ Recent weight loss
☐ Breathing problems	☐ High blood pressure	☐ Stroke
☐ Cancer	☐ Low blood pressure	☐ Thyroid problems
Others: _____		
5. **Surgeries** (list all with date, type of surgery, purpose, any complications): _____
6. **Prosthetics used:** _____
7. **Dentures/ dental problems:** _____
8. **Assistive devices:** Glasses _____ Hearing aids _____
Mobility assistance _____
9. **Contact names and telephone numbers:** _____
10. **Current medications** (prescription drugs; over-the-counter drugs; natural health products; others):
 Name of medication(s) _____
 Dosage(s) _____
 Frequency of doses _____
 Reasons for use of medications _____

Loop diuretics (if taken at high doses as ordered) may increase the risk for fluid volume and electrolyte depletion (e.g., hypokalemia, hyponatremia, dehydration). Monitoring of therapy includes frequent assessment of blood pressure and pulse rate—including orthostatic blood pressures and pulse rates (supine and standing)—hydration status, and capillary refill, as well as daily measurement of weight. Acute hypotensive episodes may occur with higher doses of loop diuretics and precipitate syncope and falls. Therefore, educate patients about safety measures to put in place to help prevent falls. Hypokalemia is the most commonly encountered electrolyte imbalance and may be very dangerous. Symptoms include anorexia, nausea, lethargy, muscle weakness, mental confusion, and hypotension. If IV dosage forms are given, it is crucial to check for diluents, drug incompatibilities, and intactness of the IV site. Double-check rates of infusion and use an infusion pump. With potassium-sparing diuretics, potassium is reabsorbed and not excreted (as previously discussed), so hyperkalemia, rather than hypokalemia, may become

problematic. Signs and symptoms of hyperkalemia include nausea, vomiting, diarrhea, and abdominal cramping (see [Chapter 30](#)) and should be reported immediately. See Patient Teaching Tips for more information.

◆ EVALUATION

The therapeutic effects of diuretics include the resolution of or reduction in edema, fluid volume overload, heart failure, or hypertension (or the restoration of normal intraocular pressures, if used for such a purpose, as with the CAIs). Monitor patients for the occurrence of adverse reactions to diuretics, such as hypotension (from volume loss), electrolyte imbalances, metabolic alkalosis (arterial blood gas values may need to be measured), drowsiness (with CAIs), hypokalemia, tachycardia (less significant with mannitol), and hyperkalemia (with potassium-sparing diuretics). Review all goals and outcome criteria in the evaluation process.

PATIENT TEACHING TIPS

- Patients taking diuretics need to maintain proper nutritional intake and fluid volume and eat potassium-rich foods, except when contraindicated or when potassium-sparing diuretics are used. Foods high in potassium include bananas, oranges, apricots, dates, raisins, broccoli, green beans, potatoes, tomatoes, meats, fish, wheat bread, and legumes.
- Health care providers may recommend potassium supplementation, depending on the symptoms and serum levels of the individual patient. Continue to monitor potassium levels of those on potassium supplements. Normal serum potassium levels are 3.5–5 mmol/L (see Chapter 30).
- Frequent laboratory tests may be indicated at the beginning of and throughout therapy with diuretics. These tests may include measurement of electrolytes, uric acid, and blood gases.
- Encourage patients to change positions slowly and to rise slowly after sitting or lying to prevent dizziness and possible fainting (syncope).
- Patients may need to be encouraged to increase their intake of fluids (if not contraindicated) to prevent dehydration and minimize constipation. Increased consumption of fibre may also help with constipation.
- Any unusual adverse effects or problems, such as excessive dizziness, syncope, weakness, or muscle aches, need to be reported immediately to the health care professional.
- Advise patients to keep a daily journal, in handwritten format or electronically; entries should include daily weights, how the patient feels each day, dosage of diuretic, and any other important information related to their diagnoses and medical treatment.
- Patients can prevent constipation with an increase in intake of fibre, bulk, roughage, and fluids, if not contraindicated.
- Educate patients about the signs and symptoms of hypokalemia, such as anorexia, nausea, lethargy, muscle weakness, mental confusion, and hypotension. In addition, emphasize the importance of being cautious regarding hot climates, excessive sweating, fevers, and the use of saunas or hot tubs. Heat raises core body temperature and causes further losses of potassium, sodium, and water through sweat, which may increase the risk of additional problems with hypotension and fluid–electrolyte imbalances. Fluid volume and electrolyte loss may also occur with vomiting or diarrhea.
- If a patient is taking a diuretic with digoxin, educate the patient, family members, and anyone involved in the patient's care about how to monitor pulse rate. The warning signs and symptoms of digoxin toxicity include headache, dizziness, confusion, nausea, visual disturbances, and bradycardia. A pulse rate of 60 beats per minute or lower is often used as a guideline, but always check facility policies or guidelines.
- Educate patients with diabetes mellitus who are also taking thiazide or loop diuretics about the need for close monitoring of blood glucose levels.

KEY POINTS

- The five main types of diuretics are CAIs and loop, osmotic, potassium-sparing, and thiazide and thiazide-like diuretics.
- The loop, potassium-sparing, and thiazide and thiazide-like diuretics are the most commonly used.
- Remember that loop diuretics are more potent than thiazides, combination diuretics, and potassium-sparing diuretics.
- It is important to have a thorough knowledge of kidney anatomy and physiology and how it relates to the action of the various diuretics; for example, if a loop diuretic is given, its site of action is the loop of Henle and it causes the excretion of sodium, potassium, and chloride into the urine.
- Methods for monitoring excess and deficit fluid volume include assessment of skin and mucous membranes, blood pressure, pulse rate, intake and output, and daily weights.

- With diuretics, always be concerned about patients from more vulnerable populations, such as older adults, those

with chronic illnesses, and patients with altered kidney or liver function.

EXAMINATION REVIEW QUESTIONS

1. The nurse is reviewing the medications for a patient who has just been prescribed a loop diuretic. The nurse identifies a possible interaction with which drug or class of drugs?
 - a. Vitamin D
 - b. warfarin sodium
 - c. Penicillin
 - d. NSAIDs
2. The nurse is monitoring laboratory test results of patients who are taking loop and thiazide diuretics. The nurse must monitor for what adverse effect in these patients?
 - a. Decreased serum levels of potassium
 - b. Increased serum levels of calcium
 - c. Decreased serum levels of calcium
 - d. Increased serum levels of sodium
3. What laboratory result for a patient taking spironolactone would be most concerning for the nurse?
 - a. Serum sodium level of 140 mmol/L
 - b. Serum potassium level of 3.6 mmol/L
 - c. Serum potassium level of 5.8 mmol/L
 - d. Serum magnesium level of 0.8 mmol/L
4. Which statement needs to be included when the nurse provides education for a patient with heart failure who is taking daily doses of spironolactone?
 - a. "Be sure to eat foods that are high in potassium."
 - b. "Avoid foods that are high in potassium."
 - c. "Avoid grapefruit juice while taking this medication."
 - d. "A low-fibre diet will help prevent adverse effects of this medication."
5. A patient with diabetes has a new prescription for a thiazide diuretic. Which statement should the nurse include when teaching the patient about this medication?
 - a. "There is nothing for you to be concerned about when you are taking the thiazide diuretic."
 - b. "Be sure to avoid foods that are high in potassium."
 - c. "You need to take the thiazide at night to avoid interactions with your diabetes medication."
 - d. "Monitor your blood glucose closely because the thiazide diuretic may cause the levels to increase."
6. An older adult patient has been discharged following treatment for a mild case of heart failure. He will be taking a loop diuretic. Which instruction(s) from the nurse are appropriate? (Select all that apply.)
 - a. "Take the diuretic at the same time each morning."
 - b. "Take the diuretic only if you notice swelling in your feet."
 - c. "Be sure to stand up slowly because the medicine may make you feel dizzy if you stand up quickly."
 - d. "Drink at least eight glasses of water each day."
 - e. "Here is a list of foods that are high in potassium—you need to avoid these."
 - f. "Please call your doctor immediately if you notice muscle weakness or increased dizziness."
7. The order reads: Give mannitol 0.5 g/kg IV now, over 2 hours. The patient weighs 165 lb, and you have a 100-mL vial of 20% mannitol. How many grams will the patient receive? How many millilitres of mannitol will you prepare for this infusion?
8. A patient is taking an aminoglycoside antibiotic for pneumonia and will also be taking the loop diuretic furosemide (Lasix) due to fluid overload. The nurse will monitor carefully for which potential effect from the interaction of these two drugs?
 - a. Nephrotoxicity
 - b. Ototoxicity
 - c. Pulmonary fibrosis
 - d. Hepatotoxicity

CRITICAL THINKING ACTIVITIES

1. While assessing a patient who is taking a diuretic, the nurse notes the following blood pressure readings: While lying in bed: 134/86 mm Hg; while sitting on the side of the bed: 130/82 mm Hg; while standing: 108/62 mm Hg. In addition, the patient commented that he felt lightheaded while standing. What has happened, and what is the nurse's priority at this time?
2. A patient has been given a new order for spironolactone, 50 mg daily. While reviewing the patient's orders, the nurse notes that the patient has an existing order for potassium

chloride (K-Dur®), 20 mmol daily. The patient's potassium level is 3.9 mmol/L. What is the nurse's priority action at this time?

3. The nurse is administering a thiazide diuretic to a patient who has been receiving digoxin for several months as part of treatment for a cardiac dysrhythmia. What is the priority for regular assessment, considering the use of these two drugs together?

Fluids and Electrolytes

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Review the function of fluid volume and compartments within the body as well as the role of each of the major electrolytes in maintaining homeostasis.
2. Identify the various electrolytes and give normal serum values for each.
3. Briefly discuss the various fluid and electrolyte disorders that commonly occur in the body, with attention to fluid volume or electrolyte deficits and excesses.
4. Identify the fluid and electrolyte solutions commonly used to correct states of deficiency or excess.
5. Discuss the mechanisms of action, indications, dosages, routes of administration, contraindications, cautions, adverse effects, toxicities, and drug interactions of the various fluid and electrolyte solutions.
6. Compare the various solutions used to expand or decrease a patient's fluid volume and electrolytes, considering how they work, why they are used, and specific antidotes available to counter any toxic effects.
7. Develop a collaborative plan of care that includes all phases of the nursing process for patients receiving fluid and electrolyte solutions.

KEY TERMS

Blood The fluid that circulates through the heart, arteries, capillaries, and veins, carrying nutrients and oxygen to the body cells; consists of plasma—its liquid component—and three major solid components: erythrocytes (red blood cells or RBCs), leukocytes (white blood cells or WBCs), and platelets. (p. 501)

Colloids Protein substances that increase the colloid oncotic pressure. (p. 504)

Colloid oncotic pressure (COP) A form of osmotic pressure exerted by protein in blood plasma that tends to pull water into the circulatory system. (p. 501)

Crystalloids Substances in a solution that diffuse through a semipermeable membrane. (p. 502)

Dehydration Excessive loss of water from body tissues. It is accompanied by an imbalance in the concentrations of essential electrolytes, particularly sodium, potassium, and chloride. (p. 502)

Edema The abnormal accumulation of fluid in interstitial spaces. (p. 502)

Euvolemia The state of normal body fluid volume. (p. 501)

Euvolemic hyponatremia A normal body sodium level with increase in total body water. (p. 510)

Extracellular fluid (ECF) The portion of the body fluid comprising the interstitial fluid and blood plasma. (p. 501)

Gradient A difference in the concentration of a substance on two sides of a permeable barrier. (p. 502)

Hydrostatic pressure (HP) The pressure exerted by a liquid. (p. 501)

Hyperkalemia A condition in which there is an abnormally high potassium concentration in the blood, most likely due to defective kidney excretion but also drugs. (p. 507)

Hypernatremia A condition in which there is an abnormally high sodium concentration in the blood; more commonly results from excessive dietary sodium, kidney disorders, or dehydration. (p. 509)

Hypokalemia A condition in which there is an inadequate amount of potassium, the major intracellular cation, in the bloodstream. (p. 507)

Hyponatremia A condition in which there is an inadequate amount of sodium, the major extracellular cation, in the bloodstream, caused by either inadequate excretion of water or excessive water intake or by drugs (e.g., diuretics). (p. 509)

Interstitial fluid (ISF) The extracellular fluid that fills in the spaces between most of the cells of the body. (p. 501)

Intracellular fluid (ICF) The fluid located within cell membranes throughout most of the body. It contains dissolved solutes that are essential to maintaining electrolyte balance and healthy metabolism. (p. 501)

Intravascular fluid (IVF) The fluid inside blood vessels. (p. 501)

Isotonic Having the same concentration of a solute as another solution and thus exerting the same osmotic pressure as that solution, such as an isotonic saline solution that contains an amount of salt equal to that found in the intracellular and extracellular fluid. (p. 501)

Osmotic pressure The pressure produced by a solution necessary to prevent the osmotic passage of solvent into it when the solution and solvent are separated by a semipermeable membrane. (p. 501)

Plasma The watery, straw-coloured fluid component of lymph and blood in which leukocytes, erythrocytes, and platelets are suspended. (p. 501)

Serum The clear, cell-free portion of the blood from which fibrinogen has been separated during the clotting process, as typically carried out with a laboratory sample. (p. 501)

OVERVIEW

Fluid and electrolyte management is one of the cornerstones of patient care. Most disease processes, tissue injuries, and surgical procedures greatly influence the physiological status of fluids and electrolytes in the body. Understanding fluid and electrolyte management requires knowledge of the extent and composition of the various body fluid compartments.

PHYSIOLOGY OF FLUID BALANCE

Approximately 60% of the adult human body weight is composed of water. This is referred to as *total body water* (TBW). The percent of body water is higher in infants and lower in older adults. Both populations are more sensitive to fluid imbalances than the adult. Total body water is distributed in two main compartments: **intracellular fluid (ICF)** and extracellular fluid (ECF). Extracellular fluid is further divided into **interstitial fluid (ISF)** and intravascular fluid (IVF) (also called plasma volume). This distribution is illustrated in [Figure 30.1](#). When the total body fluid content in the body is normal, it is referred to as **euvolemia**.

Fluid contained within the cells is called *intracellular fluid* (ICF), and it contains solutes such as electrolytes and glucose. *Extracellular fluid* (ECF) is the fluid outside the cells. Its function is to transport nutrients to cells and transport waste products away from cells. ECF is further broken down into **intravascular fluid (IVF)** (contained within blood vessels) and interstitial fluid (surrounding the cell). *Intravascular* refers to the volume of **blood** in the circulatory system and contains protein-rich plasma and large amounts of albumin. The term **plasma** is used to describe the fluid that flows through the blood vessels and is also known as intravascular fluid (IVF). **Serum** is a closely related term (see Key Terms). In contrast, interstitial fluid (ISF) contains little or no protein. ISF is further broken down to transcellular fluid, which is contained within

specialized body compartments such as the synovial, cerebrospinal, and pleural cavities. The interstitial fluid is the fluid in the spaces between cells, tissues, and organs. Water within the body is critical, not only due to its vast quantity but also because it serves as a solvent to dissolve solutes and acts as a medium for metabolic reactions. Throughout the body, water is freely exchanged among all fluid compartments and is retained in a relatively constant amount. Internal control mechanisms responsible for maintaining fluid balance include thirst, antidiuretic hormone (ADH), and aldosterone. Movement into and out of cells is carried out through the following processes: diffusion, filtration, active transport, and osmosis.

Extracellular fluid (ECF) consists of both plasma and ISF, with one important difference. Plasma has a protein concentration four times greater than that of ISF, of which albumin constitutes 80%. The reason for this higher intravascular concentration of protein is that these solutes (proteins) have a molecular weight, which makes them too large to pass through the walls of the blood vessels. Due to a difference in concentration, fluid flows from the area of low concentration in the interstitial compartment to the area of high concentration inside the blood vessel, trying to create an isotonic environment on either side of the blood vessel wall. **Isotonic** means an equal concentration of solutes across a membrane. The protein in the blood vessels exerts a constant **osmotic pressure** that prevents the leakage of too much plasma through the capillaries into the tissues (this creates a pulling pressure). When proteins suspended in plasma are in a colloidal state, this particular pressure is called **colloid oncotic pressure (COP)**, and it is normally 24 mm Hg. The opposing, pushing pressure exerted by the ISF is called **hydrostatic pressure (HP)**; normally, it is 17 mm Hg, which is less than the COP. The phenomenon of COP is illustrated in [Figure 30.3](#).

Tonicity and **osmolality** are similar terms that are often used interchangeably, but they are not exactly the same, chemically speaking. **Osmolality** is used in reference to body fluids and is the concentration of particles in a solution. Normal osmolality of body fluids is between 290 and 310 mOsm/kg. **Tonicity** is used in reference to IV fluids and is the measurement of the concentration of IV fluids as compared with the osmolality of body fluids. **Tonicity** can also be defined as the measure of osmotic pressure. The tonicity of IV solutions can be considered isotonic, hypotonic, or hypertonic. **Isotonic** means that the osmotic pressures inside and outside of the blood cell are the same. **Hypotonic** means that the solution outside the cell has a lower osmotic pressure than inside the cell. **Hypertonic** means the solution outside the blood cell has a higher osmotic pressure than inside the cell. Giving an isotonic solution such as normal saline (0.9% NaCl) or lactated Ringer solution causes no net fluid movement.

Administering a hypotonic solution (0.45% NaCl) causes fluid to move out of the vein and into the tissues and cells.

Fig. 30.1 Distribution of total body water (TBW). ECF, extracellular fluid; ICF, intracellular fluid; ISF, interstitial fluid; PV, plasma volume.

Fig. 30.2 A depiction of what happens when red blood cells are exposed to different fluids. Isotonic solutions cause no net fluid movement. Hypertonic solutions cause water to move out of the cells and can cause the cells to shrink. Hypotonic solutions cause water to move into the cells, which can cause them to burst.

Fig. 30.3 Colloid osmotic pressure (oncotic pressure). As shown, the colloids inside the blood vessel are too large to pass through the vessel wall. The resulting oncotic pressure exerted by the colloids draws fluid from the surrounding tissues and other extravascular spaces into the blood vessels and keeps fluid inside the blood vessel.

Injecting a hypertonic solution (3% NaCl) causes fluid to move from the ISF into the veins. This is depicted in [Figure 30.2](#). Acid–base balance is also important to normal bodily functions and is regulated by the respiratory system and the kidney. An acid is a substance that can donate or release hydrogen ions, such as carbonic acid or hydrochloric acid. A base is a substance that can accept hydrogen ions, such as bicarbonate. The pH is a measure of the degree of acidosis and alkalinity and is inversely related to hydrogen ion concentration. For example, when hydrogen ion concentration increases, the pH decreases and leads to acidity. As the hydrogen ion concentration decreases, the pH increases, leading to more alkalinity. With normal pH ranging from 7.35 to 7.45, acidosis occurs when pH falls below 7.35. Conversely,

alkalosis occurs when pH rises above 7.45. Regulation of the acid–base balance requires healthy functioning of the respiratory and renal systems. The respiratory system compensates for metabolic problems and pH imbalances by regulation of CO₂. In acidosis, CO₂ can be exhaled to try to normalize the lower pH; in alkalosis, carbon dioxide will be retained by the respiratory system to try to elevate the pH. The kidney also compensates by reabsorbing and generating bicarbonate and excreting hydrogen ions in acidosis to normalize the low pH. Conversely, the kidney can excrete bicarbonate and retain hydrogen ions to normalize the high pH seen with alkalosis. The influence of the respiratory system is determined by an arterial blood gas (ABG) test. The influence of the body on acid–base balance is determined by a blood test, which measures total body CO₂ and is usually represented as HCO₃⁻. Both are used in determining and treating acid–base disorders. Detailed determination and treatment of acid–base balance is complex and beyond the scope of this textbook. Certain drugs, such as the diuretic acetazolamide (see [Chapter 29](#)) and sodium bicarbonate (tablets or injection), can be used to correct metabolic acid–base disturbances.

This regulation of the volume and composition of body water is essential for life, because it is the medium in which all metabolic reactions occur. The body keeps the volume and composition remarkably constant by preserving the balance between intake and excretion. The amount of water gained each day is kept roughly equal to the amount of water lost. When the body is unable to maintain this equilibrium, therapy with select agents becomes necessary. If the amount of water gained exceeds the amount of water lost, a water excess, or overhydration, occurs. Such fluid excesses often accumulate in interstitial spaces, such as in the pericardial sac, intrapleural space, peritoneal cavity, joint capsules, and lower extremities. This accumulation of fluid in extravascular space (outside the vessel) is referred to as **edema**. In contrast, if the quantity of water lost exceeds that gained, a water deficit, or **dehydration**, occurs. Death may occur when 20 to 25% of TBW is lost.

Dehydration leads to a disturbance in the balance between the amount of fluid in the extracellular compartment and that in the intracellular compartment. Sodium is the principal extracellular electrolyte and plays a primary role in maintaining water concentration in the body because of its highly osmotic chemistry. In the initial stages of dehydration, water is lost first from the extracellular compartments. The amount of further fluid losses, COP changes, or both, determines the type of clinical dehydration that develops ([Table 30.1](#)). Clinical conditions that can result in dehydration and fluid loss, as well as the symptoms of dehydration and fluid loss, are presented in [Table 30.2](#). When fluid that has been lost must be replaced, there are three categories of agents that can be used to accomplish this: crystalloids, colloids, and blood products. The clinical situation dictates which category of agents is most appropriate.

CRYSTALLOIDS

Crystalloids are fluids given by intravenous (IV) injection that supply water and sodium to maintain the osmotic **gradient** between the extravascular and intravascular compartments.

Their plasma volume–expanding capacity is related to their sodium concentration. The different crystalloids are listed in Table 30.3.

Mechanism of Action and Drug Effects

Crystalloid solutions contain fluids and electrolytes that are normally found in the body. They do not contain proteins (colloids), which are necessary to maintain the colloid osmotic

pressure and prevent water from leaving the plasma compartment. In fact, the administration of large quantities of crystalloid solutions for fluid resuscitation decreases the COP, attributable to a dilutional effect. Crystalloids are dispersed faster into the interstitial and intracellular compartments than colloids. This makes crystalloids a better choice for treating dehydration than for expanding the plasma volume alone, such as is used for hypovolemic shock.

Indications

Crystalloid solutions are most commonly used as maintenance fluids. They are used to compensate for insensible fluid losses, to replace fluids, and to manage specific fluid and electrolyte disturbances. Crystalloids also promote urinary flow. They are much less expensive than colloids and blood products. In addition, there is no risk of viral transmission or anaphylaxis and no alteration in the coagulation profile associated with their use, unlike with blood products. The choice of whether to use a crystalloid or colloid depends on the severity of the condition. The following are the common indications for either crystalloid or colloid replacement therapy:

- Acute liver failure
- Acute nephrosis
- Acute respiratory distress syndrome
- Burns
- Cardiopulmonary bypass
- Hypoproteinemia
- Reduction of the risk for deep vein thrombosis
- Hemodialysis
- Shock

Contraindications

Contraindications to the use of crystalloids include known drug allergy to a specific product or hypervolemia, and may include severe electrolyte disturbance, depending on the type of crystalloid used.

Adverse Effects

Crystalloids are a safe and effective means of replacing needed fluid. They do, however, have some unwanted effects. Because they contain no large particles, such as proteins, they do not stay within the blood vessels and can leak out of the plasma into the tissues and cells. This can result in edema anywhere in the body; peripheral

TABLE 30.1 Types of Dehydration

Type	Characteristics
Hypertonic	Occurs when water loss is greater than sodium loss, which results in a higher concentration of solutes outside the cells and causes the fluid inside the cells to move to the extracellular space, thus dehydrating the cells. Example: elevated temperature resulting in perspiration
Hypotonic	Occurs when sodium loss is greater than water loss, which results in higher concentrations of solute inside the cells and causes fluid to be pulled from outside the cells (plasma and interstitial spaces) into the cells. Examples: kidney insufficiency and inadequate aldosterone secretion
Isotonic	Caused by a loss of sodium and water from the body, which results in a decrease in the volume of extracellular fluid. Examples: diarrhea and vomiting

TABLE 30.2 Conditions Leading to Fluid Loss and Associated Symptoms*

Condition	Associated Symptoms
Bleeding	Tachycardia and hypotension
Bowel obstruction	Reduced perspiration and mucous secretions
Diarrhea	Reduced urine output (oliguria)
Fever	Dry skin and mucous membranes
Vomiting	Reduced lacrimal (tears) and salivary secretions

*Note: There may be overlap involving more than one of the symptoms, depending on the patient's specific condition.

TABLE 30.3 Crystalloids

Product	Osmolarity	COMPOSITION (MMOL/L)						
		Na	Cl	K	Ca	Mg	Lactate	Volume (mL)
NS (0.9% isotonic)	308 mOsm	154	154	0	0	0	0	1000
Hypertonic saline (3%)	154 mOsm	513	513	0	0	0	0	500
3.3% dextrose and 0.3% NS ($\frac{2}{3}$ and $\frac{1}{3}$) (isotonic)*	259 mOsm	51	51	0	0	0	0	1000
Lactated Ringer (isotonic)	275 mOsm	130	109	4	3	0	28	1000
D ₅ W (isotonic)*	260 mOsm	0	0	1	0	0	0	1000
D ₅ W & 0.45% NS (hypertonic)	406 mOsm	77	77	0	0	0	0	1000
Plasma-Lyte (isotonic)	294 mOsm	140	103	10	5	3	8	1000

Ca, calcium; Cl, chloride; D₅W, 5% dextrose in water; K, potassium; Mg, magnesium; Na, sodium; NS, normal saline.

*D₅W alone in an IV bag is considered isotonic but acts as a hypotonic solution once in the bloodstream.

edema and pulmonary edema are two common examples. Crystalloids also dilute the proteins that are in plasma, which further reduces the COP. To be effective, large volumes (multiple litres of fluid) are usually required. As a result, prolonged infusions may worsen acidosis or alkalosis, or adversely affect central nervous system function, due to fluid overload. Another disadvantage of crystalloids is that their effects are relatively short-lived.

Interactions

Interactions with crystalloid solutions are rare because they are similar if not identical to normal physiological substances. Certain electrolytes contained in lactated Ringer solution may be incompatible with other electrolytes, forming a chemical precipitate (e.g., phenytoin sodium precipitates if mixed with dextrose).

Dosages

For the recommended dosages of crystalloids, refer to [Table 30.4](#).

DRUG PROFILE

The most commonly used crystalloid solutions are normal saline (NS or 0.9% sodium chloride) and lactated Ringer solution. The available crystalloid solutions and their compositions are summarized in [Table 30.3](#). Sodium chloride is also discussed briefly in the section on electrolytes and in the Nursing Process section.

sodium chloride

Sodium chloride (NaCl) is available in several concentrations, the most common being 0.9%. This is the physiologically normal concentration of sodium chloride, which is why it is referred to as *normal saline* (NS). Other concentrations are 0.45% (half-normal, hypotonic) and 3% (hypertonic saline). These solutions have different indications and are used in different situations, depending on how urgently fluid volume restoration is needed and the extent of the sodium loss.

Sodium chloride is a physiological electrolyte that is present throughout the body's water. Thus, there are no hypersensitivity reactions to it. It is safe to administer during any stage of pregnancy, but it is contraindicated in patients with hyponatremia or hyperchloremia. Hypertonic saline injection (3%) is contraindicated in the presence of increased, normal, or only slightly decreased serum electrolyte concentrations. Correcting sodium too rapidly with hypertonic saline can lead to osmotic demyelination syndrome, which is characterized by intramyelinic splitting, vacuolization, and myelin sheath rupture, as well as brain shrinkage, which is potentially fatal. Conversely, infusing hypotonic saline is not recommended because it can cause hemolysis of the red blood cells (RBCs). Adding potassium to hypotonic solutions makes them isotonic and safe to give. Sodium chloride is also available as a 650-mg tablet.

The dose of sodium chloride administered depends on the clinical situation. The volume of crystalloid or colloid needed to expand the plasma volume by 1 litre (1 000 mL) is provided in [Table 30.4](#), which can be used as a general guide to dosing.

PHARMACOKINETICS

Plasma Volume– Expansion*	Colloid Oncotic Pressure	Duration of Expansion
60–70 mL	30 mm Hg	A few hours

*500 mL of normal saline will expand the plasma volume by 60 to 70 mL.

COLLOIDS

Colloids are protein substances that increase the COP and move fluid from the interstitial compartment to the plasma compartment by pulling the fluid into the blood vessels. Normally, this task is performed by the three blood proteins: albumin, globulin, and fibrinogen. The total protein level must be within the range of 74 g/L. If the protein level drops below 53 g/L, fluid shifts out of the blood vessels and into the tissues. When this happens, colloid replacement therapy is required to reverse this process, by increasing the COP. The COP decreases with age and also with hypotension and malnutrition. The commonly used colloids are listed in [Table 30.5](#).

Mechanism of Action and Drug Effects

The mechanism of action of colloids is related to their ability to increase the COP. Because colloids cannot pass into extravascular space, there is a higher concentration of solutes (solid particles) inside the blood vessels (in intravascular space) than outside the blood vessels. Fluid moves from the extravascular space into the blood vessels in an attempt to make it isotonic. As such, colloids increase the blood volume, and they are often referred to as *plasma expanders*. They also make up part of the total plasma volume.

Colloids increase the COP and move fluid from outside the blood vessels to inside the blood vessels. They can maintain the COP for several hours. Colloids are naturally occurring products and consist of proteins (albumin), carbohydrates (dextran or starch), fats (lipid emulsion), and animal collagen (gelatin). Usually, they contain a combination of both small and large particles. The small particles are eliminated quickly and promote diuresis and perfusion of the kidneys; the larger particles maintain the plasma volume. Albumin is the one exception in that it contains particles that are all the same size.

Indications

Colloids are used to treat a wide variety of conditions. Clinically, colloids are superior to crystalloids because of their ability to maintain the plasma volume for a longer time. However, crystalloids are less expensive and are less likely to promote bleeding (see Adverse Effects discussion, below). Conversely, crystalloids are more likely to cause edema because of the larger volumes needed to achieve the desired clinical effect. Crystalloids are better than colloids for emergency, short-term plasma-volume expansion.

Contraindications

Contraindications to the use of colloids include known drug allergy to a specific product or hypervolemia and may include severe electrolyte disturbance.

TABLE 30.4 Crystalloids and Colloids: Dosing Guidelines

	CRYSTALLOIDS AND COLLOIDS			
	0.9% NS	3% NS*	5% Colloid†	25% Colloid‡
To Raise Plasma Volume By 1 L, Administer:	5–6 L	1.5–2 L	1 L	0.5 L
Fluid Compartment Distributed to:				
Plasma	25%	25%	100%	200–300%
Interstitial space	75%	75%	0	Decreased fluid levels
Intracellular space	0	0	0	Decreased fluid levels

NS, normal saline.

*Hypertonic saline is a high-risk drug and should not be given faster than 100 mL/hr for short periods. Frequent monitoring of serum levels is required.

†Iso-oncotic solutions such as 5% albumin, dextran 70, and hetastarch.

‡Hyperoncotic solutions such as 25% albumin.

TABLE 30.5 Commonly Used Colloids

Product	COMPOSITION (MMOL/L)		
	Na	Cl	Volume (mL)
Dextran 70†	154	154	500
Dextran 40†	154	154	500
Hetastarch	154	154	500
5% Albumin	145	145	500
25% Albumin	145	145	100

†Dextran is available in NaCl, which has 154 mmol/L of both Na and Cl. It is also available in 5% dextrose in water, which contains no Na or Cl.

Adverse Effects

Colloids are relatively safe agents, although there are some disadvantages to their use. They have no oxygen-carrying ability and contain no clotting factors, unlike blood products. Because of this, they can alter the coagulation system through a dilutional effect, resulting in impaired coagulation and potential for bleeding. They may also dilute the plasma protein concentration, which in turn may impair platelet function. Rarely, dextran therapy causes anaphylaxis or kidney failure.

Interactions

No drug interactions occur with colloids.

Dosages

For the recommended dosages of colloids, refer to Table 30.4.

DRUG PROFILES

The specific colloid used for replacement therapy varies from institution to institution. The most commonly used are 5% albumin, dextran 40, pentastarch (Pentaspán®), and hetastarch. They have a rapid onset as well as a long duration of action. They are metabolized in the liver and excreted by the kidneys. Albumin is one exception; it is metabolized by the reticuloendothelial system and excreted by the kidneys and intestines. Hetastarch is a synthetic colloid with properties similar to those of albumin

and dextran. Pentaspán is an artificial colloid derived from a waxy starch composed almost entirely of amylopectin.

albumin

Albumin is a natural protein that is normally produced by the liver. It is responsible for generating about 80% of the COP. Human albumin is a sterile solution of serum albumin that is prepared from pooled blood, plasma, serum, or placenta obtained from healthy human donors. It is pasteurized (heated at 60°C for 10 hours) to destroy any contaminants. Unfortunately, because it is derived from human donors, the supply is limited. Many institutions have specific indications for the use of albumin.

Albumin is contraindicated in patients with a known hypersensitivity to it and in those with heart failure, severe anemia, or kidney insufficiency. Albumin is available only in parenteral form, in concentrations of 5% and 25%. For use during pregnancy, the potential benefits of albumin must be considered relative to the risk to the fetus. See Table 30.4 for the dosing guidelines.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Less than 1 min	Unknown	16 hr	Less than 24 hr

dextran

Dextran is a solution of glucose. It is available in two concentrations, dextran 40 and the more concentrated dextran 70, which has a molecular weight similar to that of albumin. Of the two, dextran 40 is more commonly used. Dextran is a derivative of sugar that has actions similar to those of human albumin in that it expands the plasma volume by drawing fluid from the interstitial space to the intravascular space.

Dextran is contraindicated in patients with hypersensitivity to it and in those with heart failure, kidney insufficiency, and extreme dehydration. It is available only in parenteral form, in either a 5% dextrose solution or a 0.9% sodium chloride

solution. For use during pregnancy, the potential benefits of dextran must be considered relative to the risk to the fetus. See [Table 30.4](#) for the dosing guidelines.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	5 min	Unknown	2–6 hr	4–6 hr

BLOOD PRODUCTS

Blood products can be considered biological drugs. RBC-containing products can improve tissue oxygenation and also augment plasma volume. Blood products are more expensive than crystalloids and colloids and are less available because they are natural products and require human donors. The available blood products are listed in [Table 30.6](#). They are most often indicated when a patient has lost 25% or more blood volume.

Mechanism of Action and Drug Effects

The mechanism of action of blood products is related to their ability to increase COP and plasma volume. They achieve these outcomes in the same manner as colloids and crystalloids, by pulling fluid from the extravascular space to the intravascular space. Because of this property, they are also considered plasma expanders. RBC-containing products also have the ability to carry oxygen. They can maintain the COP for several hours to days. Because they come from human donors, they have all the benefits (and hazards) of human blood products. They are administered when a person's body is deficient in these products.

Indications

Blood products are used to treat a wide variety of clinical conditions, and the blood product used depends on the specific indication. The available blood products and the conditions they are used to treat are listed in [Table 30.7](#).

Contraindications

There are no absolute contraindications to the use of blood products. However, because there is a risk for transfer of infectious disease, although remote, their use should be based on careful clinical evaluation of the patient's condition.

Adverse Effects

Blood products can produce undesirable effects, some potentially serious. Because blood products come from other humans, they can be incompatible with the recipient's immune system. These incompatibilities are tested for before the products' administration by determining the respective blood types of the donor and recipient and by cross-matching to determine compatibility between selected blood proteins. This cross-matching helps reduce the likelihood that the recipient will reject the blood product, which would precipitate transfusion reactions and anaphylaxis. Blood products

TABLE 30.6 Blood Products

Product	Dosage
Cryoprecipitate	1 unit
Fresh frozen plasma	1 unit
Packed red blood cells	1 unit
Plasma protein fractions	1 unit
Whole blood	1 unit

TABLE 30.7 Blood Products: Indications

Product	Indications
Cryoprecipitate and plasma protein fraction	To manage acute bleeding (over 50% blood loss slowly, or 20% rapidly)
Fresh frozen plasma	To increase clotting factor levels in patients with a demonstrated deficiency
Packed red blood cells	To increase oxygen-carrying capacity in patients with anemia, in patients with substantial hemoglobin deficits, and in patients who have lost up to 25% of their total blood volume
Whole blood	Same as for packed red blood cells, except that whole blood is more beneficial in cases of extreme (over 25%) loss of blood volume, because whole blood also contains plasma, the primary fluid volume of the blood; it also contains plasma proteins, the primary osmotic component, which help draw fluid back into blood vessels from surrounding tissues

can also transmit pathogens from the donor to the recipient; examples of such pathogens are hepatitis virus and human immunodeficiency virus (HIV). Various preparation techniques are now used to reduce the risk for pathogen transmission, and these have resulted in a drastic reduction in the incidence of such problems.

Interactions

As with crystalloids and colloids, blood products are similar if not identical to normal physiological substances; therefore, they are involved in few interactions. Calcium and aspirin, which normally affect coagulation, may interact with these substances when infused in the body, in much the same way they interact with the body's blood products. Blood must not be administered with any solution other than normal saline.

Dosages

For the dosage guidelines pertaining to blood products, refer to [Table 30.8](#).

DRUG PROFILES

Packed red blood cells and fresh frozen plasma are among the most commonly used blood products. All blood products are derived from pooled blood from human donors. Other less commonly used, but still important, blood products include whole blood, plasma protein fraction, cryoprecipitate, and platelets.

TABLE 30.8 Suggested Guidelines for Blood Products: Management of Bleeding

Amount of Blood Loss	Fluid of Choice
20% or less (slow loss)	Crystalloids
20–50% (slow loss)	Nonprotein plasma expanders (dextran, pentastarch, hydroxyethyl starch [Voluven®, Volulyte®], and hetastarch)
Over 50% (slow loss) or 20% (acutely)	Whole blood or packed red blood cells or plasma protein fraction and fresh frozen plasma
80% or more	Same as above, plus for every 5 units of blood given, administer 1 to 2 units of fresh frozen plasma and 1 to 2 units of platelets to prevent the hemodilution of clotting factors and bleeding

packed red blood cells

Packed red blood cells are obtained by centrifugation of whole blood and the separation of RBCs from plasma and the other cellular elements. The advantage of packed red blood cells is that their oxygen-carrying capacity is better than that of the other blood products, and they are less likely to cause cardiac fluid overload. Their disadvantages include high cost, limited shelf life, and fluctuating availability, as well as their ability to transmit viruses, trigger allergic reactions, and cause bleeding abnormalities. The Canadian National Advisory Committee on Blood and Blood Products (2014) recommends specific guidelines for the administration of RBCs. A restrictive transfusion strategy is recommended; for example, a hemoglobin of 70 to 80 g/L is recommended for patients who are hospitalized and stable; a hemoglobin of 70 g/L or less for adult and pediatric patients in intensive care; and a hemoglobin of 80 g/L or less for patients postoperatively or for patients who are hospitalized and stable, with pre-existing cardiovascular disease. Transfusions are considered for patients with specific symptoms (i.e., chest pain, orthostatic hypotension, tachycardia unresponsive to fluid resuscitation, heart failure). Always follow agency protocols for the administration of blood products. The suggested guidelines for their use in the management of blood loss are given in [Table 30.8](#).

fresh frozen plasma

Fresh frozen plasma is obtained by centrifuging whole blood and removing the cellular elements. The resulting plasma is then frozen at -18°C . Fresh frozen plasma is not recommended for routine fluid resuscitation, but it may be used as an adjunct to massive blood transfusion in the treatment of patients with underlying coagulation disorders. The plasma-expanding capability of fresh frozen plasma is similar to that of dextran but slightly less than that of hetastarch. The disadvantage of fresh frozen plasma is that it can transmit pathogens. The suggested guidelines for its use are given in [Table 30.8](#).

PHYSIOLOGY OF ELECTROLYTE BALANCE

The chemical composition of the fluid compartments varies. The principal electrolytes in the ECF are sodium cations (Na^+) and chloride anions (Cl^-). The major electrolyte in the ICF is the potassium cation (K^+). Other important electrolytes are calcium (see [Chapter 34](#)), magnesium (see [Chapter 53](#)), and phosphorus (see [Chapter 53](#)). These different chemical components are vital to the normal function of all body systems. They are controlled by the renin–angiotensin–aldosterone system, antidiuretic hormone system, and sympathetic nervous system. When these neuroendocrine systems are out of balance, adverse electrolyte imbalances commonly result. Patients who receive diuretics (see [Chapter 29](#)) are at risk for electrolyte abnormalities.

POTASSIUM

Potassium is the most abundant cationic (positively charged) electrolyte inside cells (the intracellular space), where the normal concentration is approximately 150 mmol/L. Approximately 95% of the potassium in the body is intracellular. In contrast, the amount of potassium outside the cells in the plasma ranges from 3.5 to 5.0 mmol/L. These plasma levels are critical to normal body function.

Potassium is obtained from a variety of foods, the most common being fruits and juices, vegetables, fish, and meats. Salt substitutes also contain potassium. It has been estimated that for normal body functions to be maintained, a person must consume 5 to 10 mmol of potassium per day. Fortunately, the average adult daily diet usually provides 35 to 100 mmol of potassium, which is well above the required daily amount. Excess dietary potassium is usually excreted by the kidneys in urine. However, if the kidneys lose their ability to filter and secrete waste products, potassium can accumulate. Excessive potassium can precipitate ventricular fibrillation and cardiac arrest. Hyperaldosteronism and the use of potassium-sparing diuretics can alter normal potassium balance as well. **Hyperkalemia** refers to a serum potassium level that exceeds 5.5 mmol/L. There are several causes of hyperkalemia, including the following:

- Angiotensin-converting enzyme (ACE) inhibitor use
- Burns
- Excessive loss from cells
- Infections
- Kidney failure
- Metabolic acidosis
- Potassium supplementation
- Potassium-sparing diuretic use
- Trauma

The opposite of hyperkalemia is **hypokalemia**, a deficiency of potassium. Hypokalemia is defined as a serum potassium level of less than 3.5 mmol/L. This condition is more often the result of excessive potassium loss than of poor dietary intake. As with hyperkalemia, there are many clinical conditions and other situations that can cause hypokalemia. These include the following:

- Alkalosis
- Increased secretion of mineralocorticoids (hormones of the adrenal cortex)

BOX 30.1 Symptoms of Hypokalemia**Early**

Anorexia
Hypotension
Lethargy
Confusion
Muscle weakness
Nausea

Late

Cardiac dysrhythmias
Neuropathy
Paralytic ileus
Secondary alkalosis

- Burns
- Corticosteroid use
- Diarrhea
- Diet extreme in nutritional deprivation
- Hyperaldosteronism
- Ketoacidosis
- Consumption of large amounts of licorice
- Loop diuretic use
- Malabsorption
- Prolonged laxative misuse
- Thiazide or thiazide-like diuretic use
- Vomiting

A low serum potassium can increase the toxicity associated with digoxin, and this can precipitate serious ventricular dysrhythmias.

The early detection of hypokalemia is important to prevent serious, life-threatening consequences of this metabolic disturbance if it remains undetected. The key to early detection is recognizing its early symptoms, which are generally mild and can easily go unnoticed. Both the early (mild) symptoms and late (severe) symptoms of hypokalemia are listed in [Box 30-1](#). Treatment involves both identifying and treating the cause and restoring serum potassium levels to normal (greater than 3.5 mmol/L). The consumption of potassium-rich foods can usually correct mild hypokalemia, but clinically significant hypokalemia requires the oral or parenteral administration of a potassium supplement, which usually contains potassium chloride.

Mechanism of Action and Drug Effects

The importance of potassium as the primary intracellular electrolyte is highlighted by the number of life-sustaining physiological functions that require it. Muscle contraction, the transmission of nerve impulses, and the regulation of heartbeats (the pacemaker function of the heart) are just a few of these functions.

Potassium is also essential for the maintenance of acid–base balance, isotonicity, and the electrodynamic characteristics of the cell. It plays a role in many enzymatic reactions, and it is an essential component of gastric secretions, kidney function, tissue synthesis, and carbohydrate metabolism.

Indications

Potassium replacement therapy is indicated in the treatment or prevention of potassium depletion in patients whose dietary measures prove inadequate. Potassium salts commonly used for this purpose include potassium chloride, potassium phosphate, and potassium acetate. The chloride is necessary to correct the hypochloremia (low level of chloride in the blood) that commonly accompanies potassium deficiency, and the phosphate is used to correct hypophosphatemia. The acetate salt may be used to raise the blood pH in acidotic conditions.

Other therapeutic effects of potassium are related to its role in the contraction of muscles and the maintenance of the electrical characteristics of cells. Potassium salts may be used to stop irregular heartbeats (dysrhythmias) and to manage the tachydysrhythmias that can occur after heart surgery.

Contraindications

Contraindications to potassium replacement products include known drug allergy to a specific drug product, hyperkalemia from any cause, severe kidney disease, acute dehydration, untreated Addison's disease, severe hemolytic disease, and conditions involving extensive tissue breakdown (e.g., multiple traumas, severe burns).

Adverse Effects

The adverse effects of oral potassium therapy are primarily limited to the gastrointestinal (GI) tract and include diarrhea, nausea, and vomiting. More significant effects include GI bleeding and ulceration. The parenteral administration of potassium usually produces pain at the injection site. Cases of phlebitis have been associated with IV administration. This irritation may be intensified with the administration of IV antibiotics (e.g., cephalosporin). One option is to insert a peripherally inserted central catheter to prevent the IV line from going interstitial; this option also prevents phlebitis. The generally accepted maximum concentration for infusion is 10 mmol/L to be infused through a peripheral line and 20 to 40 mmol/L and up to 60 mmol/L for a central line. It is best practice to use a lower concentration for peripheral access and to adhere to institutional policies for central line access. Excessive administration of potassium salts can lead to hyperkalemia and toxic effects. If IV potassium is administered too rapidly, cardiac arrest may occur. IV potassium must not be given faster than 10 mmol per hour to patients who are not on cardiac monitors. For critically ill patients on cardiac monitors, rates of 20 mmol per hour or more may be used.

Toxicity and Management of Overdose

The toxic effects of potassium are the result of hyperkalemia. Symptoms include muscle weakness, paresthesia, paralysis, cardiac rhythm irregularities that can result in ventricular fibrillation, and cardiac arrest. The treatment instituted depends on the degree of hyperkalemia and ranges from reversal of life-threatening problems to simple dietary restrictions. In the event of severe hyperkalemia, the IV administration of sodium bicarbonate, calcium gluconate or chloride, or dextrose solution with insulin is often required. These drugs correct severe hyperkalemia by causing a rapid intracellular

shift of potassium ions, which reduces the serum potassium concentration. Such interventions are often followed with orally or rectally administered sodium polystyrene sulfonate (Kayexalate®) or hemodialysis to eliminate the extra potassium from the body. Less critical levels can be reduced with dietary restrictions.

Interactions

Concurrent use of potassium-sparing diuretics and ACE inhibitors can produce a hyperkalemic state. Concurrent use of non-potassium-sparing diuretics, amphotericin B, and mineralocorticosteroids can produce a hypokalemic state.

Dosages

Fluid and electrolyte therapy involves replacing any deficits or losses and providing maintenance levels for specific patient requirements. Accordingly, specific dosage amounts of fluids or electrolytes depend on several clinical factors, including the following:

- Specific patient losses
- Efficacy of patient physiological systems involved in fluid and electrolyte metabolism, especially adrenal, cardiovascular, and kidney functioning
- Current drug therapy for pathological conditions that complicate the amount and duration of replacement
- Selection of oral or parenteral replacement formulations

Suggested dosage guidelines for potassium with subsequent adjustments are 10 to 20 mmol administered orally several times a day or parenteral administration of 30 to 60 mmol every 24 hours.

DRUG PROFILES

potassium supplements

Potassium supplements (Odan K-20, Odan K-8, PMS oral solution) are administered to prevent or treat potassium depletion. The acetate, chloride, and citrate salts of potassium are available for oral administration. The parenteral salt forms of potassium for IV administration are acetate, chloride, and phosphate. The dosage of potassium supplements is usually expressed in millimoles (mmol; equal to milliequivalents [mEq]) of potassium and depends on the requirements of the individual patient. Different salt forms of potassium deliver varying milliequivalent amounts of potassium.

Potassium is contraindicated in patients with severe kidney disease, severe hemolytic disease, or Addison's disease and in those with hyperkalemia, acute dehydration, or extensive tissue breakdown stemming from multiple traumas. Potassium is safe for administration during pregnancy. Potassium is available in oral form as an extended-release tablet and oral solution. It is also available as an injection in many different formulations for IV use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Immediate	Rapid	Variable	Variable

sodium polystyrene sulfonate (potassium exchange resin)

Sodium polystyrene sulfonate (Kayexalate, Solystat®) is a cation exchange resin and is used to treat hyperkalemia. It is usually administered orally, via a nasogastric tube, or as an enema. Its action is in the intestine, where potassium ions from the body are exchanged for sodium ions in the resin. Most of this action occurs in the large intestine, which excretes potassium ions to a greater degree than the small intestine does. Although the drug effects in each case are unpredictable, approximately 1 mmol of potassium is lost from the body per gram of resin administered. It can cause disturbances in electrolytes other than potassium, such as calcium and magnesium. For this reason, patients' electrolytes are closely monitored during treatment with sodium polystyrene sulfonate. Kayexalate has been implicated in the development of intestinal necrosis, especially when used with the cathartic sorbitol. This condition may be fatal. Kayexalate should not be used in patients who do not have normal bowel function and should be discontinued in patients who develop constipation. Other adverse effects include hypernatremia, hypokalemia, hypocalcemia, hypomagnesemia, nausea, and vomiting. Drug interactions include antacids and laxatives, which should be avoided. It is typically dosed in multiples of 15 to 30 grams until the desired effect on serum potassium occurs. Onset of action varies from 2 to 12 hours and is generally faster with the oral route than with rectal administration. It is available in a powder for reconstitution, an oral suspension, and a rectal suspension. For use during pregnancy, the potential benefits of Kayexalate must be considered relative to the risk to the fetus.

SODIUM

Although sodium was discussed under crystalloids, it is also presented here in the electrolyte section because it is most commonly given for replenishing purposes. Sodium is the counterpart of potassium, in that potassium is the principal cation inside cells, whereas sodium is the principal cation outside cells. The normal concentration of sodium outside cells is 135 to 145 mmol/L, and it is maintained through the dietary intake of sodium in the form of sodium chloride, which is obtained from fish, meats, and other foods flavoured, seasoned, or preserved with salt.

Hyponatremia is a condition of sodium loss or deficiency and occurs when serum levels decrease to lower than 135 mmol/L. It is manifested by lethargy, hypotension, stomach cramps, vomiting, diarrhea, and seizures. Some of the same conditions that cause hypokalemia can also cause hyponatremia. Other causes of hyponatremia are excessive perspiration, occurring during hot weather or physical work; prolonged diarrhea or vomiting, especially in young children and older adults; kidney disorders; and adrenocortical impairment.

Hypernatremia is the condition of sodium excess and occurs when the serum levels of sodium exceed 145 mmol/L. The most common cause is poor kidney excretion stemming from kidney malfunction. Inadequate water consumption and dehydration

are other causes. Symptoms of hypernatremia include red, flushed skin; dry, sticky mucous membranes; increased thirst; temperature elevation; water retention (edema); hypertension; and decreased or absent urination.

Mechanism of Action and Drug Effects

As one of the body's electrolytes, sodium performs many physiological roles necessary for the normal functions of the body. It is the major cation in ECF and is principally involved in the control of water distribution, fluid and electrolyte balance, and osmotic pressure of body fluids. Sodium also participates along with both chloride and bicarbonate in the regulation of acid–base balance. Chloride, the major extracellular anion (negatively charged substance), closely complements the physiological action of sodium. Sodium is also capable of causing diuresis.

Indications

Sodium is administered primarily in the treatment or prevention of sodium depletion when dietary measures have proved inadequate. Sodium chloride is the primary salt used for this purpose. Mild hyponatremia is usually treated with the oral administration of sodium chloride tablets or fluid restriction. Pronounced sodium depletion is treated with IV sodium chloride or lactated Ringer solution. These drugs are discussed earlier in this chapter.

Hypertonic saline (3% NaCl) is sometimes used to correct severe hyponatremia. It is considered a high-risk drug because giving it too rapidly or in too high a dose can cause a syndrome known as *central pontine myelinolysis*, also known as *osmotic demyelination syndrome*. This syndrome can cause irreversible brainstem damage.

A new class of drugs for the treatment of euvolemic hyponatremia is the dual arginine vasopressin (AVP) V1A and V2 receptor antagonists. The drug in this class is tolvaptan (Samsca®). This class of drugs is often referred to as *vaptans*. Specific information on tolvaptan is listed under its drug profile.

Contraindications

The only usual contraindications to the use of sodium replacement products are known drug allergy to a specific product and hypernatremia.

Adverse Effects

The oral administration of sodium chloride can cause gastric upset consisting of nausea, vomiting, and cramps. Venous phlebitis can be a consequence of its parenteral administration.

Toxicity and Management of Overdose

Hypernatremia leads to hypertension, edema, thirst, tachycardia, weakness, convulsions, and possibly coma. Treatment consists of increased fluid intake and dietary restrictions. In more serious cases, diuretics may be required to enhance urinary sodium excretion. IV administration of dextrose in water solution (e.g., 5% dextrose in water [D₅W] or 10% dextrose in water [D₁₀W]) may also be helpful by producing both intravascular sodium dilution and enhanced urine volume output.

Interactions

Sodium is not known to interact significantly with any drugs.

Dosages

Fluid and electrolyte therapy involves replacing any deficit losses and providing maintenance levels for specific patient requirements. Accordingly, specific dosage amounts of fluids or electrolytes depend on several clinical factors, as follows:

- Specific patient losses
- Efficacy of patient physiological systems involved in fluid and electrolyte metabolism, especially adrenal, cardiovascular, and kidney functioning
- Current drug therapy for pathological conditions that complicate the amount and duration of replacement
- Selection of oral or parenteral replacement formulations

Suggested dosage guidelines for sodium chloride with subsequent adjustments are 1 to 2 g administered orally several times a day or parenteral administration of 1 L of sodium chloride.

DRUG PROFILES

sodium chloride

Sodium chloride is primarily used as a replacement electrolyte for either the prevention or treatment of sodium loss. It is also used as a diluent for the infusion of compatible drugs and in the assessment of kidney function after a fluid challenge. Sodium chloride is contraindicated in patients who are hypersensitive to it. It is available in many IV preparations and in oral form as 650-mg tablets. For use during pregnancy, the potential benefits of sodium chloride must be considered relative to the risk to the fetus.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Immediate	Rapid	Unknown	Variable

tolvaptan

Tolvaptan (Samsca) is a nonpeptide dual arginine vasopressin (AVP) V1A and V2 receptor antagonist. It inhibits the effects of arginine vasopressin, also known as antidiuretic hormone, on receptors in the kidneys. It is specifically indicated for the treatment of hospitalized patients with **euvolemic hyponatremia**, or low serum sodium levels at normal water volumes. Adverse effects associated with the use of tolvaptan may include dry mouth, thirst, constipation, and polyuria. Closely monitor serum sodium levels during treatment, as overly rapid increases in serum sodium levels have been associated with potentially permanent adverse events, including osmotic demyelination syndrome. Several potential drug–drug interactions have been identified. Tolvaptan is metabolized by the hepatic enzyme CYP3A4; coadministration drugs that inhibit this enzyme (including but not limited to ketoconazole, itraconazole, clarithromycin, ritonavir, and indinavir) may increase serum levels. Tolvaptan is available as 15-mg and 30-mg tablets.

PO	2–4 hr	4–8 hr	12 hr	24 hr

❖ **NURSING PROCESS**◆ **ASSESSMENT**

For fluid replacement, patients' needs vary. Any medications or solutions ordered must be given exactly as prescribed and without substitution. However, never take an order from a health care provider at face value without confirming it against authoritative resources (e.g., current drug reference guides, *Compendium of Pharmaceuticals and Specialties* [CPS], a nursing pharmacology textbook, manufacturer's drug inserts) or speaking with a pharmacist. It is important to remember that the nurse is responsible for making sure that the drug therapy administration process—beginning with the assessment phase of the nursing process through to evaluation—is accurate and safe, meeting professional standards of care.

To assist in the development of a thorough assessment process, a brief review of the various solutions is needed. Parenterally administered hydrating and hypotonic solutions, such as 0.45% NaCl/D₅W, are used primarily for the prevention or treatment of dehydration. D₅W alone in an IV bag is considered isotonic but acts as a hypotonic solution once in the bloodstream. Isotonic solutions (e.g., 0.9% NaCl [normal saline]) are customarily used to augment extracellular volume in patients experiencing blood loss or severe vomiting. Isotonic NaCl is also used as diluting fluid for blood transfusions because D₅W results in hemolysis of RBCs (in transfusions). Hypertonic solutions (3% sodium chloride) are used for replacement of fluids and electrolytes in specific situations (see earlier discussion of hypertonic solutions).

After verifying all health care providers' orders and checking for accuracy and completeness (as with all drugs), assess the solution or product, the patient, and the IV site (if applicable). Also assess the following prior to administering IV infusions of fluids and electrolytes: the solution to be infused, infusion equipment, infusion rate of solution, concentration of parenteral solution, related mathematical calculations, laboratory values (e.g., sodium, chloride, potassium), and parenteral compatibilities. More specific assessment of the patient who is to receive a parenteral replacement solution needs to focus on gathering information about the patient's medical history, including diseases of the GI, kidney, cardiac, and liver systems. Obtain a medication history, including a list of prescription drugs, over-the-counter medications, and natural health products. Also take a dietary history, including specific dietary habits and recall of all foods consumed during the previous 24 hours. Assess fluid volume and electrolyte status (through laboratory testing and measurement of urine specific gravity, vital signs, and intake and output). The skin and mucous membranes also reflect a patient's hydration status; assess skin turgor and rebound elasticity of skin on the glabella, the most prominent part of the forehead between the eyebrows, or under the clavicle. Well-hydrated skin in this

area is resilient and returns quickly to its original position, while poorly hydrated skin retains the "tent" shape of the pinched skin. For infants, the area of the abdomen near the umbilicus is used to assess skin turgor. Document the findings as "immediate" rebound or "delayed" rebound. Count the number of seconds that the patient's skin stays in the pinched-up position; normal return is immediate; return within 2 seconds suggests moderate dehydration; more than 2 seconds before return indicates severe dehydration; and skin folding that persists for several seconds is described as *tenting*.

Essential to assessment is knowledge of the normal range for potassium, usually 3.5 to 5 mmol/L. Serum potassium levels below 3.5 mmol/L, or hypokalemia, may result in a variety of problems, such as heart irregularities and muscle weakness. Early symptoms of hypokalemia include anorexia, hypotension, lethargy, confusion, muscle weakness, and nausea. Late symptoms of hypokalemia include cardiac irregularities, neuropathies, and paralytic ileus. Avoid potassium supplementation or use it with extreme caution in patients taking ACE inhibitors or potassium-sparing diuretics (such as spironolactone). These drugs are associated with adverse effects of hyperkalemia and, if given with potassium supplementation, could worsen hyperkalemia and possibly result in severe heart dysrhythmias. Other concerns regarding contraindications with potassium include severe kidney disease, untreated Addison's disease, severe tissue trauma, and acute dehydration. Oral potassium supplements are irritants and may be ulcerogenic; thus, perform a thorough GI tract assessment. If the patient has a history of ulcers or GI bleeding and oral supplementation is prescribed, contact the health care provider for further instructions.

The range of serum potassium levels defined as normal often varies depending on the institution and the health care provider. For identification and treatment of hyperkalemia, the normal range of potassium must be established. Realize that potassium levels of 5.3 mmol/L may be identified as the threshold for being considered abnormally high by some laboratories, whereas other laboratories may categorize 5 mmol/L as being abnormally high. Be sure to check hospital policy and laboratory guidelines for normal ranges and report any elevations (or decreases) in serum potassium. However, a serum level exceeding 5.5 mmol/L is considered by most sources to be toxic and dangerous to the patient; report this finding to the health care provider immediately. With close monitoring of patients, the dangerous effects of hyperkalemia (i.e., heart dysrhythmias) will be prevented or identified early and treated appropriately to prevent potentially life-threatening complications.

Venous access is an important issue with parenteral potassium supplementation because the vein can be irritated if infiltration occurs or if the solution has not been mixed thoroughly. The following are some important considerations regarding assessment and peripheral venous access (for potassium, sodium, fluid, and any other type of medication given by the IV route): (1) Assess the overall condition of the veins prior to selecting a site. (2) Try to use distal veins first. (3) Know the purpose of administering potassium and other electrolytes. (4) Calculate and set the rate, as ordered, for the infusion. (5) Know the anticipated duration of therapy. (6)

LAB VALUES RELATED TO DRUG THERAPY

Serum Potassium

Laboratory Test	Normal Ranges	Rationale for Assessment
Serum potassium	3.5–5 mmol/L	The main function of potassium is the regulation of water and electrolyte content in the cell. Potassium also assists in the cellular metabolism of carbohydrates and proteins. A serum level less than 3.5 mmol/L is known as hypokalemia and a small decrease in potassium levels may have profound effects, including lethargy, muscle weakness, hypotension, and cardiac dysrhythmias. A serum potassium level greater than 5 mmol/L is known as hyperkalemia and is manifested by muscle weakness, paresthesia, paralysis, and cardiac rhythm abnormalities. Knowing normal ranges allows quicker identification of abnormalities and thus more timely management.

Know any restrictions imposed by the patient's history. For example, in a patient who is postmastectomy with lymph node dissection, the affected arm must not be used. Likewise, the affected arm of a patient with a stroke must not be used. Limb circulation may be inadequate in these situations and lead to edema and other complications if it is used as a venous access site (see Lab Values Related to Drug Therapy: Serum Potassium box).

Sodium is another electrolyte that is an ingredient in various IV replacement solutions. Hyponatremia, or serum sodium below 135 mmol/L, if not resolved with dietary or oral intake, may need to be treated with parenteral infusions. Signs and symptoms of hyponatremia include lethargy, hypotension, stomach cramps, vomiting, and diarrhea. Carefully assess venous access sites because of possible irritation of the vein and subsequent phlebitis. If replacement to correct hyponatremic states is overzealous, the result may be hypernatremia with fluid overload, edema, and dyspnea. Assess baseline vital signs, hydration status of the skin and mucous membranes, and level of consciousness for safe IV replacement and prevention of further complications. Contraindications to sodium replacement include elevated serum sodium levels, edema, and hypertension.

Hypernatremia also requires careful assessment. Manifestations of hypernatremia include red, flushed skin; dry, sticky mucous membranes; increased thirst; temperature elevation; water retention (edema); hypertension; and decreased or absent urination. Identifying any precipitating events, medical concerns, and risky situations is important to finding timely solutions. The populations at risk for hypernatremia include

older adults, patients with kidney and cardiovascular diseases, those who are receiving sodium supplements or who have increased sodium intake, and those with decreased fluid intake. Perform an assessment of cautions, contraindications, and drug interactions.

Albumin and other colloids (e.g., dextran) have associated cautions, contraindications, and drug interactions that need to be assessed. Dextran and other colloids are rarely used in practice anymore, largely because there has been no demonstrated benefit over crystalloids and they are expensive to use. Contraindications include heart failure, severe anemia, and renal insufficiency. The rationale is that these products cause fluids to shift from interstitial to intravascular spaces. This shift places more strain on a patient's heart and respiratory systems. Assess the patient's hematocrit, hemoglobin levels, and serum protein levels. Assess the patient's blood pressure, pulse rate, respiratory status, and intake and output. Document and report any abnormal assessment findings (e.g., dyspnea, edema) immediately.

Fluid infusions may also include the giving of blood or blood components. Obtain a thorough history regarding any transfusions received previously and the patient's response. The patient's informed consent should be obtained prior to administering blood products (see Legal and Ethical Principles box). Report any history of adverse reactions to transfusions or problems with packed red blood cells or fresh frozen plasma to the health care provider, and document the nature of these reactions. Assess the status and size of venous access areas. Check the patient's laboratory values (e.g., hematocrit, hemoglobin, white blood cells [WBCs], RBCs, platelets, clotting factors). Note baseline vital signs, blood pressure, pulse rate, respiratory rate, and temperature before infusing blood or blood products. Even the patient's general appearance, energy levels, ability to carry out activities of daily living (ADLs), and colour of extremities are important to note. Assess for any potential drug interactions, specifically with aspirin and calcium, as these may potentially alter clotting. During the infusion of blood components, constantly assess for the occurrence of a febrile nonhemolytic transfusion reaction. This occurs as a result of cytokines from leukocytes in RBCs or platelets, with the common symptoms of fever (defined as an elevation of 1°C), chills, or rigour. An allergic reaction is IgE mediated. It occurs because of a hypersensitivity to allergens in the transfused blood and manifests as a rash, urticaria, or pruritus. An anaphylactic reaction may also occur and is associated with anti-IgA in recipients who are IgA deficient. Acute hemolytic transfusion reaction is the most frequent and severe reaction and is most often the result of ABO incompatibility resulting in hemolysis of the RBCs. Assess for hemoglobinuria, hyperkalemia, hypocalcemia, hypothermia, and iron overload. Transfusion-related acute lung injury results in pulmonary edema in the absence of circulatory overload. Delayed immune-mediated reactions include a delayed hemolytic transfusion reaction, transfusion associated-graft-versus-host disease, and post-transfusion purpura.

LEGAL & ETHICAL PRINCIPLES

Blood Transfusions and Informed Consent

In Canada, informed consent is required for the administration of all blood components and products and is required for hospital accreditation. The patient (or substitute decision maker) is to be informed of the type of blood component or blood product to be administered, the associated risks and benefits, as well as alternatives to transfusion if appropriate. The exception would be an emergency situation where treatment is necessary to preserve the life or health of the patient and consent cannot be obtained (if the patient is unconscious or otherwise unable to consent); in this type of case, the health care provider may administer blood products deemed essential to preserve the life or health of the patient.

The information should be presented in a language that the patient understands and in a way that allows for questions and provides the patient with sufficient time to assimilate all information and ask additional questions. Patients have the right to refuse blood products and should be informed of the risks of refusal. In Canada, where the population is culturally diverse, it is the ethical responsibility of health care providers to respect the cultural practices of patients while meeting legal and professional obligations.

Patients who are Jehovah's Witnesses are forbidden to receive blood and blood product transfusions, based on their interpretation of the Bible. This stricture may include whole blood, RBCs, WBCs, platelets, and plasma, while other products such as albumin may be acceptable.

Always refer to the agency-specific policy about acquiring and documenting informed consent and also what to do if a patient refuses care. Exact provisions will vary by province and territory.

Transfusion reactions require immediate recognition, laboratory investigation, and clinical management. Monitor for the following transfusion reactions for patients: if the temperature rises $>1^{\circ}\text{C}$ from the baseline temperature taken at the start of the transfusion or temperature $>38^{\circ}\text{C}$ during or up to 4 hours post transfusion, dyspnea, urticaria and other allergic reactions/anaphylaxis, hypotension, hemolysis after transfusion, and cytopenias after transfusion (Callum et al., 2017). When a transfusion reaction is suspected during blood administration, the best practice is to stop the transfusion and keep the IV line open with 0.9% normal saline. Then, check to make sure that the blood unit label and the patient's identification match, to ensure that the "right" blood unit was administered to the "right" patient. In most cases, the residual contents of the blood component container should be returned to the blood bank, together with a freshly collected blood sample from the patient, and a transfusion reaction investigation should be initiated. Always follow agency policy for the procedure following a suspected blood transfusion reaction.

In summary, safety and caution are top priorities when patients receive any blood product or fluid and electrolyte replacement. Deficient or excess fluid and electrolyte levels may pose tremendous risks to patients. Thorough assessment is crucial to patient safety. With many patients receiving therapies in the home setting, there is additional accountability and responsibility for performing skillful and thorough assessment before, during, and after therapy.

◆ NURSING DIAGNOSES

- Potential risk for falls as a result of fluid and electrolyte losses
- Potential risk for imbalanced fluid volume as a result of drug-induced fluid deficits and excesses
- Potential risk for injury as a result of complications of the transfusion or infusion of blood products, blood components, or related agents

◆ PLANNING

◆ Goals

- Patient will remain free from falls and injury.
- Patient will regain balanced fluid volume status.
- Patient will remain free from injury related to complications of blood product infusion.

◆ Expected Patient Outcomes

- Patient minimizes the risk for falls through careful actions.
 - Patient changes positions slowly and ambulates with assistance until symptoms (e.g., dizziness, lightheadedness) have subsided.
- Patient regains fluid volume status through replacement of up to 2 to 3 L/day of water, unless contraindicated.
 - Patient receives adequate fluid volume infusions with improvement of fluid and electrolyte status.
 - Patient's urinary output is at least 30 mL/hr.
 - Patient reports any dizziness, lethargy, confusion, disorientation, muscle weakness, irregular heart rhythm, or abdominal cramping.
- Patient remains free from injury during infusion of blood products or components.
 - Patient reports any shortness of breath, irregular heart rate or palpitations, or feelings of increased body temperature.
 - Patient's laboratory values (e.g., hemoglobin, hematocrit, RBCs) return to normal levels.

◆ IMPLEMENTATION

Continued monitoring of the patient during fluid or electrolyte therapy is crucial to ensure safe and effective treatment. It is also important to continue monitoring to identify adverse effects early and to prevent complications related to either overzealous treatment or undertreatment. During replacement therapy, serum electrolyte levels need to remain within normal ranges. Educate patients at risk for volume deficits (especially older adults) about this risk and about the effect of a hot, humid environment on physiological functioning and the danger of exacerbation by excessive perspiration. Water is at the crux of every metabolic reaction that occurs within the body, and deficits will negatively impact physiological reactions and alter the composition of fluids and electrolytes. For any age group, staying hydrated at all times is a preventive measure.

With parenteral dosing, monitor infusion rates as well as the appearance of the fluid or solution (i.e., potassium and saline solutions should be clear, whereas albumin should be brown, clear, and viscous). Frequently monitor the IV site, as per agency

policy and nursing standards of care, for evidence of infiltration (e.g., swelling, coolness to the touch around the IV site, no or decreased flow rate, and no blood return from the IV catheter) or thrombophlebitis (e.g., swelling, redness, heat, and pain at the IV site). Volume overload, drug toxicity, fever, infection, and emboli are other complications of IV therapy.

With the administration of any of the discussed drugs per the IV route, maintain a steady and even flow rate to prevent complications. Infusion pumps are used for IV administration, particularly of potassium. Ensure that infusion rates follow the health care provider's orders, and recheck all calculations for accuracy. Check the IV site, tubing, IV bag, and fluids or solutions as well as expiration dates. Always behave in a prudent, safe, and thorough manner when administering fluids and electrolyte solutions. Remember that older adults and children have an increased sensitivity to fluids and electrolytes.

With the various IV solutions, knowing their osmolality and concentrations is important to their safe use. Administration of isotonic solutions (e.g., 0.9% sodium chloride, lactated Ringer solution) requires constant monitoring of vital signs and observation for possible fluid overload during and after therapy, especially in those at particular risk or those with heart failure. Hypertonic solutions are used rarely because of the risk of cellular dehydration and vascular volume overload. These solutions are also associated with phlebitis if IV infiltration or extravasation occurs in the peripheral veins. Therefore, if ordered, administer these solutions through a larger bore vein (e.g., central line), but only with close monitoring of the patient's vital signs and cardiac status.

For patients who are at risk for hypokalemia, provide educational materials and teaching to encourage consumption of certain foods high in potassium. The minimal daily requirement for potassium is 4 700 mg for adults and 3 000 to 4 500 mg for children between the ages of 1 and 14. Information on foods containing potassium should be shared with patients; this information includes some of the following: one medium-sized banana contains 422 mg of potassium, a 250 mL glass of orange juice contains 387 mg; and 177 mL of yogurt contains 362 mg. Conversely, if a patient is already hyperkalemic, advise the patient to avoid these food items (see Patient Teaching Tips for more information). If potassium levels do not increase with dietary changes, supplementation may be needed. Oral preparations of potassium, rather than parenteral dosage forms, are preferred whenever possible. Prepare the oral dosage forms per the manufacturer's insert or per policy and standard of care. Generally, oral forms of potassium (15 mL) should be dissolved completely in 100 to 250 mL of cold water, juice, or another liquid. Often, orange juice is used as potassium's taste is bitter. Potassium should be taken with food or immediately after meals to minimize GI distress or irritation and to prevent too rapid absorption. Extended-release forms may still result in gastric upset and lead to ulcer development (being ulcerogenic). With oral supplementation, the safest and most effective intervention is frequent and close monitoring for reports of nausea, vomiting, abdominal pain, or bleeding (such as the occurrence of melena [blood in the stool] or hematemesis [blood in the vomitus]). If abnormalities are noted, continue to monitor vital signs and other parameters, and report findings to the health care provider immediately. Monitor serum levels of potassium during therapy as well.

Hyperkalemia may be treated with sodium polystyrene sulfonate (Kayexalate), short acting insulin (Humulin R), or hemodialysis, depending on the potassium level and patient's symptom presentation. Sodium polystyrene is used only in specific situations and under close monitoring of the patient and serum potassium, sodium, calcium, and magnesium levels. If it is given orally (or via nasogastric tube), elevate the head of the patient's bed to prevent aspiration. Each dose of sodium polystyrene sulfonate resin should be given as a suspension in a small quantity of water (20 to 100 mL, depending on the dose, or 3 to 4 mL per gm of resin). There is potential for intestinal necrosis associated with the use of sodium polystyrene sulfonate (see earlier discussion of this medication). It is recommended that it not be administered with sorbitol because of the connection of these two drugs with the potentially fatal condition of colonic intestinal necrosis. If the oral form is given, do not give it with antacids or laxatives. If sodium polystyrene sulfonate is given by the rectal route, a retention enema is used. Follow the medication orders carefully, and expect that more than one dose may be needed. The enema must be retained as long as possible and followed by a cleansing enema prescribed by the health care provider. Usually, an initial cleansing enema is prescribed, and then the resin solution is administered. If leakage occurs, elevating the patient's hips on a pillow or placing the patient in a knee-chest position may be helpful. If potassium levels > 5.9 mmol/L and cannot be managed safely with sodium polystyrene, management of hyperkalemia is to follow local institutional protocols (Ezekowitz, O'Meara, McDonald, et al., 2017). According to the American Heart Association (2016), serum potassium levels > 6.0 mmol/L may be treated with Humulin R intravenously and dextrose peroral to shift the potassium out of the cell. "Insulin activates the sodium/hydrogen exchanger, which helps create a favorable gradient for sodium/potassium adenosine triphosphatase function" (Pierce, Russell, & Pirkle, 2015, p. 1322). This moves potassium from the extracellular space into the intracellular space with dextrose used to minimize and prevent hypoglycemic reactions.

Potassium chloride is the salt commonly used for IV infusions. Caution should be taken with potassium chloride use to avoid overdosage, as this can lead to cardiac arrest. IV dosage forms of potassium must always be given in a DILUTED form. There is no use or place for undiluted potassium because it is associated with cardiac arrest. Therefore, parenteral forms of potassium need to be diluted properly. Most potassium infusions are prepared by the manufacturer (e.g., 40 mmol/L potassium chloride in 0.9% sodium chloride injection); however, it is still imperative to double-check the order, amount of diluent, and concentration of potassium to diluent. Never assume that whatever was premixed is 100% correct, because the nurse is ultimately responsible for whatever is administered. Additionally, give diluted potassium only when there is adequate urine output of at least 30 mL/hr (to prevent toxicity). Manufacturer instructions and policy protocols generally recommend that IV solutions be given at concentrations of less than 40 mmol/L of potassium and at a rate not exceeding 20 mmol/hr. Toxicity or overdosage of potassium (hyperkalemia) is manifested by cardiac rhythm irregularities, muscle spasms, paresthesia, and possible cardiac arrest. As previously discussed, IV potassium is to be given no faster than 10

mmol/hr to those patients not on cardiac monitoring. In patients who are critically ill and on cardiac monitors, a rate of 20 mmol/hr or more may be used. Do not add potassium chloride to an already existing IV solution because the exact concentration cannot be accurately calculated and overdosage or toxicity may result. Make sure that all IV fluids are labelled appropriately and documented, as with any medication. An infusion pump or other rate-limiting device must always be used when administering IV solutions of potassium chloride to prevent unintentional bolus doses of potassium chloride. Potassium chloride must never be administered by IV push or IV bolus. Treatment of severe hyperkalemia caused by IV administration is through use of IV dextrose solution with insulin and possibly salbutamol. These drugs work by leading to a rapid shifting of potassium ions intracellularly, thereby reducing serum potassium concentration. Dialysis is also used to remove excess potassium.

Replacement of sodium is associated with similar concerns about dosing and route of administration to those of potassium chloride. When a patient is only mildly depleted, an increase in oral intake of sodium needs to be tried. Food items high in sodium include ketchup, mustard, cured meats, cheeses, potato chips, peanut butter, popcorn, and table salt. In some situations, salt tablets may be necessary. If the patient is given salt tablets, it is important to advise the patient to drink up to 3 000 mL/24 hr, unless contraindicated. If the sodium deficit requires IV replacement, venous access issues and drip rate are important (see previous discussion regarding IV infusion and IV sites). Hypertonic saline (3% NaCl) is sometimes used for severe hyponatremia but this use is considered a high risk due to the possible occurrence of osmotic demyelination syndrome. This occurs if the 3% NaCl is given too fast or too much is given; this syndrome results in irreversible brainstem damage. Other treatment of hyponatremia includes the use of orally administered tolvaptan (Samsca). This drug is indicated for euvoletic hyponatremia (see earlier discussion of sodium). Administer tolvaptan as ordered while monitoring serum sodium levels. Hypernatremia is treated with increased fluid intake and dietary restrictions, so the nurse must provide thorough and complete patient education. IV dextrose in water (D₅W or D₁₀W) may be indicated and helps by creating intravascular sodium dilution and enhanced urine volume output with sodium excretion.

Always carry out IV infusion of albumin and other colloids slowly and cautiously. Carefully monitor the patient to prevent fluid overload and possible heart failure, especially in patients at particular risk. Fluid overload is evidenced by shortness of breath, crackles at the bases of the lungs, decreased pulse oximeter readings, edema of dependent areas, and increase in weight (see previous parameters). Determine serum hematocrit and hemoglobin values in advance of therapy, as well as during and after therapy, so that any dilutional effects can be determined. For example, if a patient has received albumin and other colloids too quickly, and hypervolemia results, the patient's hemoglobin and hematocrit may actually be decreased. This decrease would be caused by dilutional factor because of too much volume in relation to the concentration of solutes. Clinically, the patient would appear to be anemic, but in fact the deficit would be attributed to the increase in volume. It is also important to remember that albumin needs to be given at room temperature.

For infusion of blood, always check the expiration date of the blood and blood components to make sure they are not outdated. Under NO circumstances should outdated blood be used. Blood is perishable and has a 42-day "best before" date. Platelets are viable for 5 days. Policies at most health care agencies require that blood and blood products be double-checked by two registered nurses *before* the blood is hung and infused. This is important to prevent a mix-up in blood types. Blood types must always be a major concern because of the possible complications that can occur, some life threatening, if the wrong blood type is given or if the blood is given to the wrong person. The "rights" of drug administration are crucial in all that nurses do with medications, and administering blood is no exception.

When blood and blood products are infused, it is important to patient safety to document all vital signs and related parameters before, during, and after administration of the blood product component (e.g., packed red blood cells, fresh frozen plasma), or solution. Monitor vital signs, and frequently record these during and after administration. A transfusion reaction would most likely be manifested by the occurrence of the following: apprehension, restlessness, flushed skin, increased pulse and respirations, dyspnea, rash, joint or lower back pain, swelling, fever and chills (a febrile reaction beginning 1 hour after the start of administration and possibly lasting up to 10 hours), nausea, weakness, and jaundice. Report these signs and symptoms to the health care provider immediately, and (regardless of when the reaction occurs) stop the blood or product, keeping the IV line patent with isotonic NS solution infusing at a slow rate. Always follow the facility's protocol for transfusion reactions.

In summary, encourage patients receiving any type of fluid or electrolyte substance, colloid, or blood component to immediately report unusual adverse effects to their health care providers. Reports may include chest pain, dizziness, weakness, and shortness of breath.

◆ EVALUATION

The therapeutic response to fluid, electrolyte, and blood or blood component therapy includes normalization of fluid volume and laboratory values, including RBCs, WBCs, and hemoglobin, hematocrit, and sodium and potassium levels. In addition to a review of these laboratory values, evaluation of the patient's heart, respiratory, musculoskeletal, and GI functioning is also important. Therapeutic effects include improved energy levels, and tolerance for ADLs should return to normal. Skin colour will improve, and there will be improved shortness of breath as well as minimal to no dyspnea, chest pain, weakness, or fatigue. Correct treatment of blood volume problems will be evidenced by a return of laboratory values to normal, improved vital signs, an increase in energy, and near-normal oxygen saturation levels. The therapeutic response to albumin therapy includes an elevation of blood pressure, decreased edema, and increased serum albumin levels. Frequently monitor for adverse effects of any of these drugs and solutions, and check for distended neck veins, shortness of breath, anxiety, insomnia, expiratory crackles, frothy and blood-tinged sputum, and cyanosis (indicative of fluid volume overload).

CASE STUDY

Fluid and Electrolyte Replacement

Ivan, an 85-year-old retired chemist, seems somewhat confused when his daughter comes home from work. When she brings him to the emergency department, his blood pressure is 90/62 mm Hg, his heart rate is 114 beats per minute, and his skin is dry but cool. His daughter says that he seems “much weaker” than usual, and he is unable to answer questions clearly. His daughter reports that he has “lost his appetite” lately and has not taken in much food or drink. The nurse starts an IV infusion of 0.9% sodium chloride (NS) at 100 mL/hr via a gravity drip infusion.

1. What do you think is Ivan’s main medical problem at this time? The emergency department is extremely busy, and when the nurse returns, she is shocked

to see that almost the entire 500-mL bag of NS has infused within an hour’s time.

2. What will the nurse do first? What will the nurse watch for at this time?
3. When monitoring Ivan’s fluid status, which indicators will the nurse consider the most reliable?

Twenty-four hours after his admission, Ivan is much less confused and is able to transfer to a chair for lunch without much difficulty. He is receiving 5% dextrose/0.45% NS with 20 mmol of potassium chloride, at a rate of 75 mL/hr via an infusion pump. His daughter notices that the area above the IV insertion site is red, and Ivan reports that the area is “quite sore.”

4. What is the possible problem with the IV line? What needs to be done at this time?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

PATIENT TEACHING TIPS

- As needed, educate patients about the differences in the signs and symptoms of hyponatremia and hypernatremia. Hyponatremia is manifested by lethargy, hypotension, stomach cramps, vomiting, diarrhea, and seizures. Some of the causes of hyponatremia include excessive perspiration, occurring during hot weather or physical work, and prolonged diarrhea or vomiting. Hypernatremia is associated with symptoms of water retention (edema); hypertension; red, flushed skin; dry, sticky mucous membranes; increased thirst; temperature elevation; and decreased or absent urination. The most common cause is poor renal excretion as a result of kidney malfunction. Inadequate water consumption and dehydration are other causes.
- Educate patients about the early symptoms of hypokalemia, such as anorexia, hypotension, lethargy, confusion, nausea, and muscle weakness. Late symptoms include cardiac dysrhythmias (the patient may feel palpitations or shortness of breath), neuropathies, and paralytic ileus.
- Share the symptoms of hyperkalemia with patients, including muscle weakness, paresthesia, paralysis, and cardiac rhythm abnormalities.
- Provide patients with adequate and appropriate information about how to take oral potassium chloride. Encourage patients to take oral doses with food or a snack, and tell them to report any GI upset or abdominal pain (indicative of gastric irritation from the oral potassium) to their health care providers immediately. Educate patients about potential drug interactions, such as with potassium-sparing diuretics and ACE inhibitors, because their concurrent use may produce hyperkalemia.
- Educate patients regarding foods high in potassium, including bananas, oranges, apricots, dates, raisins, broccoli, green beans, potatoes, tomatoes, meats, fish, wheat bread, and legumes.
- Advise patients that sustained-release capsules and tablets must be swallowed whole and should not be crushed, chewed, or allowed to dissolve in the mouth. Each prescribed dose is to be taken with a meal and a full glass of water. If a patient has difficulty swallowing the whole tablet, and if approved by the health care provider, the patient can break the tablet in half and take each half separately, drinking approximately half a glass of water (115 mL) with each half and taking the entire dose within a few minutes. The patient must take the full dose and not save partial dosages of potassium for later. Another option is to take the extended-release dosage form and place the whole tablet in 115 mL of water (recommended as the fluid for mixing this form). Instruct patients to allow 2 minutes for the tablet to disintegrate, stir for 30 seconds, and then drink the dose immediately. After this, adding 30 mL of water to the glass, swirling it, and then drinking the residual will allow adequate dosing. A straw may be used.
- Encourage patients to report any difficulty swallowing, painful swallowing, or feeling as if the capsule or tablet is getting stuck in the throat. Other serious adverse effects that need to be reported include vomiting of coffee ground-like material, stomach or abdominal pain or swelling, and black tarry stools.
- Educate patients that salt substitutes contain potassium. Another alternative must be recommended if patients are hyperkalemic.
- If a patient is receiving IV potassium, tell the patient to report any feelings of irritation (e.g., burning) at the IV site.
- Educate patients about the safe use of salt tablets, and instruct them to take them as prescribed. Salt tablets must be taken with adequate fluid intake.

KEY POINTS

- Total body water is divided into intracellular (inside the cell) and extracellular (outside the cell) compartments. Fluid volume outside the cells is either in the plasma (intravascular volume) or interstitial fluid (between the tissues, cells, or organs).
- Colloids are large protein particles that cannot leak out of the blood vessels. Because of their greater concentration inside blood vessels, fluid is pulled into the blood vessels. Examples of colloids include albumin, hetastarch, and dextran. Administer albumin with caution because of the high risk for hypervolemia and possible heart failure. Monitor intake and output, weights, heart and breath sounds, and appropriate laboratory values.
- Blood products are the only fluids that are able to carry oxygen because they are the only fluids that contain hemoglobin. Patients will show improved energy and increasing tolerance for ADLs as a result of treatments with blood products. Pulse oximeter readings will also show improved readings.
- Dehydration may be hypotonic, resulting from the loss of salt; hypertonic, resulting from fever with perspiration; or isotonic, resulting from diarrhea or vomiting. Each form of dehydration is treated differently. Carefully assess intake and output as well as skin turgor, urine specific gravity, and blood values of potassium, sodium, and chloride.
- Hypertonic solutions must be used cautiously and given slowly because of the risk for hypervolemia from overzealous replacement.
- Early symptoms of hypokalemia include anorexia, hypotension, lethargy, confusion, nausea, and muscle weakness. Late symptoms include cardiac dysrhythmias (the patient may feel palpitations or shortness of breath), neuropathies, and paralytic ileus.
- Hyponatremia is manifested by lethargy, hypotension, stomach cramps, vomiting, diarrhea, and seizures. Hypernatremia is associated with symptoms of water retention (edema); hypertension; red, flushed skin; dry, sticky mucous membranes; increased thirst; temperature elevation; and decreased or absent urination.
- With administration of blood products, measurement of vital signs and frequent monitoring of the patient before, during, and after infusions are critical to patient safety. Blood products must be given only with normal saline (0.9% sodium chloride), because the solution of D₅W results in hemolysis of RBCs.

EXAMINATION REVIEW QUESTIONS

1. Which action by the nurse is most appropriate for the patient receiving an infusion of packed red blood cells?
 - a. Flush the IV line with normal saline before the blood is added to the infusion.
 - b. Flush the IV line with dextrose before the blood is added to the infusion.
 - c. Check the patient's vital signs once the infusion is completed.
 - d. Anticipate that flushed skin and fever are expected reactions to a blood transfusion.
2. When preparing an IV solution that contains potassium, what would be a contraindication prior to administering potassium intravenously?
 - a. Diarrhea
 - b. Serum sodium level of 145 mmol/L
 - c. Serum potassium of 5.6 mmol/L
 - d. Dehydration
3. A patient is about to receive an albumin infusion. What comorbidity of the patient would be most concerning for the nurse prior to initiating the infusion?
 - a. Acute liver failure
 - b. Heart failure
 - c. Severe burns
 - d. Fluid-volume deficit
4. The nurse is preparing an infusion for a patient who has a deficiency in clotting factors. Which type of infusion is most appropriate for this patient?
 - a. Albumin 5%
 - b. Packed red blood cells
 - c. Whole blood
 - d. Fresh frozen plasma
5. While monitoring a patient who is receiving an infusion of a crystalloid solution, the nurse should monitor for which potential adverse event?
 - a. Bradycardia
 - b. Hypotension
 - c. Decreased skin turgor
 - d. Fluid overload
6. The nurse is administering an IV solution that contains potassium chloride to a patient in the Critical Care Unit who has a severely decreased serum potassium level. Which action(s) by the nurse is/are appropriate? (Select all that apply.)
 - a. Administer the potassium by slow IV bolus.
 - b. Administer the potassium at a rate no faster than 20 mmol/hr.
 - c. Monitor the patient's cardiac rhythm with a heart monitor.
 - d. Use an infusion pump for the administration of IV potassium chloride.
 - e. Administer the potassium IV push.
7. The order reads: "Infuse 1 000 mL of normal saline over the next 8 hours." The IV tubing has a drop factor of 15 gtt/mL. Calculate the mL/hr rate, and calculate the drops-per-minute setting for the IV tubing with this gravity infusion.
8. A patient is about to receive a dose of the nonprotein plasma expander, dextran. The nurse knows that this product is indicated for which type of blood loss?
 - a. Slow loss of 20% or less
 - b. Slow loss of 20% to 50%
 - c. Slow loss of over 50% or acute loss of 20%
 - d. Loss of 80% or more

CRITICAL THINKING ACTIVITIES

1. After having vomiting and diarrhea from the flu for the previous 24 hours, a patient is admitted for treatment of dehydration. The nurse knows that the priority action is to administer which type of fluid? Explain your answer.
 2. During a transfusion of packed red blood cells, the patient reports that his back is starting to hurt and he feels anxious. His temperature is 37.1°C. What is the nurse's priority action?
 3. The latest potassium level of a patient with hyperkalemia is 6.1 mmol/L, and the health care provider has ordered one 30-g dose of sodium polystyrene sulfonate via enema. The patient questions the nurse when he hears he is to receive an enema, saying, "How in the world is an enema going to help me?" What is the nurse's best answer?
- For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Pituitary Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Describe the normal function of the anterior and posterior lobes of the pituitary gland and the impact of the pituitary gland on the human body.
2. Compare the various pituitary drugs in regard to their mechanisms of action, therapeutic effects, indications, contraindications, drug interactions, adverse effects, dosages, and routes of administration.
3. Develop a collaborative plan of care that includes all phases of the nursing process for patients receiving pituitary drugs.

KEY TERMS

Hypothalamus The gland above and behind the pituitary gland and the optic chiasm. Both glands are suspended beneath the middle area of the bottom of the brain. The hypothalamus secretes the hormones vasopressin and oxytocin, which are stored in the posterior pituitary gland. The hypothalamus also secretes several hormone-releasing factors that stimulate the anterior pituitary gland to secrete a variety of hormones that control many body functions. (p. 519)

Negative feedback loop A system in which the production of one hormone is controlled by the levels of a second hormone in a way that reduces the output of the first hormone. A gland produces a hormone that stimulates a

second gland to produce a second hormone. In response to the increased levels of the second hormone, the source gland of the first hormone reduces production of that hormone until blood levels of the second hormone fall below a certain minimum level needed; then, the cycle begins again. (p. 520)

Neuroendocrine system The system that regulates reactions to both internal and external stimuli, involving the integrated activities of the endocrine glands and nervous system. (p. 519)

Pituitary gland An endocrine gland that is suspended beneath the hypothalamus and supplies numerous hormones that control many vital processes. (p. 520)

DRUG PROFILES

octreotide acetate, p. 523

somatotropin, p. 523

vasopressin and desmopressin, p. 523

Key drug

HIGH-ALERT DRUGS

vasopressin, p. 523

ENDOCRINE SYSTEM

Maintenance of physiological stability is the primary goal of the endocrine system. The endocrine system must accomplish this task despite constant changes in the internal and external environments. Every cell and organ in the body

comes under the influence of the endocrine system. It communicates with the approximately 50 million target cells in the body using a chemical “language” called *hormones*. Hormones are a large group of natural substances that cause highly specific physiological effects in the cells of their target tissues. They are secreted into the bloodstream in response to the body’s needs and travel through the blood to their sites of action, the target cells.

For decades, the pituitary gland was believed to be the master gland that regulated and controlled the other endocrine glands. However, evidence now suggests that the central nervous system (CNS), specifically the **hypothalamus**, controls the pituitary gland. The hypothalamus and pituitary are now viewed as functioning together as an integrated unit, with primary direction coming from the hypothalamus. For this reason, these structures are now commonly referred to as the **neuroendocrine system**. In fact, understanding each of the systems can assist in the study of the other, as they are basically systems for signalling,

Fig. 31.1 Pituitary hormones and their target organs. *FSH*, Follicle-stimulating hormone; *ICSH*, male analogue of LH (interstitial cell-stimulating hormone); *LH*, luteinizing hormone. (Source: McCance, K. L., & Huether, S. E. (2014). *Pathophysiology: The biologic basis for disease in adults and children* (7th ed.; p. 696). St. Louis, MO: Mosby; Modified from Patton, K. T., & Thibodeau, G. A. (2013). *Anatomy and physiology* (8th ed.) St. Louis, MO: Mosby.)

each operating in a stimulus-and-response manner. Together, these two systems essentially govern all bodily functions.

The **pituitary gland** is made up of two distinct glands—the anterior pituitary gland (adenohypophysis) and the posterior pituitary gland (neurohypophysis). They are individually linked to and communicate with the hypothalamus, and each gland secretes its own distinct set of hormones. These various hormones are listed in **Box 31.1** and shown in **Figure 31.1**.

Hormones are either water- or lipid-soluble. The water-soluble hormones are protein-based substances, such as the catecholamines norepinephrine and epinephrine. The lipid-soluble hormones consist of the steroid and thyroid hormones.

The activity of the endocrine system is regulated by a system of surveillance and signalling, usually dictated by the body's ongoing needs. Hormone secretion is commonly regulated by a **negative feedback loop**. This is best explained using a hypothetical example: When gland X releases hormone X, this stimulates target cells to release hormone Y. When there is an excess of hormone Y, gland X senses this excess and decreases its release of hormone X. A real example is the regulation of plasma glucose (see **Chapter 33**). As the plasma sugar level increases in the bloodstream, insulin

BOX 31.1 Hormones of the Anterior and Posterior Pituitary Gland

Anterior Pituitary (Adenohypophysis)

Adrenocorticotrophic hormone (ACTH)
Follicle-stimulating hormone (FSH)
Growth hormone (GH)
Luteinizing hormone (LH)
Prolactin (PH)
Thyroid-stimulating hormone (TSH)

Posterior Pituitary Gland (Neurohypophysis)

Antidiuretic hormone (ADH)
Oxytocin

sends a signal to the liver, muscles, and other cells to store excess glucose (e.g., as body fat and as glycogen in the liver and muscles).

PITUITARY DRUGS

A variety of drugs affect the pituitary gland. They are generally used either as replacement drug therapy to make up

TABLE 31.1 Anterior and Posterior Pituitary Hormones

Hormone	Function and Mimicking Drug	Drugs
Anterior Pituitary Gland		
Adrenocorticotrophic hormone (ACTH)	Targets adrenal gland; mediates adaptation to physical and emotional stress and starvation; redistributes body nutrients; promotes synthesis of adrenocortical hormones (glucocorticoids, mineralocorticoids, androgens); involved in skin pigmentation	Cosyntropin: Used for diagnosis of adrenocortical insufficiency
Follicle-stimulating hormone (FSH)	Stimulates oogenesis and follicular growth in females and spermatogenesis in males	Menotropins: Same pharmacological effects as FSH; many of the other gonadotropins also stimulate FSH (see Chapter 35)
Growth hormone (GH)	Regulates anabolic processes related to growth and adaptation to stressors; promotes skeletal and muscle growth; increases protein synthesis; increases liver glycogenolysis; increases fat mobilization	Somatropin: Human GH for treatment of hypopituitary dwarfism Octreotide acetate: A synthetic polypeptide structurally and pharmacologically similar to GH release-inhibiting factor; inhibits GH
Luteinizing hormone (LH)	Stimulates ovulation and estrogen release by ovaries in females; stimulates interstitial cells in males to promote spermatogenesis and testosterone secretion	Mentropins, clomiphene citrate: Increase LH levels and the chance of pregnancy
Prolactin (PH)	Targets mammary glands; stimulates lactogenesis and breast growth in females; purpose in males is poorly understood	Bromocriptine mesylate: Inhibits action of prolactin and therefore inhibits lactogenesis (see Chapter 35)
Thyroid-stimulating hormone (TSH)	Stimulates secretion of thyroid hormones T_3 and T_4 by the thyroid gland	Thyrotropin α : Increases the production and secretion of thyroid hormones (see Chapter 32)
Posterior Pituitary Gland		
Antidiuretic hormone (ADH)	Increases water resorption in distal tubules and collecting duct of nephron; concentrates urine; causes potent vasoconstriction	Vasopressin: ADH; performs all the physiological functions of ADH Desmopressin acetate: A synthetic vasopressin
Oxytocin	Targets mammary glands; stimulates ejection of milk and contraction of uterine smooth muscle (see Chapter 35)	Oxytocin: A synthetic hormone used for the induction or stimulation of labor and/or to control post-partum uterine bleeding

T_3 , triiodothyronine; T_4 , thyroxine.

for a hormone deficiency or as diagnostic aids to determine the status of the patient's hormonal functions. The currently identified anterior and posterior pituitary hormones and the drugs that mimic or antagonize their actions are listed in [Table 31.1](#).

The anterior pituitary drugs discussed in this chapter are cosyntropin, somatropin, and octreotide acetate; the posterior pituitary drugs discussed in this chapter are vasopressin and desmopressin.

Mechanism of Action and Drug Effects

The mechanisms of action of the pituitary drugs differ depending on the drug, but overall, they either augment or antagonize the natural effects of the pituitary hormones. Exogenously administered cosyntropin (Cortrosyn®) elicits all of the same pharmacological responses as those elicited by the endogenous corticotropin (also known as adrenocorticotrophic hormone [ACTH]). Intravenous (IV) exogenous corticotropin is no longer manufactured; however, an intramuscular (IM) injection, known as Synacthen Depot®, is available. Cosyntropin travels to the adrenal cortex, located just above the kidney, and stimulates the secretion of the mineralocorticoid cortisol (the drug form of which is the steroid hydrocortisone sodium succinate [Solu-Cortef®]). Cortisol has many anti-inflammatory effects, including reduction of inflammatory leukocyte functions and

scar tissue formation. Cortisol also promotes kidney retention of sodium, which can result in edema and hypertension.

The drug that mimics growth hormone (GH) is somatropin. This drug promotes growth by stimulating anabolic (tissue-building) processes, liver glycogenolysis (to raise blood sugar levels), lipid mobilization from body fat stores, and retention of sodium, potassium, and phosphorus. Somatropin promotes linear growth in children who lack normal amounts of the endogenous hormone.

Octreotide acetate antagonizes the effects of the natural GH. It does so by inhibiting GH release. Octreotide acetate is a synthetic polypeptide that is structurally and pharmacologically similar to GH release-inhibiting factor, which is also called *somatostatin*. It also reduces plasma concentrations of vasoactive intestinal polypeptide (VIP), a protein secreted by a type of tumour known as a *VIPoma* that causes profuse watery diarrhea (see [Chapter 53](#)).

The drugs that affect the posterior pituitary gland, such as vasopressin and desmopressin, mimic the actions of the naturally occurring antidiuretic hormone (ADH). They increase water resorption in the distal tubules and collecting ducts of the nephrons and they concentrate urine, reducing water excretion by up to 90%. Vasopressin is also a potent vasoconstrictor in larger doses and is therefore used in certain hypotensive emergencies such as vasodilatory shock (septic shock). Desmopressin

causes a dose-dependent increase in the plasma levels of factor VIII (antihemophilic factor), von Willebrand factor (acts closely with factor VIII), and tissue plasminogen activator. These properties make it useful in treating certain blood disorders. The drug form of oxytocin mimics the endogenous hormone, thus promoting uterine contractions (see [Chapter 35](#)). Patients who experience extreme loss of fluid, marked symptomatic hyponatremia, heart failure, and Syndrome of Inappropriate Antidiuretic Hormone (SIADH), may be prescribed a vasopressin antagonist, such as tolvaptan, to treat hyponatremia.

Indications

Cosyntropin is used in the diagnosis of adrenocortical insufficiency. Upon diagnosis, actual drug treatment generally involves replacement hormonal therapy using drug forms of the deficient corticosteroid hormones. These drugs are discussed in more detail in [Chapter 34](#).

Somatropin is human GH produced by recombinant technology. It is effective in stimulating skeletal growth in patients with an inadequate secretion of normal endogenous GH, such as those with hypopituitary dwarfism.

Octreotide acetate is useful in alleviating certain symptoms of carcinoid tumours stemming from the secretion of VIP, including severe diarrhea and potentially life-threatening hypotension associated with a carcinoid crisis. It is also used for the emergency management of bleeding esophageal varices in patients with liver cirrhosis and for protection against rebleeding. Vasopressin and desmopressin are used to prevent or control polydipsia (excessive thirst), polyuria, and dehydration in patients with diabetes insipidus caused by a deficiency of endogenous ADH. Because of their vasoconstrictive properties, they are useful in the treatment of various types of bleeding, particularly gastrointestinal (GI) hemorrhage. The use of vasopressin is another strategy used to stop bleeding of esophageal varices. Vasopressin is also used in the Advanced Cardiac Life Support (ACLS) guidelines for treatment of pulseless cardiac arrest as well as an adjunctive agent to norepinephrine in the treatment of septic shock. Desmopressin is useful in the treatment of hemophilia A and type 1 von Willebrand's disease because of its effects on various coagulation factors.

Contraindications

Contraindications for the use of pituitary drugs vary with each individual drug and are listed in each of the drug profiles included in this chapter. Because even small amounts of these drugs can initiate major physiological changes, all of them should be used with special caution in patients with acute or chronic illnesses, such as migraine headaches, epilepsy, and asthma. Each of these chronic conditions may be related to increase or decrease in hormone production. With the use of pituitary hormones to treat these conditions, special consideration is necessary to monitor for other physiological symptoms that may present.

Adverse Effects

Most of the adverse effects of the pituitary drugs are specific to the individual drug. Those drugs possessing similar hormonal effects generally have similar adverse effects. The most common

TABLE 31.2 Octreotide Acetate: Common Adverse Effects

Body System	Adverse Effects
Central nervous	Fatigue, malaise, headache
Endocrine	Increase or decrease in blood glucose levels
Gastrointestinal	Diarrhea, nausea, vomiting
Respiratory	Dyspnea
Musculoskeletal	Arthralgia
Cardiovascular	Conduction abnormalities

TABLE 31.3 Desmopressin and Vasopressin: Common Adverse Effects

Body System	Adverse Effects
Cardiovascular	Increased blood pressure
Central nervous	Fever, vertigo, headache
Gastrointestinal	Nausea, heartburn, cramps
Genitourinary	Uterine cramping
Other	Nasal irritation and congestion, tremor, sweating

TABLE 31.4 Somatropin: Common Adverse Effects

Body System	Adverse Effects
Central nervous	Headache
Endocrine	Hyperglycemia, hypothyroidism
Genitourinary	Hypercalciuria
Other	Rash, urticaria, development of antibodies to growth hormone, flulike syndrome

TABLE 31.5 Selected Drug Interactions Involving Pituitary Drugs

Pituitary Drug	Interacting Drug	Potential Result
desmopressin	carbamazepine	Enhanced desmopressin effects
	lithium carbonate, alcohol	Reduced desmopressin effects
octreotide acetate	cyclosporine	Case report of transplant rejection
	ciprofloxacin hydrochloride	Prolongation of QT interval
somatropin	glucocorticoids	Reduction of growth effects
vasopressin	carbamazepine, fludrocortisone	Enhanced antidiuretic effect
	norepinephrine, lithium carbonate	Reduced antidiuretic effect

adverse effects of the pituitary drugs described here are listed in [Tables 31.2 to 31.4](#).

Interactions

Selected interactions involving pituitary drugs are summarized in [Table 31.5](#).

Dosages

For dosage information on pituitary drugs, refer to the table on page 524.

DRUG PROFILES

Octreotide acetate

Octreotide acetate (Sandostatin LAR (long-acting formulation)*, Sandostatin*) is useful in alleviating certain symptoms of carcinoid tumours stemming from the secretion of VIP, including severe diarrhea, flushing, and potentially life-threatening hypotension associated with a carcinoid crisis. It is also used for the treatment of esophageal varices (usually in combination with sclerotherapy). Octreotide acetate inhibits exocrine pancreatic secretion and reduces the incidence and severity of post-operative complications such as a fistula or abscess, which can lead to sepsis. It is contraindicated in patients who have shown a hypersensitivity to it or any of its components. Octreotide acetate may impair gallbladder function and needs to be used with caution in patients with kidney impairment. It may affect glucose regulation, and severe hypoglycemia may occur in patients with type 1 diabetes. It may cause hyperglycemia in patients with type 2 diabetes or in patients without diabetes. Octreotide acetate may enhance the toxic effects of drugs that prolong the QT interval. Ciprofloxacin may enhance the QT-prolonging effects of octreotide acetate. Octreotide acetate can be given intravenously, intramuscularly, or subcutaneously. It is available in prefilled syringes in 50-, 100-, and 500-mcg/mL dosages for subcutaneous injection. The drug is safe to use during pregnancy. Therapy with octreotide acetate is usually initiated at 50 mcg once or twice daily. The dosage is increased gradually based on tolerability, patient response, and the drug's effects on levels of tumour-producing hormones. Recommended dosages are given in the table on page 521.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Subcut or IM (LAR)	Rapid	0.4–1 hr	1.7–1.9 hr	6–12 hr

Somatropin

Somatropin (Gentropin*, Humatrope*, Norditropin Simplex*, Nutropin*, Omnitrope*, Saizen*, Serostim*) is a GH that is indicated in the treatment of growth failure due to inadequate endogenous GH secretion. Serostim is limited to use in patients with HIV infection with wasting or cachexia in conjunction with antiviral therapy. It is not considered harmful to the fetus, but it is recommended to be discontinued during pregnancy. Somatropin is contraindicated in patients with hypersensitivity to any component of the product and in children with closed growth plates, patients with tumours, and patients with acute illnesses. Adverse effects include headache, injection site reactions, muscle pain, hypoglycemia, or hyperglycemia. It is important not to shake the product. It is generally given subcutaneously; however, some manufactured products can be given intramuscularly. Check the specific prescribing information before administering. Somatropin is available in cartridges for use with pen delivery systems, disposable pens, as well as in prefilled syringes.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Subcut	Not available	2–6 hr	2–10 hr (Subcut)*	18–20 hr

* depends on the product ie: Saizen 2 hrs and Norditropin 7–10 hrs

Vasopressin and desmopressin

Vasopressin (Pressyn*) is the exact synthetic protein form of the human ADH normally secreted by the pituitary gland, while desmopressin (DDAVP*, DDAVP Rhinyle, DDAVP Spray, Nocurna*, Octostim*) is the synthetic structural analogue of the natural human hormone arginine vasopressin. Desmopressin has 10 times the antidiuretic action of vasopressin but 1 500 times less vasoconstrictor action. Desmopressin is used to reduce the polyuria, nocturia, and polydipsia associated with vasopressin-sensitive central diabetes insipidus as well as temporary polydipsia and polyuria after head injury or after surgery in the area of the pituitary. It is also used for patients over 5 years of age with nocturnal enuresis. It is available in oral sublingual disintegrating and oral tablets, nasal spray or rhinyle, and parenterally. The Octostim* injection and nasal spray forms are indicated for various types of bleeding (e.g., they prevent bleeding in patients with mild hemophilia A and mild von Willebrand's disease type 1; the prevention of bleeding in patients with uremia during surgery and postoperatively). Vasopressin causes vasoconstriction and reduces portal blood flow, portal systemic collateral blood flow, and pressure on esophageal varices. It is also used for post-traumatic or postoperative diabetes insipidus in patients who are hemodynamically unstable, for hypotension associated with vasodilatory or septic shock unresponsive to catecholamines, or in patients who are acidotic or hypoxic, and it increases myocardial oxygen delivery without increasing consumption. It may also be used during cardiac arrest (ventricular fibrillation or pulseless ventricular tachycardia) as an adrenergic agent equivalent to epinephrine. Vasopressin is available only as an injection for IM or IV use.

PHARMACOKINETICS (vasopressin)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Rapid	5–15 min	less than 10 min	10–20 min

NURSING PROCESS

ASSESSMENT

Before administering any of the pituitary drugs, perform a thorough assessment and document findings. Assess the patient's height, weight, and vital signs. Take a complete medication history with notation of allergies and use of prescription drugs, over-the-counter drugs, and natural health products. With octreotide acetate, the health care provider may order an electrocardiogram (ECG) prior to its use because of the adverse effect of conduction abnormalities. Assess baseline glucose levels and note respiratory

Dosages

Selected Pituitary Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications/Uses
octreotide acetate (Ocpyl, Sandostatin)	Somatostatin (GH inhibitor) analogue	<i>Adults*</i>	Acromegaly
		IV/Subcut/Depot IM: 100–600 mcg/day divided bid–qid	Metastatic carcinoid tumours (to control flushing and diarrhea symptoms)
		IV/Subcut/Depot IM: 200–300 mcg/day divided bid–qid	VIPomas
		IV/Subcut/Depot IM: 100–300 mcg/day divided bid–tid	Acromegaly
		Subcut: 100 mcg tid, for 7 days postsurgery	Prevention of fistula, abscess postpancreatic surgery
		IV: 25 mcg/hr by continuous infusion × 48 hr to 7 days	Bleeding esophageal varices
somatropin (Humatrope, others)	Anterior pituitary GH	<i>Children</i> Subcut: 0.16–0.24 mg/kg divided into 6–7 doses	Growth failure
Somatropin (Serostim)	Anterior pituitary hormone	<i>Adults</i> Subcut: once daily at bedtime; dosage calculated by weight	HIV wasting associated with catabolism, weight loss or cachexia
vasopressin (Pressyn AR)	Natural or synthetic ADH	<i>Adults</i>	Diabetes insipidus
		IM/Subcut: 5–10 units bid–qid (max 60 units/day)	
		<i>Children</i>	
		IM/Subcut: 2.5–10 units bid–qid (max 60 units/day)	
		<i>Adults</i>	Septic shock
		IV: 0.03 units/min + norepinephrine	
		0.03–0.1 units/min (place under indications → post-cardiotomy shock) units/min	
		<i>Children</i>	
		IV: 0.3–0.4 milliunits/kg/min	
		<i>Adults</i>	GI hemorrhage
		IV: 0.2–0.4 units/min	
		<i>Children</i>	
		IV: 0.002–0.005 units/min	

ADH, antidiuretic hormone; GH, growth hormone; GI, gastrointestinal; IM, intramuscular; IV, intravenous; Subcut, subcutaneous; VIPoma, vasoactive intestinal peptide-producing tumour.

*Normally used only in adults.

CASE STUDY

Octreotide for VIPoma-Related Diarrhea

Josette, a 56-year-old aesthetician, has been diagnosed with a VIPoma (vasoactive intestinal peptide-producing tumour). She was scheduled for surgery but developed severe diarrhea. She has been hospitalized because she became dehydrated after 2 days of watery diarrhea. She has not eaten for several days. In addition to having diarrhea, she is nauseated, has facial flushing, and has lost 2.3 kg in 2 days. IV fluid

replacement with normal saline with potassium chloride 40 mmol/L has been started, and she will be receiving octreotide acetate (Sandostatin). She had her gallbladder removed 8 years ago but has no history of other illnesses.

1. How does the octreotide acetate work to control the VIPoma-related diarrhea?
2. As Josette begins therapy with octreotide acetate, the nurse should continue to assess what parameters?

After 2 days of treatment, Josette's episodes of diarrhea have become less frequent. However, the nurse notes that her blood glucose levels are elevated.

3. What is the best explanation for this elevation?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

status with octreotide acetate use. Extra caution and close monitoring of blood glucose is warranted in patients with diabetes as octreotide may affect insulin response (or response to other antidiabetic drugs). Patients taking octreotide acetate may require special dosing if they have decreased liver and kidney function; therefore,

assess and record baseline liver and kidney function tests. It is also important that assessment includes steps to prevent medication errors and awareness of concerns regarding look-alike and sound-alike drugs. Specifically, Sandostatin (octreotide acetate) should not be confused with Sandimmune® (cyclosporine).

With desmopressin, check vital signs and assess for a history of seizures, asthma, or cardiovascular disease. These conditions require cautious use with careful monitoring of vital signs, heart sounds, and breath sounds. If vasopressin is being administered for shock, close monitoring in an intensive care setting is needed, with ECG, vital signs, and other possibly invasive monitoring methods (e.g., arterial lines, central venous pressure lines, arterial blood gases). Obtain baseline thyroid, glucose, and calcium levels in patients receiving GHs, owing to the potential adverse effects of hyperglycemia, hypothyroidism, and hypercalciuria. Specifically, use of somatropin requires attention to the growth, motor skills, height, and weight of pediatric patients. Additionally, with all of the pituitary drugs, always perform a thorough assessment of cautions, contraindications, and drug interactions prior to their administration.

◆ NURSING DIAGNOSES

- Impaired body image as a result of specific disease processes or drug adverse effects and their influence on the patient's physical characteristics
- Acute pain related to GI adverse effects associated with the use of various pituitary drugs
- Inadequate knowledge as a result of lack of information and experience with pituitary drug treatment

◆ PLANNING

◆ Goals

- Patient will maintain a positive body image while receiving drug therapy.
- Patient will experience little to no pain related to medication-induced GI upset or epigastric distress.
- Patient will gain increased knowledge about drug therapy.

◆ Expected Patient Outcomes

- Patient openly verbalizes fears, anxieties, and concerns regarding changes in body image related to disease processes and the adverse effects of drug therapy to health care providers.
- Patient experiences minimal GI upset and gastric distress by taking medication with food or at mealtimes.
- Patient states specific rationale for drug therapy as well as adverse effects.
- Patient states the importance of keeping follow-up appointments with health care providers.

◆ IMPLEMENTATION

Octreotide acetate must be given as ordered with attention to the route of administration. To avoid giving the incorrect

medication, follow the “rights” consistently and the three checks of medication administration; be careful not to confuse octreotide acetate injection with the injectable depot suspension dosage form. Use only clear solutions and always check for incompatibilities. Mix injectable solutions by gently swirling the liquid. Make sure patients understand the importance of immediately reporting to the health care provider any abdominal distress such as diarrhea, nausea, or vomiting, if not manageable. Stress the importance of follow-up appointments for laboratory testing during treatment with this drug. Octreotide acetate causes alterations in blood glucose levels; closely monitor glucose levels during therapy, especially if patients have diabetes.

Administer desmopressin according to the health care provider's orders because dosage and route may vary with the indication. For desmopressin and somatropin, rotate subcutaneous injection sites (also given IM, in ventral gluteal site) to avoid tissue damage. Desmopressin dosage forms include sublingual disintegrating tablet, oral, IV, intranasal, and subcutaneous. Intranasal use may lead to changes in the nasal mucosa, leading to unpredictable absorption. Instruct patients to contact their health care providers immediately if the condition worsens. If used in patients diagnosed with diabetes insipidus, fluid intake may be adjusted according to the predicted risk of water intoxication and sodium deficit. See the Patient Teaching Tips for more information on dosage administration.

Vasopressin is available as an injection for IM/subcutaneous or IV use. Always check the clarity of parenteral solutions before administering the medication, and discard the solution if there are visible particles or there is any fluid discoloration. Be alert to the adverse effects of elevated blood pressure, fever, nausea, abdominal cramping, or diarrhea. If these worsen or persist, notify the health care provider immediately.

◆ EVALUATION

After goals and outcome criteria have been reviewed and treatment has begun, evaluate therapeutic responses to these drugs. With octreotide acetate, therapeutic effects include improvement of symptoms related to carcinoid tumours, VIPoma, or esophageal varices. With vasopressin, an improvement in diabetes insipidus, esophageal varices, or vasodilatory shock is expected. With somatropin, increased growth is expected in those for whom it is indicated. Adverse effects for which to evaluate include fatigue, headache, altered blood glucose levels, diarrhea, nausea, vomiting, conduction disorders, and dyspnea. Adverse effects associated with desmopressin and vasopressin include increased blood pressure, fever, headache, abdominal cramps, and nausea. GHs may have the adverse effects of headache, hyperglycemia, hypothyroidism, hypercalciuria, and flulike syndrome.

PATIENT TEACHING TIPS

- Carefully discuss routes and techniques of administration with patients and anyone else involved in their care. With pediatric patients, demonstrate the technique of

administration to family members or caregivers before discharge, and evaluate their comprehension with return demonstrations. Provide written instructions to patients, if

age appropriate, but also to their family members or caregivers. A written or electronic journal about how the drug is being tolerated may prove beneficial. As for any medication or illness, patients should keep a medical alert bracelet, necklace, or wallet card with them at all times.

- Intranasal dosage forms of desmopressin are to be given only after the nasal passages have been cleared. The pump must be primed prior to use. Instruct patients to prime the nasal pump by pressing down the pump four times. The spray pump delivers 10 mcg of drug each time it is pressed. To administer a 10-mcg dose as ordered, place the spray nozzle in the nostril (for a child, have a parent, caregiver, or other adult administer the dose) and press the spray pump once. If a higher dose has been prescribed, half the dose is to be administered in each nostril. The pump cannot deliver doses smaller than 10 mcg. Once dosing is completed, replace the cap on the bottle. The pump will stay primed for up to 1 week. After 1 week, it will require repriming. The level of drug left in the pump should be carefully monitored so that there is always enough medication on hand. The pump may not have enough medication left after 25 doses (at 150 mcg per spray) or 50 doses (at 10 mcg per spray). Vasopressin is applied topically to the nasal membranes and is not to be inhaled.
- Somatropin is available in a variety of delivery forms. One is a disposable pen preloaded with a cartridge. One section of

the cartridge contains the GH in powder form, to be mixed with the diluent in the other section. Before the contents have been mixed, the syringe should be stored in the refrigerator. Educate patients or their parents, family members, or caregivers to attach the needle to the syringe by pushing it down onto the syringe and twisting it until it no longer turns. Hold the syringe with the needle pointing upward and gently turn the plunger clockwise to mix the solution; do not shake. Administer by subcutaneous injection. Dispose of the syringe safely. Somatropin is also available in a multi-dose prefilled pen with a variety of different dosages in mg/mL. The pen must be primed before the first use to ensure flow. The pen is dialed to get the correct dose (one click on the dose selector at the end of the pen). Inform patients that they must use a new needle with each injection.

- Educate parents about the fact that children with endocrine disorders may have an increased risk of bone problems. Instruct parents that if they notice their child limping, this needs to be evaluated by their health care provider. Closely monitor patients with diabetes for changes in serum glucose levels if taking octreotide acetate.
- Water intake amounts may need to be monitored closely in patients with diabetes insipidus. Exact amounts may be prescribed or determined for each patient.

KEY POINTS

- The pituitary gland is composed of two distinct glands: anterior and posterior. Each lobe secretes its own set of hormones: anterior—thyroid-stimulating hormone (TSH), GH, ACTH, prolactin, follicle-stimulating hormone (FSH), luteinizing hormone (LH); posterior—ADH, oxytocin.
- Pituitary drugs are used to either mimic or antagonize the action of endogenous pituitary hormones.
- Drugs that mimic the action of endogenous pituitary hormones include cosyntropin, somatropin, vasopressin, and

desmopressin. A drug that antagonizes the actions of endogenous pituitary hormones is octreotide acetate.

- In the assessment of patients receiving pituitary hormones, record baseline vital signs, review blood glucose levels, and measure weight.
- For patients receiving somatropin, constantly monitor levels of thyroid hormones and GHs. Include measurement of vital signs, intake and output, and weight in the assessment.

EXAMINATION REVIEW QUESTIONS

1. A patient is experiencing severe diarrhea, flushing, and life-threatening hypotension associated with carcinoid crisis. Which of the following drugs will the nurse anticipate administering to the patient??
 - a. octreotide acetate (Sandostatin)
 - b. vasopressin (Pressyn AR)
 - c. somatropin (Humatrope)
 - d. cosyntropin (Cortrosyn)
2. A patient is suspected of having adrenocortical insufficiency. Which of the following drugs will the nurse expect to administer?
 - a. octreotide acetate (Sandostatin)
 - b. vasopressin (Pressyn AR)
 - c. somatropin (Humatrope)
 - d. cosyntropin (Cortrosyn)
3. The nurse is reviewing the medication list for a patient who will be starting therapy with somatropin. Which of the following medications would the nurse follow up with the health care provider?
 - a. Nonsteroidal anti-inflammatory drug for arthritis
 - b. Antidepressant therapy
 - c. Penicillin
 - d. Glucocorticoid
4. The nurse is caring for a patient receiving intranasal desmopressin (DDAVP) in a patient who has diabetes insipidus. Which of the following assessments would the nurse make to determine effectiveness of the medication?
 - a. Increased insulin levels
 - b. Decreased diarrhea
 - c. Improved nasal patency
 - d. Decreased thirst

5. Which of the following drugs have an action similar to that of the naturally occurring hormone ADH? (Select all that apply.)
 - a. cosyntropin (Cortrosyn)
 - b. desmopressin (DDAVP)
 - c. somatropin (Humatrope)
 - d. vasopressin (Pressyn AR)
 - e. octreotide acetate (Sandostatin)
6. The order reads: “Give octreotide acetate (Sandostatin) 50 mcg Subcut twice a day.” The medication is available in an injectable form of 0.05 mg/mL. How many millilitres will the nurse draw up for the ordered dose?
7. The nurse is preparing to administer somatropin and will monitor the patient for which adverse effects? (Select all that apply.)
 - a. Increased blood pressure
 - b. Headache
 - c. Flulike syndrome
 - d. Nausea
 - e. Hyperglycemia
 - f. Fever
8. The nurse is to administer octreotide acetate to a patient. When reviewing the medication list, the nurse learns that the patient is also taking a diuretic, IV heparin, ciprofloxacin hydrochloride, and an opioid as needed for pain. Which of the following adverse events will the nurse need to monitor for?
 - a. Hypokalemia due to an interaction with the diuretic
 - b. Decreased anticoagulation because of interaction with the heparin
 - c. Prolongation of the QT interval due to an interaction with ciprofloxacin hydrochloride
 - d. Increased sedation if the opioid is given

CRITICAL THINKING ACTIVITIES

1. When the nurse checks the insertion site of a patient who is receiving an IV infusion of vasopressin, the site is swollen and cool to the touch. What is the nurse’s priority action? Explain your answer.
2. A child is experiencing delayed growth due to an endocrine disorder. Which pituitary drug is used to treat this condition, and how does it work? What is the best way for the nurse to measure the patient’s response to the drug therapy?
3. A patient will be receiving intranasal desmopressin (DDAVP), and the nurse is teaching the patient how to self-administer the drug. After the nurse explains how the pump works and how to prime the pump, what is important for the nurse to tell the patient to do just before taking the medication?

Thyroid and Antithyroid Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Briefly describe the normal anatomy and physiology of the thyroid gland.
2. Discuss the various functions of the thyroid gland and related hormones.
3. Describe the differences in the diseases resulting from the hyposecretion and hypersecretion of the thyroid gland hormones.
4. Identify the various drugs used to treat the hyposecretion and hypersecretion states of the thyroid gland.
5. Discuss the mechanisms of action, indications, contraindications, cautions, drug interactions, adverse effects, dosages, and routes of administration of the various drugs used to treat hypothyroidism and hyperthyroidism.
6. Develop a collaborative plan of care that includes all phases of the nursing process for patients receiving thyroid replacement as well as for patients receiving antithyroid drugs.

KEY TERMS

Euthyroid Referring to normal thyroid function. (p. 529)

Hyperthyroidism A condition characterized by excessive production of the thyroid hormones. Also referred to as *thyrotoxicosis*. (p. 529)

Hypothyroidism A condition characterized by diminished production of the thyroid hormones. (p. 529)

Thyroid-stimulating hormone (TSH) An endogenous substance secreted by the pituitary gland that controls the

release of thyroid gland hormones and is necessary for the growth and function of the thyroid gland (also called thyrotropin). (p. 528)

Thyroxine (T₄) The principal thyroid hormone that influences the body's metabolic rate. (p. 528)

Triiodothyronine (T₃) A secondary thyroid hormone that also affects body metabolism. (p. 528)

DRUG PROFILES

	levothyroxine (levothyroxine sodium)*, p. 530
	methimazole, p. 532
	Key drug

* Full generic name is given in parentheses. For the purposes of this text, the more common, shortened name is used.

THYROID FUNCTION

The thyroid gland lies across the larynx in front of the thyroid cartilage. Its lobes extend laterally on both sides of the front of the neck. The thyroid gland is responsible for the secretion of three hormones essential for the proper regulation of metabolism: **thyroxine (T₄)**, **triiodothyronine (T₃)**, and **calcitonin** (see [Chapter 35](#)). It is located close to and communicates with the parathyroid glands, which lie just above and behind it. The parathyroid glands are two pairs of bean-shaped glands. These glands are made up of encapsulated cells, which are responsible for maintaining adequate levels of calcium in extracellular fluid, primarily by mobilizing calcium from bone (see [Chapter 9](#)).

T₄ and T₃ are produced in the thyroid gland through the coupling of the amino acid tyrosine. The iodide (I⁻, which is the

ionized form of iodine) required for this process is acquired from the diet. One milligram of iodide is needed per week. This iodide is absorbed from the blood and then sequestered by the thyroid gland, where it is concentrated to 20 times its blood level. Here it is also converted to iodine (I₂), which is combined with tyrosine to make diiodotyrosine. The combination of two molecules of diiodotyrosine results in the formation of thyroxine, which therefore has four iodine molecules in its structure (T₄). Triiodothyronine is formed by the coupling of one molecule of diiodotyrosine with one molecule of monoiodotyrosine; thus, it has three iodine molecules in its structure (T₃). The biological potency of T₃ is almost four times greater than that of T₄, but T₄ is present in much greater quantities. After these two thyroid hormones are synthesized, they are stored in the follicles in the thyroid gland in a complex with thyroglobulin (a protein that contains tyrosine and an amino acid), called the *colloid*. When the thyroid gland is signalled to do so, it breaks down the thyroglobulin–thyroid hormone complex enzymatically to release T₃ and T₄ into the circulation. This entire process is triggered by **thyroid-stimulating hormone (TSH)**, also called *thyrotropin*. Its release from the anterior pituitary is stimulated when blood levels of T₃ and T₄ are low.

The thyroid hormones are involved in a wide variety of bodily processes. They regulate the basal metabolic rate and lipid and carbohydrate metabolism; are essential for normal growth and

development; control the heat-regulating system (thermoregulatory centre in the brain); and have several effects on the cardiovascular, endocrine, and neuromuscular systems. Therefore, hyperfunction or hypofunction of the thyroid gland can lead to a wide range of serious consequences.

HYPOTHYROIDISM

There are three types of **hypothyroidism**. Primary hypothyroidism stems from an abnormality in the thyroid gland. It occurs when the thyroid gland is not able to perform one of its many functions, such as releasing the thyroid hormones from their storage sites, coupling iodine with tyrosine, trapping iodide, converting iodide to iodine, or any combination of these defects. Primary hypothyroidism is the most common of the three forms of hypothyroidism. Secondary hypothyroidism begins at the level of the pituitary gland and results from reduced secretion of TSH. TSH is needed to trigger the release of the T_3 and T_4 stored in the thyroid gland. Tertiary hypothyroidism is caused by a reduced level of the thyrotropin-releasing hormone from the hypothalamus. This reduced level, in turn, reduces TSH and thyroid hormone levels. Symptoms of hypothyroidism include cold intolerance, unintentional weight gain, depression, dry and brittle hair and nails, and fatigue.

Hypothyroidism can also be classified by the point in the lifespan in which it occurs. Hyposecretion of thyroid hormones during youth may lead to *cretinism*. Cretinism is characterized by low metabolic rate, short stature, and severely delayed sexual development, and these features may be accompanied by intellectual disabilities. Hyposecretion of thyroid hormones as an adult may lead to *myxedema*. Myxedema is a condition manifested by decreased metabolic rate, but it also involves loss of mental and physical stamina, weight gain, hair loss, firm edema, and yellow dullness of the skin.

Some forms of hypothyroidism may result in the formation of a goitre, which is an enlargement of the thyroid gland resulting from its overstimulation by elevated levels of TSH. The TSH level is elevated because there is little or no thyroid hormone in the circulation.

Certain drugs can cause hypothyroidism. Amiodarone hydrochloride, an iodine-rich antidysrhythmic (see [Chapter 26](#)), has a wide range of effects on the thyroid. It acts as an enzyme inhibitor and decreases the peripheral conversion of T_4 to T_3 resulting in reduced T_3 levels. It also inhibits entry of T_4 and T_3 into the peripheral tissue with serum T_4 levels increasing; however, this does not create a state of hyperthyroidism ([Gopalan, 2018](#)). Amiodarone does have a direct cytotoxic effect on the follicular cells of the thyroid, which can result in hyperthyroidism or thyrotoxicosis. Patients need to be monitored for presentation of symptoms and treated accordingly.

HYPERTHYROIDISM

Excessive secretion of thyroid hormones, or **hyperthyroidism**, may be caused by several different diseases. Diseases known to cause hyperthyroidism include Graves' disease, which is the most common cause; Plummer's disease, also known as *toxic*

TABLE 32.1 Thyroid Drugs: Clinically Equivalent Doses

Thyroid Drug	Approximate Equivalent Dose
Natural Thyroid Preparation	
desiccated thyroid	60–65 mg
Synthetic Thyroid Preparations	
levothyroxine	100 mcg or more
liothyronine	25 mcg

nodular disease, which is the least common cause; multinodular disease; and thyroid storm, which is a severe and potentially life-threatening exacerbation of the symptoms of hyperthyroidism, often induced by stress or infection.

Hyperthyroidism can affect multiple body systems, resulting in an overall increase in metabolism. Commonly reported symptoms are diarrhea, flushing, increased appetite, muscle weakness, fatigue, palpitations, irritability, nervousness, sleep disorders, heat intolerance, and altered menstrual flow.

THYROID REPLACEMENT DRUGS

Hypothyroidism is treated with thyroid hormone replacement, using various thyroid preparations. These drugs can be either natural or synthetic in origin. The natural thyroid preparations are derived from the thyroid glands of animals such as cattle and pigs. Currently, only one natural preparation is available in Canada, called, simply, *thyroid* or *thyroid, desiccated*. *Desiccation* is the term for the drying process used to prepare this drug form. All natural preparations are standardized for their iodine content. The synthetic thyroid preparations are levothyroxine (T_4) and liothyronine (T_3). The approximate clinically equivalent doses of the drugs are given in [Table 32.1](#). This information is useful for guiding dosage adjustments when a patient is switched from one thyroid hormone to another. Monitoring of both serum TSH and free thyroid hormone levels is required to determine the appropriate dose of thyroid replacement drugs.

Mechanism of Action and Drug Effects

Thyroid drugs function in the same manner as endogenous thyroid hormones, affecting many body systems. At the cellular level, they act to induce changes in the metabolic rate, including the rate of protein, carbohydrate, and lipid metabolism, and to increase oxygen consumption, body temperature, blood volume, and overall cellular growth and differentiation. They also stimulate the cardiovascular system by increasing the number of myocardial β -adrenergic receptors. This, in turn, increases the sensitivity of the heart to catecholamines and ultimately increases cardiac output. In addition, thyroid hormones increase kidney blood flow and the glomerular filtration rate, which results in a diuretic effect.

Indications

Thyroid preparations are given to replace what the thyroid gland cannot produce to achieve normal thyroid levels (**euthyroid**

TABLE 32.2 Thyroid Drugs: Common Adverse Effects

Body System	Adverse Effects
Cardiovascular	Tachycardia, palpitations, angina, dysrhythmias, hypertension
Central nervous	Insomnia, tremors, headache, anxiety
Gastrointestinal	Nausea, diarrhea, cramps
Other	Menstrual irregularities, weight loss, sweating, heat intolerance, fever

condition). Levothyroxine is the preferred thyroid drug because its hormonal content is standardized and its effect is predictable. Thyroid drugs can also be used for the diagnosis of suspected hyperthyroidism (as a TSH-suppression test) and in the prevention or treatment of various types of goitre. They are also used for replacement hormonal therapy in patients whose thyroid glands have been surgically removed or destroyed by radioactive iodine in the treatment of thyroid cancer or hyperthyroidism. Hypothyroidism during pregnancy is treated with dosage adjustments every 4 weeks to maintain a TSH level at the lower end of the normal range. Fetal growth may be retarded if maternal hypothyroidism remains untreated during pregnancy.

Contraindications

Contraindications to thyroid preparations include known drug allergy, recent myocardial infarction (MI), adrenal insufficiency, and hyperthyroidism. Levothyroxine contains cornstarch and lactose as fillers, and liothyronine sodium has modified food starch, which contains gluten. Many individuals with hypothyroidism have allergies to these ingredients. Patients with celiac disease should be counselled to adjust their lifestyle to a gluten-free diet. Absorption of levothyroxine is improved with celiac treatment as there is less inflammation of the intestine, leading to a lower dose of levothyroxine required to treat hypothyroidism (Collins, Wilcox, Nathan, et al., 2012).

Adverse Effects

The adverse effects of thyroid medications are usually the result of overdose, which may be accidental or unintentional. The most significant adverse effect is cardiac dysrhythmia, with the risk for life-threatening or fatal irregularities. Other more common undesirable effects are listed in Table 32.2.

Interactions

Thyroid drugs may enhance the activity of oral anticoagulants, the dosages of which may need to be reduced. Taking thyroid preparations concurrently with digoxin may decrease serum digoxin levels. Cholestyramine binds to thyroid hormone in the gastrointestinal (GI) tract, which possibly reduces the absorption of both drugs. Patients with diabetes taking a thyroid drug may require increased dosages of their hypoglycemic drugs. In addition, the use of thyroid preparations with epinephrine in patients with coronary disease may induce coronary insufficiency. See Table 32.3 for more drug interactions.

TABLE 32.3 Thyroid Drugs: Interactions

Drug	Action
Insulin	Decreased efficacy of insulin (resulting in increased blood glucose levels)
Oral antihyperglycemics	Decreased efficacy of antidiabetic drugs (resulting in increased blood glucose levels)
Estrogen	Reduced thyroid drug activity
Digoxin	Decreased digoxin effectiveness
phenytoin and fosphenytoin	Reduced levothyroxine effectiveness
Phenobarbital	Reduced levothyroxine effectiveness

Dosages

For dosage information on the thyroid drugs, refer to the table on p. 531.

DRUG PROFILES

The most commonly used thyroid replacement drug is the synthetic drug levothyroxine. Some patients experience better results with the animal-derived products. Although the thyroid drugs differ chemically, their therapeutic actions are all the same. Factors to be considered before the initiation of drug therapy with a thyroid drug include the desired ratio of T_3 to T_4 (normal ratio is 1:17) to balance the cost, the risk for hyperthyroidism with clinical symptoms of hypothyroidism, and the desired duration of effect. Thyroid hormone replacement is safe for use during pregnancy. Thyroid replacement drugs are all contraindicated in patients who have had a hypersensitivity reaction to them in the past and in those with adrenal insufficiency, previous MI, or hyperthyroidism.

levothyroxine sodium

Levothyroxine sodium (Eltroxin®, Synthroid®), or T_4 , is the most commonly prescribed synthetic thyroid hormone and is the drug of choice. One advantage it has over the natural thyroid preparations is that it is chemically pure, being 100% T_4 (thyroxine); this makes its effects more predictable than those of other thyroid preparations. Levothyroxine's half-life is long enough that it is administered once a day. It is available in oral form and in parenteral form. Liothyronine sodium (Cytomel®) and desiccated thyroid (Thyroid®) are examples of similar drugs.

Switching between different brands of levothyroxine during treatment can destabilize the course of treatment. Thyroid function test results need to be monitored more carefully when switching products. Recommended dosages are given in the table on this page. Levothyroxine is dosed in micrograms. A common medication error is to interpret the intended dose in milligrams instead of micrograms. If not caught, this error would result in a thousandfold overdose. Doses higher than 200 mcg need to be questioned in case this error has occurred. The intravenous dose of levothyroxine is generally 50% of the oral dose.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	3–5 days	2–4 hrs	6–10 days	1–3 wk

Dosages

Selected Thyroid Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications/Uses
levothyroxine sodium (Eltroxin, Synthroid)	Synthetic levothyroxine (thyroid hormone T ₄)	<i>Children 0–12 yr</i> PO: 3–15 mcg/kg/day <i>Adults</i> PO: 1–1.7 mcg/kg/day IM/IV: 75% of oral dose IV: 300–500 mcg in a single dose; then 75–100 mcg/day until thyroid levels improve	Congenital hypothyroidism Hypothyroidism Myxedema coma
liothyronine sodium (Cytomel)*	Synthetic liothyronine (thyroid hormone T ₃)	<i>Adults</i> PO: 25–75 mcg/day PO: 50–100 mcg daily PO: 20–50 mcg daily	Hypothyroidism
desiccated thyroid (Thyroid)	Desiccated (dried) animal thyroid gland	<i>Children 0–12 yr</i> PO: 15–90 mg/day <i>Adults</i> PO: 15–120 mg/day	Congenital hypothyroidism Hypothyroidism

*Liothyronine is synonymous with triiodothyronine (T₃).
IM, intramuscular; IV, intravenous; PO, oral.

ANTITHYROID DRUGS

Treatment of hyperthyroidism is aimed at treating either the primary cause or the symptoms of the disease. Antithyroid drugs, iodides, ionic inhibitors, and radioactive isotopes of iodine are used to treat the underlying cause, and drugs such as β -blockers are used to treat the symptoms. The focus of this discussion is on the antithyroid drugs called *thioamide derivatives*, thiamazole and propylthiouracil. In addition to the thioamides, radioactive iodine (iodine-131) may be used to treat hyperthyroidism. Radioactive iodine destroys the thyroid gland in a process known as *ablation*. It does this by emitting destructive β -rays once it is taken up into the follicles of the thyroid gland. Radioactive iodine is a commonly used treatment for both hyperthyroidism and thyroid cancer. Potassium iodide is also used as prophylaxis for radiation exposure. Thyroid surgery involves removal of part or all of the thyroid gland. It is usually an effective way to treat hyperthyroidism, but lifelong hormone replacement therapy is normally required after thyroid surgery.

Mechanism of Action and Drug Effects

Thiamazole and propylthiouracil act by inhibiting the incorporation of iodine molecules into the amino acid tyrosine, a process required to make the precursors of T₃ and T₄. This inhibition of iodine impedes the formation of thyroid hormones. Propylthiouracil has the added ability to inhibit the conversion of T₄ to T₃ in the peripheral circulation. Neither drug can inactivate already existing thyroid hormone.

The drug effects of thiamazole and propylthiouracil are limited primarily to the thyroid gland, and their overall effect is a decrease in the thyroid hormone level. Administration of these drugs to patients with hyperthyroidism lowers the high

levels of thyroid hormone, thereby normalizing the overall metabolic rate.

Indications

Antithyroid drugs are used to treat hyperthyroidism and to prevent the surge in thyroid hormones that occurs during radioactive iodine therapy for or after the surgical treatment of hyperthyroidism or thyroid cancer. In some types of hyperthyroidism, such as that seen in Graves' disease, the long-term administration of these drugs (for several years) may induce a spontaneous remission. Surgical resection of the thyroid (thyroidectomy) is often used in patients who are intolerant of antithyroid drug therapy and in pregnant women, in whom both antithyroid drugs and radioactive iodine therapy are usually contraindicated.

Contraindications

The only usual contraindication to the use of the two antithyroid drugs is known drug allergy. Their use in pregnancy, though it may be necessary, is somewhat controversial. Propylthiouracil and thiamazole are effective drugs for the treatment of hyperthyroidism in pregnant women. However, the drug readily crosses the placenta and can cause goitre or cretinism in the fetus. Hyperthyroidism may be exacerbated by the metabolic demands of pregnancy; the lowest effective dose is recommended. However, there are case reports of scalp abnormalities when thiamazole is used. The choice of how to treat patients who are pregnant is specific to individual health care providers.

Adverse Effects

The most serious adverse effects of the antithyroid medications are liver and bone marrow toxicity. These and the more common adverse effects of thiamazole and propylthiouracil are listed in [Table 32.4](#).

TABLE 32.4 Antithyroid Drugs: Common Adverse Effects

Body System	Adverse Effects
Central nervous	Drowsiness, headache, vertigo, paresthesia
Gastrointestinal	Nausea, vomiting, diarrhea, hepatitis, loss of taste
Genitourinary	Cloudy urine, decreased urine output
Hematological	Agranulocytosis, leukopenia, thrombocytopenia, hypotherbinemia, lymphadenopathy, bleeding
Integumentary	Rash, pruritus
Musculoskeletal	Myalgia, arthralgia
Renal	Increased blood urea nitrogen and serum creatinine levels
Other	Enlarged thyroid gland, nephritis

Interactions

Drug interactions that occur with antithyroid drugs include an increase in the activity of oral anticoagulants and additive leukopenic effects when they are taken in conjunction with other bone marrow depressants.

Dosages

For dosage information on propylthiouracil and thiamazole, refer to the table above.

DRUG PROFILES

methimazole

Methimazole is a thioamide antithyroid drug. Approximately 6 weeks of therapy with propylthiouracil may be necessary before symptoms improve. It is available only in oral form. Thiamazole is the only alternative drug in this class and is rarely used clinically.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	12–18 hr	1–2 hr	4–6 hr	36–72 hr

PHARMACOKINETIC BRIDGE TO NURSING PRACTICE

Nurses must understand the pharmacokinetics of thyroid replacement drugs in order to think critically through clinical situations involving patients who are taking them. Thyroid replacement drugs possess specific pharmacokinetic characteristics.

For levothyroxine (Eltroxin®, Synthroid®), the pharmacokinetic characteristics include an onset of action of 3 to 5 days, peak plasma concentrations within 3 to 4 days, elimination half-life of 6 to 10 days, and a duration of action of 1 to 3 weeks. Levothyroxine has a narrow therapeutic margin. Due to its prolonged half-life, there is an increased risk of toxicity. Toxicity is manifested by the following: weight loss, tachycardia, nervousness, tremors, hypertension, headache, insomnia, menstrual irregularities, and cardiac irregularities or palpitations. Clinical and laboratory evaluations are recommended at 6- to 8-week intervals (or 2- to 3-week intervals in patients who have severe hypothyroidism), and the dosage

Dosages

Selected Antithyroid Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications/Uses
thiamazole (Tapazole®)	Antithyroid	<i>Children</i> PO: 0.4 mg/kg/day; maintenance half of initial dose <i>Adult</i> PO: 15–60 mg/day	Hyperthyroidism
propylthiouracil* (generic only)	Antithyroid	<i>Children 6–10 yr</i> PO: 50–150 mg/day <i>Children over 10 yr</i> PO: 150–300 mg/day <i>Adults</i> PO: 300–900 mg/day	Hyperthyroidism

*Often abbreviated PTU.
PO, oral.

will need to be adjusted until the serum TSH concentration is normalized and signs and symptoms resolve. Once optimal replacement is achieved, evaluations are recommended at least annually, or whenever warranted by a change in patient status. Another important pharmacokinetic property of levothyroxine is that the drug is highly protein bound. A protein-bound drug acts like a biological sustained-release drug and remains in the body longer, with increased risk of more interactions with other highly protein-bound drugs as well as greater risk for toxicity. Consumption of foods such as soybean flour (e.g., as found in infant formula), cottonseed meal, walnuts, calcium (e.g., as found in calcium-fortified orange juice), and dietary fibre may bind to and consequently decrease the absorption of levothyroxine sodium from the GI tract, thereby necessitating adjustments in dosing. This is yet another example of how important a current and thorough knowledge base about drugs—and specifically about their pharmacokinetics—is to their safe and efficient administration.

❖ NURSING PROCESS

◆ ASSESSMENT

In assessing patients taking thyroid replacement drugs for hypothyroidism, record baseline vital signs for comparative purposes. Assess T₃, T₄, and TSH before and during drug therapy, as ordered. It is important to thoroughly assess and document all past and present medical problems or concerns. Take a medication history that includes drug allergies and a list of all prescription drugs, over-the-counter drugs (OTC), and natural health products a patient is taking. Cautions, contraindications, and drug interactions associated with the use of thyroid hormone have been previously discussed; thoroughly assess patients for these prior to the initiation of therapy with these drugs. Review

baseline vital signs, paying attention to any history of cardiac dysrhythmias because of the possible adverse effects of cardiac irregularities; these may be life-threatening. For female patients, perform a thorough assessment of the reproductive system owing to the impact of thyroid hormones on this system.

It is also important to remember that certain thyroid hormones may work faster than others because of their dosage form and properties (see Pharmacokinetic Bridge to Nursing Practice). Drug interactions that deserve emphasis (because of their importance to patient safety and because they involve commonly used medications) include interactions with oral anticoagulants (leading to increased anticoagulant activity), digoxin (leading to a decrease in digoxin levels), cholestyramine, and oral antihyperglycemic drugs. See Table 32.3 for a more detailed listing of drug interactions. If the patient is taking an oral anticoagulant, monitor blood levels of the anticoagulant closely. Lifespan considerations include increased sensitivity to the effects of thyroid medications in older adults. Individualization of drug therapy is important with thyroid replacement because different patients may respond differently to the same drug or dosage (see Special Populations: Older Adults: Thyroid Hormones).

SPECIAL POPULATIONS: OLDER ADULTS

Thyroid Hormones

- Older adult patients are much more sensitive to thyroid hormone replacement drugs (as they are to most drugs). They are also more likely to experience adverse reactions to thyroid hormones than are patients in any other age group.
- Older adult patients experience more negative consequences related to drug therapy because their liver and kidney functioning is decreased.
- Thyroid hormone replacement requirements are approximately 25% lower in patients 60 years of age and older than in younger patients. Dosage in older adult patients may therefore need to be adjusted or titrated downward.
- Older adult patients must contact their health care providers immediately if they experience palpitations, chest pain, stumbling, falling, depression, incontinence, sweating, shortness of breath, symptoms of aggravated heart disease, cold intolerance, or weight gain.
- Drug therapy for older adult patients must be initiated with caution and with individualized dosages. If higher dosages are necessary, increases must be made with the health care provider's guidance and done gradually.

For antithyroid drugs, such as propylthiouracil and thiamazole, first, measure vital signs and assess for signs and symptoms of a thyroid crisis, or what is often called *thyroid storm*. Thyroid storm is manifested by exacerbation of the symptoms of hyperthyroidism (see previous discussion of hyperthyroidism symptoms on p. 529) and is potentially life-threatening. Although rare, death can occur within 48 hours without treatment. Monitor for systemic symptoms of a thyroid storm, which may include hyperthermia; tachycardia (atrial tachycardias); high-output heart failure; agitation or delirium; and nausea, vomiting, or diarrhea, which may contribute to fluid depletion (Huether, McCance, Brashers, et al., 2018). Treatment includes

symptom management, inhibition synthesis and release of thyroid hormone, and use of β -blockers.

Assessing for thyroid storm also means assessing for its potential causes, such as stress or infection. Related cautions and contraindications have been discussed previously, but some important drug interactions to re-emphasize include interactions with oral anticoagulants (which can cause an increase in anticoagulation and thus risk for bleeding) and any medications that may lead to bone marrow suppression or cause leukopenia (antithyroid drugs may cause additive effects or worsening of bone marrow suppression).

NURSING DIAGNOSES

- Potential for nonadherence to drug therapy as a result of lack of experience or education related to thyroid hormone replacement and the need for daily self-administration
- Limited health management as a result of lack of experience or education related to the use of thyroid medication
- Risk for infection as a result of bone marrow depression caused by antithyroid medication

PLANNING

Goals

- Patient will remain adherent to daily administration of thyroid hormone replacement therapy.
- Patient will demonstrate improvement in health management behaviours through having more experience in and education regarding the rationale for use of the thyroid drug and its related adverse effects.
- Patient will remain free from infection while receiving antithyroid medication.

Expected Patient Outcomes

- Patient states the importance of taking thyroid hormone replacement therapy daily, as ordered.
 - Patient takes thyroid hormone replacement therapy upon awakening in the morning and on an empty stomach, to maximize therapeutic effects.
- Patient takes medication in a single daily dose before breakfast and does not stop the medication without consulting a health care provider.
- Patient understands that replacement therapy will be lifelong in most situations.
- Patient states the importance of taking the medication as prescribed as well as the rationale for its use.
 - Patient states the adverse effects associated with thyroid replacement therapy that need to be reported to a health care provider (e.g., cardiac dysrhythmias [felt as palpitations]).
 - Patient reports adverse effects that may indicate the need for re-regulation of dosage, such as signs and symptoms of hyperthyroidism (e.g., irregular heartbeat, palpitations).
- Patient states ways to decrease the risk for infection while receiving an antithyroid medication, such as avoiding persons with infections, eating a nutritious diet, getting adequate rest, and increasing fluid intake.

CASE STUDY

Antithyroid Drug Therapy

Rima, a 28-year-old restaurant manager, has been diagnosed with hyperthyroidism due to Graves' disease. Her health care provider has explained the proposed therapy with propylthiouracil to her and her husband. She has no other known health problems at this time.

1. What laboratory studies will be performed before drug therapy with propylthiouracil is started? Explain your answer.
2. Rima asks, "What do I need to know while I'm taking this drug?" List pertinent patient teaching points.

3. After 1 month of therapy, Rima comes into the health care provider's office for a follow-up visit. She is upset because a friend told her about a relative who had antithyroid therapy for cancer and said he was "radioactive." She is wondering if her medication has made her "radioactive." How will the nurse answer her question?
4. Six months later, Rima calls her health care provider's office and says, "I think I might be pregnant. What do I do about taking this drug?" What does the nurse need to tell her?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

IMPLEMENTATION

When thyroid drugs are administered, it is important that they are taken at the same time every day to maintain consistent blood levels of the drug. Emphasize to patients that it is best to take thyroid drugs once daily in the morning (e.g., 60 minutes before breakfast for optimum absorption) if possible, to decrease the likelihood of insomnia, which may result from evening dosing and the subsequent increase in energy level. Patients must also avoid interchanging brands because of problems with the bioequivalence of drugs from different manufacturers. If needed, patients may crush tablets. If a patient is scheduled to undergo radioactive isotope studies, thyroid medication is usually discontinued about 4 weeks before the test, but only as prescribed. Older adult patients may require alteration of the dosage amount, with a decrease of up to 25% for patients 60 years of age and older. Dosage is individualized and there is considerable variability in response, although improvement in symptoms is usually seen in 2 weeks, with good results seen within 4 to 8 weeks.

Educate patients taking the antithyroid drug propylthiouracil about taking the medication with meals to help decrease GI upset. Any fever, sore throat, mouth ulcers or sores, skin eruptions, or any unusual bleeding or bruising needs to be reported to the health care provider immediately. These symptoms may indicate liver and bone marrow toxicity and possible leukopenia. Further educate patients to avoid consuming iodized salt or shellfish because of their potential for altering the drug's effectiveness. Advise patients

to be aware of the signs and symptoms of hypothyroidism, including unexplained weight gain, loss of mental and physical stamina, hair loss, edema (particularly around the face), and yellow dullness of the skin (indicative of myxedema or a decrease in metabolic rate). If these symptoms occur, patients must report them immediately to the health care provider. Frequently monitor complete blood counts to watch for potential problems with leukopenia. It is also important to monitor the results of liver function studies during follow-up visits with the health care provider.

EVALUATION

A therapeutic response to thyroid drugs is manifested by the disappearance of symptoms of hypothyroidism; patients should demonstrate improved energy levels as well as improved mental and physical stamina. Monitor for the adverse effect of cardiac dysrhythmia (see Table 32.2). If a patient is receiving inadequate doses of the thyroid medication, a return of the symptoms of hypothyroidism may occur (see previous discussion).

Adverse effects include the possibility of leukopenia, which may be manifested by fever, sore throat, lesions, or other signs of infection. Symptoms indicating that a patient is not receiving adequate doses include tachycardia, insomnia, irritability, fever, and diarrhea, as well as continued signs and symptoms of hyperthyroidism (see previous discussion).

PATIENT TEACHING TIPS

- Patients should be aware that oral thyroid replacement drugs are best taken 1 hour before breakfast on an empty stomach to enhance their absorption, maintain constant hormone levels, and help prevent insomnia.
- Thyroid replacement medications are not to be abruptly discontinued; patients should know that lifelong therapy is usually the norm.
- Emphasize to patients the importance of keeping follow-up visits so that the health care provider can monitor thyroid hormone levels, complete blood counts, and results of liver function studies.
- Brands of thyroid replacement drugs cannot be interchanged. Advise patients to always check that the pharmacy has provided the correct brand of thyroid replacement drug.

- Signs and symptoms associated with hypothyroidism include myxedema with decreased metabolic rate, loss of mental and physical stamina, weight gain, hair loss, firm edema, and yellow dullness of the skin. Share this information with patients.
- Instruct patients taking thyroid replacement drugs to immediately report any of the following to the health care provider: chest pain, weight loss, palpitations, tremors, sweating, nervousness, shortness of breath, or insomnia, as these may indicate toxicity.
- Encourage patients to keep a daily journal with notations about how they are feeling, their energy levels and appetite, and any adverse effects.
- Advise patients that it may take up to 3 to 4 weeks to see the full therapeutic effects of thyroid drugs.
- Inform patients that all thyroid tablets must be protected from light.
- Signs and symptoms of hyperthyroidism include increased metabolic rate, diarrhea, flushing, increased appetite, muscle weakness, fatigue, palpitations, irritability, nervousness, sleep disorders, heat intolerance, and altered menstrual flow. Patients with this disorder and those on drug therapy need to be aware of these signs and symptoms.
- Antithyroid medications are better tolerated when taken with meals or a snack. These drugs must also be given at the same time every day to maintain consistent blood levels of the drug. They must never be withdrawn abruptly. Instruct patient to avoid taking thyroid medications together with vitamins/minerals (iron, magnesium, calcium, aluminum) or other binders (sevelamer, cholestyramine) as they reduce absorption of thyroid medication. Space by at least 4 hours.
- Instruct patients taking thyroid or antithyroid drugs to read all drug labels thoroughly and not to take any OTC medications without first consulting their health care provider or pharmacist.
- Patients taking antithyroid medications must avoid eating foods high in iodine, such as tofu and other soy products, turnips, seafood, iodized salt, and some breads. These foods may interfere with the effectiveness of the antithyroid drug.
- There are numerous drugs that interact with thyroid medications (e.g., antacids, digoxin, antidiabetic drugs [see Table 32.3]). Provide a list of all medications to patients before and during therapy with thyroid medications.
- Provide patients with information on the Thyroid Foundation of Canada (<http://www.thyroid.ca/>).

KEY POINTS

- T_4 and T_3 are the two hormones produced by the thyroid gland; thyroid hormones are made by iodination and coupling with the amino acid tyrosine.
- Thyroid hormone replacement is generally carried out carefully by the health care provider, with frequent monitoring of serum levels until stabilization appears to have occurred. It is important to monitor and review laboratory values to be sure that serum levels are within normal limits to avoid possible toxicity.
- Hyperthyroidism is caused by excessive secretion of thyroid hormone by the thyroid gland and may be caused by different diseases (Graves' disease, Plummer's disease, multinodular disease) or drugs. Always assess and document important information about the patient's medical history appropriately.
- Patients receiving levothyroxine need to report the occurrence of excitability, irritability, or palpitations to the health care provider because these symptoms may indicate toxicity.
- Adverse effects associated with thyroid drugs include tachycardia, palpitations, angina, dysrhythmias, hypertension, insomnia, tremors, headache, anxiety, nausea, diarrhea, cramps, menstrual irregularities, weight loss, sweating, fever, and heat intolerance.
- Adverse effects associated with antithyroid drugs include drowsiness, headache, vertigo, nausea, vomiting, diarrhea, loss of taste, bleeding, leukopenia, rash, myalgia, and arthralgia.

EXAMINATION REVIEW QUESTIONS

1. The nurse is reviewing the laboratory values of a patient who is taking antithyroid drugs. Which of the following values should the nurse monitor?
 - a. Increased platelet counts
 - b. Decreased white blood cell counts
 - c. Decreased blood urea nitrogen level
 - d. Increased blood glucose levels
2. The pharmacist notifies a patient that the current prescribed brand of thyroid medication is on back order. The patient contacts the clinic and asks for guidance moving forward. Which of the following would be the most appropriate response by the nurse?
 - a. "Go ahead and take the other brand that the pharmacy has available for now."
 - b. "You can stop the medication until your current brand is available."
 - c. "You can split the thyroid pills that you have left so that they will last longer."
 - d. "You may require additional testing of thyroid hormone levels with a change in drug."
3. The nurse is assessing an older adult patient for nonspecific symptoms of hypothyroidism. Which of the following would make the nurse follow up with the health care provider?
 - a. Leukopenia, anemia
 - b. Loss of appetite, polyuria
 - c. Weight loss, dry cough
 - d. Cold intolerance, depression
4. The nurse is providing teaching to a patient complaining of insomnia associated with thyroid hormone replacement therapy. Which of the following statements should the nurse include?

- a. Take half the dose at lunchtime and the other half 2 hours later.
 - b. Use a sedative to assist with falling asleep.
 - c. Take the dose upon awakening in the morning.
 - d. Reduce the dosage as needed if sleep is impaired.
5. The nurse is teaching a patient who has a new prescription for the antithyroid drug propylthiouracil. Which of the following statements by the nurse would be most appropriate?
- a. "There are no food restrictions while on this drug."
 - b. "You need to avoid foods high in iodine, such as iodized salt, seafood, and soy products."
 - c. "This drug is given to raise the thyroid hormone levels in your blood."
 - d. "Take this drug in the morning on an empty stomach."
6. The nurse is teaching a patient who has a new prescription for thyroid hormone. Which of the following adverse effects does the nurse need to instruct the patient to notify the health care provider of if they occur? (Select all that apply.)
- a. Palpitations
 - b. Weight gain
 - c. Angina
 - d. Fatigue
 - e. Cold intolerance
7. The nurse is giving an intravenous dose of levothyroxine (Synthroid). The order reads: "Give 0.1 mg IV push now." What is the ordered dose in micrograms?
8. Which laboratory tests does the nurse need to know that are used to monitor thyroid hormone replacement therapy? (Select all that apply.)
- a. Serum TSH
 - b. Blood urea nitrogen (BUN)
 - c. Complete blood count (CBC)
 - d. Free thyroid hormone levels
 - e. Serum iodine levels

CRITICAL THINKING ACTIVITIES

1. A patient has been taking thyroid drugs for about 16 months and has recently noted palpitations and some heat intolerance. What are the nurse's priority actions at this time?
2. A patient with a history of hypothyroidism is in her first trimester of pregnancy. She asks the nurse, "How often will they check my thyroid hormone levels? I'm very worried about how this medication will affect my baby." What is the nurse's best response?
3. A 33-year-old man, newly admitted to the medical-surgical unit from the step-down Critical Care Unit, underwent

a thyroidectomy 2 days earlier. While reviewing the orders, the nurse notices that the patient is to start receiving his thyroid medication upon transfer to the medical-surgical unit. The written orders specify that 25 mcg of levothyroxine is available in stock. However, the pharmacy has only 25 mcg of liothyronine in stock. What is the nurse's priority action at this time?

Antidiabetic Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Discuss the normal actions and functions of the pancreas.
2. Contrast age of onset, signs and symptoms, pharmacological and nonpharmacological treatment, incidence, and etiology of type 1 and type 2 diabetes.
3. Differentiate gestational diabetes from type 1 and type 2 diabetes.
4. Discuss the various factors influencing plasma glucose levels in individuals without diabetes and in patients with diabetes.
5. Identify the drugs used to manage type 1 and type 2 diabetes.
6. Discuss the mechanisms of action, indications, contraindications, cautions, drug interactions, and adverse effects of insulin, oral antihyperglycemic drugs, and injectable antidiabetic drugs.
7. Compare rapid-, short-, intermediate-, and long-acting insulins in regard to their onset of action, peak effects, and duration of action.
8. Compare the signs and symptoms of hypoglycemia and hyperglycemia and their related treatments.
9. Develop collaborative plans of care that include all phases of the nursing process for patients with type 1 or type 2 diabetes, with a focus on drug therapies.

KEY TERMS

Diabetes A complex disorder of carbohydrate, fat, and protein metabolism resulting from the lack of insulin secretion by the β -cells of the pancreas or from defects of the insulin receptors; sometimes referred to as *diabetes mellitus*. There are two major types of diabetes: type 1 and type 2. (p. 539)

Diabetic ketoacidosis (DKA) A severe metabolic complication of uncontrolled diabetes that, if untreated, may lead to serious hyperglycemic emergencies. (p. 541)

Gestational diabetes Diabetes that develops during pregnancy; it may resolve after pregnancy but may also be a precursor of type 2 diabetes in later life. (p. 542)

Glucagon A hormone produced by the α -cells in the islets of Langerhans; glucagon stimulates the conversion of glycogen to glucose in the liver. (p. 538)

Glucose One of the simple sugars that serves as a major source of energy. It is found in foods (e.g., fruits, refined sweets) and also is the final breakdown product of complex carbohydrate metabolism in the body; it is commonly referred to as *dextrose*. (p. 538)

Glycogen A polysaccharide that is the major carbohydrate stored in animal cells. (p. 538)

Glycogenolysis The breakdown of glycogen into glucose. (p. 538)

Hemoglobin A_{1C} (HbA_{1C}) Hemoglobin molecules to which glucose molecules are bound; also referred to as *glycosylated hemoglobin* and is most commonly referred to as *A_{1C}*. Blood levels of HbA_{1C} are used to monitor and diagnose diabetes. (p. 543)

Hyperglycemia A fasting plasma glucose level of 7 mmol/L or higher or a nonfasting plasma glucose level of 11.1 mmol/L or higher. (p. 539)

Hyperosmolar hyperglycemic state (HHS) A metabolic complication that occurs in patients with type 2 diabetes, characterized by hyperglycemia, hyperosmolarity, and dehydration without significant ketoacidosis. (p. 541)

Hypoglycemia A plasma glucose level of less than 4 mmol/L with autonomic or neuroglycopenic symptoms that respond to administration of a carbohydrate or the use of glucagon. (p. 553)

Impaired fasting glucose level A fasting glucose level of at least 6.1 mmol/L but lower than 6.9 mmol/L; it defines a prediabetic state often referred to as *prediabetes*. (p. 542)

Insulin A naturally occurring hormone secreted by the β -cells in the islets of Langerhans in the pancreas in response to increased levels of glucose in the blood. (p. 538)

Ketones Organic chemical compounds produced through the oxidation of secondary alcohols (e.g., fat molecules), including dietary carbohydrates. (p. 538)

Metabolic syndrome A cluster of risk factors including abdominal obesity, hypertension, dyslipidemia, and elevated plasma glucose that places individuals at significant risk of developing type 2 diabetes and cardiovascular disease. (p. 541)

Polydipsia Excessive intake of water; one of the common symptoms of uncontrolled diabetes. (p. 538)

Polyphagia Excessive hunger; one of the common symptoms of uncontrolled diabetes. (p. 538)

Polyuria Increased frequency or volume of urinary output; one of the common symptoms of uncontrolled diabetes. (p. 538)

Prediabetes A state in which one or more of the fasting glucose, glucose tolerance, or A_{1C} levels are higher than normal but

not diagnostic; individuals with prediabetes are at high risk of developing diabetes and the resulting complications. (p. 542)

Type 1 diabetes caused by an autoimmune disease resulting in β -cell destruction and that makes the individual prone to hyperglycemia and ketoacidosis; most commonly develops in children and adolescents. (p. 540)

Type 2 diabetes A type of diabetes that is most common in adults and is becoming increasingly common in children and adolescents; characterized by hyperglycemia that occurs as a result of predominant insulin resistance with relative insulin deficiency to a predominant secretory defect with insulin resistance. (p. 541)

PANCREAS

The pancreas is a large, elongated organ located behind the stomach. It functions as an exocrine gland (secreting digestive enzymes through the pancreatic duct) and a ductless endocrine gland (secreting hormones directly into the bloodstream). The endocrine functions of the pancreas are the focus of this chapter. **Insulin** and **glucagon** are the two main hormones produced by the pancreas. Both hormones play an important role in the regulation of glucose homeostasis, specifically the mobilization, use, and storage of glucose by the body. **Glucose** is one of the primary sources of energy for the cells of the body. It is also the simplest form of carbohydrate found in the body, and is often referred to as *dextrose*. There is a normal amount of glucose that circulates in the blood to meet body requirements for quick energy. Excess glucose is stored as **glycogen** in the liver and, to a lesser extent, in skeletal muscle tissue, where it remains until the body needs it. Glucose is also stored in adipose tissue as triglyceride body fat. When more circulating glucose is needed, glycogen—primarily that stored in the liver—is converted back to glucose through a process called **glycogenolysis**. The hormone responsible for initiating this process is glucagon. Glucagon has only minimal effects on muscle glycogen and adipose tissue triglyceride stores.

Glucagon is released from the α -cells of the islets of Langerhans in the pancreas. Glucagon is a protein hormone consisting of

a single chain of amino acids (polypeptide chain). Its molecules are about half the size of those of insulin. Insulin is secreted from the β -cells of the islets. Insulin is a protein hormone composed of two amino acid chains (acidic A chain and basic B chain) joined by a disulfide linkage. There is a continuous homeostatic balance in the body between the actions of insulin and those of glucagon. This natural balance serves to maintain optimal plasma glucose levels, which normally range between 4 and 6 mmol/L. Because of the crucial role of the pancreas in producing and maintaining these two hormones, pancreatic or islet cell transplants are sometimes undertaken to treat type 1 diabetes that has not been successfully controlled by other means. Another common treatment is continuous insulin administration via a computerized insulin pump, which may be used to treat type 1 or type 2 diabetes. One of the newest advances in insulin delivery systems is the OmniPod Insulin Management System (**Figure 33.1**), which consists of just two parts. The Pod is a tubeless, small, lightweight*, waterproof** self-adhesive device that continuously delivers insulin (for up to 72 hours) worn directly on the body. The Pod delivers precise, personalized doses of U-100 rapid-acting insulin through a small cannula with automated insertion system. The Personal Diabetes Manager (PDM) is a wireless, handheld device that programs the Pod with patient personalized insulin-delivery instructions, wirelessly monitors the Pod's operation. The blood glucose meter is integrated into the PDM for convenient self-monitoring of plasma glucose. More information is available at <http://www.omnipod.ca/>.

Insulin has several important metabolic functions in the body. It stimulates carbohydrate metabolism in skeletal and cardiac muscle and in adipose tissue by facilitating the transport of glucose into these cells. In the liver, insulin facilitates the phosphorylation of glucose to glucose-6-phosphate, which is then converted to glycogen for storage. By causing glucose to be stored in the liver as glycogen, insulin keeps the kidneys free of glucose. Without insulin, blood glucose levels rise; when the kidneys are unable to reabsorb this excess glucose, they excrete large amounts of glucose (a critical body nutrient and energy source), **ketones**, and other solutes into the urine. This loss of nutrient energy sources eventually leads to **polyphagia**, weight loss, and malnutrition. The presence of these solutes in the distal kidney tubules and collecting ducts also draws large volumes of water into the urine through osmotic diuresis, which leads to **polyuria**, **polydipsia**, and dehydration. These are all classic manifestations of type 1 diabetes.

Insulin also has a direct effect on fat metabolism. It stimulates lipogenesis and inhibits lipolysis and the release of fatty acids from adipose cells. In addition, insulin stimulates protein

*Weight without insulin is 25 grams Pod: 3.9 cm wide $\times$ 5.2 cm long $\times$ 1.45 cm high

**The Pod has an IP28 rating for up to 7.6 meters for 60 minutes. The PDM is not waterproof.

synthesis and promotes the intracellular shift of potassium and magnesium into the cells, thereby temporarily decreasing elevated blood concentrations of these electrolytes. Other substances such as cortisol, epinephrine, and growth hormone work synergistically with glucagon to counter the effects of insulin and cause increases in plasma glucose levels.

DIABETES

Hyperglycemia is a state involving excessive concentrations of glucose in the blood and results when the normal counterbalancing actions of glucagon and insulin fail to maintain normal glucose homeostasis (i.e., serum levels of 4 to 6 mmol/L). Complications in protein and fat metabolism (dyslipidemia; see [Chapter 28](#)) are also involved. The current key diagnostic criterion for diabetes is hyperglycemia with a fasting plasma glucose of higher than 7 mmol/L or a hemoglobin A_{1C} level greater than or equal to 6.5%. An A_{1C} level of 6.5% is the threshold for the development of microvascular disease and a predictor for the development of macrovascular disease. Diagnostic indicators are described in more detail in [Box 33.1](#). Although there may be some variability in the diagnostic criteria for diabetes, this text uses the [Diabetes Canada 2018 Clinical Practice Guidelines](#) as a reference.

Diabetes is primarily a disorder of carbohydrate metabolism that involves either a deficiency of insulin, a resistance of tissue (e.g., muscle, liver) to insulin, or both. Whatever the cause of the diabetes, the result is hyperglycemia. Uncontrolled hyperglycemia correlates strongly with serious long-term macrovascular and microvascular complications. Macrovascular complications are usually secondary to large vessel damage caused by the deposition of atherosclerotic plaque. This damage compromises both central and peripheral circulation. In contrast, microvascular complications are secondary to damage to capillary vessels, which impairs peripheral circulation and damages eyes and kidneys. In addition, both autonomic and somatic nerve damage occur, caused primarily by metabolic changes and, to a lesser degree, by compromised circulation. [Table 33.1](#) lists the common long-term complications of diabetes.

BOX 33.1 Criteria for Diagnosis of Diabetes

Fasting plasma glucose level equal to or higher than 7 mmol/L ("Fasting" is defined as no caloric intake for at least 8 hours.)
OR
A_{1C} greater than 6.5% (in adults)
OR
Two-hour plasma glucose level of 11.1 mmol/L or higher during a 75-g oral glucose tolerance test (OGTT; note that OGTT is not recommended for routine clinical use) screened at 24–28 weeks during investigation of gestational diabetes
OR
Random plasma glucose level of 11.1 mmol/L or higher, measured at any time of day without regard to time since last meal

Diabetes has been recognized since 1550 BCE, when Egyptians wrote of a malady they called *honeyed urine*. Not until the early 1920s was insulin finally isolated in Toronto, Ontario, by Nobel Prize-winners Frederick Banting and Charles Best. Its discovery is now considered one of the greatest triumphs of 20th-century medicine, and its use in the treatment of diabetes has proved to be life-saving for millions of people affected by the disease.

Diabetes is not a single disease but a group of progressive diseases. For this reason, it is often regarded as a syndrome rather than a disease. In some cases, diabetes is caused by a relative or absolute lack of insulin that is believed to result from the destruction of β -cells in the pancreas, which leads to the inability to produce insulin. Hyperglycemia can also be caused by defects in insulin receptors that result in insulin resistance. The glycoproteins that serve as insulin receptors are attached to the surface of cells in the liver, muscle, and adipose tissue. These receptor proteins are stimulated by insulin molecules to move glucose from blood to cells. When insulin receptors become defective, they no longer respond normally to insulin molecules. Although serum insulin and glucose levels are both elevated in this situation, they do not respond, and transport glucose into the cell where it is needed. The result is that glucose molecules remain in the blood, rather than being stored in the cells or tissues.

Two major types of diabetes are currently recognized and designated by Diabetes Canada: type 1 and type 2. As of 2019, there are

TABLE 33.1 Major Long-Term Consequences of Diabetes (Type 1 and Type 2)

Pathology	Potential Consequences
Macrovascular (Atherosclerotic Plaque)	
Coronary arteries	Myocardial infarction
Cerebral arteries	Stroke
Peripheral vessels	Peripheral vascular disease (e.g., neuropathies [see below], foot ulcers, possible amputations)
Microvascular (Capillary Damage)	
Retinopathy (retinal damage)	Partial or complete blindness
Neuropathy (autonomic and somatic nerve damage, due to both metabolic alterations and compromised circulation)	Autonomic nerve damage: Examples include diabetic gastroparesis, bladder dysfunction, unawareness of hypoglycemia, sexual dysfunction Somatic nerve damage: Examples include diabetic foot ulcer or leg or foot amputation (resulting from undetected injuries due to loss of sensation and from compromised circulation)
Nephropathy (kidney damage)	Proteinuria (microalbuminuria), chronic kidney failure (may require dialysis or kidney transplantation)

TABLE 33.2 Characteristics of Type 1 and Type 2 Diabetes

Characteristic	Type 1	Type 2
Etiology	Autoimmune destruction of β -cells in the pancreas	Multifactorial genetic defects; strong association with obesity and insulin resistance resulting from a reduction in the number or activity of insulin receptors
Incidence	10% of cases	90% of cases
Onset	Usually younger than 20 yr	Age older than 40 yr; now increasingly seen in younger adults, adolescents, and children; attributed to rising prevalence of obesity
Endogenous insulin	Little or none	Normal levels in early disease; reduced later in disease
Insulin receptors	Normal	Decreased or defective
Body weight	Usually nonobese	Obese (80% of cases)
Treatment	Insulin	Weight loss, diet and exercise, and oral antihyperglycemics; earlier use of insulin is associated with improved outcomes

eleven million Canadians living with diabetes or prediabetes (Calder, 2019). Diabetes Canada has reviewed and suggested 2018 Clinical Practice Guidelines (Houlden, 2018). The numerical designations for both conditions were adopted by Diabetes Canada as the preferred terms in 1995. Previous designations (e.g., insulin-dependent diabetes and noninsulin-dependent diabetes) were abandoned for several reasons: (1) Many patients with type 2 diabetes do eventually become dependent on insulin therapy for control of their illness, and (2) The current epidemic of child and adult obesity in Canada is resulting in an increasing incidence of type 2 diabetes in children, adolescents, and young adults. Obesity is one of the major risk factors for the development of type 2 diabetes. Members of certain ethnic groups, including South Asian, Hispanic, and Indigenous, are at higher risk of developing type 2 diabetes than are White people. The usual differences between type 1 and type 2 diabetes are listed in Table 33.2.

Approximately 10% of people with type 2 diabetes have circulating antibodies that suggest an autoimmune origin for the disease. This condition is known as *latent autoimmune diabetes in adults* (LADA) and is essentially a more slowly progressing form of type 1 diabetes.

The most common signs and symptoms of type 1 diabetes are elevated plasma glucose levels (fasting glucose level higher than 7 mmol/L), polyuria, polydipsia, polyphagia, glucosuria, weight loss, blurred vision, and fatigue. These symptoms may also be observed in patients with type 2 diabetes, especially blurred vision and fatigue; however, other acute signs and symptoms may also occur (see Type 2 Diabetes, below).

Type 1 Diabetes

Type 1 diabetes is characterized by a lack of insulin production or by the production of defective insulin, which results in acute hyperglycemia. Affected patients require exogenous insulin to lower their plasma glucose level and prevent diabetic complications. It is believed that a genetically determined autoimmune reaction gradually destroys the insulin-producing β -cells of the pancreatic islets of Langerhans (Figure 33.2). The preclinical phase of β -cell destruction may be prolonged and can last up to several years. At some critical point, a rapid transition from preclinical to clinical type 1 diabetes occurs. This transition may be triggered by a specific event, such as an acute illness or major emotional stress. An unidentified viral infection is also strongly suspected to be an environmental trigger. Such stressors trigger the release of the counter-regulatory hormones cortisol and epinephrine. These hormones then mobilize glucagon to release glucose from the storage sites in the liver. This action further increases the already rising levels of glucose in the blood secondary to islet cell damage. At some point during this cascade of events, an autoimmune reaction may be initiated, destroying the insulin-producing β -cells of the pancreatic islets of Langerhans. The result is essentially a complete lack of endogenous insulin production by the pancreas, which necessitates long-term insulin replacement therapy. Fortunately, type 1 diabetes accounts for fewer than 10% of all diabetes cases. Patients with glucose variability have large fluctuations in their plasma glucose levels.

Fig. 33.2 The pancreas. A) Pancreas dissected to show main and accessory ducts. B) Exocrine glandular cells (around small pancreatic ducts) and endocrine glandular cells of the pancreatic islets (adjacent to blood capillaries). Exocrine pancreatic cells secrete pancreatic enzymes, α -endocrine cells secrete glucagon, and β -endocrine cells secrete insulin. (Source: Patton, K. T., & Thibodeau, G. A. (2010). *Anatomy and physiology* (7th ed.). St. Louis, MO: Mosby.)

Type 2 Diabetes

Type 2 diabetes is by far the most common form of diabetes, accounting for 90% to 95% of all cases of diabetes; (Powderley, 2019). Because this form of diabetes does not always require insulin therapy, there are many common and dangerous misconceptions about type 2 diabetes: that it is a mild diabetes; that it is easy to treat; and that tight metabolic control is unnecessary because patients with this condition, who are mostly older adults, will die before diabetic complications develop. The clinical realities of this disease demonstrate otherwise.

Type 2 diabetes is caused by genetic and environmental factors that result in both insulin resistance and insulin deficiency; there is no absolute lack of insulin as in type 1 diabetes. One of the normal roles of insulin is to facilitate the uptake of circulating glucose molecules and movement into tissues to be used as energy. In type 2 diabetes, all of the main target tissues of insulin (muscle, liver, and adipose tissue) are resistant to the effects of the hormone. Not only is the absolute number of insulin receptors in these tissues reduced, but their individual sensitivity and responsiveness to insulin are decreased as well. Therefore, it is possible

for a patient with type 2 diabetes to have normal or elevated levels of insulin yet still have high plasma glucose levels. These processes also result in impaired postprandial (after a meal) glucose metabolism, which is another problematic feature of type 2 diabetes that contributes to hazardous hyperglycemic states.

In addition to the reduction in the number and sensitivity of insulin receptors in type 2 diabetes, there is often reduced insulin secretion by the pancreas. This insulin deficiency results from a loss of the normal responsiveness of the β -cells in the pancreas to elevated plasma glucose levels. When the β -cells do not recognize glucose, they do not secrete insulin, and the normal insulin-facilitated transport of glucose into cells of muscle, liver, and adipose tissue does not occur. This situation is analogous to the loss of responsiveness of insulin receptors to insulin described earlier.

Type 2 diabetes is a multifaceted disorder. Although loss of plasma glucose control is its primary hallmark, several other significant conditions are strongly associated with the disease. These include obesity, coronary artery disease, dyslipidemia, hypertension, microalbuminuria (proteinuria), and an increased risk for thrombotic events. For patients with type 2 diabetes, Diabetes Canada recommends the regular use of aspirin (for secondary prevention of coronary artery disease), an angiotensin-converting enzyme inhibitor or an angiotensin receptor blocker, and antihyperlipidemic drug therapy (see Chapter 28), when indicated, in addition to any necessary antidiabetic drug therapy. **Metabolic syndrome** (or cardiometabolic syndrome) refers to a cluster of risk factors, including abdominal obesity, hypertension, dyslipidemia, and elevated plasma glucose; it places individuals at significant risk of developing type 2 diabetes and cardiovascular disease. Approximately 80% of patients with diabetes are obese at the time of initial diagnosis. Obesity serves only to worsen insulin resistance because adipose tissue is often the site of a large proportion of the body's defective insulin receptors. According to most recent Diabetes Canada Guidelines (2018), the goal for patients living with diabetes is a blood pressure less than 130/80 mm Hg and a low density lipid (LDL) less than 2.0 mmol/L or greater than 50% reduction from baseline.

Acute Diabetic Complications: Diabetic Ketoacidosis and Hyperosmolar Hyperglycemic State

When plasma glucose levels are high but no insulin is present to allow glucose to be used for energy production, the body may break down fatty acids for fuel, producing ketones as a metabolic by-product. If this occurs to a sufficient degree, **diabetic ketoacidosis (DKA)** may result. DKA is a complex, multisystem complication of uncontrolled diabetes. It occurs in 4.6 to 8 of 1 000 patients with diabetes. Without treatment, DKA will lead to unconsciousness and death. DKA is characterized by extreme hyperglycemia, the presence of ketones in the serum and urine, acidosis, dehydration, and electrolyte imbalances. Approximately 25 to 30% of patients with newly diagnosed type 1 diabetes present with DKA. Another complication of comparable severity that is triggered by extreme hyperglycemia is a **hyperosmolar hyperglycemic state (HHS)**. The most common precipitator of DKA and HHS is often emotional or physical (e.g., infection) stress. It was formerly believed that DKA occurred only in type 1 diabetes and HHS occurred only in type 2 diabetes. However, it is now recognized that both disorders can occur with diabetes of

TABLE 33.3 Comparison of Features of Ketoacidosis and Hyperosmolar Hyperglycemic State Associated with Diabetes

Feature	CONDITION	
	Ketoacidosis	Hyperosmolar Hyperglycemic State
Age of patient	Younger than 65 yr	Older than 65 yr
Duration of symptoms	Less than 2 days	More than 5 days
Plasma glucose level	Equal to or greater than 14 mmol/L	Equal to or higher than 34 mmol/L
Plasma Na level	Within normal range (135–145 mmol/L) or less than 135 mmol/L	Within normal range (135–145 mmol/L) or greater than 145 mmol/L
Plasma K level	Less than 3.5 mmol/L (normal range 3.5–5 mmol/L)	Less than 3.5 mmol/L (normal range 3.5–5 mmol/L)
Plasma HCO ₃ level	Low (equal to or less than 15 mmol/L [normal 21–28 mmol/L])	Normal
Ketone bodies in urine and plasma	Positive	
pH	Low (equal to or less than 7.3)	Normal
Serum osmolality	Less than 320 mOsm/kg	More than 320 mOsm/kg
Prognosis	3 to 10% mortality	10 to 20% mortality
Subsequent course	Insulin therapy required in all cases	Insulin therapy not required in many cases after initial treatment

Adapted from Goguen, J., & Gilbert, J. (2013). Hyperglycemic emergencies in adults. *Canadian Journal of Diabetes*, 37(Suppl. 1), S72–S76; Lenahan, C. M., & Holloway, B. (2015). Differentiating between DKA and HHS. *Journal of Emergency Nursing*, 41(3), 201–207. <https://doi.org/10.1016/j.jen.2014.08.015>

either type. This overlap is increasingly common, with the rapidly decreasing age of people with type 2 diabetes.

Table 33.3 describes the subtle differences between DKA and HHS. Treatment for either complication involves fluid and electrolyte replacement as well as intravenous (IV) insulin therapy (more common for DKA).

Gestational Diabetes

Gestational diabetes is a type of hyperglycemia that develops during pregnancy. It occurs in approximately 3.7 to 20% of Canadian pregnancies. Many patients control it well with diet, but the use of insulin may be necessary to decrease the risk of birth defects, hypoglycemia in the newborn, and high birth weight. In most cases, gestational diabetes subsides after delivery. However, an estimated 30% of patients who develop gestational diabetes develop type 2 diabetes within 5 to 15 years. This percentage is higher among women of Indigenous descent.

All pregnant women need to have plasma glucose screenings at regular prenatal visits. Women who develop gestational diabetes should be screened for lingering diabetes 6 to 8 weeks postpartum and be advised of their increased risk for recurrent diabetes and of the importance of regular medical checkups and weight control. Women who are known to have diabetes before pregnancy should have detailed prepregnancy counselling and prenatal care from a specialist experienced in managing pregnancies in women with diabetes. Specific issues pertaining to drug therapy for gestational diabetes are discussed further in the section on insulins.

Prevention and Screening

Both macrovascular and microvascular problems are now recognized at fasting plasma glucose levels as low as 7 mmol/L. **Fasting** is defined as an 8-hour or overnight fast (no food from midnight until after the plasma sample is taken in the morning). Diabetes Canada guidelines identify **prediabetes** as impaired fasting glucose, impaired glucose tolerance, or an A_{1C} of 6 to 6.4%, each of which places individuals at high risk of developing diabetes and its complications. **Impaired fasting glucose** is defined as a

fasting plasma glucose level higher than or equal to 6.1 mmol/L but less than 6.9 mmol/L. **Impaired glucose tolerance** is identified using an oral glucose challenge test (see Box 33.1). Diabetes Canada recommends that all adults 40 years of age and older be screened for elevated fasting plasma glucose or A_{1C} levels every 3 years. Several preventive measures are also recommended. Reducing alcohol consumption is helpful because alcohol is broken down in the body to simple carbohydrates, which leads to increases in plasma glucose levels. Regular exercise also lowers plasma glucose levels by increasing insulin receptor sensitivity.

Indigenous people in Canada have a high risk for the development of diabetes and its associated complications. Screening for risk factors should be initiated in early childhood, with prevention being a priority. Screening should be undertaken every 1 to 2 years for adults who have one or more risk factors and every 2 years for children over 10 years of age or with established puberty who have one or more risk factors, including being exposed to diabetes in utero. A culturally appropriate comprehensive program of care, following the national guidelines, needs to be implemented. An available resource is the National Aboriginal Diabetes Association (<http://www.nada.ca>).

Nonpharmacological Interventions

For patients with new-onset type 2 diabetes, nonpharmacological lifestyle interventions are usually initiated as a first step in treatment. Weight loss not only lowers the plasma glucose and lipid levels of these patients, but it also reduces another common comorbidity, hypertension. Even a modest weight loss of 5% of initial body weight can reduce the risk of disease progression (from impaired glucose tolerance to type 2 diabetes) by 60%. Other recommended lifestyle changes include improvement of dietary habits (e.g., consumption of a diet higher in protein and lower in fat and carbohydrates), smoking cessation, reduced alcohol consumption, and regular physical exercise. Cigarette smoking doubles the risk of cardiovascular disease in patients with diabetes, largely because of its effects on peripheral vascular circulation and respiratory function.

Glycemic Goal of Treatment

The glycemic goal recommended by Diabetes Canada for patients with diabetes is a **hemoglobin A_{1C} (HbA_{1C})** level of less than 7%. The A_{1C} test measures the percentage of hemoglobin A that is irreversibly glycosylated. A_{1C} is an indicator of glycemic control in a patient over the preceding 2 to 3 months (the average lifespan of a red blood cell) and is not affected by recent fluctuations in plasma glucose levels. The mean level of plasma glucose in the 30 days immediately before the blood sampling contributes 50% of the A_{1C} level result, the period from 30 to 90 days prior contributes 40%, and the period from 90 to 120 days prior contributes 10%. Diabetes Canada recommends a fasting plasma glucose goal for patients with diabetes of 4 to 7 mmol/L and a 2-hour postprandial target of 5 to 10 mmol/L. Diabetes Canada suggests a more lenient A_{1C} target (7 to 8.5%) for patients that are: functionally dependent, with recurrent hypoglycemia/unawareness, limited life expectancy, frail older adults, and patients living with dementia.

ANTIDIABETIC DRUGS

The two major classes of drugs used to treat diabetes are the insulins and oral antihyperglycemic drugs. Several new classes of injectable drugs with unique mechanisms of action have been developed that may be used in addition to insulins or oral antihyperglycemic drugs to treat resistant diabetes. All of these drugs are referred to as *antidiabetic drugs*, and they are aimed at producing what is known as a *normoglycemic* or *euglycemic* (normal plasma sugar) state.

Insulins

Insulin is required in patients with type 1 diabetes. Patients with type 2 diabetes are not generally prescribed insulin until other measures (e.g., lifestyle changes and oral drug therapy) no longer provide adequate glycemic control. Currently, insulin is synthesized in laboratories with recombinant deoxyribonucleic acid (rDNA) technology and is referred to as *human insulin*. Insulin was originally isolated from cattle or pigs, but bovine (cow) and porcine (pig) insulins are associated with a higher incidence of allergic reactions and insulin resistance than is human insulin. Beef-derived insulin is no longer available on the Canadian market. To accommodate patients who still depend on animal-derived insulin, porcine insulins under the brand names of Hypurin Regular® and Hypurin NPH® continue to be available for purchase at Canadian pharmacies. Recombinant insulin is produced by bacteria or yeasts that have been altered to contain the genetic information necessary to reproduce an insulin that is like human insulin. The pharmacokinetic properties of insulin (onset of action, peak effect, and duration of action) can be altered by making various minor modifications to either the insulin molecule or the drug formulation (final product). This practice has led to the development of several different insulin preparations, including many combination insulin products that contain more than one type of insulin in the same solution. Such chemical manipulation of insulin activity helps to meet the individualized meal-oriented metabolic demands for insulin of patients with diabetes. Further modifications can be accomplished by mixing compatible insulin preparations in a syringe before administration. The latest syringe compatibility data for currently available insulin products are given in Table 33.4. It

TABLE 33.4 Insulin Mixing Compatibilities

Type of Insulin	Compatible With
Regular insulin (Humulin R®, Novolin ge Toronto®)	All insulins except glargine and glulisine
Insulin glulisine (Apidra®)	NPH only
Insulin lispro (Humalog®), insulin aspart (NovoRapid®)	Regular, NPH insulins
Insulin detemir (Levemir®)	Must be given alone
Insulin glargine (Lantus®, Basaglar®)	Must be given alone due to low pH of diluent
Regular insulin 30% and NPH 70% and (Humulin 30/70®, Novolin ge 30/70®); others	Premixed; do not mix with other insulins (e.g., regular, glulisine, lispro, aspart, detemir, glargine)

is important to thoroughly educate patients regarding how, when, and whether they can (or cannot) mix different types of insulin. Some combinations are chemically incompatible and can result in an undesirable alteration of glycemic effects.

There are currently four major classes of insulin, as determined by their pharmacokinetic properties: rapid acting, short acting, intermediate acting, and long acting/ultra-long acting. The duration of action ranges from several hours to over 24 hours, depending on the insulin class (Figure 33.3). Insulin regimes consistent with basal and bolus dosing are tailored to individual patient needs based on age, general health, treatment goals, lifestyle, diet, ability for self-management, hypoglycemic awareness status, and adherence to treatment (McGibbon, Adams, Ingersoll, et al., 2018). The use of basal insulin, such as intermediate- or long-acting solutions, provides glucose control for the patient during fasting periods or in between meals. The use of bolus insulin, such as rapid- or short-acting solutions, help to control glycemic rise at the time of meals or to treat hyperglycemia.

Mechanism of Action and Drug Effects

Exogenous insulin functions as a substitute for the endogenous hormone. It serves to replace the insulin that is either not made at all or is made defectively in patients with diabetes. The drug effects of exogenously administered insulin involve many body systems, and these effects are the same as those of normal endogenous insulin. That is, exogenous insulin restores the patient's ability to metabolize carbohydrates, fats, and proteins; to store glucose in the liver; and to convert glycogen to fat stores. However, exogenous insulin does not reverse defects in insulin receptor sensitivity. Insulin pumps are an attractive way to administer insulin to patients, providing an alternative to multiple daily subcutaneous injections and allowing patients to match their insulin intake to their lifestyle. When an insulin pump is used, insulin is administered constantly over a 24-hour period, and the patient is then allowed to give bolus injections based on their food intake and activity level. Insulin pumps are described further in the Nursing Process section.

Indications

All insulin preparations can be used to treat both type 1 and type 2 diabetes, but each patient requires careful customization of the dosing regimen for optimal glycemic control. Additional therapeutic approaches indicated include lifestyle modifications

(e.g., changes to dietary and exercise habits) and, for type 2 diabetes, oral drug therapy.

Contraindications

Contraindications to the use of all insulin products include known drug allergy to a specific product. Insulin is never to be administered to a patient who is already hypoglycemic. Plasma glucose must always be tested prior to administration.

Adverse Effects

Hypoglycemia resulting from excessive insulin dosing can result in confusion, coma, or seizure, as well as long-term complications of mild cognitive impairment. Hypoglycemia is the most immediate and serious adverse effect of insulin. Other adverse effects of insulin therapy include weight gain, lipodystrophy at the site of repeated injections, and, in rare cases, allergic reactions. Because weight gain is a common and often undesirable adverse effect, insulin therapy is usually delayed in type 2 patients until other drugs and lifestyle changes have failed to bring plasma glucose to target levels.

Interactions

Drug interactions that can occur with the insulins are significant; they are listed in [Table 33.5](#).

Dosages

For dosage information on the various insulin products, refer to the table on p. 547. The concentration of insulin is expressed as the number of units of insulin per millilitre. For example, unit-100 insulin has 100 units in 1 millilitre. For this reason, insulin is a high-alert medication; the consequences of an error in calculation and administration can have devastating consequences (see [Chapter 6](#) for more information on high-alert medications). Insulin is usually given by subcutaneous injection or via a subcutaneous infusion pump. In emergency situations requiring prompt insulin action, regular insulin can be given intravenously. Regular insulin is the only insulin that can be administered intravenously, and careful monitoring (e.g., of hourly plasma glucose levels) is required.

The insulin dosage regimen for all patients with diabetes is highly individualized and may consist of one or more classes of insulin administered at either fixed dosages or variable dosages in response to self-measurements of plasma glucose levels or the number of grams of carbohydrate consumed. With the use of insulins, clarity, colour, and appearance are important to understand for patient safety and for the prevention of adverse effects and complications. Several insulins are clear, colourless solutions. These include regular insulin, insulin lispro (Humalog), and insulin glargine (Lantus). Other insulins, such as NPH insulin (insulin isophane), are opaque (cloudy), white solutions. These differences are discussed further in the Implementation section under Nursing Process.

Insulin Use in Special Populations

Two special patient populations for whom careful attention is required during insulin therapy include children and pregnant women. Insulin dosages for members of both groups are calculated by weight, as they are for the general adult population. The usual range of a starting dose is 0.2 to 0.5 units/kg/day, followed by a total daily dose is 0.5 to 1 unit/kg/day. Be aware that there are a few important differences regarding the use of some of the more unusual insulin products in children. The rapid-acting insulin lispro is approved for use in children older than 3 years of age. However, the combination lispro product Humalog® Mix25, which contains 75% insulin lispro protamine (an intermediate-acting insulin) and 25% insulin lispro (a rapid-acting insulin), is not currently approved for use in children younger than 18 years of age. Glycemic targets are graduated with age; an A_{1C} of less than 8% is the target with children younger than 6 years of age. In addition, severe hypoglycemia must be minimized in this age group because of its association with later cognitive impairment. The target A_{1C} for children between the ages of 6 and 12 is 7.5% or less, and for adolescents, the target A_{1C} is the same as for adults. Children need age-appropriate education and supervision from health care providers and parents, which includes a safe and gradual transfer of responsibility to support a transition to self-management of their diabetes, as appropriate.

TABLE 33.5 Selected Drug Interactions with Antidiabetic Drugs

Drug	Interacting Drug	Mechanism	Result
Insulin	Corticosteroids, niacin, diuretics, sympathomimetic drugs, thyroid drugs	Antagonizes insulin effect	Increased plasma glucose levels
	Alcohol, anabolic steroids, sulfa antibiotics, MAOIs, salicylates	Increases the hypoglycemic effects of insulin	Decreased plasma glucose levels
	Nonselective beta blockers	Masks the tachycardia from hypoglycemia	Risk of not noticing hypoglycemic symptoms
metformin hydrochloride	Hypoglycemic drugs	Additive effects	Additive hypoglycemia
	Cimetidine	Inhibits metabolism	Increased metformin effects
	Diuretics, steroids	Additive effects	Additive hypoglycemia
Gliclazide	Contrast media	Decreases excretion	Lactic acidosis
	Long-acting sulfonamides, tuberculostatics, phenylbutazone, MAOIs, coumarin derivatives, salicylates, probenecid, propranolol hydrochloride, miconazole nitrate, cimetidine, disopyramide, ACE inhibitors	Enhanced effects	Increased hypoglycemia
	Diuretics (thiazides, furosemide), corticosteroids, oral contraceptives	Increases metabolism	Decreased effectiveness

ACE, angiotensin-converting enzyme; MAOI, monoamine oxidase inhibitor.

Children under the age of 18 years old may qualify for pediatric subsidy programs which help cover costs associated with use of an insulin pump and supplies; however, at the age of 18 years old, funding may be canceled.

Women who are pregnant also require special care in regard to diabetes management. Although many such patients will return to a normal glycemic state after pregnancy, they also have a 30% risk of developing diabetes again in later life. Oral medications are generally not recommended for patients who are pregnant because of a lack of firm safety data. For this reason, insulin therapy is the currently recommended drug therapy for pregnant women with diabetes. Use of insulin can provide

tighter glycemic control, which is why it is recommended. Studies have demonstrated that women can safely take metformin and glyburide until insulin is required (Feig, Berger, Donovan, et al., 2018). Further studies are being conducted on the efficacy of oral antidiabetic agents, such as metformin and glyburide, which cross the placenta. There are no current studies that address the use of DPP-4 inhibitors in women with gestational diabetes. Approximately 15% of women who develop gestational diabetes require insulin therapy during pregnancy. Insulin does not normally cross the placenta.

Effective glycemic control during pregnancy is essential because infants born to women with gestational diabetes have a twofold to

Fig. 33.3 Comparison of the pharmacokinetics of various insulins. (Source: Messenger-Rapport, B. J., Thomas, D. R., & Gammack, J. K. (2008). Clinical update on nursing home medicine. *Journal of the American Medical Directors Association*, 9(7), 460–475.)

threefold greater risk of developing congenital anomalies than those born to women without gestational diabetes. In addition, the incidence of stillbirth is directly related to the degree of maternal hyperglycemia. Weight reduction is generally not advised for pregnant women because it can jeopardize fetal nutritional status. Women with gestational diabetes tend to have babies that weigh more, and these children may have low plasma glucose postnatally. Insulin is excreted into human milk. It is currently unknown whether insulin glargine is excreted in breast milk, and thus its use is to be avoided in breastfeeding women. It is important that insulin therapy and diet be well controlled for nursing mothers because inadequate or excessive glycemic control may reduce milk production.

DRUG PROFILES

Rapid-Acting Insulins

insulin lispro

There are currently three insulin products classified as rapid acting: insulin lispro (Humalog), insulin aspart (NovoRapid), and, more recently developed, insulin glulisine (Apidra). These products have the most rapid onset of action (approximately 15 minutes) as well as a shorter duration of action than that of insulins in other categories. The effect of insulin lispro is most like that of the endogenous insulin produced from the pancreas in response to a meal. After or during a meal, the glucose that is ingested stimulates the pancreas to secrete insulin. This insulin then facilitates the uptake of the excess glucose at hepatic insulin receptor sites for storage in the liver as glycogen. In individuals with diabetes, the insulin response to meals is often impaired; therefore, a rapid-acting insulin product is often used within 15 minutes of mealtime. This corresponds to the time required for the onset of action of rapid-acting insulins. It is essential that patients with diabetes eat a meal after an injection of rapid-acting insulin; otherwise, profound hypoglycemia may result. Insulin lispro was approved by Health Canada in 1998, becoming the first new insulin product to appear on the market in many years. Lispro 200 units/mL KwikPen® became available in 2015 and is used for patients with diabetes who require daily doses of more than 20 units of rapid-acting insulin.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Subcut	10–15 min	1–1.5 hr lispro: 1–2 hr	60–80 min	3.5–6 hr lispro: 3.5–4.75 hr

Short-Acting Insulin

regular insulin

Regular insulin (Humulin R, Novolin ge Toronto) is currently the only insulin that is classified as a short-acting insulin. Regular insulin can be administered via IV bolus, IV infusion, or even intramuscularly. These routes, especially the IV infusion route, are often used in cases of DKA or coma associated with uncontrolled type 1 diabetes. It also can be administered subcutaneously for the management of diabetes.

Regular insulin solution was the first medicinal insulin product developed. It was originally isolated from bovine and porcine sources, but it is now made primarily from human insulin sources, using rDNA technology.

There are some differences between regular insulin and the newer rapid-acting drugs. Both rapid-acting insulins, lispro and insulin aspart, are human insulin analogues. This means that they are insulin molecules with synthetic alterations to their chemical structures that change their onset or duration of action. Both of these insulins have a faster onset of action and take a shorter time to reach peak plasma level than regular insulin, but they also have a shorter duration of action.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Subcut	30 min	2–3 hr	1.5 hr	6.5 hr

Intermediate-Acting Insulins

insulin isophane suspension (NPH)

Insulin isophane suspension (Humulin N, Novolin ge NPH [also known as *NPH insulin*]) is the only available intermediate-acting insulin product. NPH is an acronym for *neutral protamine Hagedorn* insulin, the original name of this type of insulin. NPH insulin is a sterile suspension of zinc insulin crystals and protamine sulphate in buffered water for injection. The suspension appears cloudy or opaque (white). NPH insulin has a slower onset and a longer duration of action than that of regular insulin, but not as slow and long as the long-acting insulins. NPH insulin is often combined with regular insulin to reduce the number of insulin injections needed per day.

PHARMACOKINETICS-NPH

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Subcut	2–4 hr	4–10 hr	Unknown	12–18 hr

Long-Acting Insulins

insulin detemir and insulin glargine

Two long-acting basal insulin products are now available: insulin glargine (Basaglar, Lantus) and insulin detemir (Levemir). Insulin glargine is normally a clear, colourless solution with a pH of 4. Once it is injected into subcutaneous tissue at a physiological pH of approximately 7.4, it forms microprecipitates that are slowly absorbed over the next 24 hours (for glargine, the duration is 24 hours, while for detemir the peak is 16 to 24 hours). It is an rDNA-produced insulin analogue and is unique in that it provides a constant level of insulin in the body. This enhances its safety because it does not cause blood levels to rise and fall, as do other insulins (i.e., there is no peak). Insulin glargine is usually dosed once daily, but it may be dosed every 12 hours, depending on the patient's glycemic response. Because insulin glargine provides a prolonged, consistent plasma glucose level, it is sometimes referred to as a *basal insulin*. Often, for those being switched from twice-daily

NPH to insulin glargine, the initial daily glargine dose is reduced to 80% of the previous total NPH dose. Insulin detemir has a different mechanism of action from insulin glargine; these two insulins are not considered interchangeable. The duration of action of insulin detemir is dose dependent, so that lower doses require twice-daily dosing and higher doses may be given once daily.

Insulin glargine recently became available in a 300 unit/mL disposable (prefilled) pen (1.5 mL) as Toujeo SoloStar®. It contains three times as much insulin in 1 mL as that in standard insulin. Toujeo has an onset of action over 6 hours following the injection, and its duration of action is up to 30 hours. It comes with a lower risk of hypoglycemia after transfer from other insulins, independent of time of injection, and is associated with less weight gain than other insulins. Toujeo is not to be mixed with any other insulin products. If converting a patient from insulin Lantus to Toujeo, the dose may need to be increased by 10–15%. The drug is indicated for once-daily subcutaneous administration in the treatment of patients over the age of 18 years with type 1 or type 2 diabetes who require basal (long-acting) insulin for glycemic control.

PHARMACOKINETICS-GLARGINE

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Subcut	2–4 hr	No Peak	Unknown	20–24 hr

Fixed-Combination Insulins

Currently available fixed-combination insulin products include Humulin 30/70; Novolin 30/70, 40/60, and 50/50; NovoMix 30®; and Humalog Mix25 and Mix50. Each of these products contains two different insulins—one intermediate-acting type and either one rapid-acting type (Humalog, NovoLog) or one short-acting type (Humulin). The numeric designations indicate the percentages of each of the two components in the product. For example, Novolin 30/70 has 30% intermediate-acting insulin and 70% short-acting insulin. Notice that the numbers add up to 100 (%).

These products were developed to more closely simulate the varying levels of endogenous insulin that occur normally in people who do not have diabetes. In most insulin regimens, patients take a combination of a rapid-acting insulin to deal with the surges in glucose that occur after meals and an intermediate- or long-acting insulin for the periods between meals, when glucose levels are lower. However, this requires mixing and administering different types of insulins. Fixed-combination products were developed in an attempt to simplify the dosing process. The insulin lispro protamine component of Humalog Mix25 (25% insulin lispro injection, 75% insulin lispro protamine suspension) is a modified insulin lispro molecule with a longer duration of action. Combinations allow for twice-daily dosing but often result in glycemic control that is not as tight as daily dosing with meals. Patients who cannot afford frequent glucose monitoring or who refuse more than two injections per day may insist on using a combination insulin with twice-daily dosing.

Basal–Bolus and Sliding-Scale Insulin Dosing

Historically, sliding-scale insulin was used to correct plasma glucose levels. In this method, subcutaneous doses of rapid-acting (lispro or aspart) or short-acting (regular) insulin are adjusted according to plasma glucose test results. This method was typically used in treating hospitalized patients with diabetes, whose insulin requirements may vary dramatically because of stress (e.g., infections, surgery, acute illness), inactivity, or variable caloric intake, including receipt of total parenteral nutrition (TPN) or time spent on a “nothing by mouth” (NPO) diet. Other hospital diets that result in high numbers of carbohydrates consumed are full-liquid and clear-liquid diets.

When an individual is on a sliding-scale insulin regimen, plasma glucose concentrations are determined several times a day (e.g., before meals and at bedtime) for patients on normal meal schedules, or every 4 to 6 hours around the clock for patients receiving TPN or enteral tube feedings. Subcutaneously administered regular insulin or rapid-acting insulin is then given in an amount that increases with the rise in plasma glucose. The

Dosages

Selected Human-Based Insulin Products

Drug	Pharmacological Class	Usual Dosage Range	Indications
Rapid-Acting			
 insulin lispro (Humalog)	Human recombinant rapid-acting insulin analogue	Subcut: 0.1–0.5 units/kg/day (including both rapid-acting and basal insulin dosing); doses are highly individualized to desired glycemic control; rapid-acting insulins are best given 15 min before a meal May be given per sliding scale or as basal–bolus; may also be given via continuous Subcut infusion pump	Diabetes, type 1 and type 2
Short-Acting			
 regular insulin (Humulin R, Novolin ge Toronto)	Human recombinant short-acting insulin	Subcut: same dosage as insulin lispro; subcut doses of regular insulin are best given 30 min before a meal Regular insulin may also be given per sliding scale and is the insulin usually given IV as a continuous infusion	Diabetes, type 1 and type 2
Long-Acting			
 insulin detemir (Levemir) insulin glargine (Lantus)	Human recombinant long-acting insulin analogues	Subcut only: same dosage as others but approved only for once- or twice-daily dosage (basal dosing)	Diabetes, type 1 and type 2

IV, intravenous; Subcut, subcutaneous.

disadvantage of sliding-scale dosing is that, because it delays insulin administration until hyperglycemia occurs, it does not meet basal insulin requirements and results in large swings in glucose control. Current research does not support the use of sliding scales or of insulin without concurrent use of basal insulin, and many institutions are moving away from sliding-scale coverage. Nonetheless, sliding-scale dosing is still commonly used.

Basal-bolus insulin therapy is now the preferred method of treatment for hospitalized patients with diabetes. Basal-bolus therapy involves attempting to mimic a healthy pancreas by delivering insulin constantly as a basal and then as needed as a bolus. The basal insulin is a long-acting insulin (insulin glargine), administered constantly to keep the plasma glucose from fluctuating due to the normal release of glucose from the liver. Bolus insulin (insulin lispro or insulin aspart) mimics the burst secretions of the pancreas in response to increases in plasma glucose levels. Bolus insulin is broken up into meal and correction boluses. Meal boluses are given to reduce plasma glucose with the intake of carbohydrates. Correction boluses are any boluses taken to bring plasma glucose back to normal. Plasma glucose levels are monitored frequently when using basal-bolus insulin. This method of treatment is far superior to the traditional sliding scale. Still, patients who need to receive nothing by mouth for therapeutic or diagnostic reasons are not good candidates for basal insulin owing to the risk of hypoglycemia and the unpredictability of the insulin needed for glucose control while not eating.

Oral Antihyperglycemic Drugs

Type 2 diabetes is a complex illness. Effective treatment involves several elements, including lifestyle modifications (e.g., diet control, exercise, smoking cessation, nutrition therapy), careful monitoring of plasma glucose levels, and therapy with one or more drugs. In addition, the treatment of associated comorbid conditions (such as high cholesterol and high blood pressure) can further complicate the entire process of treatment.

Diabetes Canada 2018 clinical practice guidelines recommend that new-onset type 2 diabetes with an A_{1C} less than 7.0% be treated with lifestyle interventions for 2 to 3 months to achieve glycemic targets, with the addition of the oral biguanide drug metformin if lifestyle changes are not effective. The maximum effect of oral antihyperglycemic monotherapy is seen at 3 to 6 months. In patients with an A_{1C} of greater than or equal to 1.5% above target, metformin is initiated together with lifestyle interventions, with consideration given to adding insulin to the regimen. A combination of oral antihyperglycemics and insulin often effectively controls glucose levels. Consideration is given to the chosen type of insulin when it is being added to oral drugs. Often, a lower dose of an intermediate-acting or a long-acting insulin combined with oral antihyperglycemics may result in better glycemic control, less weight gain, and less hypoglycemia than the use of a more typical dose of insulin alone. The use of bedtime insulin with metformin results in less weight gain than insulin therapy alone. Dipeptidyl peptidase-4 (DPP-4) inhibitors and glucagon-like peptide 1 (GLP-1) receptor agonists may also be combined with insulin and are effective at lowering plasma glucose levels. As type 2 diabetes progresses, insulin needs will probably increase, and the addition of short-acting or rapid-acting insulins may also need to be considered.

The initial use of combinations of submaximal doses of antihyperglycemics produces more rapid and improved glycemic control with fewer adverse effects, compared to monotherapy at maximal doses. Studies have shown that metformin and the sulfonylureas (available in generic form) were either similar or superior to the more expensive thiazolidinediones, glinides, and α -glucosidase inhibitors. Numerous combined formulations of oral hyperglycemic drugs are available (e.g., Avandamet® [metformin and rosiglitazone]).

Biguanide

Mechanism of Action and Drug Effects

Metformin is currently the only drug classified as a biguanide. It is considered a first-line drug, especially for patients with a body mass index over 25, and is the most commonly used oral drug for the treatment of type 2 diabetes. It is not used for type 1 diabetes. Metformin works by decreasing hepatic glucose production. It may also decrease intestinal absorption of glucose and improve insulin receptor sensitivity. This results in increased peripheral glucose uptake and use as well as decreased liver production of triglycerides and cholesterol. Unlike sulfonylureas, metformin does not stimulate insulin secretion and therefore is not associated with weight gain and significant hypoglycemia when used alone.

Indications

Diabetes Canada 2018 guidelines recommend metformin as the initial oral antihyperglycemic drug for treatment of newly diagnosed type 2 diabetes if no contraindications exist. Because it may also cause moderate weight loss, it is particularly useful for the many patients with type 2 diabetes who are overweight or obese. It is also used in patients who are prediabetic. Metformin may be used as monotherapy or in combination with other oral antihyperglycemic drugs if single-drug therapy is unsuccessful. For this reason, it is available in combination products containing either thiazolidinediones or incretin mimetics. Metformin may also be combined with insulin. The extended-release tablets can be used as monotherapy or in combination with a sulfonylurea. It is not approved by Health Canada for use in children.

Contraindications

Metformin is contraindicated in patients with kidney disease or kidney dysfunction (creatinine clearance less than 30 mL/min). Because metformin is excreted primarily by the kidneys, it can accumulate in these individuals, increasing the risk of development of lactic acidosis. Other contraindications include alcoholism, metabolic acidosis, liver disease, heart failure, and other conditions that predispose patients to tissue hypoxia and increase the risk of lactic acidosis. Caution should be exercised in patients prescribed metformin who are scheduled for contrast-enhanced examinations (i.e., angiography, computed tomography [CT], and venography) and with glomerular filtration rates of less than 60 mL/min. Patients are at risk for contrast-induced nephropathy ([Baerlocher, Myers, & Myers, 2013](#)).

Adverse Effects

The most common adverse effects of metformin are gastrointestinal (GI). Metformin can cause abdominal bloating, nausea, cramping, a feeling of fullness, and diarrhea, especially at the start of therapy. Some research attributes the weight loss

experienced early in the course of treatment to these adverse effects. These effects are all usually self-limiting and can be lessened by starting with low dosages, titrating up slowly, and taking the medication with food. Less common adverse effects with metformin are a metallic taste, hypoglycemia, and a reduction in vitamin B₁₂ levels after long-term use. Metformin-associated lactic acidosis is an extremely rare complication with metformin, but the risk of this increases with extremely high plasma glucose levels or clinical conditions predisposing patients to hypoxemia. Metformin enhances anaerobic metabolism, which, with a lack of insulin, results in an increased lactic acid production. Lactic acidosis is lethal in up to 50% of cases. Symptoms of lactic acidosis include hyperventilation, cold and clammy skin, muscle pain, abdominal pain, dizziness, and irregular heartbeat.

Interactions

Drug interactions with metformin are listed in Table 33.5. In addition, the use of metformin with iodinated (iodine-containing) radiological contrast media has been associated with both acute kidney injury and lactic acidosis. For these reasons, metformin therapy is to be discontinued the day of the test and for at least 48 hours after the patient undergoes any radiological study that requires the use of such contrast media.

Dosages

For dosage information on metformin, refer to the table on p. 554.

Sulfonylureas

Mechanism of Action and Drug Effects

The sulfonylureas comprise the oldest group of oral antihyperglycemic drugs. The drugs in this category that are currently used are considered second-generation drugs and have better potency and adverse effect profiles than those of first-generation drugs (e.g., acetazolamide and tolbutamide), which are no longer used clinically. Second-generation sulfonylureas include gliclazide (Diamicon®), glyburide (Diabeta®), and glimepiride (Amaryl®). Sulfonylureas bind to specific receptors on β -cells in the pancreas to stimulate the release of insulin. In addition, sulfonylureas appear to secondarily decrease the secretion of glucagon. For this class of drugs to be effective, the patient must still have functioning β -cells in the pancreas. Thus, these drugs work best during the early stages of type 2 diabetes and are not used in type 1 diabetes.

Indications

Diabetes Canada guidelines currently recommend sulfonylureas as an option for second line medications for patients living with type 2 diabetes whose A_{1C} levels remain elevated after metformin is initiated. Because they have different mechanisms of action, sulfonylureas can be used in conjunction with metformin and thiazolidinediones. Sulfonylureas should not be used in patients with advanced diabetes dependent on insulin administration because the β -cells in such patients are no longer able to produce insulin. Once insulin is started, sulfonylureas are stopped.

Contraindications

Contraindications to the use of sulfonylureas include hypoglycemia or conditions that can predispose patients to hypoglycemia, such as reduced caloric intake (e.g., being made NPO), ethanol use, or advanced age. There is a potential for cross-allergy in

patients who are allergic to sulfonamide antibiotics. Although such an allergy is listed as a contraindication by the manufacturer, most health care providers will prescribe sulfonylureas for such patients. However, it is important to be aware of the potential for cross-allergy and to inform patients of this possibility.

Adverse Effects

The most common adverse effect of the sulfonylureas is hypoglycemia, the degree of which depends on the dose, the patient's eating habits, and the presence of liver or kidney disease. Another predictable adverse effect is weight gain because of the stimulation of insulin secretion. Other adverse effects include skin rash, nausea, epigastric fullness, and heartburn.

Interactions

Drug interactions with the second-generation sulfonylureas are listed in Table 33.5.

Dosages

For dosage information on sulfonylureas, refer to the table on p. 554.

Glinides

Mechanism of Action and Drug Effects

Repaglinide (GlucoNorm®) and nateglinide (Starlix®) are the two drugs available in the glinide class. They are structurally different from the sulfonylureas but have a similar mechanism of action in that they also increase insulin secretion from the pancreas. However, they have a much shorter duration of action and must be given with each meal.

Indications

Like the sulfonylureas, the glinides are indicated for the treatment of type 2 diabetes. They may be particularly useful for patients with diabetes who have high postprandial glucose levels and low levels of circulating insulin. The glinides can be used with metformin and thiazolidinediones, but they cannot be combined with sulfonylureas because they share a similar mechanism of action.

Contraindications

Contraindications to the use of glinides are similar to those of the sulfonylureas.

Adverse Effects

The most commonly reported adverse effect of the glinides is hypoglycemia, which can occur if food is not eaten after a dose. Weight gain is also commonly reported.

Interactions

Drug interactions with the glinides are similar to those with the sulfonylureas.

Dosages

For dosage information on the glinides, refer to the table on p. 554.

Thiazolidinediones (Glitazones)

Mechanism of Action and Drug Effects

The third major drug category to emerge for the oral treatment of type 2 diabetes is the thiazolidinediones, most commonly referred

to as *glitazones*. This class of drugs acts by regulating genes involved in glucose and lipid metabolism. Glitazones are referred to as *insulin-sensitizing drugs*. They work to decrease insulin resistance by enhancing the sensitivity of insulin receptors. These drugs are also known to directly stimulate peripheral glucose uptake and storage, as well as to inhibit glucose and triglyceride production in the liver. Because glitazones affect gene regulation, they have a slow onset of activity over several weeks, and maximal activity may not be evident for several months. Some amount of preservation of β -cell function has also been reported with glitazone administration, thereby slowing disease progression in type 2 diabetes.

Indications

Thiazolidinediones are indicated for the management of type 2 diabetes. Because of their cost, adverse effect profile, and slow onset of action, they are usually reserved for patients who cannot tolerate or cannot achieve glucose control with metformin or the sulfonylureas. Rosiglitazone mesylate (Avandia®) is associated with increased cardiovascular risk when compared to the other glitazone, pioglitazone hydrochloride (Actos®). These drugs may also be combined with metformin or a sulfonylurea for a synergistic effect. Pioglitazone hydrochloride can be used with insulin.

Contraindications

Thiazolidinediones are contraindicated for use in patients with New York Heart Association class III or IV heart failure and are to be used with caution in patients with liver or kidney disease.

Adverse Effects

The glitazones commonly cause peripheral edema and weight gain. This weight gain may be due to both water retention and an increase in adipose tissue. Their use has also been associated with reduced bone mineral density and an increased risk of fractures.

Interactions

Pioglitazone hydrochloride is partly metabolized by cytochrome P450 enzyme 3A4 (CYP3A4). Serum concentrations of pioglitazone hydrochloride may be increased if the drug is taken concurrently with a CYP3A4 inhibitor such as ketoconazole or erythromycin.

Dosages

For dosage information on thiazolidinediones, refer to the table on p. 554.

α -Glucosidase Inhibitors

Mechanism of Action and Drug Effects

Among the less commonly used oral drugs is the α -glucosidase inhibitor acarbose (Glucobay®). As the category name implies, this drug works by reversibly inhibiting the enzyme α -glucosidase that is found in the small intestine. This enzyme is responsible for the hydrolysis of oligosaccharides and disaccharides to glucose. When this enzyme is blocked, glucose absorption is delayed. The timing of administration of α -glucosidase inhibitors is important, and they must be taken with food. When an α -glucosidase inhibitor is taken with a meal, excessive postprandial plasma glucose elevation (a glucose “spike”) can be prevented or reduced, making this medication impractical for directly lowering fasting plasma glucose.

Indications

Alpha-glucosidase inhibitors are used to treat type 2 diabetes, usually in combination with another oral antihyperglycemic drug. Acarbose may be particularly effective in controlling high postprandial glucose levels.

Contraindications

Because of its adverse GI effects, acarbose is not recommended for use in patients with inflammatory bowel disease, malabsorption syndromes, or intestinal obstruction.

Adverse Effects

Acarbose can cause a high incidence of flatulence, diarrhea, and abdominal pain. At high dosages, it may also elevate levels of liver enzymes (transaminases). Unlike sulfonylureas, it does not cause hypoglycemia or weight gain. In the rare instance that a patient develops hypoglycemia from acarbose, complex carbohydrates cannot be used because α -glucosidase is blocked; IV or oral glucose must be administered.

Interactions

The bioavailability of digoxin, ranitidine hydrochloride, and propranolol hydrochloride may be reduced when they are taken with an α -glucosidase inhibitor.

Dosages

For dosage information on α -glucosidase inhibitors, refer to the table on p. 554.

Dipeptidyl Peptidase 4 (DPP-4) Inhibitors

Mechanism of Action and Drug Effects

Dipeptidyl peptidase-4 (DPP-4) inhibitors work by delaying the breakdown of incretin hormones (see Incretin Mimetics) by inhibiting the enzyme DPP-4. Incretin hormones are released throughout the day and are increased after a meal. When plasma glucose concentrations are normal or high, the incretin hormones increase insulin synthesis and lower glucagon secretion. By inhibiting the enzyme responsible for incretin breakdown (DPP-4), the DPP-4 inhibitors reduce fasting and postprandial glucose concentrations. Currently, there are four DPP-4 inhibitors: sitagliptin phosphate monohydrate (Januvia®), alogliptin benzoate (Nesina®), saxagliptin hydrochloride (Onglyza®), and linagliptin (Tradjenta®). They are all available in combination formulations with metformin (e.g., Jentadueto® is the combination of linagliptin and metformin). There are several DPP-4 inhibitors currently under investigation. This class of drugs is commonly referred to as the *gliptins*.

Indications

The DPP-4 inhibitors are indicated as an adjunct to changes in diet and exercise habits to improve glycemic control in adults with type 2 diabetes.

Contraindications

The DPP-4 inhibitors are contraindicated in patients with known drug allergy.

Adverse Effects

The most common adverse effects of DPP-4 inhibitors are upper respiratory tract infection, headache, and diarrhea. Hypoglycemia

can occur and is more common if these drugs are used in conjunction with a sulfonylurea. Cases of pancreatitis have been reported.

Interactions

Sitagliptin phosphate monohydrate may increase digoxin levels. Concurrent use of sulfonylureas and insulin may increase the risk of hypoglycemia. The use of CYP3A4 inducers such as carbamazepine, dexamethasone, phenobarbital, phenytoin, and rifampin may decrease the glycemic lowering effect of saxagliptin. Rifampin may decrease the efficacy of linagliptin.

Dosages

The recommended dosage of sitagliptin phosphate monohydrate is 100 mg daily; for saxagliptin hydrochloride, it is 5 mg daily; for alogliptin benzoate, 25 mg daily; and for linagliptin, 5 mg daily.

Sodium–Glucose Cotransporter 2 Inhibitor

A new class of oral antihyperglycemic drugs, introduced in 2014, comprises the sodium–glucose cotransporter 2 inhibitors. There are currently four drugs available in this class: canagliflozin (Invokana®), and dapagliflozin (Forxiga®), empagliflozin (Jardiance®) and ertugliflozin (Steglatro®).

Mechanism of Action and Drug Effects

Sodium–glucose cotransporter 2 inhibitors block the tubular reabsorption of glucose in the kidney via the sodium–glucose cotransporter, a protein that facilitates 90% of glucose reabsorption in the proximal tubules of the kidneys. Selective inhibition of the sodium–glucose cotransporter results in a reduction of plasma glucose as kidney glucose excretion is increased. Consequently, glycemic control is improved. In addition, weight loss and a reduction in systolic blood pressure occur. They also raise the high-density lipoprotein cholesterol and the low-density lipoprotein cholesterol levels. The incidence of hypoglycemia related to sodium–glucose cotransporter 2 inhibitors is low, compared to that caused by the other oral antihyperglycemics.

Indications

Canagliflozin and dapagliflozin are recommended as adjuncts to changes in diet and exercise habits in combination with other glucose-lowering drugs (e.g., sulfonylurea, pioglitazone, insulin) and as a monotherapy for metformin-intolerant patients with type 2 diabetes and add-on therapy for patients with established cardiovascular disease.

Contraindications

The sodium–glucose cotransporter 2 inhibitors are contraindicated in patients with known drug allergy. These drugs are not to be used in patients with type 1 diabetes, in patients with kidney disease, or for the treatment of DKA.

Adverse Effects

The most frequently reported adverse effects of sodium–glucose cotransporter 2 inhibitors include vaginal yeast infections and urinary tract infections due to high concentrations of glucose in the urine. The greatest risk is in female patients and in male patients who are uncircumcised. Other adverse effects include diarrhea, constipation, and nausea. The use of canagliflozin or dapagliflozin creates osmotic diuresis, which may lead to

intravascular volume depletion and associated manifestations (e.g., hypotension, dizziness, orthostatic hypotension, syncope, dehydration). Hyperkalemia may occur in individuals with kidney insufficiency. Elevated levels of LDLs, hemoglobin, serum creatinine, blood urea nitrogen, and serum phosphate, as well as a decrease in serum urate, have been reported. In 2015, Health Canada initiated a safety review for dapagliflozin and canagliflozin and the risk of DKA ([Government of Canada, 2015](#)). The symptoms of DKA occur unexpectedly and can occur with only slightly increased blood sugar levels in those with type 2 diabetes. There has been one known case of DKA related to sodium–glucose cotransporter 2 inhibitor use in Canada to date.

Interactions

Canagliflozin and dapagliflozin may increase the risk of hypoglycemia when combined with insulin or an insulin secretagogue. Use of the sodium–glucose cotransporter 2 inhibitors with insulin decreases efficacy and clinical benefit, requiring the dosage of the sodium–glucose cotransporter 2 inhibitors to be increased from 100 to 300 mg. Canagliflozin increases digoxin levels, requiring monitoring of digoxin levels. St. John's wort may reduce the clinical response to canagliflozin.

Dosages

The recommended initial dosage of canagliflozin is 100 mg once daily, preferably before breakfast. For those who are able to tolerate the 100-mg dose, require tighter glycemic control, and have adequate kidney function, the 300-mg dose may be considered. This class of drug's use during pregnancy is indicated only if the potential benefit justifies the potential risk to the fetus. The dosage of dapagliflozin is 5 mg taken once daily at any time of the day, with or without food. It can be increased to 10 mg daily for patients requiring additional glycemic control. The recommended starting dose of empagliflozin is 10 mg taken once daily, at any time of the day, with or without food, and may be increased to one 25 mg tablet daily to further control blood sugar levels. The recommended initial dose of ertugliflozin is to start therapy with 5 mg, to be taken once a day in the morning, and with or without food. The dose can be increased to 15 mg daily to further control blood sugar levels.

DRUG PROFILES

acarbose

Acarbose (Glucobay) is the only available α -glucosidase inhibitor. Acarbose works by blunting the elevation of blood glucose levels after a meal. In order for it to work optimally, it should be taken with the first bite of each meal. It may also be taken along with sulfonylureas or metformin. Use of acarbose is contraindicated in patients with a hypersensitivity to α -glucosidase inhibitors, as well as with DKA, cirrhosis, inflammatory bowel disease, colonic ulceration, partial intestinal obstruction, or chronic intestinal disease.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1–1.5 hr	2 hr	2–3 hr	Unknown

gliclazide

Gliclazide (Diamicon) is a second-generation sulfonylurea drug. In contrast to another second-generation sulfonylurea, glimepiride, it has a rapid onset and a short duration of action, with no active metabolites. This rapid onset of action allows it to function much like the pancreas normally does in response to meals, after which greater levels of insulin are required rapidly to deal with the increased glucose in the blood. When a patient with type 2 diabetes takes gliclazide, it rapidly stimulates the pancreas to release insulin. This, in turn, facilitates the transport of excess glucose from the blood into the cells of the muscles, liver, and adipose tissues. Gliclazide also has antiplatelet and antioxidant properties.

Gliclazide use is contraindicated in cases of known drug allergy as well as in patients with type 1 diabetes or those with type 2 diabetes who experience variations in blood glucose levels. Unlike most other oral antihyperglycemic drugs, it is not contraindicated in patients with severe kidney failure. Gliclazide immediate release is given twice daily and works best if given 30 minutes before meals. This allows the timing of the insulin secretion induced by the gliclazide to correspond with the elevation in blood glucose level induced by a meal, in much the same way as endogenous insulin levels are raised in a person without diabetes. The modified-release dosage form of gliclazide can be given once daily, usually before breakfast.

PHARMACOKINETICS-GLICLAZIDE

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1 hr	6 hr	16 hr	24 hr

metformin hydrochloride

Metformin hydrochloride (Glucophage®, Glumetza®) is currently the only biguanide oral antihyperglycemic drug. It works primarily by inhibiting hepatic glucose production and increasing the sensitivity of peripheral tissue to insulin. Because its mechanism of action differs from that of sulfonylurea drugs, it may be given along with these drugs.

Metformin use is contraindicated in patients with a known hypersensitivity to biguanides, with liver or kidney disease, alcoholism, or cardiopulmonary disease.

PHARMACOKINETICS (IMMEDIATE RELEASE)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	initial onset within days and max effect within 2 weeks	1–3 hr	4–9 hr	up to 4 days

pioglitazone hydrochloride

Pioglitazone hydrochloride (Actos) is classified as a glitazone or derivative. It is marketed for the treatment of patients with type 2 diabetes. Pioglitazone hydrochloride is used alone or with metformin, insulin, or a sulfonylurea. It works by decreasing insulin

resistance. It can worsen or precipitate heart failure and is best avoided in patients with heart disease. The safety of this drug for use in pregnant women and children has not been established.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Delayed	2 hr	3–7 hr	Unknown

repaglinide

Repaglinide (GlucoNorm) is one of two antidiabetic drugs classified as *glinides*, the other being nateglinide (Starlix). These drugs have a mechanism of action similar to that of the sulfonylureas in that they also stimulate the release of insulin from pancreatic β -cells. They are especially helpful in the treatment of patients with erratic eating habits, because the drug dose is skipped when a meal is missed. Contraindications include known drug allergy.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	15–60 min	1 hr	1 hr	4–6 hr

sitagliptin phosphate monohydrate

Sitagliptin phosphate monohydrate (Januvia) was the first DPP-4 inhibitor approved by Health Canada. It is an oral drug that selectively inhibits the action of DPP-4, thereby increasing concentrations of the naturally occurring incretins GLP-1 and gastric inhibitory peptide (GIP). Sitagliptin phosphate monohydrate is indicated for the management of type 2 diabetes, either as monotherapy or in combination with metformin, a sulfonylurea, or a glitazone, but not with insulin. Clinical trials of sitagliptin phosphate monohydrate have demonstrated A_{1C} reductions of 0.6 to 0.8%, which is less than the reductions seen with traditional oral antihyperglycemic drugs. Significant hypoglycemia may occur when the drug is combined with a sulfonylurea. There have been no significant adverse effects documented. Because of postmarketing cases of acute pancreatitis, patients must be monitored closely for the development of pancreatitis after both initiation and dose increases. Sitagliptin phosphate monohydrate is given once daily as a 100-mg tablet with or without food. It is not recommended for use during pregnancy.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	15–30 min	1–4 hr	12 hr	Unknown

INJECTABLE ANTIHYPERGLYCEMIC DRUGS

Incretin Mimetics

Mechanism of Action and Drug Effects

Incretins are hormones released by the GI tract in response to food. Incretins do the following:

1. Stimulate insulin secretion
2. Reduce postprandial glucagon production

3. Slow gastric emptying
4. Increase satiety

The most important incretin hormones identified to date are GLP-1 and GIP. These hormones are rapidly deactivated by the enzyme DPP-4. The incretin mimetics enhance glucose-dependent insulin secretion, suppress elevated glucagon secretion, and slow gastric emptying. Currently, there are four incretin mimetics: albiglutide, dulaglutide, exenatide, and liraglutide.

Indications

Exenatide (Byetta®) was approved by Health Canada in 2010 as the first incretin mimetic drug. Exenatide is a long-acting analogue of GLP-1 that was initially derived from the salivary gland of the Gila monster. This drug is available only as a subcutaneous injection by prefilled pen and is indicated only for patients with type 2 diabetes who have been unable to achieve blood glucose control with metformin, a sulfonylurea, or insulin glargine. It is best given 60 minutes before a meal. Liraglutide (Victoza®) is similar to exenatide. At the time of writing, albiglutide (Eperzan®) had received a Notice of Compliance by Health Canada. Dulaglutide (Trulicity®), approved in January 2016, is another incretin mimetic available in a single-use, prefilled syringe or a pen. It is administered once weekly, at any time of day, with or without meals.

These drugs are not recommended for use during pregnancy.

Contraindications

Incretin mimetics are contraindicated in patients with known drug allergy. They should not be used in patients with end-stage kidney failure or severe kidney impairment.

Adverse Effects

Adverse effects of incretin mimetics include nausea, vomiting, and diarrhea. Rare cases of hemorrhagic or necrotizing pancreatitis after both initiation and dose increases have also been reported. Patients may experience rapid weight loss of more than 1.5 kg per week; however, at 12 months, most patients lose an average 1.5–2 kg of weight.

Interactions

Incretin mimetics can delay absorption of other orally administered drugs by slowing gastric emptying. In patients taking sulfonylurea drugs, the dose of the incretin mimetic may need to be reduced if hypoglycemia appears on initiation of exenatide therapy.

Dosages

The usual starting dosage of exenatide is 5 mcg within 1 hour of both the morning and evening meals. If necessary, the dosage may be increased after 1 month to 10 mcg twice daily before meals. The dose of liraglutide is initially 0.6 mg, then it is titrated up to 1.2 or 1.8 mg daily. The recommended dosage of albiglutide is 30 mg once weekly given as a subcutaneous injection. The dosage may be increased to 50 mg once weekly if the glycemic response is inadequate. The recommended dosage of dulaglutide is 0.75 mg once weekly. The dose may be increased to 1.5 mg once weekly for additional glycemic control. The recommended dosage of semaglutide is 0.25 mg subcutaneous weekly over 4 weeks then 0.5 mg subcutaneous once weekly up to a maximum dose of 1 mg.

Glucose-Elevating Drugs

Hypoglycemia is an abnormally low blood glucose level (generally below 4 mmol/L). When the cause is organic and the effects are mild, treatment usually consists of dietary modifications (a higher intake of protein and lower intake of carbohydrates), to prevent a rebound postprandial hypoglycemic effect. Hypoglycemia is also a common adverse effect of many antihypoglycemic drugs when their pharmacological effects are greater than expected. The severity of hypoglycemia is determined by clinical manifestations. Initial manifestations are neurogenic from adrenergic mechanisms (related to the sympathetic nervous system) and include sweating, trembling, palpitations, anxiety, and a sensation of hunger. Because the brain needs a constant amount of glucose to function, neuroglycopenic manifestations include the central nervous system (CNS) manifestations of difficulty concentrating, confusion, weakness, drowsiness, vision changes, difficulty speaking, dizziness, and headache. Later symptoms include hypothermia and seizures. Without adequate restoration of normal plasma and CNS glucose levels (typically the plasma glucose is less than 2.8 mmol/L in hypoglycemia), coma and death will occur.

Oral forms of concentrated glucose are available for patients to use in the event of a hypoglycemic crisis. Diabetes Canada recommends the administration of 15 grams of glucose (e.g., four glucose tablets, three packets of sugar dissolved in water, 8 Life Savers, 175 mL of a regular soft drink or juice, 1 package of candy Rockets, or 15 mL of honey) to produce an increase in plasma glucose of approximately 2.1 mmol/L within 20 minutes. These fast-acting glucose sources are preferable to milk, orange juice, and glucose gels, which are slower to increase plasma glucose levels and provide symptom relief. Glucose gel acts quite slowly (less than 1 mmol/L increase at 20 minutes) and must be swallowed to have a significant effect. Plasma glucose should be retested 15 minutes after glucose administration, and if the level is less than 4 mmol/L, the individual should be re-treated with an additional 15 grams of carbohydrate. When the hypoglycemia is reversed, a normal meal should be eaten; however, if the meal is longer than 1 hour away, a snack of 15 grams of carbohydrate and a protein should be consumed.

Table sugar (sucrose) will not produce as rapid an effect as the glucose products intended for use by patients with diabetes. This is because sucrose is a disaccharide (two-molecule sugar) that must first be digested in the body to yield glucose as a monosaccharide (one-molecule sugar) by-product. Commercially available, fast-acting glucose is available in gel, liquid, or tablet form. Because the α -glucosidase inhibitor acarbose interferes with the digestion of some carbohydrates, patients taking this drug must use glucose (dextrose) tablets or, if these are unavailable, milk or honey to treat hypoglycemia. In the hospital setting or when a patient is unconscious, IV glucose is an obvious option to treat hypoglycemia. Concentrations of up to 50% dextrose in water (D₅₀W) are most often used for this purpose.

In addition to oral or IV glucose, glucagon, a natural hormone secreted by the pancreas, is available as a subcutaneous injection to be given when a quick response to severe hypoglycemia is needed. Because glucagon injection may induce vomiting, roll an unconscious patient onto their side before injection. Glucagon is useful in treating the unconscious hypoglycemic patient without established IV access.

Dosages

Selected Oral Antihyperglycemic Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications
acarbose (Glucobay)	α -Glucosidase inhibitor	PO: 50–100 mg tid, taken with first bite of meal	Type 2 diabetes
 gliclazide (Diamicon, Diamicon MR)	Second-generation sulfonylurea	PO: 80–320 mg daily (doses above 160 mg divided, bid) MR: 30–120 mg once daily	
glimepiride (Amaryl)	Second-generation sulfonylurea	PO: 1–4 mg daily (max 8 mg daily)	
 metformin hydrochloride (Glucophage)	Biguanide	PO: 500 mg bid–qid or 850 mg bid–tid daily; max daily dose 2550 mg	
Glutmetza (ER)	Biguanide	PO: 500–2000 mg once daily (2000 mg/day max)	
 pioglitazone (Actos)	Thiazolidinedione	PO: 15–45 mg once daily	
repaglinide (GlucoNorm)	Meglitinide	PO: 0.5–4 mg tid; best taken 15 min before a meal; max daily dose 12 mg/day	
sitagliptin phosphate monohydrate (Januvia)	DPP-4 inhibitor	PO: 100 mg daily	
empagliflozin (Jardiance)	SGLT-2 inhibitor	PO: 10–25 mg once daily	
liraglutide (Victoza)	GLP-1 agonist	SC: 0.6–1.8 mg once daily	
Combination Oral Drugs			
rosiglitazone/metformin (Avandamet)	Combination thiazolidinedione/biguanide	PO: 4 mg /500 mg–8 mg/2000 mg bid	
sitagliptin/metformin (Janumet®)	Combination incretin mimetic/biguanide	PO: 50 mg/500 mg–50 mg/850 mg–50 mg/1000 mg bid with meals	
Sitagliptin/metformin ER (JanumetXR®)	Combination incretin mimetic/biguanide modified release	PO: 50 mg/500 mg–50 mg/1000 mg–100 mg/1000 mg once daily with meals	
saxagliptin/metformin (Kombiglyze®)	Combination incretin mimetic/biguanide	PO: 2.5 mg/500 mg–2.5 mg/850 mg–2.5 mg/1000 mg bid with meals	
linagliptin/metformin (Jentadueto®)	Combination incretin mimetic/biguanide	PO: 2.5/500 mg–2.5/850 mg–2.5/1000 mg bid	
alogliptin/metformin (Kazano®)	Combination incretin mimetic/biguanide	PO: 12.5 mg/500 mg–12.5 mg/850 mg–12.5 mg/1000 mg bid with meals	

ER, extended release; MR, modified release; PO, oral.

Pharmacokinetic Bridge to Nursing Practice

Continuous subcutaneous insulin infusion (CSII) has been used in patients with type 1 diabetes for over 25 years. Provision of insulin therapy by CSII is becoming an option for selected patients with diabetes in an attempt to minimize the risks and complications of the disease. Two options for achieving intensive diabetes management are used: basal–bolus regimens (long-acting basal insulin analogues and rapid-acting bolus insulin analogues) and CSII. With CSII, normal serum glucose levels are maintained by the continuous delivery of basal insulin, and then with food intake, primarily carbohydrate consumption, bolus doses of insulin are given. Use of an insulin pump (i.e., CSII) leads to a more rapid, consistent absorption of the drugs and a reduction in the occurrence of hypoglycemia. Research has also shown that use of an insulin pump helps to decrease the occurrence of elevated prebreakfast serum glucose levels, often called the *dawn phenomenon* (referring to the dawn of the day). The dawn phenomenon occurs when the counter-regulatory hormones (i.e., growth hormone, cortisol, and catecholamines) stimulate the liver to release glucose. By contrast, the Somogyi effect occurs when the same hormones are released in response to a low early morning plasma glucose level, which can result in an early morning

hyperglycemia. In these instances, hyperglycemia is caused by an excess of insulin, poorly timed insulin (including inadvertent insulin administration), or missed meals or snacks. Because insulin pumps deliver insulin through the subcutaneous route and the infusion is a continuous one, fewer problems occur with the pump method than with once- or twice-daily injections. Patients using CSII achieve mean serum glucose and HbA_{1C} levels that remain somewhat lower than those associated with basal–bolus therapy alone, so their risk for hypoglycemia is decreased. The use of CSII with a continuous glucose sensor results in improved plasma glucose control over basal–bolus therapy. Understanding new and different drugs and their pharmacokinetic properties allows the nurse to help patients achieve a better quality of life, minimize risks, and maximize wellness.

❖ NURSING PROCESS

◆ ASSESSMENT

Before administering any type of antidiabetic drug, assess the patient's knowledge about the disease and recommended treatment. Complete a head-to-toe physical assessment, medication history, and nursing assessment, and document the findings.

Prior to beginning treatment with insulin, as well as that with antidiabetic drugs, take a thorough medication history that includes a list of the patient's current medications, including over-the-counter (OTC) drugs and natural health products. Review the appropriate laboratory test results (e.g., plasma glucose, fasting plasma glucose level, A_{1C} level) for any abnormalities compared with baseline levels. Assess the health care provider's order for insulin so that the correct drug, route, type of insulin (e.g., rapid acting, short acting, intermediate acting, short- and intermediate-acting mixtures, long acting), and dosage are implemented correctly. Assess the specific insulin, paying additional attention to its unique pharmacokinetics, including onset of action, peak, and duration of action. Knowing this information prior to giving the insulin is crucial to patient safety because these drug properties actually define the parameters within which reactions, adverse effects, or therapeutic effects may potentially occur. If more than one insulin type is prescribed, mixing of insulins may be ordered. It is important for the nurse to know what combinations are chemically compatible (see Table 33.4) so as to avoid an undesirable altered glycemic effect. Additionally, with all insulin orders, perform a second check of the prepared insulin dosage against the medication order with another registered nurse, or perform checks per facility policy and document accordingly.

Assess blood glucose levels prior to administering insulin to avoid giving the drug to a patient who is already hypoglycemic. Diabetes Canada guidelines identify the key diagnostic criterion for diabetes as a fasting plasma glucose of greater than 7 mmol/L or an HbA_{1C} greater than 6.5% (see Box 33.1). Furthermore, Diabetes Canada recommends the following control criterion for most patients with type 1 or type 2 diabetes: fasting blood glucose within the range of 4 to 7 mmol/L or an HbA_{1C} of less than 7%. Diabetes Canada recommends more lenient target HbA_{1C} values of 7.1–8.5% for the following people with: functional dependency to anti-hyperglycemic agents, recurrent severe hypoglycemia especially if accompanied by hypoglycemia unawareness, limited life expectancy, and frail elderly and/or with dementia. Keep in mind that allergic reactions are less likely to occur with recombinant human insulins because of their similarity to endogenous insulin; however, allergies may still occur and have to be considered in the assessment. Contraindications and cautions associated with insulin have been previously discussed. Significant drug interactions are presented in Table 33.5; nonetheless, it is important to remember the drugs that work against the effect of insulin, including corticosteroids, thyroid drugs, and diuretics. Drugs that increase the hypoglycemic effects of insulin include alcohol, sulfa antibiotics, and salicylates.

Oral antihyperglycemic drugs also require close assessment for contraindications, cautions, and drug interactions, so it is important to obtain a thorough medication and patient history before administering these. Make sure to know each patient's history because type 2 diabetes can be treated with oral antihyperglycemic drugs, most of which require functioning β -cells in the pancreas. Functioning β -cells are not present in type 1 diabetes. With biguanides, be aware that older adults or malnourished patients may react adversely to this group of drugs. Contraindications, cautions, and interactions for this drug class have been previously discussed; in addition, it is important to patient safety to emphasize the interaction between metformin and the iodine-containing

radiological contrast media used for certain diagnostic purposes (e.g., CT with contrast). This interaction is associated with an increased risk for acute kidney injury and lactic acidosis. If a patient is taking metformin, closely assess and monitor for this scenario so that the metformin may be discontinued the day of the test and for at least 48 hours afterward. See Table 33.5 for more drug interactions associated with the oral antihyperglycemic drugs.

With sulfonylureas, it is important to know baseline glucose levels and conditions that may predispose a patient to hypoglycemia, such as a drop in caloric intake, alcohol use, changes in exercise, or advanced age. As well, assessment of allergic reactions to sulfonamide antibiotics is important because of the potential for cross-allergic reactions. With glinides, cautions, contraindications, and drug interactions are similar to those for sulfonylureas. With thiazolidinediones (glitazones), a major contraindication is class III or IV heart failure (as per the New York Heart Association classification). With α -glucosidase inhibitors (e.g., acarbose), assess for contraindications such as inflammatory bowel disease or malabsorption syndromes. With second-generation sulfonylureas, determine the patient's type of diabetes because these drugs are contraindicated in type 1 diabetes.

Exenatide, an incretin mimetic, requires assessment of the patient's diagnosis because the drug is used for patients with type 2 diabetes and an inability to control blood glucose levels with metformin, a sulfonylurea, or a glitazone.

For patients with diabetes, unstable serum glucose levels require immediate attention; assess for any signs and symptoms of hypoglycemia (e.g., acute onset of confusion, irritability, tremor, and sweating, with progression to possible hypothermia and seizures, and blood glucose levels of less than 4 mmol/L) or of hyperglycemia (e.g., polyuria, polydipsia, polyphagia, glucosuria, weight loss, and fatigue, with plasma glucose levels of 14 mmol/L or higher). Assessment is even more critical for patients with diabetes who are also under stress, have an infection or are ill, are pregnant or lactating, or are experiencing trauma or any serious change in health status. With treatment, patients with hyperglycemia are at risk of hypoglycemia with the potential danger of loss of consciousness; therefore, it is important to constantly assess serum glucose levels and neurological status. Along with assessment of the therapeutic regimen and patient adherence to treatment, note any relevant ethnocultural factors, socioeconomic factors, and sources of social support, and continue to be aware of these throughout therapy.

Glucose-elevating drugs are to be given only after thorough assessment of a patient's presenting clinical picture and a thorough collection of data, including laboratory values, medication and health history, and a comprehensive list of current medications. Also assess for level of consciousness. Because glucagon injection may induce vomiting, and precautions must be implemented to prevent aspiration.

◆ NURSING DIAGNOSES

- Inadequate imbalanced nutrition, less than body requirements, as a result of the body's inability to use glucose (for type 1 diabetes)

- Reduced family therapeutic regimen management as a result of lack of experience with a significant daily treatment regimen for diabetes
- Potential risk for unstable glucose as a result of recent onset of possible signs and symptoms of diabetes

◆ PLANNING

◆ Goals

- Patient will maintain adequate and balanced nutrition, stabilizing weight and improving dietary habits, in support of the overall management of diabetes.
- Patient and family will state the importance of adherence to medication regimens, lifestyle changes, dietary restrictions, and avoidance of high-risk behaviours.
- Patient will begin to understand the etiology of unstable glucose levels and learn management strategies.

◆ Expected Patient Outcomes

- Patient adheres to the diet recommended by Diabetes Canada, *Canada's Food Guide* (Health Canada, 2019), or other dietary advisor per the orders of the health care provider or registered dietitian.
 - Patient eats a nutritious diet, gets sufficient rest and relaxation, and notifies a health care provider if any unusual problems occur when customary activities are changed.
- Patient and family report improvement in adherence to therapeutic regimen and disease management, demonstrating awareness of the potential complications and keeping all scheduled appointments with the health care provider to monitor therapeutic effectiveness of drug therapy, diet, and lifestyle changes.
 - Patient takes medication as scheduled, monitors plasma glucose levels as prescribed, and watches for any signs and symptoms of hyperglycemia or hypoglycemia.
 - Patient's fasting plasma glucose (i.e., after 8 hours without food) goal is to be within the range of 4 to 7 mmol/L or HbA_{1C} less than 7%.

◆ IMPLEMENTATION

With any patient who is taking insulin (or oral antihyperglycemic drugs), always check plasma glucose levels (and other related laboratory values, as ordered) before giving the drug so that accurate baseline glucose levels are obtained and documented. Do not shake NPH (which appears cloudy) or premixed insulin mixtures, but roll them between the hands before administering the prescribed dose. Rolling helps to avoid air being trapped in the syringe and thus inaccurate dose administration. Administer insulins at room temperature. If insulin is to be used within 1 month, it may be stored at room temperature; otherwise, refrigeration is needed. Refrigeration is also recommended in warm or hot climates and during any major changes in environmental temperatures from hot to cold. Never use expired or discoloured insulin. For information about the handling, mixing, storage, and administration of insulin, refer to [Box 33.2](#).

Administer insulin subcutaneously at a 90-degree angle unless the patient is emaciated, in which case it may be administered at a

45-degree angle. Only regular insulin may be administered intravenously; this method is often used in critical care settings. Use insulin syringes only for subcutaneous injections or when drawing up insulin dosage amounts. These syringes are easy to identify because of their orange caps and calibration in units, not millilitres. These syringes have preattached ultrafine needles that are 29 gauge and 12.7 millimetres in length (these are not changed after withdrawing the insulin). If mixed insulins are ordered, withdraw the regular or rapid-acting insulin (unmodified and clear) first, followed by the intermediate-acting or NPH insulin (modified and cloudy). Do this only after the appropriate amount of air has been injected into the vials. The amount of air to inject into the vials equals the prescribed number of units. Inject air into the intermediate-acting insulin vial first. Next, inject air into the regular, rapid-, or short-acting insulin vial. This technique helps keep the intermediate-acting insulin from contaminating the rapid-acting insulin vial. This contamination would lead to a change in the regular, rapid-, or short-acting, unmodified insulin by the NPH, intermediate-acting, modified insulin. The net effect is an interference with the activity of the regular insulin, thus impacting its effect in the patient (see [Table 33.3](#) and [Chapter 10](#)).

Understanding the action of types of insulin and their related pharmacokinetics (e.g., onset, peak, duration) is critical for safe care and for patient education. For example, it is important to know that the rapid-acting insulins (insulin lispro, insulin aspart, insulin glulisine) have an onset of action of about 15 minutes and must be given 15 minutes before meals, compared with regular insulin or a short-acting insulin, which should be given 30 minutes before meals, as their onset of action is 30 to 60 minutes. If insulin lispro is to be mixed with NPH (intermediate-acting) insulin, give the combination 15 minutes before meals. Always double-check the health care provider's orders for clarification of the dosage and drug as well as of any dietary changes, such as a possible increase in carbohydrates and decrease in fat to avoid postprandial hypoglycemia). A meal high in fat can delay carbohydrate absorption, while rapid-acting insulin is already in its peak action.

Regardless of the specific type of recombinant human insulin used, understanding the peak, onset, and duration of action of the insulin (e.g., rapid acting versus short acting versus intermediate acting versus long acting) will help determine when food or meals are to be taken. The intermediate-acting insulin (NPH) has an onset of action of 1 to 2 hours, so meals should be served at least 30 to 45 minutes prior to its administration. Many combination products of rapid- or short-acting insulins with intermediate-acting insulin are available; give these combination insulins 15 to 30 minutes before meals. In the hospital setting, be sure that meal trays have arrived on the unit before giving insulin, to avoid time lapses from unexpected delays and subsequent hypoglycemic episodes. Also be sure that other forms of allowed foods are available to patients in case meals are delayed and insulin has already been administered.

Patients may require dosing by the sliding-scale or a basal-bolus method in a hospital setting. Sliding scale has historically been the method for administering subcutaneous regular insulin doses adjusted according to serum glucose test results. Although controversial (see previous pharmacology discussion),

BOX 33.2 Administration, Handling, and Storage of Insulin**Dosages, Storage, Handling, and Mixing**

1. Individualize insulin dosages and monitor patients closely for adequate control of hypoglycemia and hyperglycemia. Follow guidelines for basal–bolus insulin therapy or sliding-scale dosing, depending on the specific regimen to be used in the hospital setting.
2. Adjust dosages, as ordered, to achieve the health care provider's specific fasting plasma glucose level for the patient. Using the Diabetes Canada guidelines, this would be a fasting blood glucose level of 4 to 7 mmol/L or hemoglobin A_{1c} less than 7% for the patient with diabetes.
3. Store insulin for current use at room temperature. Avoid extreme temperatures and exposure to sunlight because these cause the insulin's protein structure to be permanently denatured. Extra vials not in use may be stored in the refrigerator. Vials being used in high environmental temperatures need to be stored in a refrigerator, but never give cold insulin. Never freeze insulin. To maintain drug stability, store insulin for only up to 1 month at room temperature or up to 3 months in the refrigerator.
4. Discard unused vials if they have not been used within several weeks (or follow hospital policy). Do not use any insulin that does not have the proper clarity or colour (e.g., clear for regular, cloudy for NPH).
5. Store prefilled insulin syringes in a refrigerator for up to 1 week.
6. Always check expiration dates of insulin and all equipment.

Administration

1. Administer insulin subcutaneously (see [Chapter 10](#)); however, regular insulin may be given intravenously in special situations (e.g., in postoperative patients, as a continuous infusion in a patient with DKA), if ordered.
2. Roll the drug vial gently between the hands without shaking to avoid bubble formation in the vial, which may lead to inaccurate dosage withdrawal. Give freshly mixed insulins within 5 minutes of mixing to avoid binding of the solution and subsequent altered activity of the drugs.
3. Administer insulin at the recommended times but always with meals or meal trays ready. Give insulin lispro and other rapid-acting insulins approximately

15 minutes before meals (due to quick onset of action) and only after monitoring the patient's fasting serum glucose level (as with all insulin administration). Give regular insulin (short-acting insulin) 30 minutes before meals, and NPH insulin 30 to 60 minutes before meals.

4. When giving regular and NPH insulin at the same time (if ordered), mix the two appropriately (see discussion of mixing insulins in the Implementation subsection under Nursing Process). This mixture is usually given at least 30 minutes before mealtime.
5. Administer insulin subcutaneously at a 90-degree angle. However, if the patient is emaciated, a 45-degree angle may be more effective. Use only insulin syringes (see text discussion and [Chapter 10](#)).
6. Instruct patients using insulin injections to rotate sites within the same general location for about 1 week before moving to a new location (e.g., all injections for a week in the upper right thigh before moving a little lower on the right thigh). This technique allows for better insulin absorption and prevents the development of lipodystrophy (see below). Each injection site should be at least 1.25 to 2.5 centimetres away from the previous injection site. If this practice is followed, it will be approximately 6 weeks before the patient will have to rotate to a totally new area of the body. Note the following sites for subcutaneous insulin injections: thigh areas (front and back), outer areas of the upper arm (middle third of the upper arm between the shoulder and the elbow) and the abdominal area using the iliac crests as landmarks and using the fatty part of the abdomen, but not within 5 centimetres of the umbilicus or any incision or stoma (see [Chapter 10](#)).

Lipodystrophy is characterized by small nodules (lipomas) or scar tissue within the skin. Lipodystrophy occurs less frequently with insulin analogues but can still occur. It is caused by the anabolic effect of insulin on fat and protein synthesis and is the result of injecting insulin in the same site rather than rotating sites. Insulin absorption will be altered in areas of lipodystrophy.

7. Continuous subcutaneous insulin infusion or multiple daily injections may be ordered for tight glucose control. Date the multiuse insulin vial when opened and refer to agency policies for expiration dates.

sliding-scale dosing may be used for hospitalized patients with diabetes who are experiencing drastic changes in plasma glucose levels due to physical or emotional stress, infections, surgery, acute illness, inactivity, or variable caloric intake, as well as for patients needing intensive insulin therapy, or for patients—even those without diabetes—receiving TPN with a high glucose concentration. When this insulin regimen is used, measure blood glucose levels several times per day (e.g., every 4 hours, every 6 hours, or at specified times, such as 0700 hours, 1100 hours, 1600 hours, and midnight) to obtain fasting or preprandial blood glucose values. The newer method, basal–bolus insulin dosing, is now the preferred method of treatment for hospitalized patients with diabetes; orders for dosages and frequency will be issued by the health care provider. A long-acting insulin (insulin glargine) is used to mimic the basal secretion of a healthy pancreas and to create constant delivery of an amount of insulin, and then the bolus is used (insulin lispro or insulin aspart) to control increases in daily blood glucose levels. Bolus insulin is divided into meal and correction boluses (see pharmacology discussion). Monitor blood glucose levels frequently when using these methods.

Oral antihyperglycemic drugs are usually administered at least 30 minutes before meals, as ordered. With any antihyperglycemic drug or insulin, it is important for the nurse and patient to know what to do if symptoms of hypoglycemia occur; for example, the patient should take glucagon; eat glucose tablets, liquid, or gel;

consume corn syrup or honey; drink fruit juice or a nondiet soft drink; or eat a small snack, such as crackers or half a sandwich (see previous discussion on hypoglycemia). If a patient receiving metformin is to undergo diagnostic studies with contrast dye, the health care provider will need to discontinue the drug prior to the procedure and restart it after the tests, only after re-evaluation of the patient's kidney status. During therapy with metformin, the risk of lactic acidosis is possible, so it is important to monitor for and then report any hyperventilation, cold and clammy skin, muscle pain, abdominal pain, dizziness, or irregular heart-beat. Some of the sulfonylureas are to be taken with breakfast; the α -glucosidase inhibitors are always taken with the first bite of each main meal, and the thiazolidinediones are given once daily or in two divided doses. Always check the exact timing of the dose against the health care provider's order and with consideration of the drug's onset of action.

It is critical to the safe and efficient use of oral antihyperglycemics to be certain, before the dose is given, that food will be tolerated or is being tolerated. If the oral drug is taken and no meal is consumed or it is consumed at a later time than usual, hypoglycemia may occur and result in negative health consequences and even unconsciousness. Because the glitazones (i.e., rosiglitazone maleate and pioglitazone) may both cause moderate weight gain and edema, it is important to weigh patients daily at a consistent time and with the same amount of clothing.

Several combination oral antihyperglycemic drug products are available (see the pharmacology discussion) and need to be given exactly as prescribed. Exenatide is given by subcutaneous injection in patients with type 2 diabetes and cannot be used with insulin. Sitagliptin phosphate monohydrate is also not to be used with insulin and may be taken with or without food.

In special situations, such as when a patient has been ordered to have nothing by mouth (NPO status) and is taking either an oral antihyperglycemic drug or insulin, it is crucial to follow the health care provider's orders regarding drug administration. If there are no written orders related to this situation, contact the health care provider for further instructions. If a patient is on NPO status but is receiving an IV solution of dextrose, the health care provider may still order insulin, but always clarify this with the health care provider. Contact the health care provider if a patient becomes ill and unable to take the usual dosage of an

oral antihyperglycemic drug (or insulin). Encourage patients to always wear a medical alert bracelet, necklace, or tag indicating their diagnoses, medications, and emergency contacts.

It is also important to stay informed and up to date about the latest research on diabetes and to keep patients and family members well informed, although many patients already will be. The patient needs to be considered a member of the team when making decisions about diabetes management. A knowledgeable patient will have better long-term glycemic control. See the Evidence in Practice box for more information on specific nursing research.

In summary, there are many nursing considerations related to drug therapy in patients with diabetes. Patient education is also important and needs to begin the moment the patient has entered into the health care system or upon diagnosis. Instruction that is tailored to each patient's educational level and that uses appropriate teaching–learning concepts and

EVIDENCE IN PRACTICE

Sensor-Augmented Insulin Pump Therapy Trumps Multiple Daily Injections

Review

In patients with type 1 diabetes and poor glycemic control, the use of a sensor-augmented insulin pump significantly improves glycated hemoglobin levels as compared with regimens involving multiple daily insulin injections. Landmark research has confirmed that more effective glycemic control has been demonstrated with the use of these pumps than with the use of multiple daily injections.

Type of Evidence

Some 329 adults and 156 children were randomly assigned to either begin pump therapy with the MiniMed Paradigm REAL-Time system (Medtronic®) or continue with their regimen of multiple daily injections; patients were under close supervision for the duration of the study that lasted for 1 year. Patients in the study received intensive diabetes management education and training, including regarding carbohydrate counting and the administration of correction doses of insulin. Those who were randomized to insulin pump therapy were placed on it for 2 weeks. After they had become comfortable with using the pump, the glucose sensor was added. This group used the insulin aspart, and the injection therapy group used both insulin aspart and insulin glargine. All patients were seen at 3, 6, 9, and 12 months and used Carelink, which is a diabetes-management software program. This program was used to relay the patients' glucose data to their health care providers from home. The patients needed to have computer access in order to participate in the study. The sensor-augmented pump therapy uses the two technologies of an insulin pump and continuous glucose monitoring all in one system. This pump allows patients and their health care providers to monitor treatment and their response through Internet-based software.

Results of Study

After 1 year, the researchers found that the patients on pump therapy had hemoglobin A_{1c} levels that were significantly lower than those of the injection-therapy group. The baseline mean glycated hemoglobin level, which was initially 8.3% in the two groups, decreased to 7.5% in the pump-therapy group as compared to 8.1% in the injection-therapy group. Among the adults, the absolute reduction in the mean glycated hemoglobin level was $1.0 \pm 0.7\%$ in the pump-therapy group and $0.4 \pm 0.8\%$ in the injection-therapy group. The between-group difference in the pump-therapy group was -0.6% . The occurrence of hypoglycemia and DKA were similar in both groups. There was no significant weight gain in adult or child participants.

Link of Evidence to Nursing Practice

This study has been identified as one of the longest and largest randomized controlled studies of sensor-augmented insulin pump therapy in patients with type 1 diabetes. Another significant aspect of this study was its comparison of two therapeutic approaches. For nursing and for the care of patients with diabetes, the impact of this study is important, as it indicated that patients may be able to achieve better control of their diabetes, with improved outcomes and safety, through the use of pump therapy. Such favourable results, without the occurrence of increased hypoglycemia, represent an important breakthrough in the care of patients with type 1 diabetes. The possibility of improving patients' adherence to treatment and enhancing their quality of life is exciting; the results of this study hold great promise for enhancing evidenced-informed nursing practice and the treatment of type 1 diabetes.

CASE STUDY

Diabetes

Joseph is a 58-year-old bus driver who received a diagnosis of type 2 diabetes 10 years ago; he has needed to take insulin for the last 2 years. He has been recovering, without complications, from a laparoscopic cholecystectomy; however, his plasma glucose levels have shown significant fluctuations over the last 24 hours.

The health care provider has changed his insulin to lispro (Humalog) to evaluate whether this improves control of his plasma glucose levels.

1. What is the rationale for the use of oral antihyperglycemic drugs in a patient with type 2 diabetes? Why do some patients with type 2 diabetes need to begin taking insulin? What can be done to measure the control of a patient's diabetes over the short term and long term?
2. What are the pharmacokinetics of insulin lispro?
3. What special instructions, if any, should be given to Joseph about insulin lispro before he is discharged home from the hospital?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

teaching aids is important to support patient adherence to the treatment regimen. In addition, nurses need to be sure that all necessary resources are made available to patients (e.g., financial assistance, visual assistance, dietary plans, daily menus, Diabetes Canada information, transportation assistance, Meals on Wheels, other community services). See Patient Teaching Tips for more information.

◆ EVALUATION

It is important to understand current therapeutic guidelines in the care of patients with diabetes. The prevailing key diagnostic criterion for diabetes is hyperglycemia with a fasting plasma glucose of 7 mmol/L or higher or a nonfasting blood glucose level of 11.1 mmol/L or higher. However, the therapeutic response to insulin and any of the oral antihyperglycemic drugs is a decrease in plasma glucose to the level prescribed by the health care provider or to near-normal levels. Most often, fasting plasma glucose levels are used to measure the degree of glycemic control achieved. Both fasting plasma glucose and postprandial plasma glucose are directly correlated

to the risk of complications. The postprandial measure may indicate a stronger risk factor for cardiovascular complications than fasting levels. To estimate a patient's adherence to the therapy regimen for the previous several months, the level of A_{1C} is measured. This value reflects how well the patient has been managing diet and drug therapy. Patients with diabetes need to be monitored frequently by their health care providers (as well as at home) to make sure they are adhering to their therapy regimens, evidenced by normalization of plasma test results. It is important to monitor patients for indications of hypoglycemia or hyperglycemia and insulin allergy as well. With short-acting insulins such as lispro, the onset of action is more rapid than with regular insulin and the duration of action is shorter, so plasma glucose levels need to be monitored closely until the dosage is regulated and plasma glucose is at the level the health care provider desires. If a patient is switched from one insulin or oral antihyperglycemic drug to another, advise the patient that glucose levels must be monitored closely at home or by the health care provider. Always evaluate whether identified goals and expected outcome criteria are being achieved, and plan nursing care accordingly.

PATIENT TEACHING TIPS

- Encourage patients to wear medical alert jewellery, to carry a medical alert card or electronic device with important relevant information, including diagnoses, medications, and allergies, at all times, and to keep medical information in clear view at home on the refrigerator.
- Provide instructions and demonstrations to patients regarding the proper storage of insulin, the equipment needed for administration, the drawing up and mixing of insulins (if ordered), correct technique for insulin injections, and the importance of rotation of subcutaneous insulin injection sites. Provide the opportunity for return demonstrations from patients, including of site rotation (see [Chapter 10](#) for more information about insulin injections). Emphasize that insulin may be stored at room temperature unless heat is extreme or the patient is travelling. Encourage the patient to keep a daily dietary intake and blood glucose journal. Agency policy often includes the use of alcohol to cleanse the skin prior to injection for infection control purposes, although patients often do not use alcohol in their own environments.
- Educate patients about the need to have plasma glucose levels monitored. Emphasize instructions that are specific to the patient's glucometer. Stress the importance of exercise, hygiene, foot care, dietary plans, and weight control in the management of diabetes. Remind patients that illness can cause elevated plasma glucose levels; they should monitor levels closely and seek advice if unsure about managing the illness and the elevated plasma glucose levels but must not stop taking antidiabetic medications. Educate patients about sick day management, monitoring glucose levels, and advising when to administer and hold certain medications.
- Pay attention to and assess patients' financial situation when teaching about the frequency of blood glucose monitoring. Each blood glucose check costs over \$1, and if patients must pay for supplies, this expense can add up quickly, especially for those who are economically disadvantaged. There is a wide variation in access to diabetes medications, supplies, and medical devices listed on federal, provincial, and territorial formularies. Provincial or territorial drug plans provide Canadians with diabetes who are over the age of 65 or receiving social assistance with access to diabetes medications, devices, and supplies listed on provincial formularies. Many provinces and territories provide drug and supplies coverage through income-related deductibles and copayment programs. Provinces and territories may have financial assistance programs for diabetes-related expenses not otherwise covered.
- Advise patients to avoid smoking and alcohol consumption while using oral antihyperglycemic drugs, as well as to maintain strict adherence to dietary instructions. Instruct patients to avoid skipping meals or skipping doses of insulin or oral antihyperglycemic drugs and to contact a health care provider for further instructions when needed.
- Explain the difference between hypoglycemia and hyperglycemia (see earlier text discussion for specific signs and symptoms) to patients, with emphasis on the treatment of each (e.g., having on hand quick sources of glucose such as candy; sugar packets; OTC glucose tablets, liquid, or gel; sugar cubes; honey; corn syrup; apple juice; or nondiet soft drinks for hypoglycemia, and having more insulin on hand for hyperglycemia, as ordered). Especially, encourage patients to have quick dosage forms of glucose available at all times.
- Educate patients about situations or conditions that lead to altered serum plasma glucose levels, such as fever, illness, stress, increased activity or exercise, surgery, and emotional distress. Encourage patients to contact their health care provider regarding any questions or concerns about maintaining glucose control.

- Educate patients about the importance of knowing preprandial plasma glucose levels prior to taking insulin and the importance of timing meals specifically, taking into account the type of insulin being used.
- Emphasize to patients the importance of having adequate supplies of insulin and equipment at all times and planning ahead for vacations. Instruct patients to keep all medications and related equipment out of the reach of children. If needed, magnifying attachments are available for syringes and vials, and specialized syringes are available for people with vision impairments. Patients using these types of syringes learn to rely on the sound the syringe makes when a dosage is selected; for example, with a Novolog pen, 5 clicks equals 5 units.
- Encourage patients with diabetes to report any yellow discoloration of the skin, dark urine, fever, sore throat, weakness, unusual bleeding, or easy bruising.
- Emphasize to patients the importance of A_{1C} monitoring (e.g., at least two times per year for those with good glycemic control and quarterly for patients who are not at target values, have changed their therapy, or are not adhering to the therapy regimen). Review lifestyle modifications that support weight control and plasma glucose level maintenance, including changes in diet and exercise as well as drug therapy. Patients with type 2 diabetes have greater therapeutic responses to improvements in diet, exercise, and plasma glucose level control than patients with type 1 diabetes do. Diabetes Canada recommendations for measurement of fasting plasma glucose level need to be followed. Educate patients about the importance of engaging in supervised exercise as prescribed, as a lifelong lifestyle change. A registered dietitian is usually involved in patient care and assists with specific menu planning to help with changes in intake (e.g., implementing a low-fat diet with 160 to 300 g of carbohydrates). Nutrition therapy can reduce A_{1C} by 1 to 2% when combined with other aspects of diabetes management. Initially, encourage patients to follow a healthy diet plan using Health Canada's publication, *Canada's Food Guide* (Health Canada, 2019). Educate patients about replacing high-glycemic index foods with low-glycemic index foods, and explain that, in doing so, they will improve glycemic control. Examples of typical low-glycemic index food sources include beans, peas, lentils, pasta, pumpnickel or rye breads, parboiled rice, bulgur, barley, oats, quinoa, and fruits such as apples, pears, oranges, peaches, plums, apricots, cherries, or berries. Examples of higher-glycemic index foods include white or whole wheat bread, potatoes, highly extruded or crispy puffed breakfast cereals (e.g., corn flakes, puffed rice, puffed oats, puffed wheat), and fruits such as pineapple, mango, papaya, cantaloupe, and watermelon. Educate patients that a higher intake of fibre, in particular cereal fibre, is associated with a decreased risk for cardiovascular disease and that a higher intake of soluble dietary fibre (e.g., eggplant, okra, oat products, beans, psyllium, barley) improves postprandial plasma glucose because it slows gastric emptying and delays the absorption of glucose in the small intestine.
- Emphasize the importance of Diabetes Canada recommendations for patients with diabetes, including 150 minutes of moderate- to vigorous-intensity aerobic exercise each week, spread over at least 3 days of the week, with no more than 2 consecutive days without exercise. Resistance exercise should be included at least two times per week.
- Emphasize that therapy will be lifelong and that strict management of plasma glucose control, drug therapy, and lifestyle changes are critical to preventing and reducing the complications of diabetes.
- Stress the importance of strict foot care to patients and others involved in their care. Begin with discussing the need for a daily basic assessment of feet and toes to check for sores, lesions, cuts, bruises, ingrown toenails, and any other changes. Foot care is needed to enhance circulation and prevent infections. It may include soaking the feet daily or as ordered in lukewarm water (the temperature of the water must be checked), followed by adequate drying of the feet and application of moisturizing lotion. The feet and legs should be checked for abnormal changes in colour (e.g., purplish or reddish discoloration), swelling, the appearance of any drainage, or cool temperature of the feet to the touch. Emphasize the importance of contacting the health care provider for further instructions if there is suspicion of any type of wound or alteration in skin integrity. Frequent pedicures and nail trimming by a podiatrist or other licensed, certified individual may be indicated.
- Some of the oral antihyperglycemic drugs cause photosensitivity, so instruct patients to wear protective sunblock and appropriate clothing when exposed to the sun. Advise against the use of tanning beds.

KEY POINTS

- Insulin normally facilitates removal of glucose from the plasma and its storage as glycogen in the liver.
- Little or no endogenous insulin is produced by individuals with type 1 diabetes. It is much less common than type 2 diabetes and affects only about 10% of patients with diabetes. Patients with type 1 diabetes usually are not obese. Because insulin therapy is required for patients with type 1 diabetes, those who have the cognitive and financial ability should be encouraged to consider incorporating an insulin pump with continuous glucose monitoring as part of their therapy. Diabetes Canada is advocating for public funding for insulin pumps because the use of insulin pump technology leads to improved health outcomes for people living with diabetes.
- The primary treatment for individuals with type 1 diabetes is insulin therapy. Patients with type 2 diabetes are initially managed with lifestyle changes (dietary changes, exercise, smoking cessation). If normal blood glucose levels are not achieved after 2 to 3 months of lifestyle changes, treatment with one or more oral antihyperglycemic drugs is often added to the regimen.
- Insulin was originally isolated from cattle and pigs, but bovine and porcine insulins are associated with a higher

incidence of allergic reactions and insulin resistance than human insulin. Porcine insulin is still available in Canada.

- Complications associated with diabetes include retinopathy, neuropathy, nephropathy, hypertension, cardiovascular disease, and coronary artery disease. Annual screening by an ophthalmologist specializing in retinopathies is needed in the care of patients with diabetes. Because of kidney complications (i.e., nephropathies), annual urinalysis screening and kidney function studies are also recommended for patients with diabetes.
- All rapid-acting, short-acting, and long-acting insulin preparations are clear solutions. Intermediate-acting insulins are cloudy solutions. Mixtures of short- and intermediate-acting

insulin still look uniformly cloudy. The cloudy appearance of these mixtures is due to the presence of the intermediate-acting insulin. When used, insulin vials are to be rolled in the hands instead of shaken.

- Always carefully check the exact timing of the dose of insulin or oral antihyperglycemic drug against the health care provider's order. Take into consideration the drug's pharmacokinetics, including onset of action, peak, and duration of action.

Nursing care must be individualized, with patient education focused on the patient's needs and learning abilities. Include pertinent and age-appropriate information on the disease process, drug therapy, and lifestyle modifications.

EXAMINATION REVIEW QUESTIONS

1. The nurse is to administer rapid-acting insulin to a hospitalized patient. Which would be the most appropriate timing for the patient to receive the dose?
 - a. Give it 15 minutes before the patient begins a meal.
 - b. Give it ½ hour before a meal.
 - c. Give it 1 hour after a meal.
 - d. The timing of the insulin injection does not matter with a rapid-acting insulin.
2. The nurse is teaching a patient about type 2 diabetes. Which of the following statements would be most appropriate for the nurse?
 - a. "Insulin injections are never used with type 2 diabetes."
 - b. "You don't need to measure your blood glucose levels because you are not taking insulin injections."
 - c. "A person with type 2 diabetes still has functioning β -cells in the pancreas."
 - d. "Patients with type 2 diabetes usually have better control over their diabetes than those with type 1 diabetes."
3. The nurse monitoring a patient for a therapeutic response to oral antihyperglycemic drugs. What of the following adverse events will the nurse monitor?
 - a. Fewer episodes of diabetic ketoacidosis (DKA)
 - b. Weight loss of 2.3 kg
 - c. Hemoglobin A_{1C} levels of less than 7%
 - d. Glucose levels of 9.5 mmol/L
4. A patient with type 2 diabetes is scheduled for magnetic resonance imaging (MRI) with contrast dye. The nurse is reviewing the orders and notices that the patient is receiving metformin (Glucophage). Which action by the nurse would be most appropriate?
 - a. Proceed with the MRI as scheduled.
 - b. Notify the radiology department that the patient is receiving metformin.
 - c. Expect to hold the metformin the day of the test and for 48 hours after the test is performed.
 - d. Call the health care provider regarding holding the metformin for 2 days before the MRI is performed.
5. A patient with type 2 diabetes has a new prescription for repaglinide (GlucoNorm). After 1 week, the patient contacts the office to ask what to do if there are missed meals. "I work right through lunch sometimes, and I'm not sure whether I need to take it. What do I need to do?" Which of the following would be the nurse's best response?
 - a. "You need to try not to skip meals, but if that happens, you will need to skip that dose of repaglinide."
 - b. "We will probably need to change your prescription to insulin injections because you can't eat meals on a regular basis."
 - c. "Go ahead and take the pill when you first remember that you missed it."
 - d. "Take both pills with the next meal, and try to eat a little extra to make up for what you missed at lunchtime."
6. When checking a patient's blood glucose level, the nurse obtains a reading of 2.3 mmol/L. The patient is awake but states feeling a bit "cloudy-headed." After double-checking the patient's glucose level and getting the same reading, which of the following nursing actions would be most appropriate?
 - a. Administer two packets of table sugar.
 - b. Administer oral glucose in the form of a semisolid gel.
 - c. Administer 50% dextrose IV push.
 - d. Administer the morning dose of insulin lispro.
7. A patient is taking metformin for new-onset type 2 diabetes. When teaching the patient about potential adverse effects, which of the following information would the nurse include? (Select all that apply.)
 - a. Abdominal bloating
 - b. Nausea
 - c. Diarrhea
 - d. Headache
 - e. Weight gain
 - f. Metallic taste

CRITICAL THINKING ACTIVITIES

1. A 25-year-old woman has been diagnosed with type 1 diabetes. She has been placed on a 1 500-calorie diabetic diet and is to be started on insulin glargine. Today she received teaching about her diet, insulin injections, and management of diabetes. She received the first dose of insulin glargine at 9 PM; the next morning she reported feeling “dizzy.” The nurse assesses that she is diaphoretic, weak, and pale, with a heart rate of 110 beats per minute. What is the nurse’s priority action? What is the best explanation for these symptoms?
2. While making morning rounds, the nurse assesses a patient’s ordered medications and finds that the patient is to be given NPH insulin each morning but is also on orders to receive nothing by mouth because of a scheduled surgical procedure. What is the nurse’s priority action at this time regarding administration of the insulin?
3. A patient with type 2 diabetes comes to the emergency department with an acute asthma attack and pneumonia. Her condition is stabilized, and she is admitted to the hospital to receive IV doses of antibiotics and corticosteroids. She says that, before this episode, she took oral drugs for diabetes and had her diabetes “under control,” with fasting plasma glucose levels ranging from 5.6 to 5.9 mmol/L on most mornings. However, the next morning, her fasting plasma glucose level is 9.9 mmol/L, and her glucose levels remain elevated for the next few days. The patient is upset and declares, “I’m hardly eating anything extra. Why is my blood sugar so high?” What is the nurse’s best answer to the patient’s concerns?

Adrenal Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Discuss the normal anatomy, physiology, and related functions of the adrenal glands, including specific hormones released from the glands.
2. Briefly compare the hormones secreted by the adrenal medulla with those secreted by the adrenal cortex.
3. Contrast Cushing's syndrome, Addison's disease, and acute adrenal crisis (addisonian crisis).
4. Compare the glucocorticoids and mineralocorticoids in regard to the roles they perform in normal bodily functions, the diseases that alter them, how they are used in pharmacotherapy, and their basic properties.
5. Contrast the mechanisms of action, indications, dosages, routes of administration, cautions, contraindications, drug interactions, and adverse effects of glucocorticoids and mineralocorticoids.
6. Develop a collaborative plan of care that includes all phases of the nursing process for patients taking adrenal drugs.

KEY TERMS

Addison's disease A potentially life-threatening condition caused by partial or complete failure of adrenocortical function, with resulting decrease in glucocorticoid, mineralocorticoid, and androgenic hormones; a chronic disease of hyposecretion of steroids. (p. 565)

Adrenal cortex The outer portion of the adrenal gland. (p. 563)

Adrenal crisis An acute, life-threatening state of profound adrenocortical insufficiency requiring immediate medical management; characterized by glucocorticoid deficiency, a drop in extracellular fluid volume, hyponatremia, and hyperkalemia. (p. 570)

Adrenal medulla The inner portion of the adrenal gland. (p. 563)

Aldosterone A mineralocorticoid hormone produced by the adrenal cortex that acts on the kidney tubules to regulate sodium and potassium balance in the blood. (p. 564)

Cortex The outer layers of a body organ or structure. (p. 563)

Corticosteroids Any of the natural or synthetic adrenocortical hormones, including those produced by the cortex of the adrenal gland (adrenocorticosteroids). (p. 564)

Cushing's syndrome A metabolic disorder characterized by abnormally increased secretion of the adrenocorticosteroids. (p. 564)

Epinephrine An endogenous hormone secreted into the bloodstream by the adrenal medulla; also a synthetic drug

that is an adrenergic vasoconstrictor and also increases cardiac output. (p. 564)

Glucocorticoids A major group of corticosteroid hormones that regulate carbohydrate, protein, and lipid metabolism and inhibit the release of adrenocorticotrophic hormone (corticotropin). (p. 564)

Hypothalamic–pituitary–adrenal (HPA) axis A negative feedback system involved in regulating the release of corticotropin-releasing hormone by the hypothalamus, adrenocorticotrophic hormone (corticotropin) by the pituitary gland, and corticosteroids by the adrenal glands. Suppression of the HPA may lead to Addison's disease and possible adrenal crisis or addisonian crisis; this suppression results from chronic disease or exogenous sources, such as long-term glucocorticoid therapy. (p. 564)

Medulla The most interior portions of an organ or structure. (p. 564)

Mineralocorticoids A major group of corticosteroid hormones that regulate electrolyte and water balance; in humans, the primary mineralocorticoid is aldosterone. (p. 564)

Norepinephrine An adrenergic hormone, also secreted by the adrenal medulla, that increases blood pressure by causing vasoconstriction but does not appreciably affect cardiac output; the immediate metabolic precursor to epinephrine. (p. 564)

DRUG PROFILES

fludrocortisone 21-acetate, p. 568

methylprednisolone (methylprednisolone sodium succinate)*, p. 568

prednisone, p. 568

Key Drug

ADRENAL SYSTEM

The adrenal gland is an endocrine organ that sits on top of the kidneys like a cap. It is composed of two distinct parts called the **adrenal cortex** and the **adrenal medulla**; they are structurally and functionally different from one another. In general, the term **cortex** refers to the outer layers of various organs (e.g.,

TABLE 34.1 Adrenal Gland: Characteristics

Type of Tissue	Type of Hormone Secreted	Hormones Secreted and Related Drugs
Adrenal Cortex		
Endocrine	Glucocorticoids	Adrenocorticotrophic hormone (ACTH), betamethasone valerate, cortisone acetate, dexamethasone, hydrocortisone acetate, triamcinolone acetonide
	Mineralocorticoids	Aldosterone
Adrenal Medulla		
Neuroendocrine	Catecholamines	Epinephrine, norepinephrine

cerebral cortex), while the term **medulla** refers to the most internal layers. The adrenal cortex comprises approximately 80 to 90% of the entire adrenal gland; the remainder is the medulla. The adrenal cortex is made up of regular endocrine tissue (hormone driven). The adrenal medulla is made up of neurosecretory endocrine tissue (driven by both hormones and peripheral autonomic nerve impulses). Therefore, the adrenal gland actually functions as two different endocrine glands, each secreting different hormones.

The adrenal medulla secretes two important hormones, both of which are catecholamines. These are **epinephrine**, which accounts for about 80% of the secretion, and **norepinephrine**, which accounts for the other 20%. (Both these hormones are discussed in [Chapter 19](#) and are not described in any detail in this chapter.) Characteristics of the adrenal gland and the various hormones secreted by each type of tissue are presented in [Table 34.1](#).

The hormones secreted by the adrenal cortex, which are the focus of this chapter, are broadly referred to as **corticosteroids**. They arise from the cortex and are made from the steroid known as *cholesterol*. There are two types of corticosteroids: **glucocorticoids** and **mineralocorticoids**. They are secreted by two different layers, or zones, of the cortex. The *zona glomerulosa*, the outer layer, secretes the mineralocorticoids, and the *zona fasciculata*, which lies under the *zona glomerulosa*, secretes the glucocorticoids. A third, inner layer, the *zona reticularis*, secretes small amounts of sex hormones. All the hormones secreted by the adrenal cortex are steroid hormones—that is, they have the steroid chemical structure.

The mineralocorticoids get their name from their important role in regulating mineral salts (electrolytes) in the body. In humans, the main physiologically important mineralocorticoid is **aldosterone**. Its primary role is to maintain normal levels of sodium in the blood (sodium homeostasis) by causing sodium to be resorbed from the urine back into the blood in exchange for potassium and hydrogen ions. In this way, aldosterone not only regulates blood sodium levels but also influences potassium and pH levels of the blood.

The glucocorticoids have a broad range of effects and are necessary for many vital bodily functions. They are efficacious

BOX 34.1 Adrenal Cortex Hormones

Biological Functions

Glucocorticoids

- Anti-inflammatory actions
- Carbohydrate and protein metabolism
- Fat metabolism
- Maintenance of normal blood pressure
- Stress effects

Mineralocorticoids

- Blood pressure control
- Maintenance of serum potassium levels
- Maintenance of pH levels in blood
- Sodium and water resorption

anti-inflammatory drugs as they suppress every component of the inflammatory process and play significant roles in carbohydrate, protein, and lipid metabolism, the immune response, and the response to stress. Natural glucocorticoids also have some mineralocorticoid activity and as a result affect fluid and electrolyte balance. Some of the more important functions are listed in [Box 34.1](#). Without these hormones, life-threatening consequences may arise.

Adrenal corticosteroids are synthesized as needed; the body does not store them as it does other hormones. The body levels of these hormones are regulated by the **hypothalamic–pituitary–adrenal (HPA) axis** in much the same way that the levels of hormones secreted by the pituitary, thyroid, and pancreas are regulated. As the name implies, this axis consists of a highly organized system of communication between the adrenal gland, the pituitary gland, and the hypothalamus ([Figure 34.1](#)). As is the case for the other endocrine glands, it uses hormones as the messengers and a negative feedback mechanism as the controller and sustainer of the process. This feedback mechanism operates as follows: When the level of a particular corticosteroid is low, corticotropin-releasing hormone is released from the hypothalamus into the bloodstream and travels to the anterior pituitary gland, where it triggers the release of adrenocorticotrophic hormone (ACTH; also called *corticotropin*). The ACTH is then transported in the blood to the adrenal cortex, where it stimulates the production of the corticosteroids. Corticosteroids are then released into the bloodstream. When they reach peak levels, a signal (negative feedback) is sent to the hypothalamus, and the HPA axis is inhibited until the level of corticosteroids again falls below the physiological threshold, whereupon the axis is stimulated once again ([Figure 34.2](#)).

The oversecretion (hypersecretion) of adrenocortical hormones can lead to a group of signs and symptoms called **Cushing’s syndrome**. This hypersecretion of glucocorticoids results in the redistribution of body fat from the arms and legs to the face, shoulders, trunk, and abdomen, which leads to the characteristic “moon face” (moon facies). Such a glucocorticoid excess can be due to several causes, including ACTH-dependent adrenocortical hyperplasia or tumour, ectopic ACTH-secreting tumour, or excessive administration of steroids. The hypersecretion of aldosterone, or *primary aldosteronism*, leads to increased

Fig. 34.1 Hypothalamic–pituitary–adrenal axis. (From Tucci, V., & Sokari, T. (2014). The clinical manifestations, diagnosis, and management of adrenal emergencies. *Emergency Medical Clinics of North America*, 32(2), 465–484. doi:10.1016/j.emc.2014.01.006)

Hypothalamic–Pituitary–Adrenal (HPA) Axis

Fig. 34.2 Negative feedback control mechanism of adrenocortical hormones.

retention of water and sodium, which causes muscle weakness due to the potassium loss.

The undersecretion (hyposecretion) of adrenocortical hormones causes a condition called **Addison's disease**. Patients with this disease often have vague, chronic, and nonspecific complaints. It is associated with abnormal laboratory values (e.g., hyponatremia, hyperkalemia, hypercalcemia, mild

TABLE 34.2 Available Synthetic Corticosteroids

Type of Hormone	Method of Administration	Individual Drugs
Adrenal steroid inhibitor	Systemic	ketoconazole
Glucocorticoid	Topical	amcinonide, betamethasone dipropionate, betamethasone valerate, clobetasol propionate, desoximetasone, dexamethasone, diflucortolone valerate, fluocinolone acetonide, hydrocortisone acetate, mometasone furoate, prednicarbate, prednisolone acetate, triamcinolone acetonide
	Systemic	betamethasone, dexamethasone sodium phosphate, hydrocortisone sodium succinate, methylprednisolone sodium succinate, prednisolone sodium phosphate, prednisone, triamcinolone acetonide
	Inhaled	beclomethasone dipropionate, budesonide, fluticasone propionate, mometasone furoate
	Nasal	beclomethasone dipropionate, budesonide, flunisolide, fluticasone propionate, mometasone, triamcinolone acetonide
Mineralocorticoid	Systemic	fludrocortisone 21-acetate

hypoglycemia, azotemia, anemia). Clinical signs and symptoms include dehydration, hyperpigmentation, weakness and fatigue, nausea, vomiting, anorexia, and weight loss. A decrease in glucocorticoid production can be caused by inadequate stimulation of the adrenal gland or inability of the adrenals to respond to adrenocortical hormones. The combination of a mineralocorticoid (fludrocortisone 21-acetate) and a glucocorticoid (prednisone or some other suitable drug) is used for treatment.

ADRENAL DRUGS

Most corticosteroids (naturally occurring or synthetic) have both glucocorticoid and mineralocorticoid properties. All of the naturally occurring corticosteroids are available as exogenous drugs. There are also higher-potency synthetic analogues. The adrenal glucocorticoids are an extremely large group of steroids and can be categorized in various ways. They can be classified by whether they are a natural or synthetic corticosteroid by their method of administration (e.g., systemic, topical), by their salt- and water-retention potential (mineralocorticoid activity), by their duration of action (i.e., short, intermediate, or long acting), or by some combination of these methods. The only corticosteroid drug with exclusive mineralocorticoid activity is fludrocortisone 21-acetate. Its uses are much more specific than those of the glucocorticoids and are discussed in the drug profile for fludrocortisone 21-acetate (p. 568). The currently available synthetic adrenal hormones and adrenal steroid inhibitors are listed in Table 34.2.

Mechanism of Action and Drug Effects

The action of the corticosteroids is related to their involvement in the synthesis of specific proteins. There are several steps to this process. Initially, the steroid hormone binds to a receptor on the surface of a target cell to form a steroid–receptor complex, which is then transported through the cytoplasm to the nucleus of that target cell. Once inside the nucleus, the complex stimulates the cell's deoxyribonucleic acid (DNA) to produce messenger ribonucleic acid (mRNA), which is then used as a template for the synthesis of a specific protein. It is these proteins that exert specific effects.

Most of the corticosteroids exert their effects by modifying enzyme activity; therefore, their role is more intermediary than direct. The naturally occurring mineralocorticoid aldosterone affects electrolyte and fluid balance by acting on the distal kidney tubules. It promotes sodium resorption from the nephrons into the blood, which pulls water and fluid along with it. In doing so, it causes fluid and water retention, which leads to edema and hypertension. It also increases urinary excretion of potassium and hydrogen via the kidney.

The glucocorticoid drug hydrocortisone (called *cortisol* in its naturally occurring form) has some mineralocorticoid activity and, therefore, has some of the same effects as aldosterone (i.e., fluid and water retention). However, its main effect is inhibition of inflammatory and immune responses. Glucocorticoids inhibit or help control the inflammatory response by stabilizing the cell membranes of inflammatory cells called *lysosomes*, decreasing the permeability of capillaries to the inflammatory cells and decreasing the migration of white blood cells into already inflamed areas. They may lower fever by reducing the release of interleukin-1 from white blood cells. They also stimulate the erythroid cells that eventually become red blood cells. The glucocorticoids also promote the breakdown (catabolism) of protein, the production of glycogen in the liver (glycogenesis), and the redistribution of fat from the peripheral to the central areas of the body. In addition, they have the following effects on various bodily functions: increasing levels of blood sugar, increasing the breakdown of proteins to amino acids, inducing lipolysis, stimulating bone demineralization, and stabilizing mast cells. The mechanism of bone demineralization is multifactorial but includes reduced calcium absorption in skeletal cells, resulting in secondary hyperparathyroidism.

Indications

All of the systemically administered glucocorticoids have a similar clinical efficacy but differ in their potency, mineralocorticoid and glucocorticoid potency, and duration of action, and in the extent to which they cause salt and fluid retention (Table 34.3). Glucocorticoids have broad indications, including the following:

- Adrenocortical deficiency
- Adrenogenital syndrome
- Allergic disorders (e.g., anaphylaxis)
- Autoimmune blistering diseases
- Bacterial meningitis, particularly in infants
- Cancer
- Cerebral edema
- Collagen diseases (e.g., systemic lupus erythematosus)
- Chronic rhinosinusitis
- Dermatological diseases (e.g., exfoliative dermatitis, pemphigus, severe psoriasis)
- Endocrine disorders (e.g., thyroiditis)
- Gastrointestinal (GI) diseases (e.g., ulcerative colitis, regional enteritis)
- Exacerbations of chronic respiratory illnesses (e.g., asthma, chronic obstructive pulmonary disease)
- Hematological disorders (e.g., autoimmune hemolytic anemia, idiopathic thrombocytopenia; reduce bleeding tendencies)
- Nonrheumatic inflammation (e.g., acute or subacute bursitis, acute tendosynovitis)
- Ophthalmic disorders (decrease nonpyogenic inflammation)
- Organ transplant (decrease immune response to prevent organ rejection)
- Leukemias and lymphomas (palliative management)
- Nephrotic syndrome (remission of proteinuria)
- Rheumatic disorders (e.g., rheumatoid arthritis, psoriatic arthritis, acute gouty arthritis; adjunctive therapy in ankylosing spondylitis)
- Spinal cord injury
- Thyroiditis (e.g., nonsuppurative thyroiditis)

Glucocorticoids are also administered by inhalation for the control of steroid-responsive bronchospastic states. However, glucocorticoid inhalers are not used as rescue inhalers for acute bronchospasm but are for control. Nasally administered glucocorticoids are used to manage allergic rhinitis and to prevent the recurrence of polyps after surgical removal (see

TABLE 34.3 Systemic Glucocorticoids: A Comparison

Drug	Origin	Duration of Action	Equivalent Dose (mg)*	Salt and Water Retention Potential
betamethasone	Synthetic	Long	0.75	Minimal
dexamethasone sodium succinate	Synthetic	Long	0.75	Minimal
hydrocortisone sodium succinate	Natural	Short	20	High
methylprednisolone sodium succinate	Synthetic	Intermediate	4	Low
prednisolone sodium phosphate	Synthetic	Intermediate	5	Low
prednisone	Synthetic	Intermediate	5	Low
triamcinolone acetonide	Synthetic	Intermediate	4	Minimal

*Drugs with higher potency require smaller milligram doses than those with lower potency. This column illustrates the approximate dose equivalency between different drugs that is expected to achieve a comparable therapeutic effect.

Chapter 37). Topical steroids are used in the management of inflammation of the eye, ear, and skin. Methylprednisolone sodium succinate is the most commonly used injectable glucocorticoid, followed by hydrocortisone sodium succinate and dexamethasone sodium succinate. Betamethasone or dexamethasone are the drugs of choice for women in premature labour (before 34 weeks' gestation) to accelerate fetal lung maturation (Skoll, Boutin, Bujold, et al., 2018). They promote the maturation of many vital fetal organs through the action of cortisol that binds to the glucocorticoid receptors of target cells and, therefore, help to decrease the incidence of respiratory distress syndrome and neonatal mortality associated with premature birth. They also increase the effectiveness of surfactant therapy (Msan, Usta, Mirza, et al., 2015).

Contraindications

Contraindications to the administration of glucocorticoids include drug allergy and may include cataracts, glaucoma, peptic ulcer disease, GI bleeding, mental health concerns, and diabetes mellitus. The adrenal drugs may intensify these conditions. For example, one common adverse effect of these drugs seen in hospitalized patients is an increase in blood glucose levels, often requiring insulin. This is not to say that patients with diabetes who require glucocorticoids should not receive them, but it is important to be aware of the potential for increase in blood glucose levels. Because of their immunosuppressant properties, glucocorticoids are often avoided in the presence of any serious infection, systemic fungal infections, and varicella. Exceptions to this rule are septic shock, when low-dose hydrocortisone is added to the treatment regimen for patients with septic shock that is unresponsive to intravenous (IV) fluids and vasopressor therapy, and in tuberculous meningitis, for which glucocorticoids may be used to prevent inflammatory central nervous system damage. Caution is emphasized in treating any patient with gastritis, reflux disease, or ulcer disease, because of the potential of these drugs to cause gastric perforation, as well as in patients with heart, kidney, or liver dysfunction, because of associated alterations in elimination.

Adverse Effects

The potent metabolic, physiological, and pharmacological effects of corticosteroids can influence every body system, so these drugs can produce a wide variety of significant undesirable effects. The more common of these are summarized in Table 34.4. Moon facies is a common adverse effect of long-term use. Two of the adverse effects most commonly seen in hospitalized patients are hyperglycemia and psychosis. The most serious adverse effect of glucocorticoids is adrenal (HPA) suppression, which is discussed in the drug profiles table (p. 568). Because of their ability to cause fluid retention, glucocorticoids should be used with caution in patients with heart failure.

Interactions

Systemically administered corticosteroids can interact with many drugs:

- Their use with non-potassium-sparing diuretics (e.g., thiazides, loop diuretics) can lead to severe hypocalcemia and hypokalemia.

TABLE 34.4 Corticosteroids: Common Adverse Effects

Body System	Adverse Effects
Cardiovascular	Heart failure, edema, hypertension, all due to electrolyte imbalances (e.g., hyperkalemia, hyponatremia); impaired glucose intolerance, dysrhythmias, bradycardia, pulmonary edema, syncope, vasculitis
Central nervous	Convulsions; headache; vertigo; mental health status changes such as mood swings, nervousness, aggressive behaviours, or psychotic symptoms; neuritis peripheral neuropathy; paresthesia; arachnoiditis; meningitis; insomnia
Endocrine	Growth suppression, Cushing's syndrome, menstrual irregularities, carbohydrate intolerance, hyperglycemia, hypothalamic–pituitary–adrenal (HPA) axis suppression (particularly at times of stress as in trauma, surgery, or illness), hirsutism, hypertrichosis (abnormal growth of hair on the body), glycosuria
Gastrointestinal	Peptic ulcers with possible perforation, pancreatitis, ulcerative esophagitis, abdominal distension
Integumentary	Fragile skin, petechiae, ecchymosis, facial erythema, poor wound healing, urticaria, hypersensitivity reactions, acne, dry skin, skin hyperpigmentation, skin striae
Musculoskeletal	Myopathy, muscle weakness, loss of muscle mass, osteoporosis, osteonecrosis of femoral and humeral heads, pathological fracture, malaise
Reproductive	Irregular menstruation, sperm motility abnormalities, abnormal sperm concentration
Ocular	Increased intraocular pressure, glaucoma, cataracts
Other	Weight gain, leukocytosis, opportunistic infections, hypokalemia alkalosis, impaired healing

- Their use with aspirin, other nonsteroidal anti-inflammatory drugs (NSAIDs), and other ulcerogenic drugs produces additive GI effects and an increased chance of gastric ulcer development.
- Their use with anticholinesterase drugs produces weakness in patients with myasthenia gravis.
- Their use with immunizing biologics inhibits the immune response to the biological agent.
- Their use with antidiabetic drugs may reduce the hypoglycemic effects of the latter and result in elevated blood glucose levels.

Many other drugs can interact with glucocorticoids, including thyroid hormones and antifungal drugs (such as fluconazole), which can decrease kidney clearance of the adrenal drug. Barbiturates and hydantoins can increase the metabolism of prednisone and similar drugs. Oral anticoagulants interact with adrenal drugs in ways that can affect the international normalized ratio (INR). Oral contraceptives can increase the half-life of adrenal drugs. Various other drug interactions may be possible between adrenal drugs and over-the-counter (OTC) drugs and natural health products.

Dosages

For dosage information on adrenal drugs, refer to the table on p. 569.

DRUG PROFILES

◆ Corticosteroids

The systemic corticosteroids consist of seven chemically different but pharmacologically similar hormones. They all exert varying degrees of glucocorticoid and mineralocorticoid effects. Their differences are due to slight variations in their chemical structures.

Corticosteroids can cross the placenta and produce fetal abnormalities. For this reason, they are not recommended for use during pregnancy unless the potential benefits outweigh the risk. They can also be secreted in breast milk and cause abnormalities in the nursing infant. Their use is contraindicated in patients who have exhibited hypersensitivity reactions to them in the past, as well as in patients with fungal or bacterial infections. Short- or long-term use can lead to a condition known as *steroid psychosis*. One important point to know about long-term use of steroids is that they must not be stopped abruptly. These drugs require a tapering of the daily dose because their administration causes the endogenous (body's own) production of the hormones to stop. This is referred to as *HPA* or *adrenal suppression*. This suppression can cause impaired stress response and place the patient at risk of developing hypoadrenal crisis (shock, circulatory collapse) in times of increased stress (e.g., surgery, trauma). Adrenal suppression can occur as early as 1 week after a corticosteroid is started. HPA suppression typically does not occur in patients taking prednisone 5 mg/day (or equivalent) or less. Tapering of daily doses allows the HPA axis the time to recover and start stimulating the normal production of the endogenous hormones. Patients on long-term steroid therapy who are taking at least 10 mg/day (or equivalent) of prednisone and who undergo trauma or require surgery need additional doses of steroids (also known as *stress doses*).

It is important to differentiate between corticosteroids and anabolic steroids. Anabolic steroids are hormones, available for oral intake or by injection. These drugs are used for performance-enhancing purposes and to enhance muscle growth. Anabolic steroids act much like testosterone in the body. They increase muscle mass and masculine characteristics.

▶▶ fludrocortisone 21-acetate

Fludrocortisone 21-acetate (Florinef®) is the only available mineralocorticoid. It is used as partial replacement therapy for adrenocortical insufficiency in Addison's disease and in the treatment of salt-losing adrenogenital syndrome. It is contraindicated in cases of systemic fungal infection. Adverse effects generally pertain to water retention and include heart failure, hypertension, and elevated intracranial pressure (potentially leading to seizures). Other possible adverse effects involve several body systems and include skin rash, menstrual irregularities, peptic ulcer, hyperglycemia, hypokalemia, muscle pain and weakness, compression bone fractures, glaucoma, and thrombophlebitis, among others. Drugs with which fludrocortisone 21-acetate interacts include anabolic steroids (increased edema); barbiturates, hydantoins, and rifamycins (increased fludrocortisone 21-acetate clearance); estrogens (reduced fludrocortisone 21-acetate clearance); amphotericin B and thiazide and loop diuretics (hypokalemia); anticoagulants (enhanced or reduced anticoagulant activity); antidiabetic drugs (reduced activity leading to hyperglycemia); digoxin (increased risk for dysrhythmias due to hypokalemia

induced by fludrocortisone 21-acetate); salicylates (reduced efficacy); and vaccines (increased risk of neurological complications). Fortunately, adverse effects and serious drug interactions secondary to fludrocortisone 21-acetate therapy are uncommon because of the relatively small doses of the drug that are normally prescribed; fludrocortisone 21-acetate is preferably administered in conjunction with 10- to 20-mg daily doses of hydrocortisone sodium succinate (10 to 20 mg daily in divided doses). Fludrocortisone 21-acetate is available only in oral form as a 0.1-mg tablet. Recommended dosages are given in the table on p. 569.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	10–20 min	1.7 hr	18–36 hr	1–2 days

▶▶ prednisone

Prednisone is one of the four intermediate-acting glucocorticoids; the others are methylprednisolone sodium succinate, prednisolone sodium phosphate, and triamcinolone acetonide. These drugs have half-lives that are more than double those of the short-acting corticosteroids (2 to 5 hours), and therefore they have longer durations of action. Prednisone is the preferred oral glucocorticoid for anti-inflammatory or immunosuppressant purposes. Along with methylprednisolone sodium succinate and prednisolone sodium phosphate, it is also used for exacerbations of chronic respiratory illnesses such as asthma and chronic bronchitis. Prednisone has minimal mineralocorticoid properties and therefore alone is inadequate for the management of adrenocortical insufficiency (Addison's disease). Prednisolone acetate, a prednisone metabolite, is the liquid drug form of prednisone. Prednisone is available in oral tablets. For recommended dosages, refer to the table on p. 569.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	within 1 hr	1–2 hr	2.5 hr	8–36 hr

methylprednisolone sodium succinate

Methylprednisolone sodium succinate (Solu-Medrol®) is the most commonly used injectable glucocorticoid drug. It is used primarily as an anti-inflammatory or immunosuppressant drug (see Preventing Medication Errors box).

It is usually given intravenously. Like prednisone, it is not recommended for use during pregnancy. Most injectable formulations contain a preservative (benzyl alcohol) that cannot be given to children younger than 28 days of age.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	within 1 hr	30 min	2.5 hr	24–36 hr

DOSAGES

Selected Antiadrenal and Corticosteroid Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications
 fludrocortisone 21-acetate (Florinef)	Synthetic mineralocorticoid	<i>Children (including infants) and adults</i> PO: 0.1–0.2 mg daily	Addison's disease; salt-losing adrenogenital syndrome
		<i>Adults</i>	Wide variety of endocrine disorders (including adrenocortical insufficiency) and rheumatic, collagen, dermatological, allergic, ophthalmic, respiratory, hematological, neoplastic, gastrointestinal, and nervous system disorders; edematous states
methylprednisolone sodium succinate (Solu-Medrol)	Systemic corticosteroid	IV: 10–500 mg depending on problem being treated	
 prednisone (Winpred®)	Synthetic intermediate-acting glucocorticoid	<i>Children</i> PO: 0.05–2 mg/kg/day divided daily qid <i>Adults</i> PO: 5–60 mg/day	Wide variety of endocrine (including adrenocortical insufficiency) and rheumatic, collagen, dermatological, allergic, ocular, respiratory, hematological, neoplastic, gastrointestinal, and nervous system disorders; edematous states

IV, intravenous; PO, oral.

⚡ PREVENTING MEDICATION ERRORS

Look-Alike, Sound-Alike Drugs: Solu-Cortef® and Solu-Medrol®

Be careful about look-alike, sound-alike drugs. Medication errors often occur when drug names are similar.

Solu-Cortef is a trade name for hydrocortisone sodium succinate; Solu-Medrol is a trade name for methylprednisolone sodium succinate. Both are commonly used glucocorticoids and are given intravenously. However, 4 mg of Solu-Medrol is equivalent to 20 mg of Solu-Cortef; therefore, Solu-Medrol is five times stronger than Solu-Cortef. Despite their similar names, these drugs are not interchangeable!

document baseline height and weight measurements in children. Older adults are more prone to adrenal suppression with prolonged adrenal therapy and may require dosage alterations by the health care provider to minimize the impact of the drug on muscle mass, blood pressure, and serum glucose and electrolyte levels. Adrenal drugs may exacerbate muscle weakness; produce fatigue; worsen or precipitate osteoporosis, peptic ulcer disease, glaucoma, and cataracts; and increase intraocular pressure. Additionally, because the adrenal drugs are associated with the adverse effect of sodium retention, closely assess patients for exacerbation of any pre-existing edema or cardiac disease.

❖ NURSING PROCESS

◆ ASSESSMENT

Before administering any of the adrenal drugs, perform a thorough physical assessment to determine the patient's baseline nutritional, hydration, and immune status; baseline weight; intake and output; vital signs (especially blood pressure ranges); and skin condition (noting bruising, fragility, turgor, and colour). Assess important baseline laboratory values, including serum sodium, serum potassium, and serum glucose. These specific laboratory tests are important because of potential drug-related adverse effects (see [Table 34.4](#)). For instance, serum potassium levels usually decrease and blood glucose levels increase when a glucocorticoid (e.g., prednisone) is given. In addition, assess and document the patient's muscle strength and body stature. In the assessment, include the identification of potential contraindications, cautions, and drug interactions, including interactions with prescription drugs, OTC drugs, and natural health products.

For adrenal drugs, lifespan considerations include concern about their use during pregnancy and lactation. Growth suppression may occur in children receiving long-term adrenal drug therapy (e.g., glucocorticoids) if the epiphyseal plates of the long bones have not closed. However, there may be situations in which the benefits to the therapy outweigh the risks of the drug's adverse effects. Perform and

◆ NURSING DIAGNOSES

- Distorted body image as a result of the physiological effects of diseases of the adrenal gland on the body or the cushingoid appearance caused by glucocorticoid therapy (e.g., prednisone)
- Increased fluid volume related to fluid retention associated with glucocorticoid and mineralocorticoid use
- Potential risk for infection as a result of the anti-inflammatory, immunosuppressive, metabolic, and dermatological effects of long-term glucocorticoid therapy
- Reduced skin integrity as a result of the adverse effects of glucocorticoids

◆ PLANNING

◆ Goals

- Patient will experience minimal body image disturbances.
- Patient will exhibit normal fluid volume status during treatment with glucocorticoid or mineralocorticoid therapy.
- Patient will remain free from infection during adrenal drug therapy.

◆ Expected Patient Outcomes

- Patient openly verbalizes fears about body image disturbances and other changes to health care providers, family members, and significant others.

- Patient experiences minimal problems with fluid volume excess and experiences minimal to no edema.
 - Patient records daily weights.
 - Patient reports to the health care provider any increase in weight of more than 1 kilogram in 24 hours or 2.3 kilograms or more in 1 week.
- Patient notifies the health care provider if body temperature is higher than 38°C.
 - Patient performs frequent mouth and skin care to prevent infections.

◆ IMPLEMENTATION

It is important to understand how glucocorticoids work in the body so that patients may receive adequate explanations and education to maximize the drug's therapeutic effects and minimize adverse effects. Remember the following points when giving these drugs: (1) Hormone production by the adrenal gland is influenced by time of day and follows a diurnal (daily or 24-hour) pattern, with peak levels occurring early in the morning between 0600 and 0800 hours, a decrease occurring during the day, and a lower peak in the late afternoon between 1600 and 1800 hours. (2) Cortisol levels increase in response to both emotional and physiological stress. (3) Cortisol levels increase when endogenous levels decrease owing to a physiological negative feedback system. (4) When exogenous glucocorticoids are given, endogenous levels decrease; for endogenous production to resume, exogenous levels must be decreased gradually so that hormone output responds to the negative feedback system. (5) The best time to give exogenous glucocorticoids, if at all possible, is early in the morning (0600 to 0900 hours) to minimize adrenal suppression. It is important to remember, however, that patients must not alter dosing or abruptly discontinue medication without consulting a health care provider.

Prednisone, a synthetic glucocorticoid, and fludrocortisones 21-acetate, a synthetic mineralocorticoid, are given orally. It is recommended that oral dosage forms be given with milk or food to help minimize GI upset. Another option is for the health care provider to prescribe an H₂ receptor antagonist or a proton pump inhibitor to prevent ulcer formation because these drugs are ulcerogenic. Emphasize to patients the importance of avoiding use of alcohol, caffeine, aspirin, and other NSAIDs to minimize gastric irritation and possible gastric bleeding from compounding ulcerogenic effects. In long-term therapy, alternate-day dosing of glucocorticoids, if possible, will help minimize the adrenal suppression. Because of delayed wound healing, monitor patients taking these drugs for flulike symptoms, sore throat, and fever. Methylprednisolone sodium succinate, a systemic corticosteroid, is given intravenously. Mix all parenteral forms per manufacturer guidelines, with IV doses administered over the recommended time period and in the proper diluent.

With oral and all other forms of glucocorticoids that are given in the short or long term, abrupt withdrawal must be avoided. Abrupt withdrawal of adrenal drugs (e.g., prednisone, methylprednisolone sodium succinate) may lead to a sudden decrease in or no production of endogenous glucocorticoids, resulting in adrenal insufficiency. Higher doses of glucocorticoids have greater incidence for adverse events due to abrupt withdrawal. Signs and symptoms of partial or complete adrenal insufficiency or Addison's

disease include fatigue, headache, confusion, fever, nausea, vomiting, abdominal pain, tachycardia, diaphoresis, dehydration, and hypotension. If left untreated, this condition could lead to an **adrenal crisis** or a life-threatening state of profound adrenocortical insufficiency requiring immediate medical management. Signs and symptoms of adrenal crisis, also referred to as *addisonian crisis*, include a severe drop in extracellular fluid volume with hypotension, hypoglycemia, hyponatremia, and hyperkalemia.

Other adrenal drug dosage forms include those for intra-articular, intrabursal, intradermal, intralesional, and intrasynovial administration. Administration of corticosteroids into these sites is done by an orthopedic or dermatology specialist, family physicians, and nurse practitioners with appropriate knowledge and skills necessary for this treatment. Do not overuse intra-articular injections, and if a joint is injected with medication, the patient needs to rest that area for up to 48 hours after the injection is given. Application of cold packs over the injected area may be indicated for up to the first 24 hours to help minimize the discomfort associated with intra-articular injections. Topical dosage forms (e.g., for skin, eyes, or inhalation into the bronchial tree) are also available and must be administered as ordered. For dermatological use, clean and dry the skin before application. Wear gloves and apply the medication with either a sterile tongue depressor or a cotton-tipped applicator. Use sterile technique if the skin is not intact. Nasally administered glucocorticoids (e.g., beclomethasone dipropionate) must also be used exactly as ordered (see Chapter 37). Any written instructions that come with the product must be read and followed carefully. Before using nasal sprays, the patient needs to first clear the nasal passages and then use the spray exactly as per the instructions. After the nasal passages are cleared, the container is placed gently inside the nasal passage and the medication is released at the same time that the patient breathes in through the nose, one nasal passage at a time or as ordered.

Glucocorticoid inhalers (e.g., beclomethasone dipropionate, budesonide, fluticasone propionate, mometasone furoate) are to be used strictly as ordered; explain the negative consequences of overuse to the patient. Use of these inhaled glucocorticoids may lead to fungal infections (candidiasis) of the oral mucosa and oral cavity, larynx, and pharynx. Therefore, the patient must rinse the mouth and oral mucous membranes with lukewarm water after each use to prevent fungal overgrowth and further complications. In addition to fungal infections, hoarseness, throat irritation, and dry mouth are possible adverse effects associated with the use of inhaled corticosteroids. Occurrence of any of these conditions needs to be discussed with a health care provider. See Chapter 10 and Patient Teaching Tips for more information on inhaled dosage forms.

If a patient is receiving long-term maintenance glucocorticoid therapy and requires surgery, recognize the importance of reviewing the patient's medical records for laboratory values, cautions, contraindications, and drug interactions. If preoperative orders do not include the maintenance dosage of glucocorticoid therapy, contact the surgeon or another health care provider, and ensure that the situation is explained, including the possible need for a rapid-acting corticosteroid. After surgery, the dosage of the steroid may well be increased, with a gradual decrease in dosage over several days until the patient returns to

CASE STUDY

Glucocorticoid Drug Therapy

Jong-Ui, a 68-year-old factory worker, has been in the hospital for 1 week because of an exacerbation of chronic obstructive pulmonary disease, which was aggravated by drywall dust during home renovations. He has a history of type 2 diabetes. His current plasma glucose is 9.7 mmol/L. He says that he stopped smoking 4 years ago and tries to “watch what he eats” because he has gained weight recently. He also reports feeling more irritable than normal, and he has experienced difficulty sleeping. He has no history of drug allergies. He is receiving

oxygen at 1 L/min through a nasal cannula. At this time, he is breathing more easily and hopes to be going home soon. His medication orders include the following, among others:

- metformin/sitagliptin phosphate monohydrate (Janumet®) 500 mg/50 mg twice a day by mouth (PO) with meals
- prednisone (Winpred), 20 mg every morning PO
- salbutamol sulphate (Ventolin®) inhaler, 2 puffs every 4 hours

Jong-Ui is reporting a headache. When you check the medication sheet, you see two orders:

- acetaminophen (generic), 650 mg PO every 4 hours as needed for pain
 - ibuprofen (generic), 200 mg PO every 6 hours as needed for pain
1. Which medication will you choose to give to Jong-Ui? Explain your answer.
 2. Considering Jong-Ui's medications, what could be contributing to his elevated glucose level? What other laboratory values need to be monitored closely during this time?
 3. What do you expect happened to cause Jong-Ui's report of weight gain, irritability, and difficulty sleeping?
 4. What nursing diagnoses are appropriate for Jong-Ui?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

baseline. In addition, be aware of the decrease in wound healing in patients taking corticosteroids on a long-term basis.

In summary, because of their suppressed immune systems, patients taking corticosteroids need to avoid contact with people with known infections and report any fever, increased weakness, lethargy, or sore throat to a health care provider. Monitoring of nutritional status, weight, fluid volume, electrolyte status, blood pressure, skin turgor, and glucose levels during therapy is important to ensure safe and effective therapy. The health care provider needs to be notified if any of the following symptoms occur: edema, shortness of breath (indicating possible heart failure), joint pain, fever, mood swings, or other unusual symptoms.

◆ EVALUATION

A therapeutic response to glucocorticoids includes a resolution of the underlying manifestations of the disease or pathology, such as a decrease in inflammation, increased feelings of well-being, less pain and discomfort in the joints, a decrease in lymphocytes, or other improvements in the condition for which the medication was ordered. Adverse effects include weight gain; increased blood pressure; sodium increase and potassium loss; mental health status changes such as mood swings, nervousness, aggressive behaviours, or psychosis; abdominal distension; ulcer-related symptoms; and changes in vision. Cushing's syndrome occurs with prolonged or frequent use of glucocorticoids and is characterized by moon facies, obesity of the trunk area (often referred to as *belly fat*), increase in blood glucose and sodium levels, loss of serum potassium, wasting of muscle mass, buffalo hump (accumulation of fat behind the neck), and other features previously discussed. Cataract formation and osteoporosis may also occur with long-term corticosteroid use. Rapid drops in cortisol levels (e.g., from abrupt withdrawal of medication) may lead to Addison's disease and addisonian crisis (see previous discussions).

PATIENT TEACHING TIPS

- Patients should be aware that glucocorticoids are to be taken exactly as ordered and never abruptly discontinued. The health care provider should be contacted if there are situations that prevent proper dosing. Abrupt withdrawal may precipitate adrenal crisis, Addison's disease, or addisonian crisis.
- If a once-a-day dose of glucocorticoids is missed, the patient needs to take the dose as soon as possible after remembering that the dose was missed. If the patient does not remember until close to the time for the next dose, then the patient is usually instructed to skip the dose and resume the dosing on the next day without doubling up. If any questions arise, the patient should seek clarification from a health care provider. Educate patients about the adverse effects of long-term therapy, such as changes in body appearance, including acne, buffalo hump, truncal obesity, moon facies, and thinning of the extremities.
- For patients taking glucocorticoids, emphasize the importance of bone health and the use of fall prevention strategies, because long-term therapy with these drugs may lead to osteoporosis. The health care provider may suggest a daily

supplement of oral calcium and vitamin D (see [Chapter 9](#)), and bisphosphonates (see [Chapter 35](#)) may also be considered. Foods high in vitamin D include cod liver oil (amount to be recommended by a health care provider) and salmon. Foods high in calcium include milk, cheese, yogurt, and ice cream. Fortified dairy products are high in both vitamin D and calcium.

- Glucocorticoid therapy involves a risk of vulnerability to infection. Educate patients who take these to avoid contact with people with known infections and to report any fever, increased weakness, lethargy, or sore throat to a health care provider.
- Contact the health care provider immediately if any signs and symptoms of acute adrenal insufficiency appear, such as dehydration and weight loss.
- Patients taking fludrocortisone 21-acetate, a mineralocorticoid, should be aware that it is better tolerated if taken with food or milk to minimize GI upset. With any of the adrenal drugs, weight gain of 1 kg or more in 24 hours or 2.3 kg or more in 1 week needs to be reported to the health care provider immediately.

- Encourage patients to keep a journal to document responses to treatment, blood pressure readings, daily weight measurements, mood changes, and any adverse effects.
- Emphasize to patients the importance of follow-up appointments with the health care provider so that electrolyte levels and any adverse effects may be monitored. Also, stress the

importance of maintaining a low-sodium and high-potassium diet, if ordered.

- Encourage patients to wear medical alert identification jewelry. A medical card or electronic device with important relevant information, including diagnoses, medications, and allergies, needs to be kept on their person at all times and updated frequently.

KEY POINTS

- The adrenal gland is an endocrine organ that is located on top of the kidneys and is composed of two distinct tissues: the adrenal cortex and the adrenal medulla. The adrenal medulla secretes two important hormones: epinephrine and norepinephrine. The adrenal cortex secretes two classes of hormones known as corticosteroids: glucocorticoids and mineralocorticoids.
- The biological functions of glucocorticoids include anti-inflammatory actions; maintenance of normal blood pressure; carbohydrate, protein, and fat metabolism; and stress effects. The biological functions of mineralocorticoids include sodium and water resorption, blood pressure control, and maintenance of potassium levels and blood pH.
- Patients taking adrenal drugs may receive them by various routes, such as orally, intramuscularly, intravenously, intranasally, intra-articularly, and by inhalation.
- Glucocorticoid inhaled dosage forms are to be used only as prescribed and only after adequate patient education. Rinsing of the mouth after each use is needed to avoid oral fungal infections (oral candidiasis) and oral-pharyngeal irritation.
- Long-term or frequent glucocorticoid use produces increased levels of glucocorticoids, which can lead to Cushing's syndrome. Abrupt withdrawal of glucocorticoids leads to adrenal insufficiency and negative effects on a patient's homeostasis.
- When once-a-day dosing of corticosteroids is prescribed, adrenal suppression from corticosteroid therapy can be minimized if the dose is given between 0600 and 0900 hours, but it needs to be given only as ordered.

EXAMINATION REVIEW QUESTIONS

1. The nurse is reviewing orders prior to administering medication to a patient. Which of the following statements is correct regarding corticosteroids?
 - a. They have few adverse effects.
 - b. They are often used for their anti-inflammatory effects.
 - c. They may be administered only by inhalant dosage forms.
 - d. They may be used long term without major complications.
2. The nurse is providing teaching to a patient about oral corticosteroid therapy. Which of the following statements by the patient demonstrates more teaching is needed?
 - a. "I will report any fever or sore throat symptoms."
 - b. "I will stay away from anyone who has a cold or infection."
 - c. "I can stop this medication if I have severe adverse effects."
 - d. "I will take this drug with food or milk."
3. The nurse is caring for a patient receiving long-term corticosteroid therapy. Which of the following symptoms will the nurse monitor for Cushing's syndrome?
 - a. Weight loss
 - b. Moon facies
 - c. Hypotension
 - d. Thickened hair growth
4. The nurse is teaching a patient who is taking a prescribed daily dose of prednisone (Winipred). Which of the following should the nurse include in the teaching about the time of day to take the medication to reduce adrenal suppression?
 - a. In the morning
 - b. At lunchtime
 - c. At dinnertime
 - d. At bedtime
5. The nurse is teaching a patient about taking an inhaled glucocorticoid for asthma. Which of the following statements should the nurse include in the teaching?
 - a. "Exhale while pushing in on the canister of the inhaler."
 - b. "Blow your nose after taking the medication."
 - c. "Rinse your mouth thoroughly after taking the medication."
 - d. "Do not eat immediately after taking the medication."
6. The nurse is reviewing the laboratory results of a patient taking long-term corticosteroid therapy. Which of the following adverse events will the nurse monitor for? (Select all that apply.)
 - a. Increased serum potassium levels
 - b. Decreased serum potassium levels
 - c. Increased sodium levels
 - d. Decreased sodium levels
 - e. Hyperglycemia
 - f. Hypoglycemia
7. The order reads: "Give methylprednisolone sodium succinate (Solu-Medrol) 100 mg IV every 6 hours." The drug is available in vials of 80 mg/mL. How many millilitres will the nurse draw up for each dose?
8. A patient with acute adrenal insufficiency is to receive 300 mg/day of hydrocortisone (Solu-Cortef), divided into 3 doses every 8 hours. How many milligrams will the patient receive for each dose?

CRITICAL THINKING ACTIVITIES

1. A patient with type 2 diabetes mellitus will be receiving IV doses of methylprednisolone sodium succinate (Solu-Medrol) to prevent cerebral edema after a head injury. A new nurse is working with you as you prepare to give this medication. The nurse asks, “Isn’t this drug going to cause problems for this patient? Should we be giving it?” What is your best answer?
2. A patient has been taking high doses of oral prednisone for 1 week because of an exacerbation of asthma symptoms. He is about to go home and is given a prescription for another week of prednisone (Winpred) therapy, but with doses tapering downward before the medication is stopped. The patient asks, “Why do I need to bother with this drug if it’s only for a week? Can’t I just stop it now?” What is the priority when the nurse answers this patient’s questions? Explain your answer.
3. Your patient is a 15-year-old male with a history of steroid-dependent asthma. He reports “always feeling tired and

weak.” He has been using inhaled bronchodilators for the past 5 years, and for the past 3 years, the doses have been increased. Over the previous 8 months, he has been hospitalized twice for severe asthma attacks (status asthmaticus), during which he was given IV and oral corticosteroid bursts (high doses over a few days). In addition, he has been taking daily oral steroids for the last 5 months. He has had a weight gain of 10 kg over the previous 3 months and an increased incidence of recent “colds,” and his mother has expressed concern that he does not seem to be growing as quickly as his siblings did at this age. His mother also asks why, if her son is getting “steroids,” he looks as he does rather than like “all the bodybuilders on TV who are using steroids.” What are the priority concerns for this patient? How would you respond to his mother’s concerns? Explain your answer.

Women's Health Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Discuss the normal anatomy and physiology of the female reproductive system.
2. Discuss the normal hormonally mediated feedback system that regulates the female reproductive system.
3. Briefly describe the variety of disorders affecting women's health and the drugs used to treat them.
4. Discuss the rationales for use, indications, adverse effects, cautions, contraindications, drug interactions, dosages, and routes of administration of estrogen, progestins, uterine motility-altering drugs, and osteoporosis drugs.
5. Develop a collaborative plan of care that includes all phases of the nursing process for patients receiving any of the drugs related to women's health (estrogens, progestins, uterine motility-altering drugs, and osteoporosis drugs).

KEY TERMS

Chloasma Hyperpigmentation due to an increase in melanin in the skin, characterized by brownish macules on the cheeks, forehead, lips, and neck; a common dermatological adverse effect of female hormonal medications (also called *melasma*). (p. 578)

Corpus luteum The structure that forms on the surface of the ovary after every ovulation and acts as a short-lived endocrine organ that secretes progesterone. (p. 575)

Endocrine glands Glands that secrete one or more hormones directly into the blood. (p. 575)

Estrogens A major class of female sex steroid hormones; of the estrogens, estradiol is responsible for most estrogenic physiological activity. (p. 575)

Fallopian tubes The passages through which ova are carried from the ovaries to the uterus. (p. 575)

Gonadotropin The hormone that stimulates the testes and ovaries. (p. 575)

Hormone therapy (HT) Any replacement of natural hormones with hormonal drug forms (also referred to simply as *hormone therapy [HT]*). Most commonly, HRT refers to estrogen replacement therapy for treating symptoms associated with menopause-related estrogen deficiency. (p. 577)

Implantation The attachment to, penetration of, and embedding of the fertilized ovum in the lining of the uterine wall; one of the first stages of pregnancy. (p. 575)

Menarche The first menses in a young woman's life and the beginning of cyclic menstrual function. (p. 575)

Menopause The cessation of menses for 12 consecutive months that marks the end of a woman's child-bearing capability. (p. 575)

Menses The normal flow of blood that occurs during menstruation. (p. 575)

Menstrual cycle The recurring cycle of changes in the endometrium in which the decidual layer is shed, regrows,

proliferates, is maintained for several days, and is shed again at menstruation unless a pregnancy begins; also referred to as the *uterine cycle*. (p. 575)

Nucleic acids Specific molecules in cells that are composed of strings of repeating units that serve to encode information; the two most common ones are DNA and RNA, whose functions have to do with the storage and expression of genetic information. (p. 577)

Osteoporosis A condition characterized by the progressive loss of bone density and thinning of bone tissue and associated with an increased risk of fractures. (p. 582)

Ova Female reproductive or germ cells (singular: *ovum*; also called *eggs*). (p. 575)

Ovarian follicles The location of egg production and ovulation in the ovary; the follicle is the precursor to the corpus luteum. (p. 575)

Ovaries The pair of female gonads located on each side of the lower abdomen beside the uterus; they store the *ova* (eggs) and release them during the ovulation stage of the menstrual cycle. (p. 575)

Ovulation The rupture of the ovarian follicle, which results in the release of an unfertilized ovum into the peritoneal cavity, from which it normally enters the fallopian tube. (p. 575)

Progesterone A sex hormone produced by the corpus luteum that serves to prepare the uterus for possible implantation. (p. 575)

Progestins Synthetic or natural substances that have properties similar to progesterone but are not considered to be the naturally occurring progesterone that is present in the human female body. (p. 575)

Uterus The hollow, pear-shaped female organ in which the fertilized ovum is implanted (see implantation) and the fetus develops. (p. 575)

Vagina Part of the female genitalia that forms a canal from its external orifice through its vestibule to the uterine cervix. (p. 575)

DRUG PROFILES

OVERVIEW OF FEMALE REPRODUCTIVE FUNCTIONS

The female reproductive system consists of the **ovaries**, **fallopian tubes**, **uterus**, **vagina**, and the external structure known as the **vulva**. The development of these primary sex structures, initiation of their subsequent reproductive functions (starting at puberty), and their maintenance are controlled by pituitary **gonadotropin** hormones and the female sex steroid hormones, **estrogens** and **progestins**. Pituitary gonadotropins include follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Both play a primary role in hormonal communication between the pituitary gland (see [Chapter 31](#)) and the ovaries in the continuous regulation of the **menstrual cycle** from month to month.

Estrogens are also responsible for stimulating the development of secondary female sex characteristics, including breast, skin, and bone development and distribution of body fat and hair. **Progesterone** helps create optimal conditions for pregnancy in the endometrium just after **ovulation** and also promotes the start of **menstruation** in the absence of a fertilized ovum.

The ovaries (female gonads) are paired glands located on each side of the uterus. They function both as **endocrine glands** and as reproductive glands. As reproductive glands, they produce within **ovarian follicles** mature **ova**, which are then ovulated or released into the space in the peritoneal cavity between the ovary and the fallopian tube. Fingerlike projections known as **fimbriae** lie adjacent to each ovary and serve to “catch” the released ovum and guide it into the fallopian tube. Once inside the fallopian tube, the ovum is moved through the lumen to the uterus. This

movement is accomplished through the muscular contractions of the tube walls and the actions of ciliated cells inside the lumen of the tube, which “beat” in the direction of the uterus. Fertilization of the ovum, when it occurs, takes place in the fallopian tube.

As endocrine glands, the ovaries are responsible for producing the two types of sex steroid hormones, estrogens and progesterone. Chemically, the estrogens and progestational hormones include several distinct substances. However, only two of these hormones occur in significant amounts, and these have the greatest physiological activity. They are the estrogen estradiol and the progestational hormone progesterone. Estradiol is the principal secretory product of the ovary and has several estrogenic effects. One of these effects is the regulation of gonadotropin (FSH and LH) secretion via negative feedback to the pituitary gland. Others include promotion of the development of female secondary sex characteristics, monthly endometrial growth, thickening of the vaginal mucosa, thinning of the cervical mucus, and growth of the ductal system of the breasts. Progesterone is the principal secretory product of the **corpus luteum** and has progestational effects. These include promotion of tissue growth and secretory activity in the endometrium following the estrogen-driven follicular phase of the menstrual cycle. This important secretory process is required for endometrial egg **implantation** and maintenance of pregnancy. Other progestational effects include induction of menstruation when fertilization has not occurred and, during pregnancy, inhibition of uterine contractions, increase in the viscosity of cervical mucus (which protects the fetus from external contamination), and growth of the alveolar glands of the breasts.

The uterus consists of three layers: the outer protective **perimetrium**, the muscular **myometrium**, and the inner mucosal layer, known as the **endometrium**. The myometrium provides the powerful smooth muscle contractions needed for childbirth. The endometrium is the site of the following:

- Implantation of a fertilized ovum and subsequent development of the fetus
- Initiation of labour and birthing of the infant
- Menstruation

The vagina serves as a common passageway for birthing and menstrual flow. In addition, it is a receptacle for the penis during sexual intercourse and the sperm after male ejaculation.

The menstrual cycle usually takes approximately 1 month to complete. Menstrual cycles begin during puberty with the first menses (**menarche**) and cease at **menopause**, which in most women occurs between 45 and 55 years of age. The hormonally controlled menstrual cycle consists of four distinct but interrelated phases that occur in overlapping sequence. Phase names correspond to activity in either the ovarian follicle or the endometrium ([Table 35.1](#)).

- **Phase 1:** The **menstruation phase** (uterine cycle) initiates the cycle and lasts from 5 to 7 days.
- **Phase 2:** During the **follicular phase** (ovarian cycle), a mature ovum develops from an ovarian follicle. This phase is also called the **proliferative** or **preovulatory phase** and is characterized by rising estrogen secretion from the ovary and LH secretion from the pituitary gland. It terminates on or about day 14 of the cycle.

*The authors of this edition would like to respectfully acknowledge that absence of a more fulsome discussion regarding pharmacological interventions for transgender women and women who may be in transition. An addendum will follow the publication to include more concise information and will be subsequently included in future publications.

- **Phase 3:** The *ovulation phase* involves release of the unfertilized ovum from the ovary. This process occurs over an approximately 24- to 48-hour period starting at about day 14. Both estrogen and LH levels peak near this time.
- **Phase 4:** The final phase of the cycle is the *luteal or post-ovulatory phase*. It is also known as the *secretory phase*. It occurs when the corpus luteum forms from the ruptured ovarian follicle. The corpus luteum is a mass of secretory cells on the surface of the ovary. Its primary function is to produce progesterone, which helps to optimize the endometrial mucosa for implantation of a fertilized ovum. The corpus luteum also serves as an initial source of progesterone needed during early pregnancy. This function is later assumed by the developing placenta. If fertilization does not

occur, the corpus luteum then degenerates, causing a fall in progesterone levels. The menstrual cycle begins again on or about day 28.

Figure 35.1 illustrates the sequence of hormone secretions and related events that take place during the menstrual cycle.

FEMALE SEX HORMONES

Estrogens

There are three major endogenous estrogens: estradiol, estrone, and estriol. All are synthesized from cholesterol in the ovarian follicles and have the basic chemical structure of a steroid, known as the *steroid nucleus*. For this reason, they are sometimes referred to as *steroid hormones*. Estradiol is the principal and most active of the three and represents the end product of estrogen synthesis.

Exogenous estrogenic drugs, those used as drug therapy, were developed because most of the endogenous estrogens are inactive when taken orally. These synthetic drugs fall into two categories: steroidal and nonsteroidal. The estrogenic drugs currently in use are as follows:

- Conjugated estrogens (Premarin®)
- Esterified estrogens (Estragyn®)

TABLE 35.1 Phases of the Menstrual Cycle

Phase	Ovarian Follicle Activity	Endometrium Activity
Phase 1	Menstruation	Menstruation
Phase 2	Follicular phase (preovulatory)	Proliferative phase
Phase 3	Ovulation	Ovulation
Phase 4	Luteal phase (postovulatory)	Secretory phase

Fig. 35.1 Hormonal activity during the monthly menstrual cycle. Gonadotropin-releasing hormone (GnRH) from the hypothalamus stimulates the pituitary gland, causing it to secrete follicle-stimulating hormone (FSH) early in the cycle (coinciding with menses) and later luteinizing hormone (LH). FSH stimulates the ovaries to produce estrogen (primarily estradiol). Later in the cycle, the combined surges in the levels of estrogen, GnRH, FSH, and LH stimulate ovulation. The corpus luteum then secretes estrogen and progesterone, providing negative feedback to the hypothalamus and pituitary gland to reduce GnRH, FSH, and LH secretions. If the ovum (egg) is not fertilized by a spermatozoon, levels of estrogen and progesterone then fall to their monthly lows, GnRH and FSH rise again, and the onset of menses begins a new cycle. (Right, source: Thibodeau, G. A., & Patton, K. T. (2010). *Anatomy and physiology* (7th ed.; p. 1055, Fig. 32-14). St. Louis, MO: Mosby.)

- Estradiol transdermal (Climara®, Divigel®, Estrogel®, Sandoz Estradiol Derm®, Oesclim®, Estradot®)
- Estradiol vaginal ring (Estring®)
- Estradiol valerate
- Estrone (Folliculum®, Estrone Vaginal Cream®)
- Estropipate (Ogen®)
- Ethinyl estradiol (Alesse®, Alysen®, Aviane®, many others)
- Estradiol vaginal dose forms (Premarin®, Vagifem®)
- Micronized estradiol (Estrace)

The most widely used estrogen product is an estrogen mixture known as *conjugated estrogens*. This mixture contains a combination of natural estrogen compounds derived from and equivalent to the average estrogen composition of the urine of pregnant mares, hence its brand name of Premarin. A nonanimal source for this conjugated estrogen mixture is also available. The product Estrace is composed of various conjugated estrogens obtained from soybeans. This product was developed in response to consumer demand from women who wanted an alternative to animal-derived products (see the Natural Health Products box below). Some women obtain other natural estrogen products from naturopathic prescribers and prefer these to standard prescription drugs such as Premarin.

Patients report varying degrees of satisfaction with the numerous products available, and it can take both time and patience to find the best choice for a given individual. Ethinyl estradiol is one of the more potent estrogens and is most commonly found in oral contraceptive drugs. Another commonly used form of estrogen is the patch formulation. Several patches exist, all of which are dosed differently; thus patient education is necessary to ensure proper use. The most commonly used patch is Climara (estradiol).

NATURAL HEALTH PRODUCTS

Soy (*Glycine Max*)

Overview

Soy is a bean commonly grown throughout the world. The isoflavones in soy are chemically similar to the female hormone estradiol. Some studies have shown soy to be useful in the prevention of menopausal symptoms in perimenopausal women. Other studies have found that soy reduces both low-density lipoprotein (LDL) and total cholesterol levels. To achieve any reduction in symptoms, a woman would need to consume between 20-60 grams of soy per day.

Common Uses

Reduction of cholesterol level, relief of menopause symptoms (alternative to hormone therapy), osteoporosis prevention.

Adverse Effects

Nausea, bloating, diarrhea, abdominal pain (ingested forms), and hypersensitivity reactions have been reported following the use of soy.

Potential Drug Interactions

Orally administered soy may interfere with thyroid hormone absorption (avoid concurrent use), increased effect of theophylline, decreased effect of levothyroxine, and may decrease effects of tamoxifen and warfarin.

Contraindications

Allergy to soy products. Soy should be avoided when patients are living with hormone sensitive conditions such as receptor positive breast cancer.

Follow manufacturer's directions on the label for use of specific preparations.

Nonsteroidal estrogen products are no longer available for use in Canada for obstetric use because of major adverse effects with the use of diethylstilbestrol (DES). [Box 35.1](#) describes this important episode in medical history.

Mechanism of Action and Drug Effects

The binding of estrogen to intracellular estrogen receptors stimulates the synthesis of **nucleic acids** (deoxyribonucleic acid [DNA] and ribonucleic acid [RNA]) and proteins, which are the building blocks for all living tissue. Estrogens are also required at puberty for the development and maintenance of the female reproductive system and the development of female secondary sex characteristics, a process known as *feminization*. Estrogens produce their effects in estrogen-responsive tissues, which have a large number of estrogen receptors, proteins that bind estrogens with high affinity and specificity. These tissues include the female genital organs, the breasts, the pituitary gland, and the hypothalamus. At the time of puberty, the production of estrogen increases greatly. This causes initiation of menses, breast development, redistribution of body fat, softening of the skin, and other feminizing changes. Estrogens play a role in the shaping of body contours and development of the skeleton. For instance, long bones are usually inhibited from growing, with the result that females are usually shorter than males. Estrogen receptors are found throughout the body and act on many other organ systems such as cardiovascular, skeletal, immune, gastrointestinal (GI), and neural sites. They have a significant role in health and disease. For example, the incidence of cardiovascular disease increases in women after menopause. It is believed that the decrease in estrogen levels is associated with the disruption of lipid or glucose regulation. Estrogen's cardioprotective effect may be due to the reduction of cholesterol levels through the elimination of LDLs from the circulating blood. Estrogen receptors are also expressed in endothelial and smooth muscle cells of vascular tissues and are thought to reduce the development of atherosclerosis.

Indications

Estrogens are used in the treatment or prevention of a variety of disorders that result primarily from estrogen deficiency. These conditions are listed in [Box 35.2](#). **Hormone therapy (HT)** to counter such estrogen deficiency is most commonly known for its benefits in treating menopausal symptoms (e.g., vasomotor symptoms or hot flashes). Hot flashes result from ovarian follicular depletion and marked reduction in ovarian estrogen secretion. The thermoregulatory system in the hypothalamus is disrupted, with small changes in body temperature eliciting

BOX 35.1 Diethylstilbestrol

Between 1940 and 1971, an estimated 6 million mothers and their fetuses were exposed to diethylstilbestrol (DES). The drug was used to prevent reproductive problems such as miscarriage, premature delivery, intrauterine fetal death, and toxemia. This use resulted in significant complications involving the reproductive systems of both female and male offspring. Two large groups have been established to monitor these complications: the International Registry for Research on Hormonal Transplacental Carcinogenesis and the National Cooperative Diethylstilbestrol Adenosis (DESAD) Project.

an exaggerated sweating (from vasodilation) and shivering response as well as an increase in heart rate. In combination with cyproterone, ethinyl estradiol is used to treat certain severe types of acne with associated symptoms of androgenization, including seborrhea and mild hirsutism in women who have been unsuccessfully treated with antibiotics and other treatments. This combination medication works by regulating hormones that affect the skin.

Contraindications

Contraindications for estrogen administration include known drug allergy, any estrogen-dependent cancer, undiagnosed abnormal vaginal bleeding, pregnancy, and active thromboembolic disorder (e.g., stroke, thrombophlebitis, active smokers) or a history of such a disorder.

Adverse Effects

Estrogens increase plasma fibrinogen and the activity of coagulation factors (e.g., factors VII and X) and decrease antithrombin III, the inhibitor of coagulation. Platelet activity is also enhanced, with the acceleration of aggregation. These changes create a state of hypercoagulability. Consequently, the most serious adverse effects of the estrogens are thromboembolic events such as deep vein thrombosis (DVT), stroke, and pulmonary embolism. The incidence of these effects is decreased with lower-dose formulation of estrogens. The most common undesirable effect of estrogen use is nausea. Photosensitivity may also occur with estrogen therapy. One common dermatological effect of note is known as **chloasma**. Chloasma consists of brownish, macular spots that often occur on the forehead, cheeks, lips, and neck. This and other adverse effects are listed in [Table 35.2](#).

Interactions

Estrogens can decrease the activity of oral anticoagulants, and the concurrent administration of rifampin and St. John’s wort can decrease their estrogenic effect. Their use with tricyclic antidepressants may promote toxicity of the antidepressant. Smoking should be avoided during estrogen therapy because this, too, can diminish estrogenic effects and add to the risk for thrombosis.

Dosages

For dosage information on some of the many available estrogen products, refer to the table on p. 579.

 DRUG PROFILES

estrogen

Estrogen is indicated for the treatment of many clinical conditions, primarily those resulting from estrogen deficiency (see [Box 35.2](#)). Many of these conditions occur around menopause, when the endogenous estradiol level is declining. Any estrogen capable of binding to the estrogen receptors in target organs can alleviate menopausal symptoms. As a general rule, the smallest dosage of estrogen that relieves the symptoms or prevents the condition is used. Although many women receive estrogen or estrogen–progestin therapy for many months or years, some health care providers (and patients) may prefer that patients be weaned from estrogen therapy because of known adverse effects. Two studies that were performed as part of the Women’s Health Initiative (WHI), a large research program sponsored by the National Institute of Health (NIH) in the United States, demonstrated the detrimental effects of estrogen and combined estrogen–progestin therapy. Both studies attempted to determine the value of HRT, if any, in preventing diseases and conditions commonly affecting older women, including breast cancer, heart disease, stroke, and hip fracture. The WHI was launched in 1991 under the direction of the US National Heart, Lung, and Blood Institute (NHLBI). In one of the WHI studies of HRT, research subjects who took certain estrogen–progestin drugs were found to have an increased risk of breast cancer, heart disease, stroke, and blood clots, although their risks of hip fracture and colon cancer were reduced. These preliminary results were so alarming that this study of combined estrogen–progestin therapy was discontinued in 2002.

A part of the WHI investigation focusing on cognitive function, the WHI Memory Study, also identified adverse cognitive effects in women receiving combination estrogen–progestin therapy. These patients showed an increased risk of developing dementia and demonstrated reduced performance on tests of cognitive function. A second HRT study was begun in which women who had undergone hysterectomy received estrogen alone without progestin. In March 2004, however, these participants were advised to stop taking their assigned medications because the estrogen-only therapy appeared to be associated with an increased risk of stroke. The data also indicated that estrogen therapy had no effect on the rates of coronary artery disease or breast cancer but was associated with a reduced rate of hip fracture.

TABLE 35.2 Estrogens: Common Adverse Effects	
Body System	Adverse Effects
Cardiovascular	Hypertension, thrombophlebitis, edema, thrombosis
Gastrointestinal	Nausea, vomiting, diarrhea, constipation
Genitourinary	Amenorrhea, breakthrough uterine bleeding, enlarged uterine fibromyomas
Dermatological	Chloasma (facial skin discoloration; also called <i>melasma</i>), hirsutism, alopecia
Other	Tender breasts, fluid retention, decreased carbohydrate tolerance, headaches

BOX 35.2 Indications for Estrogen Therapy
• Atrophic vaginitis (shrinkage of the vagina or urethra) • Hypogonadism • Oral contraception (in combination with a progestin) • Ovarian failure or castration (or removal of ovaries) • Uterine bleeding • Breast or prostate cancer (palliative treatment of advanced inoperable cases) • Osteoporosis (treatment and prophylaxis) • Cross-gender hormone treatment of male-to-female transgender individuals • Vasomotor symptoms of menopause (e.g., hot flashes) • Severe acne (in combination with cyproterone, an antiandrogen)

Since publication of the WHI studies, much confusion and controversy has arisen regarding estrogen use. One of the biggest challenges related to the WHI is that the majority of the women involved were at least 10 years postmenopause. Recent data have suggested that the use of estrogen in women who are younger is beneficial. Follow-up with the WHI study participants began in 2010. The North American Menopause Society (NAMS) also updated its position statement in 2017 regarding estrogen use in perimenopausal and postmenopausal women. The updated recommendation indicates that HRT therapy should be individualized on the basis of calculating woman's baseline cardiovascular and breast cancer risk. The benefit–risk ratio for menopausal hormone therapy is favourable for women who initiate hormone therapy close to menopause but decreases in older women and with time since menopause. A recent 18-year observational follow-up study of participants suggests that hormone replacement postmenopause was not associated with all-cause cardiovascular or cancer-related risk (Manson, Aragaki, Rossouw, et al., 2017). More research is needed to identify associated long-term risks with the use of HRT; however, this study suggests that HRT may not be harmful for women. At this time, HRT is not recommended for women with histories of endometrial cancer. In women with breast cancer, the use of estrogen therapy is still proceeded with caution, as further research is being conducted. When hormone therapy is discontinued after several years of use, it is important to assess bone mineral density and begin treatment if indicated. Because HRT is a topic about which views are so rapidly changing, readers are referred to the website of the NAMS at www.menopause.org for the latest position statements. The Society of Obstetricians and Gynecologists of Canada supports the recommendations of the NAMS.

The pharmacological effects of all estrogens are similar because there are only slight differences in their chemical

structure. These differences yield drugs of different potencies that, in turn, make them useful for a variety of indications. They also allow the drugs to be given by different routes of administration and often at highly customized doses.

Many fixed estrogen–progestin combination products have been developed over the years. Their use is commonly referred to as *continuous combined hormone replacement therapy*. The use of estrogen therapy alone has been associated with an increased risk of endometrial hyperplasia, a possible precursor of endometrial cancer. The addition of continuously administered progestin to an estrogen regimen reduces the incidence of endometrial hyperplasia associated with unopposed estrogen therapy. Examples of these fixed combinations are conjugated estrogens with medroxyprogesterone, norethindrone acetate with ethinyl estradiol, and estradiol with norethindrone acetate.

Progestins

Available progestational drugs, or progestins, include both natural and synthetic drugs. Progesterone is the most active natural progestational hormone and is the primary progestin component in most drug formulations. It is produced by the corpus luteum after each ovulation and during pregnancy by the placenta. In addition, there are two other major natural progestational hormones. The first is 17-hydroxyprogesterone, an inactive metabolite of progesterone. The second is pregnenolone, a chemical precursor to all steroid hormones that is synthesized from cholesterol in the ovary as was described for the estrogens. Administered progesterone is relatively inactive, and parenterally administered progesterone causes local reactions and pain; therefore, other chemical derivatives were developed that are more effective and more potent than oral administration. For example, Mirena® and Kyleena® are hormonal intrauterine devices that are inserted into the uterus for long-term contraception. Their actions are more hormonally specific and

DOSAGES Selected Estrogenic Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications
 conjugated estrogens (Premarin) and esterified estrogens (Estragyn, Estrace)	Estrogenic hormone	PO: 0.3 mg/day cyclically, 3 wk on, 1 wk off or continuously PO: 0.3 mg/day; adjust to needs of patient PO: 0.3–0.625 mg/day cyclically, 3 wk on, 1 wk off or continuously PO: 1.25 mg/day cyclically, 3 wk on, 1 wk off or continuously; adjust to needs of patient	Atrophic vaginitis, vulvar atrophy Menopausal symptoms, osteoporosis Female hypogonadism Oophorectomy, primary ovarian failure
estradiol estradiol transdermal (Climara, Divigel, Estrogel, Sandoz Estradiol Derm, Oesclim, Divigel)	Estrogenic hormone	Transdermal patch 0.05 mg, applied once a week on a clean, dry area of intact skin such as buttocks, lower abdomen or hip; adapted to patient needs; Divigel 0.1% usual dose is 0.25 mg/0.25 g daily; Estrogel 0.75 mg/1.25 g (0.06%) one pump to each arm daily	Vasomotor symptoms of menopause, osteoporosis prophylaxis
estradiol valerate	Estrogenic hormone	IM: Cyclic therapy schedule (28-day cycle; repeated every 4 wk) Day 1 of each cycle: 20 mg; 2 wk after Day 1: 5 mg; 4 wk after Day 1: This is Day 1 of next cycle. Stop after 4 cycles	Amenorrhea, oophorectomy, primary ovarian failure, menopause, senile vaginitis, pruritus vulvae, palliation of inoperable progressing prostatic carcinoma in males

IM, intramuscular; PO, oral.

may remain in the uterus for longer duration. The following are some of the most commonly used progestins:

- levonorgestrel (Min-Ovral®, Minera®, Next Choice®, Nor-levo®, Option 2®)
- medroxyprogesterone (Depo-Provera®, Medroxy®, Provera®)
- megestrol (Megace®)
- norethindrone acetate (Norlutate®); norethindrone (Micronor®, Jenxyla®, Movisse®)
- progesterone (Crinone®, Prometrium®)

Mechanism of Action and Drug Effects

All of the progestin products produce the same physiological responses as those produced by progesterone. These responses include induction of secretory changes in the endometrium, such as diminished endometrial tissue proliferation; an increase in the basal body temperature; thickening of the vaginal mucosa; relaxation of uterine smooth muscle; stimulation of mammary alveolar tissue growth; feedback inhibition (negative feedback) of the release of pituitary gonadotropins (FSH and LH); and alterations in menstrual blood flow, especially in the presence of estrogen.

Indications

Progestins are useful in the treatment of functional uterine bleeding caused by a hormonal imbalance, fibroids, or uterine cancer; in the treatment of primary and secondary amenorrhea; in the adjunctive and palliative treatment of some cancers and endometriosis; and alone or in combination with estrogens in the prevention of conception. They may also be helpful in preventing a threatened miscarriage and alleviating the symptoms of premenstrual syndrome. Medroxyprogesterone is the most commonly used progestin. Norethindrone acetate is commonly used alone or in combination with estrogens as contraceptives. Megestrol is commonly used as adjunct therapy in the treatment of breast and endometrial cancers. When estrogen replacement therapy is initiated after menopause, progestins are often included to decrease the endometrial proliferation that can be caused by unopposed estrogen in women with an intact uterus. Formulations of progesterone are also used to treat female infertility (refer to the Dosages table on p. 581).

Contraindications

Contraindications for progestins are similar to those for estrogens.

Adverse Effects

The most serious undesirable adverse effects of progestin use include liver dysfunction, commonly manifested as jaundice; thrombophlebitis; and thromboembolic disorders such as pulmonary embolism. The more common adverse effects are listed in Table 35.3.

Interactions

There are reports of possible decreases in glucose tolerance when progestins are taken with antidiabetic drugs, and the dosage of the antidiabetic drug may need to be adjusted. The concurrent use of medroxyprogesterone or norethindrone or rifampin induces increased metabolism of the progestin.

TABLE 35.3 Progestins: Common Adverse Effects

Body System	Adverse Effects
Gastrointestinal	Nausea, vomiting
Genitourinary	Amenorrhea, spotting
Other	Edema, weight gain or loss, rash, pyrexia, somnolence or insomnia, depression

Dosages

For recommended dosages of the progestins, refer to the table on p. 581.

DRUG PROFILES

medroxyprogesterone acetate

Medroxyprogesterone acetate (Depo-Provera®, Medroxy®, Provera®) inhibits the secretion of pituitary gonadotropins, which prevents follicular maturation and ovulation, stimulates the growth of mammary tissue, and has an antineoplastic action against endometrial cancer. Medroxyprogesterone is used to treat uterine bleeding, secondary amenorrhea, and endometrial cancer, and in combination with conjugated estrogens, is also used as a contraceptive. Its most common use is to prevent endometrial cancer caused by estrogen replacement therapy. It is sometimes used as adjunct therapy in certain types of cancer (Chapter 52). Medroxyprogesterone is available in oral and parenteral preparations. It is also available in a long-acting injection formulation called Depo-Provera. Depo-Provera is used for birth control, and one injection prevents conception for 3 months. There is concern about its use in women younger than 25 years of age and its use for longer than 2 years, due to the potential for bone density loss it creates (Di Meglio, Crowther, & Simms, 2018).

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IM	6–12 months	3 weeks	50 days	3 mo

megestrol acetate

Megestrol acetate (Megace®) is a synthetic progestin that is structurally similar to progesterone. Although megestrol shares the actions of the progestins, it is primarily used in the palliative management of recurrent, inoperable, or metastatic endometrial or breast cancer. Because it can cause appetite stimulation and weight gain, it is also used in the management of anorexia, cachexia, or unexplained substantial weight loss in patients with cancer. It is available only for oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	6–8 wk	1–3 hr	13–105 hr	4–10 mo

DOSAGES *Selected Progestational Drugs*

Drug	Pharmacological Class	Usual Dosage Range	Indications
 medroxyprogesterone acetate (Depo-Provera, Medroxy, Premplus, Provera-Pak)	Progestin	PO: 5–10 mg/day for set number of days or cyclically (smaller doses may be given on a continuous daily basis) IM 150 mg every 13 weeks	Amenorrhea, uterine bleeding
		PO: 2.5–10 mg daily on last 10–14 days of each month to accompany estrogen dosing	Vasomotor symptoms of menopause
megestrol acetate (Megace)	Antineoplastic, hormone, appetite stimulant, progestin	PO: 400–800 mg/day	Anorexia, cachexia, or significant weight loss in patients with cancer
		PO: 160 mg/day	Palliative or adjunctive breast carcinoma
		PO: 80–320 mg/day, divided	Endometrial carcinoma
		PO: 120 mg/day, single dose	Advanced hormone-responsive carcinoma of prostate

PO, oral.

Selective Progesterone Receptor Modulator

Ulipristal acetate (Fibristal®) is approved by Health Canada for treatment of moderate to severe signs and symptoms of uterine fibroids in adult women of reproductive age who are eligible for surgery. This is the first drug to be approved within a new class of drugs, that of the selective progesterone receptor modulators.

Uterine fibroids (leiomyomas) are benign, hormone-sensitive, smooth-muscle tumours of the uterus. Fibroids are the most common tumours of the female reproductive tract in premenopausal women, with a prevalence of 20–40% in women between the age of 35 and 55 years (Vilos, Allair, Laberge, et al., 2015). Fibroids occur more frequently and are more severe in Black women. The etiology of fibroids remains elusive and there are currently no long-term treatments available. Patients can be asymptomatic; however, symptoms may include heavy, prolonged menstrual bleeding and subsequent anemia; abdominal pressure; pelvic pain; increased urinary frequency; and infertility. Surgery includes myomectomy (surgical removal of fibroids) or a hysterectomy.

Ulipristal is a tissue-specific, partial progesterone antagonist. It reduces or eliminates uterine bleeding through its antiproliferative effect on endometrial tissue. It also reduces the size of fibroids by inhibiting cell proliferation and causing cell death. The usual dose is one 5-mg tablet per day, taken continuously for 3 months. Ulipristal should be initiated during the first 7 days of the menstrual period. The drug is contraindicated during pregnancy or in women who have a hypersensitivity to the drug.

Contraceptive Drugs

Contraceptive drugs are medications used to prevent pregnancy. Contraceptive devices are methods of pregnancy prevention such as reversible intrauterine devices, male and female condoms, cervical diaphragms, and others, which are beyond the scope of a pharmacology text. However, it is important to note that long-acting reversible contraceptive methods (e.g., intrauterine devices and implants) are superior in preventing

pregnancy when compared to other common contraceptive methods, including oral contraceptive pills, the transdermal patch, contraceptive vaginal ring, and depot medroxyprogesterone acetate injection (Di Meglio et al., 2018; Winner, Peipert, QiuHong, et al., 2012). Patients must be informed, for their own safety, of the fact that the use of contraceptive drug therapy only prevents pregnancy. These include spermicidal drugs, such as the over-the-counter (OTC) foams for intravaginal use. These products most often contain the spermicide nonoxynol-9, which does kill sperm cells to prevent pregnancy but does not necessarily kill microbes capable of causing sexually transmitted infections, including HIV infection.

Estrogen–progestin combinations, often referred to as “the pill,” are oral contraceptives that contain both estrogenic and progestational steroids. The most common estrogenic component is ethinyl estradiol, a semisynthetic steroidal estrogen. The most common progestin components are norethindrone and drospirenone.

The currently available oral contraceptives may be *biphasic*, *triphasic*, or *monophasic*, depending on the doses taken at different times of the menstrual cycle. The newest are the extended-cycle oral contraceptives. The biphasic drugs contain a fixed estrogen dose combined with a low progestin dose for the first 10 days and a higher progestin dose for the rest of the cycle; they are available in 21- or 28-day dosage packages. The triphasic products most closely duplicate the normal hormonal levels of the female cycle. There are also oral contraceptives that are progestin-only drugs. The monophasic and triphasic oral contraceptives are the most numerous on the market and the most widely prescribed. The extended-cycle oral contraceptives differ from the traditional 21-days-on, 7-days-off pills by decreasing or eliminating the hormone-free dosing interval. Consecutive days of hormone therapy may extend to between 84 and 365 days. Reasons for switching to an extended-cycle product include improved efficacy in women who forget to restart the pill, shorter hormone free periods, and patient preference to decrease the frequency of menstrual bleeding. Some patients (e.g., those with menstrual irregularities) may require special

assistance in selecting drug products with their health care providers. Three other important contraceptive medications are a long-acting injectable form of medroxyprogesterone, a transdermal contraceptive patch, and, most recently, an intravaginal contraceptive ring.

Mechanism of Action and Drug Effects

Oral contraceptive drugs have the same hormonal effects as the endogenous estrogen and progesterone. The drugs inhibit the release of gonadotropins by the hypothalamic–pituitary system, thus inhibiting ovulation. The exogenous hormones also directly increase uterine mucous viscosity, which results in (1) decreased sperm movement and fertilization of the ovum and (2) possible inhibition of implantation (nidation) of a fertilized egg (zygote) into the endometrial lining.

Other incidental benefits to their use are that they improve menstrual-cycle regularity and decrease blood loss during menstruation. A decreased incidence of functional ovarian cysts and ectopic pregnancies has also been associated with their use.

Indications

Oral contraceptives are used primarily to prevent pregnancy. In addition, they are used to treat endometriosis and hypermenorrhea and to produce cyclic withdrawal bleeding in patients with amenorrhea. Occasionally, combination oral contraceptives are used to provide postcoital contraception. Postcoital contraception pills are not effective if the woman is already pregnant (i.e., egg implantation has occurred) as they do not cause any changes to the lining of the uterus. They should be taken within 72 hours of unprotected intercourse with a follow-up dose 12 hours after the first dose. They are intended to prevent pregnancy after known or suspected contraceptive failure or unprotected intercourse. Ovral® is an ethinyl estradiol (50 mcg) and levonorgestrel (250 mcg) combination drug that is commonly used for this indication. It is taken orally and repeated 12 hours later. Levonorgestrel (Plan B®, NorLevo®, Next Choice®) is also used for postcoital contraception. Plan B and NorLevo consist of two tablets of levonorgestrel 750 mcg taken as a single dose. Next Choice consists of two tablets of levonorgestrel 750 mcg taken 12 hours apart.

One oral contraceptive of note is Seasonale®, which includes both estrogen and progestin components. It is sold in packages containing 3 months of medication, including 1 week of non-hormonal tablets because Seasonale reduces a woman's menstrual cycles to once every 3 months.

Contraindications

Contraindications to the use of oral contraceptives include known drug allergy to a specific product, pregnancy, known high risk for or history of thromboembolic events such as myocardial infarction (MI), venous thrombosis, pulmonary embolism, or stroke, and history of or current breast cancer. Women older than 35 years who smoke, patients with diabetes who have vascular disease, patients with migraine headache who are older than 35 years, and women with hypercoagulopathies should also not take oral contraceptives.

TABLE 35.4 Oral Contraceptives: Common Adverse Effects

Body System	Adverse Effects
Cardiovascular	Hypertension, edema, thromboembolism, pulmonary embolism, myocardial infarction
Central nervous	Dizziness, headache, migraines, depression, stroke
Gastrointestinal	Nausea, vomiting, diarrhea, anorexia, cramps, constipation, increased weight, cholestatic jaundice
Genitourinary	Amenorrhea, cervical erosion, breakthrough bleeding, dysmenorrhea, breast changes

Adverse Effects

Common adverse effects associated with the use of oral contraceptives are listed in Table 35.4. These effects include hypertension, thromboembolism, alterations in carbohydrate and lipid metabolism, increases in serum hormone concentrations, and alterations in serum metal ion concentrations (e.g., zinc, selenium, phosphorus, magnesium) and plasma protein levels. It is the estrogen component that appears to be the source of most of these metabolic effects.

Interactions

Several drugs and drug classes can potentially reduce the effectiveness of oral contraceptives, resulting in an unintended pregnancy. Educate patients about the need to use alternative birth control methods for at least 1 month during and after taking any of the following drugs: antibiotics (especially penicillins and cephalosporins), barbiturates, isoniazid, and rifampin. The effectiveness of other drugs, such as anticonvulsants, β -blockers, hypnotics, antidiabetic drugs, warfarin, theophylline, tricyclic antidepressants, and vitamins, may be reduced when they are taken with oral contraceptives.

Dosages

For the recommended dosages of oral contraceptives, refer to the table below. The Dosages table provides selected examples of the many contraceptive drugs available. All work in similar fashion to prevent pregnancy. They are not to be used during pregnancy. Drugs that are intended for termination of pregnancy are known as *abortifacients* and are discussed later in this chapter.

Drugs for Osteoporosis

Over their lifetime, 1 in 3 Canadian women and 1 in 5 men will experience a fracture as a direct result of **osteoporosis**, characterized by low bone density and deterioration of bone tissue. The majority of fractures (over 80%) occur in individuals over the age of 50 and are more prevalent than heart attacks, strokes, and breast cancer combined. The annual cost to Canadian society is estimated at \$2.3 billion (*Osteoporosis Canada, 2019a*). Risk factors for postmenopausal osteoporosis include gender, age, a fragility fracture over the age of 40, a parent who has

DOSAGES Selected Contraceptive Medications			
Drug	Pharmacological Class	Usual Dosage Range	Indications
Oral Contraceptives			
Levonorgestrel and ethinyl estradiol (Alesse, Alysena, Avian, Esme®, Min-Ovral®, Ovima®, Portia®)	Biphasic: fixed estrogen–variable progestin 21- or 28-day products	3 or 4 monthly phases of variable estrogen and progestin combinations; 21- or 28-day products; 28-day products contain 7 inert tabs	Prevention of pregnancy
norethindrone and ethinyl estradiol (Brevicon®, Loestrin®, Symphasic®)	Monophasic: fixed estrogen–progestin combinations; 21- or 28-day products	Monthly phase of 21-day or 28-day products; 28-day products contain 7 inert tablets	
levonorgestrel and ethinyl estradiol (Ortho 7/7/7®, Triquilar®)	Triphasic: 3 or 4 monthly phases of variable estrogen and progestin combinations	Monthly phase of 21-day or 28-day products; 28-day products contain 7 inert tablets	
levonorgestrel and ethinyl estradiol (Seasonale)	Extended-cycle products		
Norgestimate and ethinyl estradiol (Tri-cyclen®, Tri-Cyclen Lo®, Cyclen®)			
Desogestrel and ethinyl estradiol (Linessa®, Marvelon®)			
Drospirenone and ethinyl estradiol (Yaz®, Yasmin®, Mya®, Zarah®, Zamine®)			
Injectable Contraceptives (Depot)			
 medroxyprogesterone acetate (Depo-Provera)	Progestin-only injectable contraceptive	IM: 150 mg q3 months	
Transdermal Contraceptives			
norelgestromin and ethinyl estradiol (Ortho Evra®)	Fixed-combination estrogen–progestin transdermal contraceptive	Transdermal patch: 1 patch applied weekly ×3 each month, scheduled around menses in wk 4	
Intravaginal Contraceptives			
etonogestrel/ethinyl estradiol vaginal ring (NuvaRing®)	Fixed-combination estrogen–progestin intravaginal contraceptive	One ring inserted into vagina by patient and left in place for 3 wk, followed by 1-wk removal. A new ring is then inserted.	
Hormonal Intrauterine System			
Mirena®, Kyleena®, Skyla®	Hormonal intrauterine device that releases progestin	Up to 5 years. A new IUS is then inserted.	

IM, intramuscular.

had a hip fracture, use of glucocorticoid drugs for more than 3 months, vertebral compression fracture, medical conditions in which absorption of nutrients is inhibited, and any other medical condition that may cause bone loss ([Osteoporosis Canada, 2019a](#)). Additional risk factors include smoking, heavy alcohol consumption, particularly during adolescence and young adulthood, menopause before age 45, low estrogen levels, and weight under 60 kg. The emphasis of the most recent osteoporosis guidelines is on the need to assess for fracture risk with the goal of preventing the excess morbidity, mortality, and economic burden associated with osteoporosis and associated fragility fractures. Approximately 30 000 hip fractures occur annually in Canada, with 1 in 3 patients with hip fracture refracturing within 1 year and more than 1 in 2 within 5 years ([Osteoporosis Canada, 2019a](#)).

Peak bone mass is achieved between the ages of 16 to 20 in girls and between the ages of 20 to 25 in young men. Bone loss

begins in the mid-30s for both women and men, and at menopause, women begin to lose bone at a rate of between 2% to 3% per year ([Osteoporosis Canada, 2019a](#)). Supplementation with calcium and vitamin D is thought to play a role in the prevention of osteoporosis. Current Canadian recommendations are that women older than age 50 have a daily intake of 1 200 mg of calcium through diet and supplements (those from 19 to 50 should have a daily intake of 1 000 mg). Also to support bone health, [Osteoporosis Canada \(2019b\)](#) recommends daily supplementation with 800 to 2 000 units of vitamin D for adults over the age of 50 or young adults at high risk (and 400 to 1 000 units for adults between the age of 19 to 50).

Several drug classes are used for the treatment of existing osteoporosis: the bisphosphonates, the selective estrogen receptor modulators (SERMs), the hormones calcitonin and teriparatide, and, more recently, denosumab. Currently available bisphosphonates used for osteoporosis prevention and treatment

include alendronate, etidronate disodium in combination with 500 mg of calcium carbonate (Didrocal® and Etidrocal® are the only forms used for the treatment of osteoporosis), risedronate sodium hemipentahydrate (Actonel®, Actonel DR®), and once-a-year injection of zoledronic acid. Raloxifene and tamoxifen are the currently available SERMs. Tamoxifen is primarily used in oncology settings and is discussed further in [Chapter 53](#). Raloxifene is indicated for use in the prevention and treatment of osteoporosis. Teriparatide stimulates bone formation, while denosumab (Prolia®, Xgeva®) prevents bone resorption.

Mechanism of Action and Drug Effects

Bisphosphonates. The bisphosphonates work by inhibiting osteoclast-mediated bone resorption, which in turn indirectly enhances bone mineral density. Osteoclasts are bone cells that break down bone, causing calcium to be reabsorbed into the circulation; this resorption eventually leads to osteoporosis if not controlled or countered by adequate new bone formation. Strong clinical evidence indicates that these drugs cause reversal of lost bone mass and reduction of fracture risk, and, as a result, they are considered drugs of choice for this condition.

Selective estrogen receptor modulators. Raloxifene helps prevent osteoporosis by stimulating estrogen receptors on bone and increasing bone density in a manner similar to the estrogens.

Teriparatide. In contrast to the other therapies described thus far, which inhibit bone resorption, teriparatide is the first and currently only drug available that acts by stimulating bone formation. It is a derivative of parathyroid hormone and acts to treat osteoporosis by modulating the body's metabolism of calcium and phosphorus in a manner similar to that of the natural parathyroid hormone.

Denosumab. Denosumab (Prolia) is a monoclonal antibody that blocks osteoclast activation, thereby preventing bone resorption. It is given as a subcutaneous injection once every 6 months along with daily calcium and vitamin D supplementation. Denosumab is used in the treatment of osteoporosis and bone metastases.

Indications

Raloxifene is used primarily for the prevention of postmenopausal osteoporosis. The bisphosphonates are used in both the prevention and treatment of osteoporosis. Teriparatide is used mainly for the subset of osteoporosis patients at highest risk of fracture (e.g., those with prior fracture).

Contraindications

Bisphosphonates. Contraindications to bisphosphonate use include drug allergy, hypocalcemia, esophageal dysfunction, and the inability to sit or stand upright for at least 30 minutes after taking the medication (see further discussion below under Adverse Effects).

Selective estrogen receptor modulators. Use of SERMs is contraindicated in women with a known allergy to these drugs, in women who are or may become pregnant, and in women with a history of or a current venous thromboembolic

disorder, including DVT, pulmonary embolism, and retinal vein thrombosis.

Teriparatide. Contraindications to the use of teriparatide include known drug allergy.

Denosumab. Contraindications to the use of denosumab are hypocalcemia, kidney impairment or failure, and infection.

Adverse Effects

The primary adverse effects of SERMs are hot flashes and leg cramps. They can increase the risk of venous thromboembolism and are teratogenic. Leukopenia may also occur and predispose the patient to various infections. The most common adverse effects of bisphosphonates include headache, GI upset, and joint pain. However, the bisphosphonates are usually well tolerated. There is a risk of esophageal burns with these medications if they become lodged in the esophagus before reaching the stomach. For this reason, patients must take these medications with a full glass of water and must remain sitting upright or standing for at least 30 minutes afterward.

Several early case reports of osteonecrosis of the jaw in patients taking bisphosphonates have been released. Health Canada issued a public health advisory in 2011 alerting health care providers to the possible association between long-term bisphosphonate use and the development of severe (possibly incapacitating) bone, muscle, or joint pain, as well as low-energy fractures. New information indicates a higher incidence of osteonecrosis of the jaw with intravenous (IV) bisphosphonates as opposed to oral bisphosphonate medication. Other considerations regarding the incidence of osteonecrosis of the jaw include age, oral surgery, comorbidities (i.e., diabetes), tobacco use, and dental hygiene ([Payne, Goodson, Tahim, et al., 2017](#)). IV bisphosphonates are often associated with an acute-phase reaction within 24 to 72 hours of the infusion, characterized by low-grade fever, myalgias, and arthralgias. These symptoms subside with subsequent infusions. The risk of atypical fracture of the femur is reported to be less than 1%; this is thought to be the result of bone turnover suppression, during which old bone is replaced with new bone at a slow pace, resulting in microfractures and potential fracture.

Common adverse effects of teriparatide include chest pain, dizziness, hypercalcemia, nausea, and arthralgia. Infections occur more frequently in those taking denosumab.

Interactions

Cholestyramine and ampicillin decrease the absorption of raloxifene, and raloxifene can decrease the effects of warfarin sodium. Calcium supplements and antacids can interfere with the absorption of the bisphosphonates, and therefore they need to be spaced 1 to 2 hours apart to avoid this interaction. Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) have the potential for additive GI irritation if taken with bisphosphonates.

Dosages

For the recommended dosages of osteoporosis drugs, refer to the table on p. 585.

DRUG PROFILES

alendronate sodium

Alendronate sodium (Fosamax®) is an oral bisphosphonate and the first nonestrogen–nonhormonal option for preventing bone loss. This drug acts by inhibiting or reversing osteoclast-mediated bone resorption. Recall that osteoclasts are the bone cells that cause breakdown or resorption of bone tissue as part of their normal physiological action. However, unchecked osteoclastic activity often leads to osteoporosis if not managed, so this drug represents a major breakthrough in the treatment of osteoporosis. It is indicated for the prevention and treatment of osteoporosis in men and in postmenopausal women. It is also indicated for the treatment of glucocorticoid-induced osteoporosis in men and for the treatment of Paget's disease in women. Data show that alendronate may reduce the risk of hip fracture. Take precautions in caring for patients with dysphagia, esophagitis, esophageal ulcer, or gastric ulcer because the drug can be extremely irritating to esophageal tissue. Case reports of esophageal erosions have been published. It is recommended that alendronate be taken with 240 mL of water immediately upon rising in the morning and that patients not lie down for at least 30 minutes after taking it. When patients whose condition has been stabilized on alendronate are hospitalized and cannot adhere to these recommendations, the medication is often withheld. Alendronate has an extremely long-term half-life, and so going several days without taking a dose will do little to reduce the therapeutic efficacy of the drug. There is debate over how long a woman should remain on bisphosphonate therapy, with most experts recommending a drug holiday after approximately 5 to 10 years.

Alendronate is available in tablet form combined with 2 800 and 5 600 units of vitamin D (Fosavance®). It can be taken daily (10 mg) or weekly (70 mg) for treatment of osteoporosis.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	3 wk	Unknown	Longer than 10 yr due to storage in bone tissue	Unknown

raloxifene hydrochloride

Raloxifene hydrochloride (Evista®) is a SERM. It is used primarily for the prevention of postmenopausal osteoporosis. Interestingly, raloxifene has positive effects on cholesterol levels, but it is not normally used specifically for this purpose. It may not be the best choice for women near menopause because use of the drug is associated with the adverse effect of hot flashes. It is available only for oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	8 wk	Unknown	28 hr	Unknown

DRUGS RELATED TO PREGNANCY, LABOUR, DELIVERY, AND THE POSTPARTUM PERIOD

Fertility Drugs

Infertility in women is often the result of the absence of ovulation (anovulation), which is normally due to various imbalances in female reproductive hormones. Such imbalances can occur at the level of the hypothalamus, the pituitary gland, the ovary, or any combination of these. Exogenous administration of estrogens or progestins may be used to fortify the blood levels of these hormones when ovarian output is inadequate. The uses of the drug forms of these hormones were described earlier in this chapter.

Hormone deficiencies at the hypothalamic and pituitary levels are often treated with gonadotropin ovarian stimulants. These drugs stimulate increased secretion of gonadotropin-releasing hormone (Gn-RH) from the hypothalamus, which then results in increased secretion of FSH and LH from the pituitary gland. These hormones, in turn, stimulate the development of ovarian follicles and thus ovulation. They also stimulate ovarian secretion of the estrogens and progestins that are part of the normal ovulatory cycle. Proper selection and dosage adjustment of fertility drugs often requires the expertise of a fertility specialist. The various medical techniques used in the treatment of infertility, including drug therapy, are now collectively referred to as

DOSAGES Selected Drugs Used Specifically for Osteoporosis

Drug	Pharmacological Class	Usual Dosage Range	Indications
 alendronate sodium (Fosamax)	Bisphosphonate	PO: 5 mg/day PO: 10 mg/day or 70 mg/wk	Osteoporosis prevention and treatment
etidronate disodium (Ditrocal, Etidrocal)	Bisphosphonate and calcium	PO: cyclical regimen administered in 90-day cycles. Each white 400-mg etidronate disodium tablet is taken once daily × 14 days, followed by 76 blue calcium carbonate tablets to be taken once daily × next 76 days	Osteoporosis prevention and treatment
risedronate sodium (Actonel, Actonel DR)	Bisphosphonate	PO: 5 mg/day; 35 mg/wk; 150 mg once monthly	Osteoporosis prevention and treatment
raloxifene hydrochloride (Evista)	Selective estrogen receptor modulator	PO: 60 mg daily	Osteoporosis prevention and treatment

PO, oral.

assistive reproductive technology. One common specific technique is in vitro fertilization, during which a woman's ovum is fertilized with her partner's sperm in a laboratory and the fertilized ovum is then medically implanted into the woman's uterus. The success of such fertilization techniques may be further encouraged with the use of medications such as those described earlier. Representative examples of ovulation-stimulant drugs include the drugs clomiphene, menotropins, and choriogonadotropin alfa.

Mechanism of Action and Drug Effects

Letrozole (Femara®) is a nonsteroidal aromatase inhibitor used off-label for ovarian stimulation. This action reduces estrogen production by aromatase inhibition. The inhibition of estrogen synthesis leads to feedback increases in gonadotropin (LH, FSH) levels, stimulation of follicular growth, and ovulation induction. Human chorionic gonadotropin (hCG) injections may also be added to therapy to enhance fertility. Ideally, this sequence of events leads to ovulation and increases the likelihood of conception in a previously infertile woman.

Menotropins is the drug name for a standardized mixture of FSH and LH that is derived from the urine of postmenopausal women. The FSH component stimulates the development of ovarian follicles, which leads to ovulation. The LH component stimulates the development of the corpus luteum, which supplies female sex hormones (estrogens and progesterone) during the first trimester of pregnancy. Choriogonadotropin alfa is a recombinant form (i.e., developed using recombinant DNA technology) of the hormone human chorionic gonadotropin. This hormone is naturally produced by the placenta during pregnancy and can be isolated from the urine of pregnant women. It is an analogue of LH and can provide a substitute for the natural LH surge that promotes ovulation. It does this by binding to LH receptors in the ovary and stimulating the rupture of mature ovarian follicles and the subsequent development of the corpus luteum. Human chorionic gonadotropin also maintains the viability of the corpus luteum during early pregnancy. This is crucial because the corpus luteum provides the supply of estrogens and progesterone necessary to support the first trimester of pregnancy until the placenta assumes this role. Choriogonadotropin alfa is often given in a carefully timed fashion following FSH-active therapy, such as with menotropins or clomiphene, when patient monitoring indicates sufficient maturation of ovarian follicles.

Indications

The drugs just discussed are used primarily for the promotion of ovulation in anovulatory female patients. They may also be used to promote spermatogenesis in infertile men. As was mentioned in the section on progestins, progesterone formulations are also used to treat female infertility.

Contraindications

Contraindications to the use of ovarian stimulants include known drug allergy to a specific product and may also include primary ovarian failure, uncontrolled thyroid or adrenal dysfunction, liver disease, pituitary tumour, abnormal uterine

TABLE 35.5 Fertility Drugs: Most Common Adverse Effects

Body System	Adverse Effects
Cardiovascular	Tachycardia, phlebitis, deep vein thrombosis, hypovolemia
Central nervous	Dizziness, headache, flushing, depression, restlessness, anxiety, nervousness, fatigue
Gastrointestinal	Nausea, bloating, constipation, vomiting, anorexia
Other	Urticaria, ovarian hyperstimulation, multiple pregnancies (twins or more), blurred vision, diplopia, photophobia, breast pain

bleeding, ovarian enlargement of uncertain cause, sex hormone-dependent tumours, and pregnancy.

Adverse Effects

The most common adverse effects of the ovulation stimulants are listed in [Table 35.5](#).

Interactions

The most notable drugs that interact with fertility drugs are the tricyclic antidepressants, the butyrophenones (e.g., haloperidol), the phenothiazines (e.g., promethazine hydrochloride), and the antihypertensive drug methyldopa. When any of these drugs are taken with fertility drugs, prolactin concentrations may be increased, which may impair fertility.

Dosages

For recommended dosages of clomiphene, refer to the table below.

DOSAGES Selected Fertility Drugs			
Drug	Pharmacological Class	Usual Dosage Range	Indications
clomiphene citrate (Clomid, Serophene)	Ovulation stimulant	PO: 50–100 mg daily for 5 days; cycle repeatable depending on response	Female infertility in selected patients

PO, oral.

Uterine Stimulants

A variety of medications are used to alter the dynamics of uterine contractions either to promote or prevent the start or progression of labour. In the immediate postpartum period, medications may also be used to promote rapid shrinkage (involution) of the uterus to reduce the risk of postpartum hemorrhage.

Three types of drugs are used to stimulate uterine contractions: ergot derivatives, prostaglandins, and the hormone oxytocin. These drugs all act on the uterus, a highly muscular organ that has a complex network of smooth muscle fibres and a large blood supply. They are often collectively referred to as *oxytocics*, after the naturally occurring hormone oxytocin, whose action they mimic. The uterus undergoes several changes during normal gestation and childbirth that at different times make it either resistant

or susceptible to various hormones and drugs. Oxytocin is one of the two hormones secreted by the posterior lobe of the pituitary gland; the other is vasopressin, which is also known as *antidiuretic hormone* (see [Chapter 31](#)).

Mechanism of Action and Drug Effects

The uterus of a woman who is not pregnant is relatively insensitive to oxytocin, but during pregnancy, the uterus becomes more sensitive to this hormone and is most sensitive at term (the end of gestation).

During childbirth, oxytocin stimulates uterine contraction, and during lactation, it promotes the movement of milk from the mammary glands to the nipples. Another class of oxytocic drugs is the prostaglandins, natural hormones involved in regulating the network of smooth muscle fibres of the uterus. This network is known as the *myometrium*. Prostaglandins cause potent contractions of the myometrium and may also play a role in the natural induction of labour. When prostaglandin concentrations increase during the final few weeks of pregnancy, mild myometrial contractions, commonly known as Braxton Hicks contractions, are stimulated. The third major class of oxytocic drugs is the ergot alkaloids, which are also potent simulators of uterine muscle. These drugs increase the force and frequency of uterine contractions.

Indications

Oxytocin is available in a synthetic injectable form. This drug is used to induce labour at or near full-term gestation and to enhance labour when uterine contractions are weak and ineffective. Oxytocin is also used to prevent or control uterine bleeding after delivery, to induce completion of an incomplete abortion (including miscarriages), and to promote milk ejection during lactation.

The prostaglandins may be used therapeutically to induce labour by softening the cervix and enhancing uterine muscle tone. Cervical ripening (softening of the cervix) is determined by the Bishop score, a system used to determine the readiness of the cervix for induction of labour. The Bishop score is determined by assigning points to five measurements of the pelvic examination: dilation, effacement of the cervix, station of the fetus, consistency of the cervix, and position of the cervix.

The prostaglandins may also be used to stimulate the myometrium to induce abortion during the second trimester when the uterus is resistant to oxytocin. Examples of these drugs are dinoprostone, misoprostol and, mifepristone/misoprostol. Misoprostol is an oral tablet and is also used as a stomach protectant (see [Chapter 39](#)). It is used off-label for cervical ripening and is administered orally or intravaginally. It offers the advantage of lower cost as opposed to the more expensive drug dinoprostone. Because of this, misoprostol is widely used in developing countries as well as in Canada. Be aware that the prescribing information states that misoprostol should not be used in this way; however, it is common to see it used thusly clinically.

Ergot alkaloids are used after delivery of the infant and placenta to prevent postpartum uterine atony (lack of muscle tone) and hemorrhage.

TABLE 35.6 Oxytocic Drugs: Most Common Adverse Effects

Body System	Adverse Effects
Cardiovascular	Hypotension or hypertension, chest pain
Central nervous	Headache, dizziness, fainting
Gastrointestinal	Nausea, vomiting, diarrhea
Genitourinary	Vaginitis, vaginal pain, cramping
Other	Leg cramps, joint swelling, chills, fever, weakness, blurred vision

Mifepristone (Mifegymiso®) is a progesterone antagonist that stimulates uterine contractions and is used to induce elective termination of pregnancy at between 7 and 9 weeks. The drug is often given with the synthetic prostaglandin drug misoprostol for this purpose. Mifepristone should not be prescribed to individuals who are greater than 9 weeks pregnant or have an ectopic pregnancy. If given to a patient greater than 9 weeks pregnant, the pregnancy may not be successfully terminated, there may be damage to the fetus, or there may be significant health risk to the pregnant woman. If the medication is given to woman who has an ectopic pregnancy, the mifepristone may have symptoms of a ruptured ectopic pregnancy, as symptoms associated may be similar. Health Canada (2019), suggests an ultrasound is no longer necessary prior to the administration of the medication. Ella (Ulipristal), also a progesterone antagonist, has been approved in Canada as an emergency contraceptive.

Contraindications

Contraindications to the use of labour-inducing uterine stimulants include known drug allergy to a specific product. Additional contraindications may include pelvic inflammatory disease, cervical stenosis, uterine fibrosis, high-risk intrauterine fetal positions before delivery, placenta previa, hypertonic uterus, uterine prolapse, or any condition in which vaginal delivery is contraindicated (e.g., increased bleeding risk). Contraindications to the use of abortifacients include known drug allergy, the presence of an intrauterine device, ectopic pregnancy, concurrent anticoagulant therapy or bleeding disorder, inadequate access to emergency health care, or inability to understand or adhere to follow-up instructions.

Adverse Effects

The most common undesirable effects of oxytocic drugs are listed in [Table 35.6](#).

Interactions

Few clinically significant drug interactions occur with the oxytocic drugs. The most common and important of these involve sympathomimetic drugs. Combining drugs that produce vasoconstriction, such as the sympathomimetics, with oxytocic drugs can result in severe hypertension.

Dosages

For the recommended dosages of selected oxytocic drugs, refer to the table on p. 588.

DRUG PROFILES

dinoprostone

Dinoprostone (Prostin E₂®, Cervidil®, Prepidil®) is a synthetic derivative of the naturally occurring hormone prostaglandin E₂. It is used for ripening of an unfavourable cervix in pregnant women, at or near term, with a medical or obstetric need for labour induction. It is available for vaginal use as a gel in various dosage forms, a vaginal insert, and for oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Vaginal	10 min	30–45 min	2–5 min	Not available 2–3 hr

ergonovine maleate

The ergot alkaloid ergonovine maleate is used primarily in the immediate postpartum period to enhance myometrial tone and reduce the likelihood of postpartum uterine hemorrhage. Its use is contraindicated in patients with a known hypersensitivity to ergot medications and in those with pelvic inflammatory disease. It should be used with caution in patients with hypertension. It is not to be used for augmentation of labour, before delivery of the placenta, or during a spontaneous abortion; it should also not be given to patients with pregnancy-induced hypertension. Ergonovine maleate is available for injection use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IM	2–5 min	30 min	0.5–2 hr	3 hr

oxytocin

The drug oxytocin is the synthetic form of the endogenous hormone oxytocin and has all of its pharmacological properties.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Immediate	Immediate	3–5 min	1 hr

Drugs for Preterm Labour Management

Preterm labour is defined as substantial uterine contractions that could progress to delivery, occurring prior to the 37th week of pregnancy. When contractions of the uterus begin before term, it may be desirable to stop labour because premature birth increases the risk of neonatal death. Postponing delivery increases the likelihood of the infant's survival. However, this measure is generally employed only between weeks 20 and 37 of gestation because spontaneous labour occurring before the 20th week is commonly associated with a nonviable fetus and thus is usually not interrupted.

The nonpharmacological treatment of premature labour includes bedrest, sedation, and hydration. Drugs given to inhibit labour and maintain the pregnancy are called *tocolytics*. Tocolytics have generally been found useful only in the short term to delay labour and allow for the administration of corticosteroids to accelerate the maturity of fetal lung development. Generally, tocolytics can delay labour for approximately 48 hours. Clear evidence that tocolytics reduce neonatal mortality or serious neonatal morbidity is limited. Currently available tocolytics, including the NSAIDs indomethacin and naproxen (considered prostaglandin synthesis inhibitors), the calcium

Selected Uterine Stimulants

Drug	Pharmacological Class	Usual Dosage Range	Indications
 dinoprostone (Prostin E ₂ , Cervidil, Prepidil)	Prostaglandin E ₂ abortifacient and cervical ripening drug	Vaginal insert (Cervidil): 10 mg (released at 0.3 mg/hr over 12 hr) placed transversely into posterior vaginal fornix (the space behind the cervix) Cervical gel (Prostin E ₂ gel): 1 mg in posterior fornix of vaginal canal; 1–2 mg repeated once in 6 hr PO: Tablets (Prostin E ₂): 0.5 mg followed by 0.5 mg/hr × 8 hr Vaginal gel (Prepidil): 0.5 mg into internal cervical os	Cervical ripening for induction of labour Cervical ripening for induction of labour Elective and indicated induction of labour Cervical ripening for induction of labour
 ergonovine maleate	Oxytocic ergot alkaloid	IM: 200 mcg after delivery of placenta, repeatable at 2- to 4-hr intervals, up to 5 doses IV: 200 mcg in 5 mL NS over 1 min	Postpartum uterine atony and hemorrhage Emergency situations of excessive uterine bleeding
 oxytocin (X)	Oxytocic hypothalamic hormone	IV infusion: 1–2 microunits/min, titrated to effect IV: 10–40 units in 1 L of nonhydrating solution titrated to effect IM: 10 units in a single dose after delivery of placenta	Labour induction Postpartum uterine atony and hemorrhage

IM, intramuscular; IV, intravenous; NS, normal saline; PO, oral.

channel blocker nifedipine, and magnesium sulphate have not been shown to significantly improve outcomes. A Canadian-led study on nitroglycerin found that neonatal outcomes were improved but the overall effect was insignificant (Guo, Longo, Xie, et al., 2011). Neonatal outcome improvement may be associated with the smooth muscle relaxation effect of nitroglycerin and improved placental blood flow. Because of the lack of evidence on the use of tocolytics in Canada, further discussion is not warranted here.

Pharmacokinetic Bridge to Nursing Practice

EstroGel® is a form of estrogen that is approved to help ease the severity of postmenopausal hot flashes by increasing estrogen levels when these are found to be deficient in the patient. Estradot contains estradiol, which is identical to endogenous estrogen produced in women's bodies. The absorption of the topical emulsion dosage form results in measurable levels of estradiol on the skin for up to 8 hours after application. It is important to fully understand this pharmacokinetic property because the transfer of the drug to another individual may result. In fact, traces of Estradot have been found on other individuals from such transfer for up to a 2-day period. This transfer of medication to other individuals may be reduced by allowing the dosage form to fully dry and then covering it with clothing before having contact with another individual. Although no specific investigation of the tissue distribution of the estradiol absorbed from EstroGel in humans has been conducted, it is known that the distribution of exogenous estrogens is similar to that of endogenous estrogens. The metabolism of exogenous estrogens is also similar to that of endogenous estrogens, with biotransformation taking place mainly in the liver and excretion in the urine. The specific dosage form of an emulsion is desirable because it may be applied easily, once daily to the thighs or calves. One dose is contained in two separate foil pouches, and patients need to be fully aware of the application instructions. For example, sunscreen products are not to be applied at the same time because sunscreen reduces the absorption of EstroGel.

Knowing the pharmacokinetic properties of EstroGel is necessary for safe and efficient administration of the drug. It is also important to understand all the pharmacokinetic properties of this drug in order to be able to thoroughly educate patients about the drug, its effect on the body, and subsequent implications for its absorption, distribution, metabolism, and excretion.

◆ Pituitary Gonadotropin Inhibitor

Another drug used for women's health is the synthetic androgen, danazol (Cyclomen®). Danazol suppresses the pituitary-ovarian axis and inhibits the output of gonadotropins from the pituitary gland. It is used for the treatment of endometriosis and fibrocystic breast changes in women.

Endometriosis is an estrogen-dependent disorder in which endometrial tissue develops outside of the uterus on the ovaries, fallopian tubes, bowel, bladder, or tissue lining the pelvic cavity. It occurs in approximately 10% of women of reproductive age and causes severe pelvic pain and possible infertility. Danazol

alters the endometrium so that it becomes inactive and atrophic. Danazol is administered in total daily doses ranging from 200 mg to 800 mg in 2 to 4 divided doses. It is given continuously for 3 to 6 months.

Fibrocystic breast changes are characterized by thickening, lumps, and cysts (fluid-filled sacs) in the breast tissues. These affect more than 50% of women between the ages of 30 and 50 during their lifetime. The action of danazol on the breasts is not known. The total daily dose of danazol is 100 mg to 400 mg given in 2 divided doses. Pain and tenderness usually respond to treatment after 30 to 40 days. However, breast lumps usually do not begin to regress until 60 to 90 days after the initiation of therapy.

Common adverse effects that can occur in patients receiving danazol are acne, edema (facial), mild hirsutism, decrease in breast size, deepening of the voice, oiliness of the skin or hair, weight gain, and seborrhea.

◆ NURSING PROCESS

◆ ASSESSMENT

In this section, estrogenic and progestational (progestins or progesterone drugs) medications are discussed first, followed by the major drug classes used in the treatment of osteoporosis. Next, information on fertility drugs, uterine stimulants, and preterm labour management drugs is discussed. Before initiating therapy with any of the hormonal drugs (e.g., estrogens, progestins) or other women's health-related drugs, obtain the patient's blood pressure and weight and document the findings. Assess and document drug allergies, contraindications, cautions, and possible drug interactions. Include a thorough medication history, medical history, and menstrual history in the patient assessment. Note the results of the patient's last physical examination, clinician-performed breast examination, and gynecological examination as well.

Estrogen-only hormones are to be given only after the following disorders and conditions have been ruled out: any estrogen-dependent cancer, undiagnosed abnormal uterine bleeding, or active thromboembolic disorders such as stroke or thrombophlebitis or a history of these disorders. Include questions about breast examination, breast self-examination practices, and dates of last complete physical examination and Papanicolaou (Pap) smear in the assessment. It is important to assess for potential drug interactions, such as with tricyclic antidepressants, which may reach toxic levels if given with estrogens. Advise patients to avoid smoking because of the risk of thrombosis. It has been documented that smoking also decreases the effectiveness of estrogen; hence, take a thorough smoking history. Ask about the number of packs smoked per day and the number of years the patient has smoked. Other drug interactions to assess for include oral anticoagulants (because of decreased effectiveness) as well as rifampin and St. John's wort (because of decreased estrogen effectiveness). If being used for HT for menopausal symptoms, recent changes to older recommendations from the NAMS (2017)

include the following: (1) hormone replacement is not recommended for women with histories of endometrial cancer, and (2) in women with breast cancer, estrogen therapy remains controversial, especially in estrogen-receptor positive cancers. Therefore, perform a thorough assessment for history or diagnosis of endometrial or breast cancer. Bone density may also be impacted once hormone therapy is discontinued; further assessment is needed in patients with histories of endometrial or breast cancer.

Assess patients' knowledge about the use of hormones (e.g., estrogens and progestins), whether for contraception or replacement therapy. Also assess their readiness to learn, their educational level, and the degree of adherence to other medication regimens. The success of treatment with oral contraceptives, hormone replacement medications, and other therapies depends heavily on patients' understanding of instructions. With oral contraceptive drugs (e.g., combination estrogen-progestin drugs), perform a pregnancy test and assess for history of vascular or thromboembolic disorders (e.g., MI, venous thrombosis, stroke), malignancies of the reproductive tract, and abnormal vaginal bleeding. Closely monitor patients with the following: hypertension, migraine headaches, alterations in lipid or carbohydrate metabolism, fluid retention or edema, hair loss, amenorrhea, breakthrough vaginal or uterine bleeding, and uterine fibroids. The concern in the presence of any of these conditions is the potential for their exacerbation and for subsequent complications. Closely monitor patients who smoke because of their increased risk of complications (increased risk of thrombosis) with estrogens. Assess for drug interactions, such as with drugs leading to decreased effectiveness of oral contraception—antibiotics (especially penicillins and cephalosporins), barbiturates, isoniazid, and rifampin. Drugs that may have their therapeutic effects decreased if taken concurrently with oral contraceptives include β -blockers, hypnotics, antidiabetic drugs, warfarin sodium, theophylline, tricyclic antidepressants, and vitamins. Antiepileptic medications decrease concentrations of oral contraceptives and a second method of contraception (condoms) is recommended. This information should be provided during patient education as an unintended pregnancy could be teratogenic to the fetus. When combination oral contraceptives are used for postcoital conception, the same contraindications, cautions, and drug interactions apply, even if the drug is for one-time use.

The chemically derived progestins, such as medroxyprogesterone and megestrol, have the same contraindications as estrogens. Additionally, with progestins, assess for a history of liver or gallbladder disease and thrombophlebitis. Be mindful that a significant drug interaction occurs with antidiabetic drugs. Thoroughly review the patient's medical history to be aware of the specific condition for which the progestin is ordered. Some of these include prevention of endometrial cancer caused by estrogen therapy, palliative management of recurrent endometrial or breast cancer, and management of anorexia and cachexia in patients with cancer.

With the drug class of bisphosphonates, used in the treatment of osteoporosis, there are many contraindications, cautions, and drug interactions. Assessment of the following is

therefore important to patient safety: drug allergy, esophageal dysfunction, hypocalcemia, and the inability to sit or stand upright for at least 30 minutes after taking the medication. SERMs are not to be used in patients who are or may become pregnant and in women with thromboembolic disorders including DVT. Assess for allergies to salmon with the use of the hormone calcitonin because the drug is derived from this fish. Drug interactions for which to assess include ampicillin and cholestyramine because they decrease the absorption of raloxifene. Raloxifene also decreases the effects of warfarin sodium. Assess patients for the drug interaction between bisphosphonates and calcium supplements or decreased absorption that occurs with the concurrent use of antacids as well as the potential for additive GI irritation with the concurrent use of aspirin and NSAIDs.

Use of clomiphene requires assessment of the patient's medical and medication history, with attention to the patient's menstrual history. Medical history is crucial to know, especially reproductive and uterine status, because use of the drug may result in multiple pregnancy (twins or more) and compromise maternal health status. Patients are usually followed by a fertility specialist affiliated with a specialty clinic, where assessment of family stability and economic status will be undertaken because of the additional family and financial stressors associated with a multiple birth. Also include assessment of possible contraindications, such as primary ovarian failure (or primary ovarian insufficiency), when ovaries stop functioning before the age of 40, adrenal or thyroid dysfunction, liver disease, or abnormal uterine bleeding. Assess also for potential drug interactions with tricyclic antidepressants, haloperidol, phenothiazines, and methyl dopa (an antihypertensive drug). Fertility may be impaired if clomiphene is given with these drugs.

Before administering uterine stimulants (e.g., oxytocin or prostaglandins), assess and document the patient's blood pressure, pulse, and respiration. Also determine fetal heart rate and contraction-related fetal heart rates and document findings. Contraindications to the use of labour-inducing uterine stimulants in early pregnancy include the presence of an intrauterine device for birth control, ectopic pregnancy, use of anticoagulants, bleeding disorders, and inability to understand and then adhere to instructions. Assess for the concurrent use of sympathomimetics because of enhanced vasoconstrictive effects, possibly leading to severe hypertension. For labour and delivery, the patient's cervix must be ready for induction. (Consult a current maternal child health or obstetric nursing textbook for more information on the rating of the cervix.) Perform continuous monitoring of maternal blood pressure, pulse, contractions, and fluid status, as well as of fetal heart rate. Oxytocin is *not* used during the first trimester except in some cases of spontaneous or induced abortion.

With the ergot alkaloid methylergonovine maleate, assess the medication order after vital signs have been taken and note that the first dose is given after delivery of the placenta to help stimulate the uterus to contract and decrease blood loss after delivery in special situations. Continue to assess blood pressure

during the drug's administration. Assess for contraindications such as pregnancy, labour, liver or renal disease, heart disease, and pregnancy-induced hypertension. Assess for any history of seizures. If this drug is given to women with hypertension, it may precipitate seizures or a stroke. The use of dinoprostone or other prostaglandin E₂ drugs is indicated in specific situations requiring termination of pregnancy. Ask the patient about the presence of any known contraindications, cautions, and drug interactions.

◆ NURSING DIAGNOSES

- Decisional conflict as a result of the risks versus benefits of postmenopausal estrogen replacement therapy
- Acute pain as a result of adverse effects and improper dosing of an SERM
- Nonadherence as a result of lack of information and experience with daily dosing of oral contraceptives

◆ PLANNING

◆ Goals

- Patient will make an informed decision regarding the use of estrogen replacement therapy.
- Patient will experience minimal pain (epigastric) associated with SERMs.
- Patient will remain adherent to oral contraceptive therapy.

◆ Expected Patient Outcomes

- Patient correctly self-administers estrogen replacement therapy daily after making the decision to opt for pharmacological treatment.
- Patient remains without esophageal pain after taking an SERM as ordered and with the full ability to sit or stand upright for at least 30 minutes after taking the oral dosage form, to avoid esophageal irritation.
- Patient is adherent to oral contraceptive therapy, states rationale for daily use (effectiveness based on taking medication daily), and contacts a health care provider with any high incidence of adverse effects.

◆ IMPLEMENTATION

When administering estrogens, directions need to be followed exactly. Provide precise and thorough instructions to patients when self-administration of the hormone is ordered. Oral dosage forms are best taken at the same time every day and with a meal or a snack to minimize GI upset.

It is also important to understand the indication and rationale for the use of estrogen so that you can give accurate facts about the drug to patients. If estradiol is being given, vasomotor symptoms of menopause are generally the indication, and the drug is to be given daily at the same time. If the estradiol transdermal patch is given, it is to be applied as ordered, usually with one patch applied once or twice weekly to the lower abdomen and not to the breast and chest areas. See the Patient Teaching Tips for more information.

Use of progestins is indicated for birth control, such as the use of Depo-Provera with one IM injection every 3 months. However, the use of Depo-Provera in women of reproductive age remains controversial because of associated bone density loss. Give Depo-Provera injections in deep muscle mass and rotate sites. Oral forms of medroxyprogesterone are used for amenorrhea and uterine bleeding. Doses are to be taken exactly as ordered, such as for a specific number of days or cyclically. Megestrol, a synthetic progestin, is often indicated for palliative reasons or for management of anorexia, cachexia, or weight loss in patients with cancer. It is given to maximize appetite, orally, as ordered. It is recommended, however, that the lowest dosage possible of either estrogens or progestins be used and titrated as needed, but only as ordered.

Oral contraception is available in various formulations based on doses that are taken at different times of the menstrual cycle (see Oral Contraceptives: Indications discussion on p. 582). Progestin-only oral contraceptive pills are taken daily. It is important that patients take this oral contraceptive at the same time every day so that effective hormone serum levels are maintained. Use of the progestin-only pill leads to a higher incidence of ovulatory cycles if not taken as per instructions; therefore, there is an increased rate and risk of contraceptive failure, compared with estrogen-progestin drug therapy. Be aware that progestin-only drugs are usually prescribed for those women who cannot tolerate estrogens or for whom estrogens are contraindicated. Often, they are more effective in women who are older than 35 years of age and women who are breastfeeding. Combination estrogen-progestin pills contain low doses of estrogen. Biphasic forms contain fixed estrogen and variable progestin in 21- or 28-day products. The low-dose monophasic (fixed estrogen-progestin combination) forms are provided as 21 or 28 days of pills, with the 28-day products containing 7 inert tablets. Triphasic products offer three or four phases of variable estrogen and progestin combinations, and there are also new, extended-cycle products available. Make sure patients fully understand how to take the medication. Emphasize that the reduction in the level of estrogen has been associated with a decrease in adverse effects and a decrease in the risk for complications; however, more breakthrough bleeding will occur.

The success of therapy with bisphosphonates depends on providing thorough patient teaching and ensuring that patients understand all aspects of the drug regimen. With the use of oral bisphosphonates, emphasize the need to take the medication upon rising in the morning, with a full glass (180 to 240 mL) of water, at least 30 minutes before the intake of any food, other fluids, or other medication. In addition, emphasize that patients must remain upright in either a standing or sitting position for approximately 30 minutes after taking the drug to help prevent esophageal erosion or irritation. Risedronate delayed-release tablets should be swallowed whole and should not be chewed, cut, or crushed. Inform the patient taking the SERM raloxifene that the drug must be discontinued 72 hours before and during prolonged immobility. Therapy may be resumed, as ordered, once the

patient becomes fully ambulatory. See the Patient Teaching Tips for more information.

Fertility drugs (e.g., clomiphene) are often self-administered. Provide specific instructions on how to administer the drug at home and how to monitor drug effectiveness to improve the success of treatment. Journal tracking of the medication regimen is helpful to those involved in the care of infertile patients or couples. See the Patient Teaching Tips for more information.

Administer oxytocin only as ordered, and strictly follow any instructions or protocol. The cervix must be ripe (see earlier discussion). Prostaglandin E₂ may be instilled vaginally to help accomplish this if the patient's cervix is not ripe or at a Bishop score of 5 or higher. Because oxytocin has vasopressive and antidiuretic properties, the patient is at risk for hypertensive episodes as well as fluid retention; institute continuous monitoring of maternal blood pressure and pulse rate as well as fetal monitoring. Report any of the following to the health care provider if they occur: strong contractions, edema, or changes in fetal movement. Administer IV infusions (via infusion pump) of oxytocin with the proper dilutional fluid and at the proper rate. To minimize the adverse effects of the drug, IV piggyback dosing is often ordered so that the diluted oxytocin solution can be discontinued immediately if maternal or fetal decline occurs while an IV line with hydration is maintained. Doses are generally titrated as ordered and are based on the progress of labour and degree of fetal tolerance of the drug. If labour progresses at 1 centimetre per hour dilation, oxytocin may no longer be needed. The decision to stop the drug is made by the health care provider and on an individual basis. With oxytocin therapy, if there are hypertensive responses or major changes in the maternal vital signs or if the fetal heart rate shows any indication of fetal intolerance of labour, contact the health care provider immediately. Hyperstimulation may also occur. If contractions are more frequent than every 2 minutes and last longer than 1 minute (and are accompanied by changes in other parameters), stop the infusion and contact the health care provider immediately. If this does occur, place the patient in a side-lying position, maintain administration of IV fluids, give oxygen as ordered (generally via tight face mask at 10 to 12 L/min), and monitor both the patient and fetus closely. If there is concern about overstimulation, discuss this with the health care provider and document actions thoroughly.

Dinoprostone is given by vaginal suppository to patients who are 12 to 20 weeks pregnant and are seeking pregnancy termination and to patients in whom evacuation of the uterus is needed for the management of incomplete spontaneous abortion or intrauterine fetal death (up to 28 weeks). Give the drug exactly as ordered and monitor the patient closely.

◆ EVALUATION

Measure therapeutic responses to the various drugs discussed in this chapter by evaluating whether goals and outcome criteria have been met. Many drugs have been discussed here,

CASE STUDY

Bisphosphonate Drug Therapy for Osteoporosis

Janet is a relatively healthy 73-year-old retired law clerk who has recently been diagnosed with postmenopausal osteoporosis. She has been prescribed treatment with alendronate (Fosamax), 70 mg each month. She has many questions, and you review the drug and its use with her.

1. Janet tells you that she likes to have breakfast, take her morning medicines, and then lie down on the couch to read the morning newspaper. She asks whether the alendronate will fit into her routine. What will you tell her?
2. Janet calls the clinic to ask what to use for headaches. "I have several different types of headache pills, but aren't they all the same?" How will you respond?
3. A few months later, Janet comes in for a follow-up visit. She tells you that she is due for her next osteoporosis pill next week, but she has been having some jaw pain ever since she went to the dentist 2 weeks earlier to have a tooth pulled. She is worried that her osteoporosis has affected her jaw. What could be the reason for this pain? What do you think will be done about it?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

often with several indications for their use; thus, a therapeutic response would be occurrence of the indicated therapeutic effect. Monitor patients for adverse effects and toxicity as well.

Therapeutic responses to progestins include a decrease in abnormal uterine bleeding and the disappearance of menstrual disorders (e.g., amenorrhea). The adverse effects of progestins include edema, hypertension, cardiac symptoms, changes in mood and affect, and jaundice.

Therapeutic effects of estrogens may range from prevention of pregnancy, to a decrease in menopausal symptoms, to a reduction in size of a tumour. Adverse effects of estrogens may include hypertension, thromboembolism, edema, amenorrhea, nausea, vomiting, facial skin discoloration, hirsutism, breast tenderness, and headache. Therapeutic responses to progestins include a decrease in abnormal uterine bleeding and the disappearance of menstrual disorders (e.g., amenorrhea). The adverse effects of progestins include jaundice, thrombophlebitis, liver dysfunction, and thromboembolic disorders. Adverse effects associated with oral contraceptives include hypertension, edema, thromboembolism, headaches, migraines, depression, stroke, nausea, vomiting, amenorrhea, and breakthrough bleeding.

Therapeutic effects of oxytocin and other uterine stimulants include stimulation of labour and control of postpartum bleeding. Adverse effects may include hypotension or hypertension, chest pain, nausea, vomiting, blurred vision, and fainting. The primary therapeutic effect of tocolytics is the absence of preterm labour. Adverse maternal effects may include vasodilation and increase in heart rate, and fetal side effects include possible intrauterine growth retardation.

The therapeutic effect of fertility drugs is successful conception. Adverse reactions include tachycardia, DVT, hypovolemia, central nervous system depression, nausea, vomiting, ovarian hyperstimulation, blurred vision, and photophobia.

The therapeutic effects of osteoporosis drugs and related drugs include increased bone density and prevention or management of osteoporosis. Adverse effects of SERMs are hot flashes, leg

cramps, leukopenia, headache, GI upset, joint pain, and esophageal burns if the drug is lodged in the esophagus before reaching the stomach.

PATIENT TEACHING TIPS

- Patients should be aware that hormonal drugs are better tolerated if taken with food or milk to minimize GI upset.
- With the use of oral contraceptives as well as any form of HRT with estrogens or progestins, encourage patients to openly discuss concerns about the medications. Assure patients that, although risks may be associated with HRT, the health care provider will weigh each case individually and make a recommendation based on the benefits versus risks, but with the ultimate decision being the patient's.
- With estrogens and progestins, advise patients to report any of the following to a health care provider immediately: hypertension, edema, thromboembolism, migraines, depression, and breakthrough bleeding.
- Inform patients that treatment with ulipristal acetate often leads to a significant reduction in menstrual blood loss or amenorrhea within the first 10 days of treatment. If excessive bleeding persists, the patient should inform the health care provider. Menstrual periods should return within 4 weeks after the end of the treatment with ulipristal. The use of a nonhormonal contraceptive method is recommended during treatment.
- Advise patients to report any weight gain of 1 kg or more in 24 hours, as well as any breakthrough bleeding or change in menstrual flow.
- Instruct patients to take oral contraceptives exactly as ordered and to keep all appointments for follow-up examinations (e.g., pelvic examinations, Pap smears, health care provider-performed breast examinations).
- Teach patients the importance of and the correct technique for monthly breast self-examinations during the ideal time—that is, 7 to 10 days after the start of menstruation or 2 to 5 days after menses end. Stress the need for follow-up appointments and annual examinations by a health care provider.
- Hormones make patients sensitive to sunlight and tanning beds. Emphasize to patients that they must use appropriate sun protection at all times.
- If a patient is using progesterone-only intravaginal gel with other gels, advise the patient to insert the other gels at least 6 hours before or after inserting the progesterone-based product.
- Slow-release progesterone intrauterine devices are placed in the uterine cavity by a health care provider. Provide thorough education about the fact that inserts are left in place for 5 years (after insertion) and then must be replaced. Advise patients to report abnormal uterine bleeding, cramping, abdominal pain, or amenorrhea immediately.
- Instruct patients using an estrogen-progestin vaginal ring for contraception regarding what to expect with its insertion. Use of this contraceptive device requires thorough teaching and follow-up, including instruction on insertion and removal techniques and a return demonstration, before the patient leaves the health care provider's office. Inform patients that menstruation will follow about 2 to 3 days after the ring is removed, and instruct them to replace the used ring in its foil pouch and discard it in a waste receptacle. The ring should not be flushed down the toilet.
- Oral contraceptive hormones must be taken at the same time every day and exactly as prescribed. If one dose is missed, advise the patient to take the dose as soon as it is remembered; however, if it is close to the next dose time, advise the patient not to double up and to use a backup form of contraception in these situations. Provide more specific instructions for the omission of more than 1 day's dose depending on the specific oral contraceptive drug prescribed. These specific instructions will most likely include the following: If the patient misses one "active" tablet in weeks 1, 2, or 3, the tablet needs to be taken as soon as she remembers. If the patient misses two "active" tablets in week 1 or week 2, the patient needs to take two tablets the day she remembers and two tablets the next day, and then continue taking one tablet a day until the pack is finished. The patient needs to be instructed to use a backup method of birth control, such as condoms, if she has intercourse in the 7 days after missing pills. If the patient misses two "active" tablets in the third week or misses three or more "active" tablets in a row, the patient needs to throw out the rest of the pack and start a new pack that same day. Instruct the patient to use a backup method of birth control if she has intercourse in the 7 days after missing pills.
- Emphasize to patients that OTC foams for intravaginal use do not prevent transmission of sexually transmitted infections or HIV.
- Stress to patients the importance of using condoms with hormonal contraception to prevent acquiring sexually transmitted infections.
- Emphasize to patients that backup contraception (e.g., condom use) is needed when antibiotics, barbiturates, griseofulvin, isoniazid, rifampin, or St. John's wort are taken with oral contraceptives, as these drugs and herbs diminish the effectiveness of oral contraception.
- Estradot is generally applied once daily to the thighs and calves, as ordered, with one dose provided in two separate pouches. Patients should be instructed not to apply sunscreen or other lotions at the same time because they interfere with the drug. To reduce the chance of transfer of this medication to other individuals, allow the areas to which it has been applied to dry completely before covering them with clothing. The drug contained in this dosage form, estradiol, has been found to be present on the skin up to 8 hours after application.
- Conjugated estrogens are used for menopausal symptoms and are given orally every day; however, other uses of these

estrogens may require different doses and a different dosage schedule or regimen. Emphasize to patients the expected adverse effects, such as edema, nausea, diarrhea, constipation, breakthrough uterine bleeding, chloasma (facial skin discoloration), hirsutism, tender breasts, and headaches. Encourage patients to report any of the following conditions: elevated blood pressure, severe headaches with changes in vision and vomiting, abdominal pain, and edema.

- Bisphosphonates (e.g., alendronate) are to be taken exactly as prescribed; that is, the drug is taken at least 30 minutes before the first morning beverage, food, or other medication and with at least 180 to 240 mL of water. Emphasize to patients the importance of remaining upright for at least 30

minutes after taking the medication to prevent esophageal and GI adverse effects. Esophageal irritation, dysphagia, severe heartburn, and retrosternal pain must be reported to the health care provider immediately to help prevent severe reactions.

- Patients taking bisphosphonates should be aware they may also require supplemental calcium and vitamin D, as ordered by the health care provider.
- Educate patients about making lifestyle changes as recommended, such as engaging in weight-bearing exercises (e.g., walking), stopping smoking, and limiting or eliminating alcohol intake. These measures will help minimize the adverse effects of oral contraception or drug therapy with hormones.

KEY POINTS

- Three major estrogens are synthesized in the ovaries: estradiol (the principal estrogen), estrone, and estriol. Exogenous estrogens can be classified into two main groups: steroidal estrogens (e.g., conjugated estrogens, esterified estrogens, estradiol) and the nonsteroidal estrogen diethylstilbestrol.
- Progestins have a variety of uses, including treatment of uterine bleeding, amenorrhea, and adjunctive and palliative treatment of some cancers.
- Oral contraceptives containing a combination of estrogens and progestins are the most commonly used form of reversible contraception currently available.
- Uterine stimulants (sometimes called *oxytocic drugs*) include ergot derivatives, prostaglandins, and oxytocin.
- Uterine relaxants (often called *tocolytic drugs*) are used to stop preterm labour and maintain pregnancy by halting uterine contractions.
- A thorough nursing assessment is necessary to ensure the safe and effective use of female reproductive drugs. Obtain information on the patient's past medical problems, history of menses and problems with the menstrual cycle, medications taken (prescribed and OTC), number of pregnancies and miscarriages, last menstrual period, and any related surgical or medical treatments.
- Several drug classes are used for the treatment of existing osteoporosis, including the bisphosphonates, the selective estrogen receptor modulators (SERMs), the hormones calcitonin and teriparatide, and denosumab.

EXAMINATION REVIEW QUESTIONS

1. The nurse is assessing a patient who is to receive dinoprostone (Prostin E₂). Which condition would be a contraindication to the use of this drug?
 - a. Pregnancy at 15 weeks' gestation
 - b. GI upset or ulcer disease
 - c. Ectopic pregnancy
 - d. Incomplete abortion
2. The nurse is teaching a patient who is taking oral contraceptive therapy for the first time about possible adverse effects. Which adverse effects should the nurse discuss?
 - a. Dizziness
 - b. Nausea
 - c. Tingling in the extremities
 - d. Polyuria
3. The nurse is reviewing the use of obstetric drugs. Which situation is an indication for an oxytocin infusion?
 - a. Termination of a pregnancy at 12 weeks
 - b. Hypertonic uterus
 - c. Cervical stenosis in a patient who is in labour
 - d. Induction of labour at full term
4. The nurse has provided patient education regarding therapy with the SERM raloxifene (Evista). Which of the following statements by the patient reflects a good understanding of the instruction?
 - a. "When I take that long flight to Asia, I will need to stop taking this drug at least 3 days before I travel."
 - b. "I can continue taking this drug even when travelling, as long as I take it with a full glass of water each time."
 - c. "After I take this drug, I must sit upright for at least 30 minutes."
 - d. "One advantage of this drug is that it will reduce my hot flashes."
5. The nurse is discussing therapy with the prescribed clomiphene (Clomid) for a couple who are considering trying this drug as part of treatment for infertility. It is important that they be informed of which possible effect of this drug?
 - a. Increased menstrual flow
 - b. Increased menstrual cramping
 - c. Multiple pregnancy (twins or more)
 - d. Sedation
6. The nurse is caring for a female patient who has missed one dose of an oral contraceptive. Which statement by the nurse is appropriate? (Select all that apply.)
 - a. "Go ahead and take the missed dose now, along with today's dose."
 - b. "Don't worry; you are still protected from pregnancy."
 - c. "Please come to the clinic for a re-evaluation of your therapy."

- d. "Wait 7 days, and then start a new pack of pills."
 - e. "You will need to use a backup form of contraception concurrently for 7 days."
7. The health care provider wrote the order as follows: "Give calcitonin (Calcimar) 50 units Subcut daily." The medication is available in a vial that contains 200 units/mL. How many millilitres will the nurse draw up in the syringe for this dose?
 8. A woman comes into the emergency department. She says that she is pregnant and that she is having contractions

every 3 minutes but she is "not due yet." She is very upset. While assessing her vital signs and fetal heart tones, what is the most important question the nurse must ask the patient?

- a. "What were you doing when the contractions started?"
- b. "Are you preregistered at this hospital to give birth?"
- c. "How many weeks have you been pregnant?"
- d. "Have you felt the baby move today?"

CRITICAL THINKING ACTIVITIES

1. A patient in her first pregnancy has spent 14 hours in labour and has made little progress. She is becoming exhausted, and her uterine contractions have decreased in strength. She is now receiving an oxytocin infusion. During this infusion, the nurse will perform many assessments. What are the priorities during the assessments?
2. The nurse is reviewing a cephalosporin prescription for a patient who has a severe sinus infection. The patient tells the nurse that she is taking a birth control pill and asks the nurse if there will be any problems with taking the antibiotic. What is the nurse's best answer?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Men's Health Drugs*

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Discuss the normal anatomy, physiology, and functions of the male reproductive system.
2. Compare various men's health drugs, with discussion of their rationales for use, dosages, and dosage forms.
3. Describe the mechanisms of action, dosages, adverse effects, cautions, contraindications, drug interactions, and routes of administration for the various men's health drugs discussed.
4. Develop a collaborative plan of care that includes all phases of the nursing process for patients receiving men's health drugs for treatment of benign prostatic hyperplasia, sexual dysfunction, hormone deficiency, or prostate cancer.

KEY TERMS

Anabolic activity Any metabolic activity that promotes the building up of body tissues, such as the activity produced by testosterone that results in the development of bone and muscle tissue; also called *anabolism*. (p. 596)

Androgenic activity The activity produced by testosterone that causes the development and maintenance of the male reproductive system and male secondary sex characteristics. (p. 596)

Androgens Male sex hormones responsible for mediating the development and maintenance of male sex characteristics; chief among these are testosterone and its various biochemical precursors. (p. 596)

Benign prostatic hyperplasia (BPH) Nonmalignant (noncancerous) enlargement of the prostate gland (also called *benign prostatic hypertrophy*). (p. 597)

Catabolism The opposite of anabolic activity; any metabolic activity that results in the breakdown of body tissues. Examples of conditions in which catabolism occurs are debilitating illnesses such as end-stage cancer and starvation. (p. 596)

Erythropoietic effect The effect of stimulating the production of red blood cells (erythropoiesis). (p. 597)

Prostate cancer A malignant tumour within the prostate gland. (p. 598)

Testosterone The main androgenic hormone. (p. 596)

DRUG PROFILES

finasteride, p. 599

 sildenafil (sildenafil citrate)*, p. 600

 testosterone, p. 600

 Key Drug

*Full generic name is given in parentheses. For the purposes of this text, the more common, shortened name is used.

OVERVIEW OF THE MALE REPRODUCTIVE SYSTEM

The male reproductive system consists of several structures; two of these structures, the testes and seminiferous tubules, produce the

primary male hormones. The *testes*, a pair of oval glands located in the scrotal sac, are the male gonads. The *seminiferous tubules*, which are channels in the testes, are the site of spermatogenesis, which is the process by which mature sperm cells are produced.

Androgens comprise the group of male sex hormones (primarily testosterone) that mediate the normal development and maintenance of primary and secondary male sex characteristics (Figure 36.1). Secondary male sex characteristics include advanced development of the prostate, seminal vesicles (two glands adjacent to the prostate), penis, and scrotum, as well as male hair distribution, laryngeal enlargement, thickening of the vocal cords, and male body musculature and fat distribution. Androgens must be secreted in adequate amounts for these characteristics to appear. The most important androgen is **testosterone**, which is produced from clusters of interstitial cells embedded between the seminiferous tubules. Besides having **androgenic activity**, testosterone is also involved in the development of bone and muscle tissue; inhibition of protein **catabolism** (metabolic breakdown); and retention of nitrogen, phosphorus, potassium, and sodium. These

*The authors of this edition would like to respectfully acknowledge that absence of a more fulsome discussion regarding pharmacological interventions for transgender men and men who may be in transition. An addendum will follow the publication to include more concise information and will be subsequently included in future publications.

Fig. 36.1 Regulation of male characteristics by testosterone.

functions contribute to its **anabolic activity**. The hormone initiates the synthesis of specific proteins needed for androgenic and anabolic activity by binding to chromatin (strands of deoxyribonucleic acid [DNA]), in the nuclei of interstitial cells. In addition, testosterone appears to have an **erythropoietic effect**, in that it stimulates the production of red blood cells (see Chapter 55).

ANDROGENS AND OTHER DRUGS PERTAINING TO MEN'S HEALTH

Testosterone deficiency is treated with exogenous testosterone. There are several synthetic derivatives of testosterone that have improved pharmacokinetic and pharmacodynamic characteristics over the naturally occurring hormone. This is accomplished by combining various esters with testosterone, which prolong the duration of action of the hormone. For example, testosterone propionate is formulated as an oily solution, and its hormonal effects last for 2 to 3 days; the effects of testosterone cypionate and testosterone enanthate in oil last for up to 2 to 4 weeks. Orally administered testosterone has poor absorption because most of the dose is metabolized and destroyed by the liver before it can reach the circulation (first-pass effect; see Chapters 2). To circumvent this problem, researchers developed methyltestosterone and fluoxymesterone (both are controlled substances in Canada). A transdermal dosage gel and a metered-dose pump have provided another way to circumvent

the first-pass effect that occurs with oral administration of this hormone.

There are other chemical derivatives of testosterone known as *anabolic steroids*. These are synthetic drugs that closely resemble the natural hormone but possess high anabolic activity. These drugs are no longer available in Canada by prescription. However, under Health Canada's Special Access Programme, health care providers can request medications that are not available for sale, such as the anabolic steroids oxandrolone and nandrolone deconate. Oxandrolone may be used to treat HIV-associated wasting syndrome (debilitation related to disease-induced nutritional malabsorption) and alcoholic hepatitis. Oxandrolone is also used in hospitalized patients to stimulate weight gain. Because of their muscle-building properties, anabolic steroids have a great potential for misuse by athletes, especially bodybuilders and weightlifters. Improper use of these substances can have many serious consequences, such as sterility, cardiovascular diseases, and even liver cancer. For this reason, anabolic steroids are currently classified as Schedule IV controlled substances by Health Canada. Misuse of these drugs can lead to psychological or physical dependence or both.

Mechanism of Action and Drug Effects

Natural and synthetic androgens have effects similar to those of the endogenous androgens. These include stimulation of the normal growth and development of the male sex organs (primary sex characteristics) and development and maintenance of secondary sex characteristics. Androgens stimulate the synthesis of ribonucleic acid (RNA) at the cellular level, thereby promoting cellular growth and reproduction. They also retard the breakdown of amino acids. These properties contribute to an increased synthesis of body proteins, which aids in the formation and maintenance of muscle tissue. Another potent anabolic effect of androgens is the retention of nitrogen, also essential for protein synthesis. Nitrogen promotes the storage in the body of inorganic phosphorus, sulphate, sodium, and potassium, all of which have important metabolic roles, including protein synthesis, nerve impulse conduction, and muscle contraction. All of these effects result in weight gain and an increase in muscular strength. Finally, androgens also stimulate the production of erythropoietin by the kidneys, which leads to enhanced erythropoiesis (red blood cell synthesis; see Chapters 55). However, the administration of exogenous androgens causes the release of endogenous testosterone to be inhibited as the result of feedback inhibition of the pituitary luteinizing hormone. Large doses of exogenous androgens may also suppress sperm production as a result of the feedback inhibition of pituitary follicle-stimulating hormone, which leads to infertility.

Androgen inhibitors block the effects of naturally occurring (endogenous) androgens. This is accomplished via inhibition of a specific enzyme, 5- α reductase. For this reason, these drugs are also called *5- α -reductase inhibitors*. For unknown reasons, normal male physiology often results in a common enlargement of the prostate known as **benign prostatic hyperplasia (BPH)**. This process begins as early as 30 years of age and is present in at least 85% of men by 80 years of age. The most troubling symptom is usually varying degrees of obstructed urinary outflow; a digital rectal examination is recommended as part of yearly screening for men over the age of 50 to detect enlargement of the prostate. Although surgical treatment by transurethral resection of the prostate (TURP) is a

common strategy, BPH is also treatable with a 5 α -reductase inhibitors. There are currently two such drugs: finasteride and dutasteride. Finasteride (Proscar[®]), the prototypical drug for this class, works by inhibiting this enzyme, which normally converts testosterone to 5 α -dihydrotestosterone (DHT). DHT is a more potent type of testosterone and is the principal androgen responsible for stimulating prostatic growth, as well as the expression of other male primary and secondary sex characteristics. Finasteride can dramatically lower prostatic DHT concentrations, which helps to reduce the size of the prostate to ease the passage of urine. Fortunately, finasteride does not cause antiandrogen adverse effects that might be expected, such as loss of muscle strength and fertility.

The effects of finasteride are limited primarily to the prostate, but this drug may also affect 5 α -reductase-dependent processes elsewhere in the body, such as in the hair follicles, skin, and liver. Research has demonstrated that the pharmacological inhibition of 5 α -reductase prevents the thinning of hair caused by increased levels of DHT. It has been noted that men taking finasteride experience increased hair growth. Therefore, finasteride is also indicated for the treatment of male pattern hair loss (Propecia[®]). Finasteride is indicated for treating hair loss only in men, not in women—finasteride can be teratogenic in pregnant women and its use in women of any age (pregnant or not) is still not recommended. Women need to wear gloves when handling finasteride. Another medication, minoxidil, can be used topically to treat hair loss in both men and women. It is discussed in more detail in [Chapters 56](#).

There are also two other classes of androgen inhibitors. The first includes the androgen receptor blockers flutamide (Euflex[®]), nilutamide (Anandron[®]), and bicalutamide (Casodex[®]). These drugs work by blocking the activity of androgen hormones at the level of the receptors in target tissues (e.g., prostate). For this reason, these drugs are used in the treatment of [prostate cancer](#) (see [Chapters 53](#)). The second class is the gonadotropin-releasing hormone (Gn-RH) analogues, including leuprolide acetate (Eligard[®], Lupron[®]), goserelin acetate (Zoladex[®]), and triptorelin pamoate (Trelstar[®]). These drugs work by inhibiting the secretion of pituitary gonadotropin, which eventually leads to a decrease in testosterone production. Both androgen receptor blockers and Gn-RH analogues are used most commonly to treat prostate cancer and are discussed in further detail in [Chapters 53](#).

Another class of drugs that may be used to help alleviate the symptoms of obstruction due to BPH are the α_1 -adrenergic blockers. These drugs are discussed in greater detail in [Chapters 20](#). The α_1 -adrenergic blockers that are most commonly used for symptomatic relief of obstruction secondary to BPH are terazosin hydrochloride (Hytrin[®]), doxazosin mesylate (Cardura[®]), tamsulosin hydrochloride (Flomax[®]), alfuzosin hydrochloride (Xatral[®]), and silodosin (Rapaflo[®]). Tamsulosin hydrochloride, alfuzosin hydrochloride, and silodosin appear to have a greater specificity for the α_1 -receptors in the prostate and thus may cause less hypotension. These drugs have clinical effects of prostate shrinkage immediately, as opposed to the 5 α -reductase inhibitors, which may take up to 6 months of use to achieve this. Phosphodiesterase inhibitors are used in the treatment of erectile dysfunction. Sildenafil (Viagra[®]) was the first oral drug approved for the treatment of erectile dysfunction. Sildenafil works by inhibiting the action of the enzyme phosphodiesterase. This in turn allows the buildup in the penis of the chemical

cyclic guanosine monophosphate, which causes relaxation of the smooth muscle in the corpora cavernosa (erectile tubes) of the penis and permits the inflow of blood. Nitric oxide is also released inside the corpora cavernosa during sexual stimulation and contributes to the erectile effect. Two drugs that are similar but have a longer duration of action are vardenafil hydrochloride (Levitra[®], Staxyn[®]) and tadalafil (Cialis[®]). Collectively, these drugs are referred to as *erectile dysfunction drugs*. Sildenafil and tadalafil are also used to treat pulmonary hypertension (see [Chapters 23](#)) under the trade names Revatio[®] and Adcirca[®], respectively.

A second type of drug used to treat erectile dysfunction is the prostaglandin alprostadil (Calverject[®], Muse[®]). This drug must be given by injecting it directly into the erectile tissue of the penis (Calverject) or pushing a suppository form of the drug (Muse) into the urethra.

A list of all of the drugs mentioned in the chapter used for men's health appears in [Box 36.1](#). More information on selected drugs can be found in the Drug Profiles section.

Indications

The primary use for androgens is as hormone replacement therapy. Indications for other types of drugs discussed in this chapter are listed in [Table 36.1](#).

BOX 36.1 Currently Available Men's Health Drugs

α_1 -Adrenergic-Blocking Drugs

alfuzosin hydrochloride
doxazosin mesylate
tamsulosin hydrochloride
terazosin hydrochloride

Anabolic Steroids

Not available

Other Androgens

danazol (see [Chapters 35](#))
testosterone

Antiandrogens

bicalutamide
flutamide
nilutamide

5 α -Reductase Inhibitors

dutasteride
finasteride

Gonadotropin-Releasing Hormone Analogues

goserelin acetate
leuprolide acetate
triptorelin pamoate

Peripheral Vasodilator

minoxidil

Drugs for Erectile Dysfunction

alprostadil
sildenafil
tadalafil
vardenafil hydrochloride

TABLE 36.1 Men's Health Drugs: Indications

Drug	Indication
finasteride	Benign prostatic hyperplasia
minoxidil	Male androgenetic alopecia
oxandrolone, nandrolone deconate (available via Special Access)	Hypertension
sildenafil citrate, tadalafil, vardenafil hydrochloride	Female and male androgenetic alopecia
testosterone	HIV wasting syndrome, alcoholic hepatitis
	Erectile dysfunction
	Primary or secondary hypogonadism

Contraindications

Contraindications to the use of androgenic drugs include known androgen-responsive tumours. Use of sildenafil, vardenafil, and tadalafil hydrochloride is also contraindicated in men with major cardiovascular disorders, particularly if they use nitrate medications such as nitroglycerin. Concurrent use of erectile dysfunction drugs and nitrates may cause severe hypotension, which may not respond to treatment. Use of finasteride is contraindicated in women (especially pregnant women) and children.

Adverse Effects

Although rare, some of the most devastating effects of androgenic steroids occur in the liver, where they cause the formation of blood-filled cavities, a condition known as *peliosis of the liver*. This condition is a possible consequence of the long-term administration of androgenic anabolic steroids and can be life-threatening. Other serious liver effects are hepatic neoplasms (liver cancer), cholestatic hepatitis, jaundice, and abnormal liver function. Fluid retention is another undesirable effect of androgens and may account for some of the weight gain seen with their use. The serious adverse effects that can be caused by the androgens far outweigh the advantages to be gained from their use in those seeking improved athletic ability. Other less serious adverse effects of androgens are listed in Table 36.2.

Sildenafil, vardenafil, and tadalafil hydrochloride appear to have relatively favourable adverse effect profiles, with headache, flushing, and dyspepsia being the most common adverse effects reported. However, in patients with pre-existing cardiovascular disease, especially those taking nitrates (e.g., nitroglycerin, isosorbide mononitrate, dinitrate), these drugs can lower blood pressure substantially, potentially leading to serious adverse events. *Priapism*, or abnormally prolonged penile erection, is a relatively uncommon, but possible, adverse effect of both the erectile dysfunction drugs and the androgens. This condition is a medical emergency and warrants urgent medical attention, though it is simply due to excess therapeutic response to the drug. Phosphodiesterase inhibitors can also cause unexplained vision loss.

Finasteride has been reported to cause loss of libido, loss of erection, ejaculatory dysfunction, hypersensitivity reactions, gynecomastia, and severe myopathy. The drug has also caused a 50% decrease in prostate-specific antigen (PSA) concentrations. Pregnant women must not handle crushed or broken tablets on a regular basis because of the possibility of topical absorption, which can lead to teratogenic effects.

TABLE 36.2 Men's Health Drugs: Selected Adverse Effects

Drug Class	Adverse Effects
α_1 -Adrenergic blockers	Tachycardia, hypotension, syncope, depression, drowsiness, rash, erectile dysfunction, increased urinary frequency, dyspnea, visual changes, headache
Androgens (including anabolic steroids)	Headache, changes in libido, anxiety, depression, acne, male pattern hair loss, hirsutism, nausea, abnormal liver function test results, priapism, elevated cholesterol level
5 α -Reductase inhibitors	Reduced libido, hypotension, dizziness, drowsiness
Peripheral vasodilator (topical minoxidil)	With topical route, usually limited to localized dermatological reactions, including erythema, dermatitis, eczema, pruritus
Drugs for erectile dysfunction	Dizziness, headache, muscular pain, chest pain, hypertension or hypotension, rash, dry mouth, nausea, vomiting, priapism

Interactions

Androgens, when used with oral anticoagulants, can significantly increase or decrease anticoagulant activity (see Chapters 27). Concurrent use of androgens with ciclosporin (see Chapter 50) increases the risk of ciclosporin toxicity and is not recommended. Sildenafil, vardenafil, and tadalafil hydrochloride may cause severe hypotension when given together with nitrates such as nitroglycerin, isosorbide mononitrate, or isosorbide dinitrate (see Chapter 24). α -Blockers can cause additive hypotension when given with other drugs that lower blood pressure (see Chapter 23). Effects of tamsulosin may be increased when it is taken with azole antifungal drugs, erythromycin or clarithromycin (see Chapter 43), cardiac drugs such as propranolol hydrochloride or verapamil hydrochloride (see Chapters 20 and Chapters 26), and protease inhibitors (see Chapter 45).

Dosages

For dosage information on men's health drugs, refer to the table on p. 600.

DRUG PROFILES

finasteride

Finasteride (Proscar) is available in tablet form in 1- and 5-mg strengths. The lower strength is indicated for androgenic alopecia in men. The higher strength is indicated for BPH, with clinical effects of prostate shrinkage occurring after approximately 3 to 6 months of continual therapy. A similar drug, dutasteride (Avodart®), is also indicated for BPH and is currently available in 0.5-mg capsule form. A combination of dutasteride and tamsulosin hydrochloride (Jalyn®) is available in a modified-release capsule for the treatment of moderate to severe BPH. Finasteride and dutasteride are contraindicated in patients who have shown hypersensitivity to them and in pregnant women and children. Both drugs are teratogenic. For recommended dosages, refer to the table below.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	3–12 mo	8 hr	4–15 hr	14 days

 sildenafil citrate

Sildenafil citrate (Viagra) is approved for the treatment of erectile dysfunction. Other erectile dysfunction drugs with longer durations of action include vardenafil hydrochloride and tadalafil. The medication tadalafil also has a longer onset of action as compared to sildenafil and vardenafil. It is important to educate patients on specific differences between erectile dysfunction drugs. Sildenafil potentiates the physiological sexual response, causing penile erection after sexual arousal by relaxing smooth muscle and increasing blood flow into the penis.

Sildenafil use is contraindicated in patients with a known hypersensitivity to it. Sildenafil can potentiate the hypotensive effects of nitrates, and its administration to patients who are using organic nitrates in any form, either regularly or intermittently, is contraindicated. For recommended dosages refer to the table below.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	0.5–1 hr	1 hr	4 hr	2–4 hr

 testosterone

Testosterone is a naturally occurring anabolic steroid. It is used for primary and secondary hypogonadism but may also be used to treat oligospermia in men as well as inoperable breast cancer in women, in which its purpose is to counteract tumour-enhancing

estrogen activity. It is also used as replacement therapy for transgender individuals transitioning from female to male. When it is used as hormone replacement therapy, a transdermal product is desirable. There are presently two transdermal patch formulations. They attempt to mimic the normal circadian variation in testosterone concentration seen in young healthy men, in whom maximum testosterone levels occur in the early morning hours and minimum concentrations occur in the evening. Of the available transdermal delivery systems, Androderm® and AndroGel® are always applied to skin elsewhere on the body and never to the scrotal skin. It is important to educate patients to wash their hands before application and then cover the area where testosterone has been applied, as transfer to others can occur. Natesto® is the first and only intranasal testosterone replacement therapy available in Canada.

Testosterone use is contraindicated in patients with hypersensitivity to it; severe kidney, heart, or liver disease; male breast cancer; prostate cancer; or genital bleeding, as well as in pregnant or lactating women. Testosterone is a Schedule IV controlled substance under the *Controlled Drugs and Substances Act*. It is available as an intramuscular injection, transdermal gel, transdermal patch, capsule, and pump. For recommended dosages refer to the table below.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Topical	1–2 hr	8 hr	10–100 min	24 hr

PHARMACOKINETIC BRIDGE TO NURSING PRACTICE

Drugs used to manage erectile dysfunction (e.g., sildenafil) essentially work in the same way as the body does to assist the patient in achieving an erection. The related pharmacokinetics must be

DOSAGES Selected Men's Health Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications
finasteride (Propecia, Proscar)	5 α -reductase inhibitor	<i>Adults</i> PO: 1 mg daily (Propecia)	Androgenic alopecia (baldness; males only)
		<i>Adults</i> PO: 5 mg daily (Proscar)	Benign prostatic hyperplasia
sildenafil citrate (Viagra)	Phosphodiesterase inhibitor	<i>Adults (males only)</i> PO: 25–100 mg 1 hr before sexual intercourse; no more than once daily	Erectile dysfunction
tamsulosin hydrochloride (Flomax CR®)	α_1 -Adrenoreceptor blocker	<i>Adults</i> PO: 0.4–0.8 mg once daily	Benign prostatic hyperplasia
testosterone cypionate (Depo-Testosterone), testosterone enanthate (Delatestryl)	Androgenic hormone	<i>Adults and adolescents</i> IM: 50–400 mg q3–4 wk	Delayed puberty or hypogonadism (in males)
testosterone, transdermal (Androderm, AndroGel, Testim 1%, Natesto 4.5%)	Androgenic hormone	<i>Adults and adolescents</i> Androderm patch (applied to skin of back, abdomen, upper arms, or thighs): 2.5–5 mg/day AndroGel (applied to shoulders, arms, or abdominal skin): 5 daily (delivers 50 mg of testosterone) Natesto intranasal gel applied in each nostril once daily	Male hypogonadism Male hypogonadism

understood so that the drug is taken safely and effectively. Sildenafil is a rapidly absorbed drug with onset of action within 1 hour, peak plasma concentrations within 1 hour, and a duration of action of up to 4 to 6 hours. If the drug is taken with a high-fat meal, absorption will be delayed, and it may take an additional 60 minutes for it to reach peak levels. This is yet another example of how specific drug pharmacokinetics can be affected by variables in a patient's everyday life, such as eating habits. Another pharmacokinetic consideration is that patients who are 65 years of age or older have reduced clearance of sildenafil and may experience increased plasma concentrations of free (or pharmacologically active) drug. This could possibly lead to drug accumulation and toxicity. (See [Special Populations: Older Adults, Sildenafil: Use and Concerns](#).)

SPECIAL POPULATIONS: OLDER ADULTS

Sildenafil: Use and Concerns

- One in 10 men in the world has erectile dysfunction. Over 3 million men over the age of 40 are affected in Canada. It is one-and-a-half times more common among men with cardiovascular disease and three times more common among men with diabetes than among the general population. The incidence of erectile dysfunction increases with age, with 39% at 40 years of age and 65% in those older than 65 years of age.
- Sildenafil (Viagra) is a prescription medication that is commonly ordered to treat erectile dysfunction, but it is not without concerns and cautions for the patient. This is especially true for older adults, who generally have other medical conditions (e.g., kidney disorders, hypertension, diabetes) and are usually taking more than one other prescribed medication (e.g., nitrates).
- Liver function declines with age; therefore, drugs may not be metabolized as effectively in older adults as they are in younger adults. In addition, sildenafil is highly protein bound, which causes it to stay in the body longer and thus increases the possibility for drug interactions and toxicity.
- A decreased dosage of sildenafil is generally indicated for patients over 65 years of age and for those with liver or kidney impairment.
- Adverse effects to be concerned about in all patients, particularly older patients, include headache, flushing, and dyspepsia. Sildenafil must be used cautiously in patients who have heart disease and angina, because these patients are at greater risk for complications, especially if they are taking nitrates. Severe hypotension can occur. Sildenafil produces an 8 to 10 mm decrease in systolic blood pressure and a 5 to 6 mm decrease in diastolic blood pressure that begins 1 hour after taking a dose. The effect can last for approximately 4 hours.
- Discussing topics of a sexual nature may be comfortable for some patients but produce anxiety in others. Be aware of ethnocultural and gender differences in how individuals perceive their own sexuality, how they generally deal with sexual performance issues, and with whom they share this information. Be respectful of each individual's beliefs and feelings, including their sexual beliefs and practices. This requires knowledge, sensitivity, and objectivity. The cost of erectile dysfunction medications can be expensive for patients as most drug plans do not cover the cost.

The health care provider usually performs a rectal examination to palpate for enlargement of the prostate or other possible pathology. If enlargement exists, a serum PSA test will most likely be ordered, especially prior to any treatment, and this test may also be ordered during treatment. PSA levels may be increased in pathological conditions of the prostate; establish a baseline and monitor these levels for comparative purposes. PSA levels are expected to decrease with effective therapeutic regimens. PSA levels tend to increase with age as the prostate gland grows. Recent research encourages the use of a PSA value of less than 4 mcg/L as the criterion for normal levels, although less than 2.5 mcg/L for patients under the age of 50 is recommended. (See also [Evidence in Practice: Men's Health Concerns and Screening of Prostate Cancer](#).)

Prior to the administration of testosterone and related drugs, assess patients for liver disease, because peliosis (formation of blood-filled cavities) may occur. Peliosis is associated with long-term therapy and may be life-threatening. Perform liver function studies (e.g., lactate dehydrogenase [LDH], creatine phosphokinase [CPK], bilirubin levels) as ordered, to monitor for the possible adverse effect of abnormal liver function and jaundice. Because edema is also a problem with these drugs, recording baseline weights, intake and output, and history of any cardiovascular diseases is also important. Another contraindication for which to assess is that of a history of known androgen-responsive tumours.

Finasteride requires baseline assessment of urinary patterns with attention to frequency, urgency, and flow of urine with micturition. As the tissue responds to the drug and there is a reduction in the size of the prostate gland and thus improvement in the symptoms of BPH, urinary flow will be increased. With potentially teratogenic drugs such as finasteride, follow special handling precautions and advise any pregnant caregiver or partner to do the same. Finasteride is not to be given to women. Assessment of the patient's sexual functioning and libido is important, owing to possible interference from the drug.

Before drugs for erectile dysfunction are given, the health care provider will perform a physical examination. Perform a thorough nursing assessment including vital signs, and obtain a thorough medication history, including whether the patient is on antihypertensives (e.g., diuretics such as hydrochlorothiazide and β -blockers such as atenolol), which may cause erectile dysfunction. Take a thorough cardiac history and assess for contraindications to the use of phosphodiesterase inhibitors (e.g., sildenafil, vardenafil hydrochloride [Levitra], and tadalafil [Cialis]), such as major cardiovascular disorders or the use of nitrate medications (nitroglycerin, isosorbide mononitrate, or dinitrate). The erectile dysfunction drugs and nitrates may lead to severe hypotension that may not respond to treatment.

❖ NURSING PROCESS

❖ ASSESSMENT

Before any drug is given to a male patient for the treatment of the male reproductive tract, thoroughly assess presenting symptoms and obtain a complete history of past and present diseases or other medical conditions. In addition, assess the patient's urinary elimination patterns and any difficulties, and document the findings.

❖ NURSING DIAGNOSES

- Reduced cardiac output as a result of drug interaction between erectile dysfunction drug and nitrates
- Limited sexuality pattern as a result of the effects of treatment with androgens or therapy with phosphodiesterase inhibitors
- Limited knowledge as a result of lack of information about the disease process of BPH and related drug therapy (including drug interactions with finasteride)

EVIDENCE IN PRACTICE

Men's Health Concerns and Screening of Prostate Cancer

Review

Prostate cancer is the most common nonskin malignancy diagnosed in men and the third leading cause of cancer-related death in men in Canada. It is estimated that 21 300 men were diagnosed with prostate cancer in 2017 (representing 21% of the incidence of new cancer cases in men) and 4 100 men died of this cancer (representing 10% of all cancer deaths). In Canadian men, the lifetime risk of developing prostate cancer is 1 in 8, while the risk of dying from it is 1 in 27. The risk for developing prostate cancer increases after the age of 50, and it is most commonly diagnosed in men over the age of 65. Black men have a 60% higher incidence of prostate cancer than White men; they are often diagnosed at a younger age, and the tumours tend to be more advanced and aggressive. Men of Asian ancestry tend to have a lower incidence of prostate cancer.

Screening with the prostate-specific antigen (PSA) may be done in men suspected of having prostate cancer. However, the use of the PSA test is controversial.

Types of Evidence

Hayes and Barry (2014) conducted a systematic review of the literature. Two trials dominated the literature: the Prostate, Lung, Colorectal and Ovarian screening trial and the European Randomized Study of Screening for Prostate Cancer. These trials examined whether PSA screening improved prostate cancer mortality when compared with no screening. The Prostate, Lung, Colorectal, and Ovarian trial randomized 76 685 men aged 55 to 74 years to annual PSA testing for 6 years and digital rectal examination for 4 years. The European trial randomized 182 160 men in seven countries to PSA screening without digital rectal examination every 4 years.

Results

The European trial had an increase in the incidence of prostate cancer with PSA screening and a small survival benefit with PSA screening after an 11-year follow-up; however, aggressive management (e.g., radical prostatectomy) showed adverse outcomes of erectile dysfunction, urinary incontinence, and bowel problems. In addition, the Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial found an increased incidence of prostate cancer but no mortality benefit for yearly PSA screening after a follow-up of 13 years.

Link of Evidence to Nursing Practice

The current evidence is insufficient to clearly determine whether regular screening for prostate cancer using the PSA reduces mortality from prostate cancer. PSA screening tests detect prostate cancer at an early stage; however, early detection and early intervention may not alter overall outcomes. Approximately one in four men with an abnormal PSA result will actually have prostate cancer. In addition, potential harm, such as false positive results and complications of biopsy, may outweigh the benefit of screening. It is important for health care providers to discuss the potential risks and benefits of PSA screening with men aged 55 to 69 years who are at average risk of developing prostate cancer. A discussion of close surveillance and watchful waiting should also be included.

◆ PLANNING

◆ Goals

- Patient will maintain normal and adequate cardiac output.
- Patient will maintain or regain effective sexual patterns and functioning.
- Patient will display adequate knowledge regarding disease process and recommended drug therapy.

◆ Expected Patient Outcomes

- Patient maintains blood pressure within normal limits with at least 120/80 mm Hg readings.
 - Patient experiences minimal drop in systolic and diastolic blood pressure during drug therapy with erectile dysfunction drugs or androgens.
 - Patient avoids potential interactions with medication regimen (e.g., nitrates not to be taken with erectile dysfunction drugs) as well as situations and substances that may exacerbate hypotension, such as saunas, alcohol, and hot climates.
 - Patient reports any repeated low blood pressure readings, dizziness, or feelings of lightheadedness to practitioner.
- Patient openly verbalizes feelings of inadequacy associated with changes in libido or sexual functioning and seeks out help from a health care provider.
 - Patient takes medication as prescribed to minimize adverse effects and maximize therapeutic effects.
 - Patient implements suggestions for improving libido and sexual functioning as recommended by the health care provider.
 - Patient verbalizes the ability to sustain and maintain an erection or complete the act of coitus.
- Patient states understanding of the rationale for drug therapy.

◆ IMPLEMENTATION

The therapeutic effects of testosterone are maximized when the drug is taken as ordered and at regular intervals so that steady levels are maintained. If the drug is being used for hypogonadism or induction of puberty, dosages may be managed differently, so that at the end of the growth spurt the patient is placed on maintenance dosages. Instruct patients to apply Natesto intranasal gel is to be applied in each nostril once daily. Educate patients that Androderm patches should be placed on clean, dry skin on the back, abdomen, upper arms, or thighs; the scrotum and bony areas (shoulder, hip) are not to be used with this particular drug. Be sure the proper patch is being used and that drugs are not confused. AndroGel is to be applied to shoulders, arms, or abdominal skin as ordered. If testosterone is being given intramuscularly, it is usually given every 2 to 4 weeks as prescribed. Mix the vial of medication thoroughly by agitating it before withdrawing the prescribed amount of medication.

Finasteride may be given orally without regard to meals. When used for treatment of the urinary symptoms of BPH, finasteride and related drugs may be ordered for approximately 3 to 6 months, with a re-evaluation of the condition

following this period. Advise patients to protect the drug from exposure to light and heat, and medication should not be crushed or broken due to hazards of exposure to others. Given the teratogenic effects of finasteride, emphasize that it must not be handled in any form by a pregnant woman. Recommend that female nurses and other female members of the health care team wear gloves when handling this medication. It is recommended that women of any age not take this medication.

See the **Natural Health Products** box for a description of saw palmetto, a natural health product that is often taken to relieve symptoms of an enlarged prostate.

NATURAL HEALTH PRODUCTS

Saw Palmetto (*Serenoa repens*, *Sabul serrulata*)

Overview

Saw palmetto comes from a tree that is also known as the American dwarf palm. The therapeutically active part of the tree is its ripe fruit. Saw palmetto is believed to inhibit dihydrotestosterone and 5 α -reductase. A prostatic-specific antigen (PSA) test and digital rectal examination should be performed before initiation of treatment with saw palmetto for benign prostatic hyperplasia (BPH). Evidence of efficacy with the use of saw palmetto for BPH remains contradictory.

Common Uses

Diuretic, urinary antiseptic, treatment of BPH, treatment of alopecia

Adverse Effects

Gastrointestinal upset, headache, back pain, dysuria

Potential Drug Interactions

Nonsteroidal anti-inflammatory drugs (NSAIDs), hormones such as estrogen replacement therapy and oral contraceptives, immunostimulants

Contraindications

None

For patients taking erectile dysfunction drugs, alert them to the serious adverse effect of severe drop in blood pressure caused by interaction with nitrates. When taking sildenafil, vardenafil hydrochloride, or tadalafil, priapism (the abnormally prolonged erection of the penis) may occur; it is considered a medical emergency and requires immediate and urgent medical attention. See **Patient Teaching Tips** for more information.

EVALUATION

The therapeutic effects of drugs related to the male reproductive tract include improvement of the condition and symptoms for which the patient is being treated, such as hypogonadism, sexual dysfunction, erectile dysfunction, and urinary elimination problems caused by BPH. The therapeutic effects of some drugs (e.g., finasteride) may not be seen for 6 to 12 months, so it is important for the nurse to observe and monitor the patient for the intended effects of the drugs. In addition, evaluate for the adverse effects of these medications (see the Pharmacology section for specific adverse effects). Always evaluate goals and expected outcomes to see if the patient's needs have been met.

CASE STUDY

Erectile Dysfunction Drugs

Yuri, a 63-year-old college instructor, is in the office for a yearly checkup. He feels he is generally healthy, and he does not take any medications. He says that he does have one problem that he wants to discuss with the health care provider. During his physical examination, he says, "I have something embarrassing to ask. I want to try one of those drugs that can help my sex life." The nurse practitioner reassures Yuri that he does not need to be embarrassed to ask about this. The nurse practitioner then assesses Yuri's sexual difficulties. At the end of the examination and assessment, Yuri is given a prescription for sildenafil (Viagra).

1. What teaching is important for Yuri before he starts this medication?
2. Eleven months later, Yuri is admitted to the emergency department with chest pains. After a thorough examination, including a cardiac catheterization, he is diagnosed with mild coronary artery disease and is started on an extended-release form of isosorbide-5-mononitrate, 60 mg every 12 hours. He is given a follow-up appointment with the nurse practitioner in 1 week. What specific teaching is important at this time?
3. Yuri comes to the office for the follow-up appointment and tells the nurse practitioner that he wants to try saw palmetto for his prostate health. He has a neighbour who takes it and has no problems with it, and he has noticed that he has had a slight increase in difficulty with urination. He is also upset about what he was told in the hospital about his medications. How will the nurse respond to Yuri and what assessments are needed at this time?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

PATIENT TEACHING TIPS

- Prior to the initiation of therapy with finasteride, provide education at the patient's educational level about the drug's therapeutic effects as well as adverse effects (see the previous discussion for more information). Educate female family members, significant others, and caregivers who are pregnant or of child-bearing age about the need to avoid exposure during handling of this drug, including *not* touching any broken or crushed tablets, which could result in exposure to the drug and the risk of teratogenic effects. Emphasize the need to wear gloves when handling the medication.
- Finasteride may be given orally without regard to meals. Instruct patients to protect the drug from exposure to light and heat.
- Patients taking sildenafil should be aware that it is usually prescribed to be taken about 1 hour before sexual activity. Tadalafil should be taken 1-2 hours before sexual activity and may last up to 36 hours. These drugs, and other drugs prescribed for erectile dysfunction, should not be taken with nitrates because this could lead to significant and potentially life-threatening hypotensive consequences.

- Inform patients that drug therapy for erectile dysfunction is not effective without sexual stimulation and arousal.
- Prior to therapy with testosterone, educate patients about all therapeutic and adverse effects. Emphasize the importance of follow-up appointments, which are crucial to evaluating the therapeutic effectiveness of the medication (as with any drugs discussed in this chapter).
- Patients should be informed that prolonged erections (i.e., longer than 4 hours) must be reported immediately to a health care provider and are considered a medical emergency.
- Educate patients that testosterone is not be withdrawn abruptly except under the supervision of the health care provider. Weaning is usually done over several weeks.

KEY POINTS

- The most commonly used drugs related to male health and the male reproductive tract are finasteride, sildenafil, and testosterone. It is important to know the ways these drugs work and their adverse effects, contraindications, cautions, and drug interactions to ensure their safe and effective use.
- Testosterone is responsible for the development and maintenance of the male reproductive system and secondary sex characteristics. Oral testosterone has poor pharmacokinetic and pharmacodynamic characteristics; thus, it is usually recommended that testosterone be administered parenterally or via a transdermal patch.
- Finasteride is usually indicated to stop growth of the prostate in men with BPH and to treat men with androgenic alopecia.
- Warn patients taking drugs for erectile dysfunction (e.g., sildenafil) about potential adverse effects, such as hypotension, headache, and heartburn.
- There are major concerns about deaths related to heart dysfunction associated with concurrent use of nitrates and drugs used for erectile dysfunction. Focus patient education on the prevention of drug interactions and related adverse effects and complications.

EXAMINATION REVIEW QUESTIONS

1. The nurse is caring for a patient who is taking finasteride (Proscar). Which of the following findings would the nurse monitor in this patient?
 - a. Complete blood count
 - b. PSA levels
 - c. Blood pressure
 - d. Fluid retention
2. The nurse is assessing a patient who is requesting a prescription for sildenafil (Viagra). Which of the following findings would be a contraindication to its use?
 - a. Age of 65 years
 - b. History of thyroid disease
 - c. Medication list that includes nitrates
 - d. Medication list that includes saw palmetto
3. During a counselling session for a group of adolescent athletes, the use of androgenic steroids is discussed. Which of the following details should the nurse provide?
 - a. Peliosis of the liver
 - b. Bradycardia
 - c. Kidney failure
 - d. Tachydysrhythmias
4. The nurse is teaching a patient about the possible adverse effect of priapism, which may occur when taking erectile dysfunction drugs. Which of the following statements would be most important for the nurse to include?
 - a. Stay in bed until the erection ceases.
 - b. Apply an ice pack for 30 minutes.
 - c. Turn toward the left side and rest.
 - d. Seek medical attention immediately.
5. The nurse is teaching a patient about the use of saw palmetto for prostate health. Which of the following drugs should be included when teaching about saw palmetto interactions?
 - a. Acetaminophen (Tylenol®)
 - b. Nitrates
 - c. NSAIDs
 - d. Antihypertensive drugs
6. The Testoderm form of testosterone was ordered to treat hypogonadism in an adolescent boy. Which of the following instructions should be given by the nurse? (Select all that apply.)
 - a. Place the patch on clean, dry skin on the back, upper arms, abdomen, or thighs.
 - b. Place the patch on clean, dry scrotal skin that has been shaved.
 - c. Place the patch on clean, dry scrotal skin, but do not shave the skin first.
 - d. Place the patch on any clean, dry, nonhairy area of the body.
 - e. Remove the old patch before applying a new patch.
7. A 16-year-old male is to receive testosterone cypionate (Depo-Testosterone), 50 mg IM every 2 weeks. The medication is available in 100-mg/mL vials. How many millilitres will the nurse draw up in the syringe to administer for each dose?
8. The nurse is reviewing the medication list for a patient and notes that finasteride (Proscar) 1 mg daily is on the list. This drug is for which of these problems?
 - a. Benign prostatic hypertrophy (BPH)
 - b. Erectile dysfunction
 - c. Alopecia in male patients
 - d. Alopecia in male and female patients

CRITICAL THINKING ACTIVITIES

1. During morning medication rounds, a nurse is about to give a dose of finasteride (Proscar) when the patient asks the nurse to crush the pill, which is not enteric coated. What is the nurse's priority action in response to his request?
2. A male patient calls the clinic to ask about topical testosterone gel. This morning, he applied the daily dose to his upper arms and, without thinking, picked up his young granddaughter soon afterward. He is upset because he thinks this will harm his granddaughter. What is the priority action at this time?
3. During an office checkup, a patient tells you, "Ever since I started that pill for my prostate gland I'm having trouble with sex. I just don't have the interest anymore. Could it be the pill?" When you check his medical record, you see that he started taking dutasteride (Avodart), a 5α -reductase inhibitor, 3 months ago. What is your best answer?

Antihistamines, Decongestants, Antitussives, and Expectorants

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Provide specific examples of the drugs categorized as antihistamines (both sedating and nonsedating), decongestants, antitussives, and expectorants.
2. Discuss the mechanisms of action, indications, contraindications, cautions, drug interactions, adverse effects, dosages, and routes of administration for antihistamines, decongestants, antitussives, and expectorants.
3. Develop a collaborative plan of care that includes all phases of the nursing process for patients taking any of the antihistamines, decongestants, antitussives, and expectorants.

KEY TERMS

Adrenergics (sympathomimetics) Drugs that stimulate the sympathetic nerve fibres of the autonomic nervous system that use epinephrine or epinephrine-like substances as neurotransmitters. (p. 612)

Antagonists Drugs that exert an action opposite that of another drug or compete for the same receptor sites. (p. 608)

Anticholinergics (parasympatholytics) Drugs that block the action of acetylcholine and similar substances at acetylcholine receptors, which results in inhibition of the transmission of parasympathetic nerve impulses. (p. 612)

Antigens Substances that are capable of inducing specific immune responses and reacting with the specific products of those responses, such as antibodies and specifically sensitized T lymphocytes. Antigens can be soluble (e.g., a foreign protein) or particulate or insoluble (e.g., a bacterial cell). (p. 609)

Antihistamines Substances capable of reducing the physiological and pharmacological effects of histamine. (p. 608)

Antitussives Drugs that reduce coughing, often by inhibiting neural activity in the cough centre of the central nervous system. (p. 614)

Corticosteroids Any of the hormones produced by the adrenal cortex, either in natural or synthetic form. They control many key processes in the body, such as carbohydrate and protein metabolism, the maintenance of serum glucose levels, electrolyte and water balance, and the functions of the cardiovascular system, skeletal muscle, kidneys, and other organs. (p. 612)

Decongestants Drugs that reduce congestion or swelling, especially of the upper or lower respiratory tract. (p. 612)

Empirical therapy A method of treating disease on the basis of observations and experience, rather than on knowledge of the precise cause for the disorder. (p. 607)

Expectorants Drugs that increase the flow of fluid in the respiratory tract, usually by reducing the viscosity of secretions, and facilitate their removal by coughing. (p. 615)

Histamine antagonists Drugs that compete with histamine for binding sites on histamine receptors. (p. 608)

Influenza A highly contagious infection of the respiratory tract caused by a myxovirus and transmitted by airborne droplets. (p. 607)

Nonsedating antihistamines Medications that work peripherally to block the actions of histamine and therefore do not generally have the central nervous system effects of many of the older antihistamines; also called *second-generation antihistamines* and *peripherally acting antihistamines*. (p. 611)

Reflex stimulation An irritation of the respiratory tract occurring in response to an irritation of the gastrointestinal (GI) tract. (p. 615)

Rhinovirus Any of approximately 100 serologically distinct ribonucleic acid (RNA) viruses that cause approximately 40% of acute respiratory illnesses. (p. 607)

Sympathomimetic drugs A class of drugs whose effects mimic those resulting from the stimulation of the sympathetic nervous system. (p. 613)

Upper respiratory tract infection (URI) Any infectious disease of the upper respiratory tract, including the common cold, laryngitis, pharyngitis, rhinitis, sinusitis, and tonsillitis. (p. 607)

DRUG PROFILES

- codeine (codeine phosphate)*, p. 614
- dextromethorphan (dextromethorphan hydrobromide)*, p. 615

*Full generic name is given in parentheses. For the purposes of this text, the more common, shortened name is used.

COLD MEDICATIONS

Common colds result from a viral infection, most often infection with a **rhinovirus** or an **influenza** virus. These viruses invade the tissues (mucosa) of the upper respiratory tract (nose, pharynx, and larynx) to cause an **upper respiratory tract infection (URI)**. The inflammatory response elicited by these viruses stimulates excessive mucus production. Typically this fluid drips behind the nose, down the pharynx, and into the esophagus and lower respiratory tract, which leads to symptoms of a cold: sore throat, coughing, and upset stomach. Irritation of the nasal mucosa often triggers the sneeze reflex and causes the release of several inflammatory and vasoactive substances, which results in dilation of the small blood vessels in the nasal sinuses and leads to nasal congestion.

Treatment of the common symptoms of URI involves the combined use of antihistamines, nasal decongestants, antitussives, and expectorants. In 2016, Health Canada issued a reminder that over-the-counter (OTC) cough and cold products are not to be given to children younger than 6 years of age ([Health Canada, 2016a](#)). This recommendation followed numerous case reports of symptoms such as oversedation, seizures, hallucinations, tachycardia, and abnormal heart rhythms. There is also evidence that such medications are simply not effective in small children, and parents are advised to consult their pediatrician regarding the best ways to manage these illnesses in young children. The evidence for the effectiveness of antihistamine-decongestant-analgesic combinations in adults and older children is also limited, although they may have some general benefit ([De Sutter, van Driel, Kumar, et al., 2012](#)).

Many antihistamines, nasal decongestants, antitussives, and expectorants are available without a prescription. However, these drugs can only relieve the symptoms of a URI—they do nothing to eliminate the causative pathogen. Antiviral drugs are currently the only drugs that are effective; however, treatment with these medications is often hampered by the fact that the viral cause cannot be readily identified. Because of this, the treatment rendered can be based only on what is believed to be the most likely cause, given the presenting clinical symptoms. Such treatment is called **empirical therapy**. Some patients seem to gain benefit from the use of natural health products, such as vitamin C, preventing the onset of cold signs and symptoms or at least decreasing their severity. Natural health products commonly used for colds are echinacea and goldenseal (see Natural Health Products box below). There is limited research on the

NATURAL HEALTH PRODUCTS

Echinacea (*Echinacea*)

Overview

The three species of echinacea are *Echinacea angustifolia*, *Echinacea pallida*, and *Echinacea purpurea*. Echinacea has been shown in clinical trials to reduce cold symptoms and recovery time when taken early in the illness. This is believed to be due to its immunostimulant effects. At this time, there is no strong research evidence to warrant recommending echinacea for prevention of colds; further study is needed to show evidence of its therapeutic effects and indications.

Common Uses

Stimulation of the immune system, antisepsis, treatment of viral infections and influenza-like respiratory tract infections, promotion of healing of wounds, and treatment of chronic ulcerations

Adverse Effects

Dermatitis, upset stomach or vomiting, dizziness, headache, unpleasant taste

Potential Drug Interactions

Amiodarone hydrochloride, cyclosporine, phenytoin, methotrexate, ketoconazole, barbiturates; tolerance is likely to develop if used for more than 8 weeks

Contraindications

Contraindicated for patients with AIDS, tuberculosis, connective tissue diseases, multiple sclerosis

Goldenseal (*Hydrastis canadensis*)

Overview

Goldenseal is native to wooded areas in Canada and the eastern United States. It is the dried root of a plant that is most commonly used for its biologically active alkaloids. These components have been shown to have antibacterial, antifungal, and antiprotozoal activity. The alkaloid berberine has both anticholinergic and antihistaminic activity.

Common Uses

Treatment of upper respiratory tract infections, allergies, nasal congestion, and numerous genitourinary, skin, ophthalmic, and otic conditions

Adverse Effects

Gastrointestinal (GI) distress, emotional instability, mucosal ulceration (e.g., when used as a vaginal douche)

Potential Drug Interactions

Gastric acid suppressors (including antacids, histamine H₂ blockers [e.g., ranitidine hydrochloride], proton pump inhibitors [e.g., omeprazole]): theoretically reduced effectiveness because of acid-promoting effect of the herb

Antihypertensives: theoretically reduced effectiveness because of vasoconstrictive activity of the herb

Contraindications

Acute or chronic GI disorders; pregnancy (as it has uterine-stimulant properties); should be used with caution by those with cardiovascular disease

efficacy of natural health products, and some can have significant drug–drug or drug–disease interactions.

ANTIHISTAMINES

Histamine is a substance that performs many functions. It is involved in nerve impulse transmission in the central nervous system (CNS), dilation of capillaries, contraction of smooth muscle, stimulation of gastric acid secretion, and acceleration of the heart rate. There are two types of cellular receptors for histamine. Histamine 1 (H_1) receptors mediate smooth muscle contraction and dilation of capillaries; histamine 2 (H_2) receptors mediate acceleration of the heart rate and gastric acid secretion. The release of excessive amounts of histamine can lead to anaphylaxis and severe allergic symptoms and may result in any or all the following physiological changes:

- Constriction of smooth muscle, especially in the stomach and lungs
- Increase in body secretions
- Vasodilation and increased capillary permeability, which results in the movement of fluid out of the blood vessels and into the tissues, causing a drop in blood pressure and edema

Antihistamines are drugs that directly compete with histamine for specific receptor sites. For this reason, they are also called **histamine antagonists**. Antihistamines that compete with histamine for the H_2 receptors are called H_2 **antagonists** or H_2 **blockers** and include such drugs as cimetidine, ranitidine hydrochloride (Zantac®), famotidine (Pepcid AC®), and nizatidine (Axid®). Because they act on the gastrointestinal (GI) system, they are discussed in detail in [Chapter 39](#). This chapter focuses on the H_1 antagonists (or H_1 blockers); they are the drugs commonly known as **antihistamines**. They are very useful drugs, as approximately 10 to 20% of the general population is sensitive to various environmental allergens. Histamine is a major inflammatory mediator in many allergic disorders, such as allergic rhinitis (e.g., hay fever,

mould, and dust allergies), anaphylaxis, angioedema, drug fevers, insect bite reactions, and urticaria (pale red, raised, itchy bumps).

H_1 antagonists include drugs such as diphenhydramine (Benadryl®), chlorpheniramine maleate (Chlor-Tripolon®) (generic; also found in Coricidin® in combination with acetaminophen, dextromethorphan hydrochloride, or both), fexofenadine hydrochloride (Allegra®), loratadine (Claritin®), desloratadine (Aerius®), and cetirizine hydrochloride (Reactine®). They are of greatest value in the treatment of nasal allergies, particularly seasonal hay fever. They are also given to relieve the symptoms of the common cold, such as sneezing and runny nose. When used in this way, they are palliative, not curative; that is, they can help alleviate the symptoms of a cold but can do nothing to destroy the virus causing it.

The clinical efficacy of the different antihistamines is similar, although they have varying degrees of antihistaminic, anticholinergic, and sedating properties. The actions and indications for an antihistamine are determined by its specific chemical makeup. All antihistamines compete with histamine for the H_1 receptors in the smooth muscle surrounding blood vessels and bronchioles. They also affect the secretions of the lacrimal, salivary, and respiratory mucosal glands, which are the primary anticholinergic actions of antihistamines. These drugs differ from each other in their potency and adverse effects, especially in the degree of drowsiness they produce. The antihistaminic, anticholinergic, and sedative properties of some of the more commonly used antihistamines are summarized in [Figure 37.1](#). Because of their antihistaminic properties, they are indicated for the treatment of allergies. They are also useful for the treatment of problems such as vertigo, motion sickness, insomnia, and cough. Several classes of antihistamines are listed in [Table 37.1](#), along with their various anticholinergic and sedative effects.

Mechanism of Action and Drug Effects

During allergic reactions, histamine and other substances are released from mast cells, basophils, and other cells in response

Fig. 37.1 Comparison of efficacy and adverse effects of selected antihistamines.

TABLE 37.1 Effects of Selected Antihistamines

Chemical Class	Anticholinergic Effects	Sedative Effects	Comments
Alkylamines			
brompheniramine maleate	Moderate	Low	Cause less drowsiness and more central nervous system stimulation; suitable for daytime use
chlorpheniramine maleate	Moderate	Low	
Ethanolamines			
clemastine	High	Moderate	Substantial anticholinergic effects; commonly cause sedation; at usual dosages, drowsiness occurs in about 50% of patients; diphenhydramine and dimenhydrinate also used as antiemetics
dimenhydrinate	High	High	
diphenhydramine hydrochloride	High	High	
Ethylenediamines			
pyrilamine	Low to none	Low	Weak sedative effects, but adverse GI effects are common
tripelennamine	Low to none	Moderate	
Phenothiazine			
promethazine hydrochloride	High	High	Drugs in this class are principally used as antipsychotics; some are useful as antihistamines, antipruritics, and antiemetics
Piperidines			
cycloheptadine hydrochloride	Moderate	Low	Commonly used in the treatment of motion sickness; hydroxyzine hydrochloride is used as a tranquilizer, sedative, antipruritic, and antiemetic
hydroxyzine hydrochloride	Moderate	Moderate	
Miscellaneous			
fexofenadine hydrochloride	Low to none	Low to none	Few adverse anticholinergic or sedative effects; almost exclusively antihistaminic effects, so can be taken during the day because no sedative effects occur; they are longer acting and have fewer adverse effects than other classes
loratadine	Low to none	Low to none	

**Fig. 37.2** Mediation of the allergic response by histamine.

to **antigens** circulating in the blood. Histamine molecules then bind to and activate other cells in the nose, eyes, respiratory tract, GI tract, and skin, producing the characteristic allergic signs and symptoms (see [Figure 37.2](#)). For example, in the respiratory tract, histamine causes extravascular smooth muscle (e.g., in the bronchial tree) to contract, whereas antihistamines cause it to relax. Also, histamine causes pruritus by stimulating nerve endings. Antihistamines can prevent or alleviate this itching.

Circulating histamine molecules bind to histamine receptors on basophils and mast cells. This stimulates further release of histamine stored within these cells. Antihistamine drugs work by blocking the histamine receptors on the surfaces of basophils and mast cells, thereby preventing the release and actions of histamine stored within these cells. They do not push off histamine that is already bound to a receptor but compete with histamine for unoccupied receptors. Therefore, antihistamines are most beneficial when given early in a histamine-mediated reaction, before all the free histamine molecules bind to cell membrane receptors. This binding of H_1 blockers to these receptors prevents the adverse consequences of histamine binding: vasodilation; increased GI, respiratory, salivary, and lacrimal secretions; and increased capillary permeability with resulting edema. The various drug effects of antihistamines are listed in [Table 37.2](#).

TABLE 37.2 Antihistamines: Drug Effects

Body System	Histamine Effects	Antihistamine Effects
Cardiovascular (small blood vessels)	Dilates blood vessels, increases blood vessel permeability (allows substances to leak into tissues)	Reduces dilation of blood vessels and increases permeability
Immune (release of substances commonly associated with allergic reactions)	Released from mast cells along with several other substances, which results in allergic reactions	Does not stabilize mast cells or prevent the release of histamine and other substances, but does bind to histamine receptors and prevents the actions of histamine
Smooth muscle (on exocrine glands)	Stimulates salivary, gastric, lacrimal, and bronchial secretions	Reduces salivary, gastric, lacrimal, and bronchial secretions

Indications

Antihistamines are indicated for the management of nasal allergies, seasonal or perennial allergic rhinitis (e.g., hay fever), and some of the typical symptoms of the common cold. They are also useful in the treatment of allergic reactions, motion sickness, Parkinson's disease (because of their anticholinergic effects), and vertigo. In addition, they are sometimes used as sleep aids.

Contraindications

Use of antihistamines is contraindicated in cases of known drug allergy. They are not to be used as the sole drug therapy during acute asthmatic attacks. In such cases, a rapid-acting bronchodilator, such as salbutamol or, in extreme cases, epinephrine, is usually the most urgently needed medication. Other contraindications may include acute-angle glaucoma, heart disease, kidney disease, hypertension, bronchial asthma, chronic obstructive pulmonary disease (COPD), peptic ulcer disease, seizure disorders, benign prostatic hyperplasia (BPH), and pregnancy. Fexofenadine hydrochloride is not recommended for children under 6 years of age or those with kidney impairment. Desloratadine is not recommended for children. Loratadine is not recommended for children younger than 2 years of age. Although risk is low, antihistamines should be used with caution in patients with inadequate liver function or kidney insufficiency, owing to metabolism and secretion issues, as well as in lactating mothers because of these drugs' sedative effects (So, Bozzo, Inoue, et al., 2010).

Adverse Effects

Drowsiness is usually the chief adverse effect of people who take antihistamines, but sedative effects vary among drugs

TABLE 37.3 Antihistamines: Reported Adverse Effects

Body System	Adverse Effects
Cardiovascular	Dysrhythmias, hypotension, palpitations, syncope
Central nervous	Sedation, dizziness, muscular weakness, paradoxical excitement, restlessness, nervousness, seizures
Gastrointestinal	Nausea, vomiting, diarrhea, constipation, hepatitis
Other	Dryness of mouth, nose, and throat; urinary retention; vertigo; visual disturbances; tinnitus; headache

TABLE 37.4 Antihistamines: Drug Interactions

Drug	Interacting Drug	Mechanism	Result
fexofenadine hydrochloride	Erythromycin and other cytochrome P450 inhibitors	Inhibited metabolism	Increased fexofenadine hydrochloride levels
	Phenytoin	Increased metabolism	Decreased fexofenadine hydrochloride levels
loratadine	Ketoconazole, cimetidine, erythromycin	Inhibited metabolism	Increased loratadine levels
diphenhydramine hydrochloride, cetirizine hydrochloride	Alcohol, monoamine oxidase inhibitors, central nervous system depressants, and other anticholinergics	Additive effects	Increased central nervous system depression

in this class (see Table 37.1). Fortunately, sedative effects are much less common, although still possible, with newer “nonsedating” drugs. The anticholinergic (drying) effects of antihistamines can cause adverse effects such as dry mouth, changes in vision, difficulty urinating, and constipation. Reported adverse effects of antihistamines are listed in Table 37.3.

Interactions

Drug interactions of antihistamines are listed in Table 37.4. An allergist will usually recommend discontinuation of antihistamine drug therapy at least 4 days prior to allergy testing.

Dosages

For dosage information on selected antihistamines, refer to the table on p. 611.

DRUG PROFILES

Although some antihistamines are prescription drugs, most are available over the counter. Antihistamines are available in many dosage forms to be administered orally, intramuscularly, intravenously, or topically.

Nonsedating Antihistamines

A major advance in antihistamine therapy occurred with the development of the **nonsedating antihistamines** loratadine, cetirizine hydrochloride, and fexofenadine hydrochloride. These drugs were developed partly to eliminate many of the adverse effects (mainly sedation) of the older antihistamines. These drugs act peripherally to block the actions of histamine and therefore have significantly fewer of the CNS effects of many older antihistamines. For this reason, these drugs are also called *peripherally acting antihistamines* because they do not readily cross the blood-brain barrier, unlike their traditional counterparts. Another advantage of the nonsedating antihistamines is that they have longer durations of action, allowing for once-daily dosing; this increases patient adherence to therapy.

loratadine

Loratadine (Claritin, Allertin) is a nonsedating antihistamine and is taken only once a day. It is structurally like cyproheptadine, but it does not readily distribute into the CNS, which diminishes the sedative effects associated with traditional antihistamines. However, at higher doses, central adverse effects such as drowsiness, headache, and fatigue can be seen. Loratadine is used to relieve the symptoms of seasonal allergic rhinitis (e.g., hay fever) as well as chronic urticaria. Loratadine and its primary active metabolite, desloratadine (Aerius), are both available over the counter.

Drug allergy is the only contraindication to the use of loratadine. The drug is available in oral form as a 10-mg tablet or soft gel capsule, as a 1-mg/mL syrup, as a 10-mg rapidly disintegrating tablet, and in a combination tablet with the decongestant pseudoephedrine. For recommended dosages, refer to the table below.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1–3 hr	8–12 hr	8–24 hr	24 hr

Traditional Antihistamines

The traditional antihistamines are older drugs that work both peripherally and centrally. They also have anticholinergic effects, which in some cases make them more effective than nonsedating antihistamines. Some of the commonly used older drugs are diphenhydramine, brompheniramine maleate, chlorpheniramine maleate, dimenhydrinate, and promethazine hydrochloride. They are used either alone or in combination with other drugs for the symptomatic relief of many disorders ranging from insomnia to motion sickness. It is important to note that dimenhydrinate contains between 53 and 55.5% diphenhydramine, which causes the primary effect of drowsiness, and 8-chlorotheophylline, which counteracts drowsiness and causes a lower potency. However, drowsiness is still the primary effect.

Many patients respond to and tolerate these older drugs quite well, and because many are generically available, they are much less expensive. These drugs are available both over the counter and by prescription.

diphenhydramine hydrochloride

Diphenhydramine hydrochloride (Aller-Aide®, Allernix®, Benadryl®, others) is a traditional antihistamine that acts both peripherally and centrally. It also has anticholinergic and sedative effects. In fact, it is used as a hypnotic drug because of its sedating effects. Its use is not generally advised in older adults because of the “hangover” effect and increased potential for falls. Diphenhydramine is one of the most commonly used antihistamines, in part because of its excellent safety profile and efficacy. It has the greatest range of therapeutic indications of any antihistamine available. It is used for the relief or prevention of histamine-mediated allergies, motion sickness, the treatment of Parkinson’s disease (because of its anticholinergic effects; see [Chapter 16](#)), and the promotion of sleep (see [Chapter 13](#)). It is

Dosages

Selected Antihistamines

Drug	Pharmacological Class	Usual Dosage Range	Indications
Nonsedating Antihistamines			
 loratadine (Claritin)	H ₁ antihistamine	<i>Children 2–9 yr (weighing less than 30 kg)</i> PO: 5 mg (5 mL) once daily <i>Children 10 yr and older (weighing more than 30 kg)</i> PO: 10 mg (10 mL) once daily <i>Children and adults 12 yr and older</i> PO: 10 mg once daily <i>Adults and children 6 yr and older</i> PO: 10 mg once daily <i>Children 2–5 yr</i> PO: 5 mg once daily	Allergic rhinitis, chronic urticaria

Dosages—cont'd

Drug	Pharmacological Class	Usual Dosage Range	Indications
Traditional Antihistamines (More Commonly Associated With Sedation)			
 diphenhydramine hydrochloride (Allerdryl, Allernix, Benadryl)	H ₁ antihistamine	<i>Children equal to or more than 10 kg</i>	Allergic disorders, nighttime insomnia, motion sickness
		PO/IM/IV: 12.5–25 mg tid–qid	
		<i>Adults and children 12 yr and older</i>	Nighttime insomnia
		PO: 25–50 mg hs	
		<i>Adults only</i>	Allergic disorders, PD symptoms
		PO/IM/IV: 25–50 mg tid–qid	
		<i>Adults only</i>	Motion sickness
		PO: 25–50 mg tid–qid	

IM, intramuscular; IV, intravenous; PD, Parkinson's disease; PO, oral.

also used in conjunction with epinephrine in the management of anaphylaxis and in the treatment of acute dystonia reactions.

Diphenhydramine use is contraindicated in patients with a known hypersensitivity to it. It is to be used with caution in nursing mothers, newborns, and patients with lower respiratory tract symptoms. It is available in oral, parenteral, and topical preparations. In oral form, diphenhydramine is available as caplets, capsules, chewable tablets, and liquid and in several combination products that contain other cough and cold medications. It is also available as an injection. In topical form, diphenhydramine is available as a spray. It is also available in combination with several other drugs that are commonly given topically as creams and lotions, such as calamine, camphor, and zinc oxide. For recommended dosages for the oral and injectable forms, refer to the table below.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	15–30 min	2 hr	7–12 hr	10–12 hr

DECONGESTANTS

Nasal congestion is due to excessive nasal secretions and inflamed and swollen nasal mucosa. The primary causes of nasal congestion are allergies and URIs, especially the common cold. There are three separate groups of nasal **decongestants**: **adrenergics (sympathomimetics)**, which comprise the largest group; **anticholinergics (parasympatholytics)**, which are less commonly used; and selected topical **corticosteroids** (intranasal steroids).

Decongestants can be taken orally to produce a systemic effect, can be inhaled, or can be administered topically into the nose. Each method of administration has its advantages and disadvantages. Decongestants administered by the oral route include pseudoephedrine, which is available over the counter. A commonly used nasal decongestant spray is phenylephrine hydrochloride, also available over the counter.

Drugs administered by the oral route produce prolonged decongestant effects, but their onset of action is more delayed

and the effect less potent than for decongestants applied topically. However, the clinical problem of rebound congestion associated with topically administered drugs is almost nonexistent with oral dosage forms. Rebound congestion occurs because of the rapid absorption of drug through mucous membranes followed by a rapid decline in therapeutic effectiveness of the drug. This rebound congestion can cause overuse of and dependence on the nasal spray, as patients take it frequently because of its rapid decline in activity. This is in contrast to oral dosage forms, which provide a more gradual increase and decline in pharmacological activity because of the time required for GI absorption. Nasal spray available in Canada contains oxymetazoline hydrochloride or xylometazoline, sympathomimetics associated with rebound congestion. Inhaled intranasal steroids and anticholinergic drugs are not associated with rebound congestion and are often used prophylactically to prevent nasal congestion in patients with chronic upper respiratory symptoms. Commonly used intranasal steroids include the following:

- beclomethasone dipropionate (Beconase AQ®)
- budesonide (Rhinocort®, Rhinocort Aqua®)
- fluticasone furoate (Avamys®)
- fluticasone propionate (Flonase®) (also now available OTC)
- mometasone furoate (Nasonex®)
- Ciclesonide (Omnaris®)
- triamcinolone acetonide (Nasacort®) (also now available OTC)

The only commonly used intranasal anticholinergic is ipratropium bromide nasal spray (Atrovent®). Other available nasal sprays are sodium cromoglycate (Rhinaris®-CS Anti-Allergic 2% Nasal Mist), a mast-cell stabilizer, and a combination drug, Dymista®, which contains the antihistamine azelastine hydrochloride and the corticosteroid fluticasone propionate.

Mechanism of Action and Drug Effects

Nasal decongestants are most commonly used for their ability to shrink engorged nasal mucous membranes and relieve nasal stuffiness. Adrenergic drugs (e.g., oxymetazoline) accomplish this by constricting the small arterioles that supply the structures of the upper respiratory tract, primarily the blood vessels surrounding the nasal sinuses. When these blood vessels are stimulated by α -adrenergic drugs, they constrict. Once these blood vessels shrink, the nasal secretions in the swollen mucous membranes are better able

to drain, either externally through the nostrils or internally through reabsorption into the bloodstream or lymphatic circulation. Because sympathetic nervous system stimulation produces the same effect, these drugs are sometimes referred to as *sympathomimetics*.

Nasal steroids target the inflammatory response elicited by invading organisms (viruses and bacteria) or other antigens (e.g., allergens). The body responds to these antigens by producing inflammation to isolate or wall off the area and by attracting various cells of the immune system to consume and destroy the offending antigens. Steroids exert their anti-inflammatory effect by causing these cells to be turned off or rendered unresponsive. The goal is *not* complete immunosuppression of the respiratory tract but rather to reduce the inflammatory symptoms to improve patient comfort and air exchange. The drug effects of intranasal steroids are also discussed in [Chapter 34](#).

Indications

Nasal decongestants reduce the nasal congestion associated with acute or chronic rhinitis, the common cold, sinusitis, and hay fever or other allergies. They may also be used to reduce swelling of the nasal passages and to facilitate visualization of the nasal and pharyngeal membranes before surgery or diagnostic procedures.

Contraindications

Contraindications to the use of decongestants include drug allergy. Adrenergic drugs are contraindicated in acute-angle glaucoma, uncontrolled cardiovascular disease, hypertension, diabetes, hyperthyroidism, and prostatitis. They are also contraindicated in situations in which patients are unable to close their eyes (such as after a stroke) and in patients with a history of stroke or transient ischemic attacks, cerebral arteriosclerosis, longstanding asthma, BPH, or diabetes.

Adverse Effects

Adrenergic drugs are usually well tolerated. Possible adverse effects of these drugs include nervousness, insomnia, palpitations, and tremors. The most common adverse effects of intranasal steroids are localized and include mucosal irritation and dryness as well as epistaxis (which can be prevented by spraying away from the septum).

Although a topically applied adrenergic nasal decongestant can be absorbed into the bloodstream, the amount absorbed is usually too small to cause systemic effects in normal doses; excessive doses of these drugs are more likely to cause systemic effects elsewhere in the body. These may include cardiovascular effects such as hypertension and palpitations and CNS effects such as headache, nervousness, and dizziness. These systemic effects are the result of α -adrenergic stimulation of the heart, blood vessels, and CNS.

Interactions

There are few significant drug interactions with nasal decongestants. Systemic [sympathomimetic drugs](#) and sympathomimetic nasal decongestants are likely to cause drug toxicity when given together. Monoamine oxidase inhibitors (MAOIs) may result in additive pressor effects (e.g., raising of blood pressure)

when given with sympathomimetic nasal decongestants. Other interacting drugs include methyldopa and urinary acidifiers and alkalinizers.

Dosages

For the recommended dosages of oxymetazoline hydrochloride, the only nasal decongestant profiled, refer to the table on p. 615.

DRUG PROFILES

Many of the decongestants are OTC drugs, but the more potent drugs that can cause serious adverse effects are available only by prescription. Although nasal steroids are relatively safe, their use is also contraindicated in some circumstances, including in patients with nasal mucosal infections (because of their ability to depress the body's immune response as part of their anti-inflammatory effect) or known drug allergy.

Many inhaled corticosteroids (e.g., beclomethasone, dexamethasone, and flunisolide) are discussed in greater detail in Chapter 34. The adrenergic drug oxymetazoline hydrochloride is discussed in this chapter. Both of these drug categories are generally first-line drugs for the treatment of chronic nasal congestion.

oxymetazoline hydrochloride

Oxymetazoline hydrochloride (Claritin®, Dristan®, Drixoral®, Sinufrin®, Vicks®) is chemically and pharmacologically similar to the other sympathomimetic drug, xylometazoline hydrochloride (Balminil®, Otrivin®). During a cold, the blood vessels that surround the nasal sinuses are dilated and engorged with plasma, white blood cells, mast cells, histamines, and many other blood components that are involved in fighting infections of the respiratory tract. This swelling, or dilation, blocks the nasal passages, which results in nasal congestion. When these drugs are administered intranasally, they cause dilated arterioles to constrict, which reduces nasal blood flow and congestion. Both drugs have the same contraindications as the other nasal decongestants. Oxymetazoline hydrochloride for nasal administration is available as a 0.05% solution and is meant to be instilled into each nostril. Common dosages for this drug are given in the Dosages table on p. 616.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Intranasal	5–10 min	Unknown	Unknown	up to 12 hr

ANTITUSSIVES

Coughing is a normal physiological function that serves the purpose of removing potentially harmful foreign substances and excessive secretions from the respiratory tract. The cough reflex is stimulated when receptors in the bronchi, alveoli, and pleura (lining of the lungs) are stretched. This causes a signal

to be sent to the cough centre in the medulla of the brain, which in turn stimulates the cough. Although coughing is primarily a beneficial response, there are times when it is not useful and may even be harmful (e.g., after a surgical procedure such as hernia repair, or in cases of nonproductive cough or “dry cough”). In these situations, the use of an **antitussive** drug may enhance patient comfort and reduce respiratory distress. There are two main categories of antitussives: opioid and nonopioid.

Although all opioid drugs have antitussive effects, only codeine and its semisynthetic derivative hydrocodone are used as antitussives. Both drugs are effective in suppressing the cough reflex and, if they are taken in the prescribed manner, their use does not generally lead to dependency. These two drugs are commonly incorporated into various combination formulations with other respiratory drugs and are rarely used alone for the purpose of cough suppression. There is increasing evidence that a single dose of honey might reduce mucus secretion and reduce cough in children.

Nonopioid antitussive drugs are less effective than opioid drugs. They are available either alone or in combination with other drugs in an array of OTC cold and cough preparations. Dextromethorphan is the most widely used of these antitussive drugs and is a derivative of the synthetic opioid levorphanol.

Mechanism of Action and Drug Effects

The opioid antitussives codeine and hydrocodone bitartrate, a semisynthetic opioid synthesized from codeine, suppress the cough reflex through direct action on the cough centre in the CNS (medulla). Opioid antitussives also provide analgesia and have a drying effect on the mucosa of the respiratory tract, which increases the viscosity of respiratory secretions. This helps to reduce symptoms such as runny nose and postnasal drip. The nonopioid cough suppressant dextromethorphan acts in the same way. Because it is not an opioid, however, it does not have analgesic properties, nor does it cause CNS depression.

Indications

Although they have other properties, such as analgesic effects in the case of opioid drugs, antitussives are used primarily to stop the cough reflex when the cough is nonproductive or harmful.

Contraindications

The only absolute contraindication to the antitussives is drug allergy. Relative contraindications include opioid dependency (for opioid antitussives) and high potential for respiratory depression (e.g., in frail older adults). Patients with these conditions are often able to tolerate lower drug dosages and still experience some symptom relief.

Additional contraindications and cautions include the following:

- dextromethorphan: contraindications of hyperthyroidism, advanced heart and vessel disease, hypertension, glaucoma, and use of MAOIs within the past 14 days
- diphenhydramine: see Antihistamines (page 612)

- codeine and hydrocodone bitartrate: contraindicated with alcohol use; cautious use of codeine and hydrocodone required with patients with CNS depression, anoxia, high serum levels of carbon dioxide (hypercapnia), and respiratory depression; increased intracranial pressure, inadequate kidney function, liver diseases, BPH, Addison's disease, and COPD

Adverse Effects

The following are the common adverse effects of selected antitussive drugs:

- codeine and hydrocodone bitartrate: sedation, nausea, vomiting, lightheadedness, and constipation
- dextromethorphan: dizziness, drowsiness, and nausea
- diphenhydramine: sedation, dry mouth, and other anticholinergic effects

Interactions

Opioid antitussives (codeine and hydrocodone bitartrate) may potentiate the effects of other opioids, general anaesthetics, tranquilizers, sedatives, hypnotics, tricyclic antidepressants, alcohol, and other CNS depressants.

Dosages

For the recommended dosages of selected antitussive drugs, refer to the table on p. 616.

DRUG PROFILES

Antitussives come in many oral dosage forms and are available both with and without a prescription. Most of the narcotic antitussives are available only by prescription because of their associated potential for misuse and for potential harm to children. Health Canada (2019a) has provided a listing of ingredients usually found in most cold and flu medications including dextromethorphan that are deemed unsafe for consumption by children under the age of 6 years old. Dextromethorphan is the most popular nonopioid antitussive available over the counter and is found in many trade name mixtures.

Consumption of large volumes of cough syrup containing dextromethorphan results in vomiting. Therefore, the drug is being extracted from cough syrups and sold on the Internet in a tablet form that can be swallowed or as a powder that can be snorted. Normal dosages are 15 to 30 mg. Illicit use may be 300 to greater than 1 500 mg (National Institute on Drug Abuse, 2017) and produce similar hallucinogenic effects to that of ketamine, a fast-acting anaesthetic used in animal and human medicine (Antonioni & Juurlink, 2014). Dextromethorphan is a dissociative drug that causes a feeling of detachment, reduced motor coordination, and altered perception, impairing judgement as well as creating the potential for hallucinations and coma.

codeine phosphate

Codeine phosphate is a popular opioid antitussive drug. It is used in combination with many other respiratory

medications to control coughs. Because it is an opioid, it is potentially addictive and can depress respiration as part of its CNS depressant effects. For this reason, codeine-containing cough suppressants are more tightly controlled than others (*Controlled Drugs and Substances Act*, Schedule I) but are commonly available by prescription. Health Canada (2016b) recommends that children under the age of 12 (and children under 18 years post-tonsillectomy) should not be prescribed any prescription or nonprescription codeine product because of potential breathing problems. Cough suppressants containing codeine are also available behind the counter in the pharmacy. Cough suppressants are available in many oral dosage forms: solutions, tablets, capsules, and suspensions. Their use is contraindicated in patients with a known hypersensitivity to codeine and morphine (recall that codeine is metabolized to morphine) and in those suffering from respiratory depression, increased intracranial pressure, seizure disorders, or severe respiratory disorders. Common dosages are listed in the table on p. 616.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	15–30 min	34–45 min	2.5–4 hr	4–6 hr

dextromethorphan hydrobromide

Dextromethorphan hydrobromide is a nonopioid antitussive that is available alone or in combination with many other cough and cold preparations. It is widely used because it is safe and nonaddicting and does not cause respiratory or CNS depression when used in recommended dosages. Dextromethorphan has become a popular drug of misuse and is discussed in detail in Chapter 18. Its use is contraindicated in cases of drug allergy, asthma, emphysema, or persistent headache. Dextromethorphan is available as lozenges; solutions; liquid-filled capsules; granules; caplets; chewable, extended-release, or film-coated tablets; and an extended-release syrup. Benefits of this drug may warrant use in pregnant women despite potential risks. For recommended dosages, refer to the table on p. 616.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	15–30 min	2.5 hr	Unknown	3–6 hr

EXPECTORANTS

Expectorants aid in the expectoration (i.e., coughing up and spitting out) of excessive mucus that has accumulated in the respiratory tract, by breaking down and thinning out the secretions. They are administered orally either as single

drugs or in combination with other drugs to facilitate the flow of respiratory secretions by reducing their viscosity. Expectorants are popular drugs, are contained in most OTC cold and cough preparations, and provide symptom relief for many users. The most common expectorant in most OTC products is guaifenesin, which is effective for decreasing mucus-related symptoms in URIs and chronic bronchitis (Albrecht, Dicipinigaitis, & Guenin, 2017).

Mechanism of Action and Drug Effects

Expectorants have one of two different mechanism of actions, depending on the drug. The first is **reflex stimulation**, in which loosening and thinning of respiratory tract secretions occurs in response to an irritation of the GI tract produced by the drug. Guaifenesin is the only such drug currently available. The second mechanism of action is direct stimulation of the secretory glands in the respiratory tract.

Indications

Expectorants are used for the relief of productive cough commonly associated with the common cold, bronchitis, laryngitis, pharyngitis, pertussis, influenza, and measles. They may also be used to decrease the tendency of coughs caused by chronic paranasal sinusitis. By loosening and thinning sputum and bronchial secretions, they may also indirectly diminish the tendency to cough.

Contraindications

Guaifenesin is contraindicated in cases of known drug allergy.

Adverse Effects

The adverse effects of expectorants are minimal. Guaifenesin may cause nausea, vomiting, and gastric irritation.

Interactions

There are no known significant interactions involving guaifenesin.

Dosages

For dosage information on guaifenesin, the only expectorant profiled, refer to the table on the next page.

DRUG PROFILES

guaifenesin

Guaifenesin (Balminil®, Brochophan®, Robitussin®, others) is a commonly used expectorant that is available in several different oral dosage forms: capsules, tablets, and solutions. It is used in the symptomatic management of coughs of varying origins. It is beneficial in the treatment of productive coughs because it thins the mucus in the respiratory tract that is difficult to cough up. There are few published pharmacokinetic data on guaifenesin, but its half-life is estimated to be approximately 1 hour. This short half-life helps explain why it is usually dosed several times throughout the day. For dosage information, refer to the table below.

Dosages

Selected Decongestant, Expectorant, and Antitussive Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indication
codeine phosphate (as part of a combination product such as Dimetane-Expectorant-C®, Dimetapp-C®, CoActifed®, Robitussin AC®, others)	Opioid antitussive	<i>Adults and children over 12 yr</i> PO: 10 mL q4–6h	Cough suppression
 dextromethorphan hydrobromide (as part of a combination product such as Benlyn DM-E®, Buckley's®, Dimetapp-DM®, Robitussin-DM®, Vicks, others)	Nonopioid antitussive	<i>Children 2–5 yr</i> PO: 2.5 mL q6h <i>Children 6–12 yr</i> PO: 5–10 mL q6h <i>Adults and children over 12 yr</i> PO: 10 mL q6h	Cough suppression
 guaifenesin (100 mg/mL) (Balminil, Robitussin, others)	Expectorant	<i>Children 2 yr to under 6 yr</i> PO: 2.5 mL q6h <i>Children 6 yr to under 12 yr</i> PO: 5 mL q6h PO: 10–20 mL q6h	Respiratory congestion, cough
 oxymetazoline hydrochloride (Claritin®, Drixoral, Sinufrin, Vicks, others)	Decongestant	<i>Adults and children over 12 yr</i> Nasally: 2–3 sprays each nostril q10–12h × 3 days	Nasal decongestant

PO, oral.

and would be treated completely differently. The drug of choice is then selected on the basis of type and severity of the symptoms.

Most nonsedating antihistamines (e.g., fexofenadine hydrochloride, loratadine, cetirizine hydrochloride) are contraindicated in those with known allergies to the drugs. Remember that the traditional, nonsedating antihistamines are usually discontinued at least 4 days before allergy testing is to be performed, but only on a health care provider's order and as directed. Assess for the following possible drug interactions that need to be avoided: fexofenadine hydrochloride given with erythromycin and other CYP450 inhibitors, leading to increased antihistamine levels; fexofenadine hydrochloride given with phenytoin, leading to decreased fexofenadine hydrochloride levels; loratadine given with some antifungals, cimetidine, and erythromycin, leading to increased antihistamine levels; and diphenhydramine and cetirizine hydrochloride given with alcohol, MAOIs, and CNS depressants, leading to increased CNS depression.

Before administering the traditional antihistamines such as diphenhydramine, chlorpheniramine maleate, or brompheniramine maleate, ensure that the patient has no allergies to this group of medications, even though these drugs are used for allergic reaction. Assess contraindications, cautions, and drug interactions with these and all other drugs. Use of these antihistamines is of concern in patients who are experiencing an acute asthma attack and in those who have lower respiratory tract disease with potential for pneumonia. The rationale for not using these drugs in these situations is that antihistamines (including nonsedating antihistamines) dry up secretions; if the patient cannot expectorate secretions, the secretions may become viscous (thick), occlude airways, and lead to atelectasis, infection, or occlusion of the bronchioles. It is also important to know that these drugs may lead to paradoxical reactions in older adults, with subsequent irritability as well as dizziness, confusion, sedation, and hypotension.

Use of decongestants requires assessment of contraindications, cautions, and drug interactions. Because decongestants are available in oral forms, nasal drops and sprays, and eye drop dosage forms, any condition that could affect the functional structures of the eye or nose may be a possible caution or contraindication. Decongestants may increase blood pressure and heart rate, so the patient's blood pressure, pulse, and other vital parameters need to be assessed. Patients with hypertension (controlled) can use topical decongestants short term, but it is advised against using oral decongestants. If any patient has coronary artery disease, use of decongestants of any kind should be avoided. Since so many decongestants are found in OTC cough and cold products and have been associated with numerous cases of oversedation, seizures, tachycardia, and even death, their use warrants extreme caution. Contraindications to the use of decongestants include drug allergy, acute-angle glaucoma, uncontrolled cardiovascular disease, hypertension, diabetes, and prostatitis. Topically applied adrenergic nasal decongestants may be absorbed into the circulation; however, the dosage amount absorbed is usually too small to cause systemic effects. If it is used too often, or excessive amounts are used, cardiovascular effects may be precipitated (e.g., increase in blood pressure) and there may be CNS stimulation (with headache, nervousness, or dizziness). Some drug interactions

NURSING PROCESS

ASSESSMENT

When a patient is to be given drugs to treat symptoms in the respiratory tract, begin the assessment by gathering data about the condition and determining if symptoms are caused by an allergic reaction. Obtaining the patient's medical history and medication profile, completing a thorough head-to-toe physical assessment, and taking a nursing history are critical to understanding possible causes, risks, or links to diseases or conditions such as allergy, a cold, or influenza. For example, if an allergic reaction to a drug, food, or substance has occurred, the patient may be experiencing signs and symptoms such as hives, wheezing or bronchospasm, tachycardia, or hypotension (requiring immediate medical attention). However, if the cause is a cold or influenza, the symptoms would be different

include the use of systemic sympathomimetics and sympathomimetic nasal decongestants together, which can create possible toxicity. Other drug interactions for which to assess with nasal decongestants include their use with MAOIs.

Inhaled intranasal steroids are contraindicated in situations in which the patient is experiencing a nasal mucosal infection or drug allergy. [Chapter 34](#) discusses some of the inhaled corticosteroids. With the use of any decongestant, always perform a thorough assessment of signs and symptoms before and after use of these drugs. Include descriptions of cough, secretions, and breath sounds in this assessment.

With antitussive therapy, assessment is tailored to the patient and the specific drug. Most of these drugs result in sedation, dizziness, and drowsiness, so assessment of the patient's safety is important. Complete an assessment for allergies, contraindications, cautions, and drug interactions, and document the findings. In the respiratory assessment (as for all the drugs in this chapter), include rate, rhythm and depth, as well as breath sounds, presence of cough, and description of cough and sputum if present. For individuals with chronic respiratory disease, the prescriber may order further studies to determine the safety of using these drugs without causing further respiratory concerns or depression. Pulse oximetry readings with measurement of vital signs may be used to provide more information. Assess for potential drug interactions such as those involving alcohol, MAOIs, and antihistamines. With use of codeine and hydrocodone bitartrate antitussives, there are contraindications with alcohol and other opioid drugs; these drugs must be used cautiously in those with CNS depression, anoxia, hypercapnia, respiratory depression, inadequate renal function, or COPD. With the nonopioid antitussive dextromethorphan, monitor its use carefully because it is a popular drug of abuse (see [Chapter 18](#)).

Expectorants are generally well tolerated, and the only contraindication to their use is drug allergy. There are no known drug interactions for which to assess with use of the expectorant guaifenesin.

◆ NURSING DIAGNOSES

- Inadequate gas exchange as a result of the disorder, condition, or disease affecting the respiratory system and respiratory-related signs and symptoms
- Inadequate airway clearance as a result of diminished ability to cough or a suppressed cough reflex (with antitussives)
- Inadequate knowledge as a result of the effective use of cold medications and other related products due to lack of information and patient teaching

◆ PLANNING

◆ Goals

- Patient will experience improved gas exchange with drug therapy.
- Patient will have improved airway clearance and relief of symptoms.
- Patient will display improved knowledge about drug therapy.

◆ Expected Patient Outcomes

- Patient experiences improved oxygen exchange and breath sounds and a return to normal respiratory rate and rhythm.
- Patient takes medications exactly as prescribed to enhance airway clearance.
 - Patient increases fluid intake to thin secretions and increase expectoration of mucus.
 - Patient's breath sounds clear and there is expectoration of secretions as well as a return to a respiratory rate of 12 to 20 breaths/min.
 - Patient reports any of the following symptoms to the health care provider immediately: increase in cough, congestion, or shortness of breath; chest pain; fever (above 38°C); or any change in sputum production or colour (i.e., if not clear or if a change from baseline).
- Patient states rationale for therapy as well as adverse effects to expect while on drug therapy.
- Patient remains adherent to the antihistamine, antitussive, decongestant, or expectorant medication regimen until symptoms are resolved or the health care provider orders discontinuation.

◆ IMPLEMENTATION

If patients are receiving nonsedating antihistamines, advise them to take the drugs as directed. Reduced dosages may be needed for older adult patients or for patients with decreased kidney function. The H₁ receptor antagonist drugs do not cross the blood–brain barrier as readily as older antihistamines do and are therefore less likely to cause sedation. They are generally well tolerated with minimal adverse effects.

Instruct patients taking traditional antihistamines (e.g., diphenhydramine) to take the medications as prescribed. Most of these medications, including the OTC antihistamines, are best tolerated when taken with meals. Although food may slightly decrease absorption of antihistamines, it has the benefit of minimizing the GI upset these drugs may cause. Encourage patients who experience dry mouth to chew or suck on candy (sugarless if needed) or OTC throat, cough, or cold lozenges, or to chew gum, as well as to perform frequent mouth care to ease the dryness and related discomfort. Because of the potential for serious drug interactions, other OTC or prescribed cold or cough medications must not be taken with antihistamines unless they were previously approved or ordered by the health care provider. Dosage amounts and routes may vary depending on whether the patient is an older adult, adult, or younger than 12 years of age, so encourage proper dosing and usage. Monitor blood pressure and other vital signs as needed. Monitor older adults and children for any paradoxical reactions, which are common with these drugs.

Patients taking decongestants are generally using the drugs for nasal decongestion. These drugs come in oral dosage forms, including sustained-release and chewable forms. Educate patients that all dosage forms are to be taken as instructed and encourage an increase in fluid intake of up to 3 000 mL a day, unless contraindicated. Fluid helps liquefy secretions, assists in breaking up thick secretions, and makes it easier to cough up secretions.

Counsel patients to use nasal decongestant dosage forms exactly as ordered and with no increase in frequency. Excessive use of decongestant nasal sprays or drops may lead to rebound congestion. See the Patient Teaching Tips for further information.

With antitussives, instruct patients that the various dosage forms of the drugs are to be used exactly as ordered. Drowsiness or dizziness may occur with the use of antitussives; therefore, caution patients against driving a car or engaging

in other activities that require mental alertness until they feel back to normal. If the antitussive contains codeine, the CNS depressant effects of the narcotic opiate may further depress breathing and respiratory effort. Other antitussives, such as dextromethorphan, as well as codeine-containing drugs, are to be given at evenly spaced intervals so that the drug reaches a steady state.

◆ EVALUATION

CASE STUDY

Decongestants

A 22-year-old male college student has had allergy symptoms since moving into his dormitory. When he calls the student health centre, he is told to try an OTC topical nasal decongestant. He tries one and is excited about the relief he experiences until 2 weeks later, when his symptoms return. He calls the student health centre again, upset because his symptoms are now worse.

1. What explanation do you have for the worsening symptoms?
2. What patient education should he have received about this type of drug?
3. What other OTC drugs and nonpharmacological measures could be suggested to improve this situation?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

A therapeutic response to drugs given to treat respiratory conditions, such as antihistamines, antitussives, decongestants, and expectorants, includes resolution of the symptoms for which the drugs were originally prescribed or taken. These symptoms may include cough; nasal, sinus, or chest congestion; nasal, salivary, and lacrimal gland hypersecretion; motion sickness; sneezing; watery, red, or itchy eyes; itchy nose; allergic rhinitis; and allergic symptoms. Some of the antihistamines, such as diphenhydramine, are also helpful as sleep aids, and a therapeutic response when they are taken for this purpose would be the successful induction of sleep. Monitor for the adverse effects of excessive dry mouth, nose, and throat; urinary retention; drowsiness; oversedation; dizziness; paradoxical excitement, nervousness, or restlessness; dysrhythmias; palpitations; nausea; diarrhea or constipation; and headache, depending on the drug prescribed.

PATIENT TEACHING TIPS

- Provide patients with education about the sedating effects of traditional antihistamines. Patients need to avoid activities that require alertness until tolerance to sedation occurs or until they can accurately judge that the drug has no impact on motor skills or responses. Provide patients with a list of drugs that must be avoided, such as alcohol and CNS depressants.
- Encourage intake of fluids, unless contraindicated.
- Educate patients with upper or lower respiratory symptoms or disease processes about the impact of the environment on their symptoms or condition, and instruct patients to avoid dry air, smoke-filled environments, and allergens.
- Encourage patients to always check with a pharmacist for possible drug interactions because many OTC and prescription drugs could lead to adverse effects if taken concurrently with any of the antihistamines, decongestants, antitussives, or expectorants.
- Advise patients to take medication with food to avoid GI upset.
- Instruct patients to report any difficulty breathing, palpitations, or unusual adverse effects to a health care provider immediately.
- Instruct patients to take antitussives with caution and to report symptoms of pneumonia, such as fever, chest tightness, change in sputum from clear to coloured, difficult or noisy breathing, activity intolerance, or weakness.
- Prior to the use of decongestants, emphasize the importance of taking the medication as ordered and adhering to instructions regarding dose and frequency. Emphasize that frequent, long-term, or excessive use of decongestants (whether oral forms or nasal inhaled forms) may lead to rebound congestion, in which the nasal passages become more congested as the effects of the drug wear off. When this occurs, the patient generally uses more of the drug, precipitating a vicious cycle involving more congestion. Advise patients to report to a health care provider any heart palpitations, weakness, sedation, extreme dizziness, or excessive irritability.
- Advise patients taking expectorants to avoid using alcohol and products containing alcohol and to not use these medications for longer than 1 week. If cough or other symptoms continue, the patient should contact the health care provider. Encourage intake of fluids, unless contraindicated, to help thin secretions for easier expectoration.
- Decongestants and expectorants are recommended to treat cold symptoms, but the patient must report a fever of higher than 38°C, cough, or other symptoms lasting longer than 3 to 4 days.
- Educate patients about the need for familiarity with the list of ingredients in combination drug mixtures to avoid using similar drugs. Many of the drugs used to manage colds, coughs, and sputum contain similar ingredients yet have different trade names.

KEY POINTS

- There are two types of histamine blockers: H₁ blockers and H₂ blockers. H₁ blockers are the drugs to which most people are referring when they use the term *antihistamine*. H₁ blockers prevent the harmful effects of histamine and are used to treat seasonal allergic rhinitis, anaphylaxis, reactions to insect bites, and so on. H₂ blockers are used to treat gastric acid disorders, such as hyperacidity or ulcer disease.
- It is important to educate patients about the purposes of their medication regimens, the expected adverse effects, and any drug interactions. A list of all medications (prescription and OTC, as well as natural health products) needs to be provided to all health care providers.
- Decongestants act by causing constriction of the engorged and swollen blood vessels in the sinuses, which decreases pressure and allows mucous membranes to drain. It is important to understand the action of these drugs and know other important information such as significant adverse effects, including heart and CNS-stimulating effects that may result in palpitations, insomnia, restlessness, and nervousness.
- Nonopioid antitussive drugs may also cause sedation, drowsiness, or dizziness. Patients should not drive a car or engage in other activities that require mental alertness if these adverse effects occur. Codeine-containing antitussives may lead to CNS depression; these drugs are to be used cautiously and are not to be mixed with anything containing alcohol.

EXAMINATION REVIEW QUESTIONS

1. When assessing a patient who is to receive a decongestant, the nurse will recognize that a potential contraindication to this drug would be which condition?
 - a. Glaucoma
 - b. Fever
 - c. Peptic ulcer disease
 - d. Allergic rhinitis
2. When giving decongestants, the nurse must remember that these drugs have α -adrenergic- stimulating effects that may result in which effect?
 - a. Fever
 - b. Bradycardia
 - c. Hypertension
 - d. CNS depression
3. The nurse is reviewing the medication orders for prn (as necessary) medications that can be given to a patient who has bronchitis with a productive cough. Which drug will the nurse choose?
 - a. An antitussive
 - b. An expectorant
 - c. An antihistamine
 - d. A decongestant
4. The nurse knows that an antitussive cough medication would be the best choice for which patient?
 - a. A patient with a productive cough
 - b. A patient with chronic paranasal sinusitis
 - c. A patient who has had recent abdominal surgery
 - d. A patient who has influenza
5. A patient is taking a decongestant to help reduce symptoms of a cold. The nurse will instruct the patient to observe for which possible symptom, which may indicate an adverse effect of this drug?
 - a. Increased cough
 - b. Dry mouth
 - c. Slower heart rate
 - d. Heart palpitations
6. The nurse is giving an antihistamine and will observe the patient for which of the following adverse effects? (Select all that apply.)
 - a. Hypertension
 - b. Dizziness
 - c. "Hangover" effect
 - d. Drowsiness
 - e. Tachycardia
 - f. Dry mouth
7. The order for a 4-year-old patient reads: "Give guaifenesin, 80 mg PO, every 4 hours as needed for cough. Maximum of 600 mg/24 hours." The medication comes in a bottle that has 100 mg/5 mL. How many millilitres will the nurse give per dose?
8. The nurse notes in a patient's medication history that the patient is taking dextromethorphan hydrobromide (Benlyn DM-E®) as needed. Based on this finding, the nurse interprets that the patient has which problem?
 - a. Cough
 - b. Seasonal allergies
 - c. Chronic rhinitis
 - d. Motion sickness

CRITICAL THINKING ACTIVITIES

1. A patient calls the clinic to ask the nurse about taking an antihistamine for a "terrible cold." She says she is so tired of sneezing and blowing her nose. What are the priorities when the nurse assesses the patient's medical history before answering about the use of antihistamines?
2. An older patient is discussing the use of guaifenesin with the nurse. He asks, "What else can I do to fight this terrible cold? I don't want to just take a pill." What is the nurse's best answer?
3. A patient is recovering from an emergency exploratory laparotomy. He had a cold before his surgery and is now

coughing up large amounts of whitish yellow sputum. He is receiving intravenous fluids and antibiotics. He asks the nurse for something to make him stop coughing. The nurse reviews the medication sheet and sees both an expectorant

and an antitussive ordered. Which medication would be the best choice at this time? Explain your answer.

For answers see <http://evolve.elsevier.com/Canada/Lilley/pharmacology>.

Respiratory Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Describe the anatomy and physiology of the respiratory system.
2. Discuss the impact of respiratory drugs on various upper and lower respiratory tract diseases and conditions.
3. List the classifications of drugs used to treat diseases and conditions of the respiratory system and provide specific examples.
4. Discuss the mechanisms of action, indications, contraindications, cautions, drug interactions, dosages, routes of administration, adverse effects, and toxic effects of bronchodilators and other respiratory drugs.
5. Develop a collaborative plan of care that includes all phases of the nursing process for patients who use bronchodilators or other respiratory drugs.

KEY TERMS

Allergen Any substance that evokes an allergic response. (p. 618)

Allergic asthma Bronchial asthma caused by hypersensitivity to an allergen or allergens. (p. 618)

Alveoli Microscopic sacs in the lungs in which oxygen is exchanged for carbon dioxide; also called *air sacs*. (p. 618)

Antibodies Immunoglobulins produced by lymphocytes in response to bacteria, viruses, or other antigenic substances. (p. 618)

Antigen A substance (usually a protein) that causes the formation of an antibody and reacts specifically with that antibody. (p. 618)

Asthma Recurrent and reversible shortness of breath, resulting from narrowing of the bronchi and bronchioles. Key characteristics are inflammation, bronchial smooth muscle spasticity, and sputum production; inflammation is the most important characteristic. (p. 618)

Asthma attack Sudden onset of wheezing together with difficulty breathing. (p. 618)

Bronchodilators Medications that improve airflow by relaxing bronchial smooth muscle cells (e.g., xanthines, adrenergic agonists). (p. 620)

Chronic obstructive pulmonary disease (COPD) A chronic lung disorder characterized by persistent airflow obstruction that is partially reversible. It is usually progressive and is associated with an intensified chronic inflammatory response in the lungs. Formerly known as *chronic bronchitis* and *emphysema*. (p. 618)

Immunoglobulins Proteins belonging to any of five structurally and antigenically distinct classes of antibodies present in the serum and external secretions of the body. (p. 618)

Lower respiratory tract (LRT) The division of the respiratory system composed of organs located almost entirely within the chest. (p. 617)

Status asthmaticus A prolonged asthma attack; a medical emergency. (p. 618)

Upper respiratory tract (URT) The division of the respiratory system composed of organs located outside the chest cavity (thorax). (p. 617)

DRUG PROFILES

fluticasone (fluticasone propionate)*, p. 628
ipratropium (ipratropium bromide)*, p. 624
methylprednisolone, p. 628

-  montelukast (montelukast sodium)*, p. 626
-  salbutamol (salbutamol sulphate)*, p. 622
-  salmeterol (salmeterol xinafoate)*, p. 623
-  theophylline, p. 625
-  Key drug

*Full generic name is given in parentheses. For the purposes of this text, the more common, shortened name is used.

OVERVIEW

The main function of the respiratory system is to deliver oxygen to, and remove carbon dioxide from, the cells of the body. To perform this deceptively simple task requires an intricate system of tissues, muscles, and organs called the *respiratory system*. It consists of two divisions: the upper and lower respiratory tracts. The **upper respiratory tract (URT)** is composed of the structures located outside of the chest cavity, or thorax. These are the nose, nasopharynx, oropharynx, laryngopharynx, and larynx. The **lower respiratory tract (LRT)** is located almost entirely within

the chest and is composed of the trachea, all segments of the bronchial tree, and the lungs. The URT and LRT have four main accessory structures that aid in their overall function. These are the oral cavity (mouth), the rib cage, the muscles of the rib cage (intercostal muscles), and the diaphragm. The upper and lower respiratory tracts together with the accessory structures make up the respiratory system. Elements of this system are in constant communication with each other as they perform the vital function of respiration and the exchange of oxygen for carbon dioxide.

The air we breathe is a mixture of many gases. During inhalation, oxygen molecules from the air diffuse across the semi-permeable membranes of the **alveoli**, where they are exchanged for carbon dioxide molecules, which are then exhaled. The lungs also filter, warm, and humidify the air. Oxygen is then delivered to the cells by the blood vessels of the circulatory system, in which the respiratory system transfers the oxygen it has extracted from inhaled air to the hemoglobin protein molecules contained within red blood cells. Also within the circulatory system, the cellular metabolic waste product carbon dioxide is collected from the tissues by red blood cells. This waste is then transported back to the lungs via the circulatory system, where it diffuses back across the alveolar membranes and is then exhaled into the air. The respiratory system also plays a central role in speech, sense of smell, and regulation of pH (acid–base balance).

DISEASES OF THE RESPIRATORY SYSTEM

Several diseases impair the function of the respiratory system. Those that affect the URT include colds, rhinitis, and hay fever. These conditions and the drugs used to manage them are discussed in [Chapter 37](#). The major diseases that impair the function of the LRT include **asthma** and **chronic obstructive pulmonary disease (COPD)**, formerly known as *emphysema* and *chronic bronchitis*. According to [Public Health Agency of Canada \(2018\)](#) 3.8 million Canadians were diagnosed with asthma and 2.0 million with COPD in 2011/2012. These diseases have one feature in common: they involve the obstruction of airflow through the airways. Asthma that is persistent and present most of the time despite treatment is also considered a COPD. Cystic fibrosis and infant respiratory distress syndrome are other disorders that affect the LRT, but they are not a focus of discussion in this chapter because treatment for them places more emphasis on nonpharmacological than on pharmacological measures.

Asthma

Bronchial asthma is defined as a heterogeneous disease, usually characterized by chronic airway inflammation. It is defined by the history of respiratory symptoms such as wheeze, shortness of breath, chest tightness, and cough that vary over time and in intensity, together with variable expiratory airflow limitation ([Global Initiative for Asthma \[GINA\], 2018](#), p. 14).

The alveolar ducts and alveoli distal to the bronchioles remain open, but the obstruction to the airflow in the airways prevents carbon dioxide from getting out of the air spaces and oxygen from getting into them. When an episode has a sudden and dramatic onset, it is referred to as an **asthma attack**. Most asthma attacks are short and respond to medication; normal breathing is subsequently recovered. However, an asthma attack

may be prolonged and may not respond to typical drug therapy. When this happens, it is known as **status asthmaticus** and requires hospitalization. The onset of asthma occurs before 10 years of age in 50% of patients and before 40 years of age in approximately 80% of patients.

Asthma is characterized by chronic inflammation of the airways resulting in bronchial constriction (airflow limitation) and hyper-responsiveness to various exogenous and endogenous triggers; these triggers include allergens, exercise, viral respiratory infections, nasal and sinus difficulties, air pollutants, and drugs. Environmental triggers such as a viral infection, allergens, or irritants initiate an inflammatory cascade that involves a variety of chemical mediators and inflammatory cells. Typically, the response to environmental stimuli involves two asthmatic responses: an early-phase response and a late-phase response.

An **allergen** is any substance that elicits an allergic reaction. Exposure to inhaled allergens, such as pollen, dust mites, mould, or animal dander, can initiate an acute immune response in allergen-sensitive individuals (**allergic asthma**) that leads to airway inflammation. Exposure to the offending allergen causes an immediate reaction, called the *early-phase response*. This attack is mediated by antibodies already present in the patient's body that chemically recognize the allergen as a foreign substance, or **antigen**. These **antibodies** are specialized immune system proteins known as **immunoglobulins**. The antibody in individuals with asthma is usually immunoglobulin E (IgE), which is one of the five types of antibodies in the body (the others are IgG, IgA, IgM, and IgD). On exposure to the allergen, the patient's body responds by mounting an immediate and potent antigen–antibody reaction (immune response). This reaction occurs on the surfaces of cells that are rich in histamines, leukotrienes, and other substances involved in the immune response, such as mast cells. These substances are collectively known as *inflammatory mediators*, and they are released from mast cells as part of the immune response. This, in turn, as described in [Chapter 37](#), triggers the mucosal swelling and bronchoconstriction that are characteristic of an allergic asthma attack.

The *late-phase response* peaks 5 to 12 hours after the initial response and may last from several hours to several days. It is thought that infiltration by neutrophils and eosinophils attract additional inflammatory mediators, especially leukotrienes, which create a self-sustaining cycle of inflammation and obstruction. The clinical symptoms are the same as during the early phase. However, as a result of the inflammation, airways become sensitized or hyper-responsive, such that subsequent episodes of asthma may be triggered not only by allergens but also by nonspecific stimuli such as strong odours, cold air, dust, and air pollution.

In 2012, the Canadian Thoracic Society produced and updated guidelines for the diagnosis and management of asthma. Based on these guidelines, which are currently under review ([Canadian Thoracic Society, 2020](#)), drugs are classified as either for long-term symptom control or for rapid symptom relief. The specific drugs in each classification are listed in [Box 38.1](#). Crucial to the management of asthma is patients' self-management, which should include a written individualized action plan. New to the guidelines is consideration of sputum cell counts of eosinophils, to determine the degree of inflammation and guide management for moderate-to-severe

asthma (Lougheed, Lemiere, Ducharme, et al., 2012). Asthma treatment for adults and children aged 6 years and older is based on the asthma management continuum (Figure 38.1). The recommended drug classifications for treatment are listed

BOX 38.1 Classifications of Drugs Used to Treat Asthma

Controllers

Leukotriene receptor antagonists
Mast cell stabilizers
Inhaled and oral glucocorticosteroids
Anticholinergic drugs
Inhaled long-acting β_2 -agonists (LABAs)
Combination inhaled glucocorticoid and inhaled LABA
theophylline
LABAs in combination with inhaled corticosteroids

Relievers

Inhaled short-acting β_2 -agonists
Inhaled ipratropium (rarely used)
Inhaled corticosteroid and LABA, specifically budesonide and formoterol combination (to be used as relief for patients 12 years of age and older if using the combination as maintenance)

in Table 38.1. Guidelines on the management and treatment of preschoolers were released in 2015 and are discussed in the Special Populations Box on p. 630.

Please note the Canadian Thoracic Society (2020) is in the process of changing Asthma guidelines/recommendations to include combined LABA/ICS combination inhaler (i.e. Symbicort) as first step therapy:

1) formoterol/ICS as needed

or

2) short acting beta-2 agonist WITH a low-dose ICS as needed.

Chronic Obstructive Pulmonary Disease

COPD is a relatively common, treatable, and even preventable respiratory disorder characterized by airflow limitation with a range of pathological changes in the lung, systemic manifestations, and significant comorbidities (Global Initiative for Chronic Obstructive Lung Disease [GOLD], 2019). As was the case in the 2015 version, GOLD's 2019 report on its global strategy does not include the terms *emphysema* (damage to the lung parenchyma) or *chronic bronchitis* in the definition of COPD, as they do not adequately explain the numerous structural abnormalities involved in COPD. *Chronic bronchitis*, or the presence

Fig. 38.1 The asthma management continuum. HFA, hydrofluoroalkane; ICS, inhaled corticosteroids; IgE, immunoglobulin E; LABA, long-acting β_2 -agonist; LTRA, leukotriene receptor antagonist; PEF, peak expiratory flow. (From Lougheed, M. D., Lemiere, C., Ducharme, F. M., et al. (2012). Canadian Thoracic Society 2012 guideline update: Diagnosis and management of asthma in preschoolers, children and adults. *Canadian Respiratory Journal*, 19(2), 162.)

TABLE 38.1 Asthma Management Continuum

Step	Drug Classification
Confirm diagnosis, followed by environmental control, self-management education plus a written action plan.	
Step 1: Mild intermittent	Short-acting inhaled β_2 -agonist as needed and early introduction of low-dosage inhaled glucocorticosteroid (in adults and children 6 years and older)
Step 2: Moderate persistent	Short-acting inhaled β_2 -agonist as needed and medium-dosage inhaled corticosteroid Inhaled corticosteroid and long-acting β_2 -agonist combination inhaler (in adults and children 12 years and older) Leukotriene receptor antagonist
Step 3–4 Severe uncontrolled	In addition to above therapies: Oral prednisone (FEV_1 less than 60%) Anti-IgE antagonist (omalizumab) in adults and children 12 years and over with atopic asthma

FEV_1 , forced expiratory volume in 1 second.

of cough and sputum for at least 3 months in each of 2 consecutive years, remains a useful term; however, chronic bronchitis is a separate disease.

When pulmonary tissues are exposed to inhaled smoke and other noxious particles, the physiological response in patients with COPD is an amplified chronic inflammation. The pathological changes that occur as a result of the inflammation are distributed throughout the pulmonary tissue, including the proximal airways, peripheral airways, lung parenchyma (respiratory bronchioles and alveoli), and pulmonary vasculature. The inflammatory cells in COPD are neutrophils, macrophages, and CD+8 lymphocytes. The inflammatory cells secrete numerous mediators, including tumour necrosis factor (TNF), interleukin 8 (IL-8), and leukotriene B₄ (LT-B₄). These mediators are believed to contribute to damage to lung structures. In addition, oxidative stress, produced by cigarette smoke and other inhaled particles, occurs when free radicals and other reactive species overwhelm the availability of antioxidants in the lungs. Free radicals further trigger damaging enzymes to be released from inflammatory cells and epithelial cells. Elevated levels of proteolytic (protein-degrading) enzymes then damage mucosal tissues of the airway.

The larger proximal airways (i.e., trachea, bronchi, bronchioles larger than 2 mm in diameter) respond by increasing mucus-secreting glands, increasing the number of goblet cells, and decreasing mucociliary function. These changes lead to hypersecretion of mucus, chronic cough, and increased susceptibility to bacterial infection. The peripheral airways (bronchioles smaller than 2 mm in diameter) also go through repeating cycles of injury and repair to the airway walls. This results in remodelling and eventually permanent scarring, thickening, and consolidation. Lung parenchyma (respiratory bronchioles and alveoli) is also affected, with resulting alveolar wall destruction and dilation and destruction

TABLE 38.2 Mechanisms of Antiasthmatic Drug Action

Antiasthmatic	Mechanism in Asthma Relief
Anticholinergics	Block cholinergic receptors, thus preventing the binding of cholinergic substances that cause constriction and increase secretions
Leukotriene receptor antagonists	Modify or inhibit the activity of leukotrienes, which decreases arachidonic acid-induced inflammation and allergen-induced bronchoconstriction
β -Agonists and xanthine derivatives	Raise intracellular levels of cyclic adenosine monophosphate, which in turn produces smooth muscle relaxation and dilates the constricted bronchi and bronchioles
Corticosteroids	Prevent the inflammation commonly provoked by the substances released from mast cells
Mast cell stabilizers (sodium cromoglycate and nedocromil)	Stabilize the cell membranes of the mast cells in which the antigen–antibody reactions take place, thereby preventing the release of substances such as histamine

of the respiratory bronchioles, resulting in hyperinflation and decreased gas exchange. Damage to the pulmonary vasculature leads to pulmonary hypertension, cor pulmonale, and the hypoxia and hypercapnia seen in patients with severe COPD. Assessment of COPD is based on the patient's level of symptoms, future risk of exacerbations, the severity of the spirometric abnormality, and the identification of comorbidities.

TREATMENT OF DISEASES OF THE LOWER RESPIRATORY TRACT

In the past, the treatment of asthma and other COPDs was focused primarily on the use of drugs that cause the airways to dilate. Now, there is a greater understanding of the pathophysiology of these diseases. The emphasis of research has shifted from the bronchoconstriction component of the disease to the role played by inflammatory cells and their mediators. Recent focus on inflammatory cells is also reflected in the various medication classes used to treat COPD, although bronchodilators still play an important role. A synopsis of the mechanisms of action of the classes of antiasthmatic drugs is provided in [Table 38.2](#). [Figure 38.2](#) provides an overview of the various drugs used to treat asthma.

BRONCHODILATORS

Bronchodilators are an important part of pharmacotherapy for all respiratory diseases. Bronchodilators relax bronchial smooth muscle, which causes dilation of the bronchi and bronchioles that are narrowed as a result of the disease process. There are three classes of such drugs: β -adrenergic agonists, anticholinergics, and xanthine derivatives.

β -Adrenergic Agonists

The β -adrenergic agonists are a group of drugs that are commonly used during the acute phase of an asthmatic attack to

Fig. 38.2 Overview of the effects of various antiasthmatic medications. (From McKenry, L. M., Tessier, E., & Hogan, M. (2006). *Mosby's Pharmacology in Nursing* (22nd ed.). St. Louis, MO: Mosby.)

reduce airway constriction and restore airflow to normal. They are agonists, or stimulators, of the adrenergic receptors in the sympathetic nervous system. The β - and α -adrenergic receptors are discussed in Chapters 19 and 20. The β -agonists imitate the effects of norepinephrine on β -receptors. For this reason, they are also called *sympathomimetic* bronchodilators. The β -agonists are categorized by their onset of action. Short-acting β -agonist (SABA) inhalers include salbutamol (e.g., Airomir®, Ventolin®) and terbutaline sulphate (Bricanyl®). Long-acting β -agonist (LABA) inhalers include formoterol (Foradil®, Oxeze®), indacaterol maleate (Onbrez® Breezhaler®), and salmeterol xinafoate (Serevent®). The LABAs are always prescribed with inhaled glucocorticosteroids. Traditionally, because the LABAs have a longer onset of action, they were not to be used for acute treatment; however, Health Canada has approved a combination glucocorticoid steroid and LABA, budesonide and formoterol fumarate dihydrate (Symbicort®), for use as a reliever or rescue treatment for patients with moderate-to-severe asthma when asthma symptoms worsen.

Mechanism of Action and Drug Effects

The β -agonists dilate airways by stimulating the β_2 -adrenergic receptors located throughout the lungs. There are three subtypes of β -agonists, based on their selectivity for β_2 -receptors:

1. Nonselective adrenergic drugs, which stimulate the β_1 -, β_1 -(cardiac), and β_2 -(respiratory) receptors. Example: epinephrine. Epinephrine is available as a prefilled syringe (Allerject®, EpiPen®) for self-administration by patients with severe allergic reactions (Figure 38.3).
2. Nonselective β -adrenergic drugs, which stimulate both β_1 and β_2 receptors. Example: isoproterenol hydrochloride.
3. Selective β_2 drugs, which primarily stimulate the β_2 receptors. Example: salbutamol.

Fig. 38.3 The EpiPen Auto-Injector (epinephrine) is used for immediate treatment of anaphylaxis (allergic emergencies). The adult version is available in dosages of 0.3 mg for adults and for children weighing more than 30 kg. The EpiPen Junior is available in dosages of 0.15 mg for children weighing 15 to 30 kg. The EpiPen is given into the outer thigh, through the clothing. Anaphylactic emergencies also require emergency medical services in addition to the EpiPen. Additional information is available at <http://www.epipen.ca>. (© Mylan Specialty, L.P. Used with permission.)

These drugs can also be categorized according to their routes of administration as oral, injectable, or inhalational drugs. The various β -agonist bronchodilators are listed in Table 38.3.

TABLE 38.3 β -Agonist Bronchodilators

Drug	Type	Brand Names	Route of Administration
ephedrine	α - β		PO, IM, IV, Subcut
epinephrine	α - β	Adrenalin®	Subcut, IM, inhalation
formoterol	β_2	Foradil, Oxeze	Inhalation
isoproterenol	β_1 - β_2		IV, inhalation
salbutamol	β_2	Airomir, Ventolin	PO, inhalation
salmeterol	β_2	Serevent	Inhalation
terbutaline	β_2	Bricanyl	Inhalation

IM, intramuscular; IV, intravenous; PO, oral; Subcut, subcutaneous.

The bronchioles are surrounded by smooth muscle. When the smooth muscle contracts, the airways are narrowed and the amount of oxygen and carbon dioxide exchanged is reduced. The action of β -agonist bronchodilators begins at the specific receptor stimulated and ends with the dilation of the airways. However, many reactions must take place at the cellular level for bronchodilation to occur. When a β_2 -adrenergic receptor is stimulated by a β -agonist, adenylate cyclase is activated and produces cyclic adenosine monophosphate (cAMP). Increased levels of cAMP cause bronchial smooth muscles to relax, which results in bronchial dilation and increased airflow into and out of the lungs. Nonselective adrenergic agonist drugs such as epinephrine also stimulate α -adrenergic receptors, causing constriction within the blood vessels. This vasoconstriction reduces the amount of edema or swelling in mucous membranes and limits the quantity of secretions normally produced by these membranes. In addition, these drugs also stimulate β_1 receptors, which results in cardiovascular adverse effects such as an increase in heart rate, force of contraction, and blood pressure, as well as central nervous system (CNS) effects such as nervousness and tremor. Drugs such as salbutamol that predominantly stimulate the β_2 -receptors have more specific drug effects and cause fewer adverse effects. By stimulating specifically the β_2 -adrenergic receptors of the bronchial and vascular smooth muscles, they cause bronchodilation and may also have a dilating effect on the peripheral vasculature, which results in a decrease in diastolic blood pressure. In addition, the β_2 -agonists are thought to stimulate the sodium-potassium adenosine triphosphatase ion pump in cell membranes. This action facilitates a temporary shift of potassium ions from the bloodstream into the cells, resulting in a temporary decrease in serum potassium levels. For this reason, β_2 -agonists are also useful in treating patients with acute hyperkalemia. Finally, stimulation of β_2 -receptors in uterine smooth muscle can cause beneficial uterine relaxation (see Indications).

Indications

The primary therapeutic effect of the β -agonists is the prevention or relief of bronchospasm resulting from bronchial asthma and COPD. However, they are also used for effects outside the respiratory system. Because some of these drugs have the ability to stimulate both β_1 - and α -adrenergic receptors, they may be used to treat hypotension and shock (see Chapter 19).

Contraindications

Contraindications include drug allergy, uncontrolled cardiac dysrhythmias, and high risk of stroke (because of vasoconstrictive drug actions).

Adverse Effects

Mixed α - and β -agonists produce the most adverse effects because they are nonselective. These effects include insomnia, restlessness, anorexia, heart stimulation, hyperglycemia, tremor, and vascular headache. The adverse effects of the nonselective β -agonists are limited to β -adrenergic effects, including heart stimulation (tachycardia), tremor, anginal pain, and vascular headache. The β_2 drugs can cause both hypertension and hypotension, vascular headaches, and tremor. Overdose management may include careful administration of a β -blocker while the patient is under close observation due to the risk of bronchospasm. Because the half-life of most adrenergic agonists is relatively short, the patient may just be observed while the body eliminates the medication.

Interactions

When nonselective β -blockers are used with the β -agonist bronchodilators, the bronchodilation from the β -agonist is diminished. The use of β -agonists with monoamine oxidase inhibitors (MAOIs) and other sympathomimetics is best avoided because of the associated enhanced potential for hypertension. Patients with diabetes may require an adjustment in the dosage of their antihyperglycemic drugs, particularly patients receiving epinephrine, because of the increased blood glucose levels that can occur.

Dosages

For recommended dosages of selected β -agonists, refer to the table on p. 623.

DRUG PROFILES

salbutamol sulphate

Salbutamol sulphate (Airomir, Ventolin) is a short-acting bronchodilating β -agonist. Other similar drugs include formoterol fumarate (Foradil, Oxeze), salmeterol xinaforte (Serevent), and terbutaline sulphate (Bricanyl). Salbutamol is the most commonly used drug in this class. If it is used too frequently, dose-related adverse effects may be seen because salbutamol loses its β_2 -specific actions, especially at larger doses. As a consequence, the β_1 -receptors are stimulated, which causes nausea, increased anxiety, palpitations, tremors, and an increased heart rate. Salbutamol is available for oral, parenteral, and inhalational use. Inhalation dosage forms include metered-dose inhalers (MDIs) as well as solutions for inhalation (aerosol nebulizers). It is also available combined with ipratropium (Combivent®) for inhalations.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Inhalation	Immediate	10–25 min	3–4 hr	2–6 hr

Dosages

Bronchodilators

Drug	Pharmacological Class	Usual Dosage Range	Indications
ipratropium bromide (Atrovent®, Ipratent®)	Anticholinergic	<i>Adults and children over 12 yr</i> MDI: 2 puffs tid–qid Nasal spray, 0.03%: 2 sprays bid–tid Nasal spray, 0.06%: 2 sprays bid–tid–qid <i>Children 5–12 yr</i> Nebulized solution: 125–250 mcg tid–qid <i>Adults</i> Nebulized solution: 250–500 mcg tid–qid	Asthma, bronchospasm
 salbutamol sulphate (Airomir, Ventolin)	Short-acting β_2 -agonist	<i>Children 5–12 yr</i> Nebulized solution: 1.25–2.5 mg qid <i>Adults</i> Nebulized: 2.5mg/2.5mL and 5mg/2.5mL qid <i>Children 4 yr and over</i> MDI: 1 puff q3–4/day, 100mcg/puff <i>Adults</i> MDI: 1–2 puffs qid <i>Adults</i> IV: 5 mcg/min–20 mcg/min diluted, continuous infusion	
 salmeterol xinafoate* (Serevent)	Long-acting β_2 -agonist (LABA)	<i>Adults</i> 1 puff bid, 50mcg/puff	Asthma, COPD

COPD, Chronic obstructive pulmonary disease; IV, intravenous; MDI, metered-dose inhaler; PO, oral.

*Long-acting β -agonists are no longer to be used alone; they are combined with an inhaled glucocorticoid steroid (e.g., Advair® inhaler [fluticasone propionate and salmeterol]).

Anticholinergics

The anticholinergic (also called *muscarinic antagonists*) drugs used in the treatment of COPD are ipratropium (Atrovent®) and tiotropium bromide monohydrate (Spiriva®), glycopyrronium bromide (Seebri Breezhaler®), aclidinium bromide (Tudorza Genuair®), and umeclidinium bromide (Incruse Ellipta®). Three combinations of anticholinergics and LABAs are currently available: aclidinium bromide and formoterol fumarate dihydrate (Duaklir Genuair®), tiotropium bromide and olodaterol hydrochloride (Inspiroto Respimat®), and umeclidinium bromide and vilanterol trifenate (Anoro Ellipta®).

Mechanism of Action and Drug Effects

On the surface of the bronchial tree are receptors for acetylcholine (ACh), the neurotransmitter for the parasympathetic nervous system. When the parasympathetic nervous system releases ACh from its nerve endings, the neurotransmitter binds to the ACh receptors on the surface of the bronchial tree, which results in bronchial constriction and narrowing of the airways. Anticholinergic drugs block these ACh receptors to prevent bronchoconstriction. This action indirectly causes airway dilation. Anticholinergic drugs also help to reduce secretions in patients with COPD.

Indications

Because their actions are slow and prolonged, anticholinergics are used for prevention of bronchospasm associated with COPD

and not for the management of acute symptoms. Tiotropium by inhaler is recommended as an add-on asthma control therapy that will improve outcomes for patients 18 years and older with asthma who remain symptomatic despite the use of inhaled corticosteroids and LABA maintenance therapy (GINA, 2018). This indication has not been approved in Canada.

Contraindications

The only usual contraindication to the use of bronchial anticholinergic drugs is drug allergy, including allergy to atropine sulphate. Caution is necessary in patients with acute-angle closure glaucoma or prostate enlargement.

Adverse Effects

The most commonly reported adverse effects of ipratropium and tiotropium bromide monohydrate therapy result from the drugs' anticholinergic effects and include dry mouth or throat, nasal congestion, heart palpitations, gastrointestinal (GI) distress, urinary retention, increased intraocular pressure, headache, coughing, and anxiety. Ipratropium can be used during pregnancy; benefits of the use of tiotropium bromide monohydrate during pregnancy outweigh the potential risks.

Drug Interactions

Possible additive toxicity may occur when anticholinergic bronchodilators are taken with other anticholinergic drugs.

Dosages

For dosage information on anticholinergic drugs, refer to the table on p. 623.

DRUG PROFILES

ipratropium bromide

Ipratropium bromide (Atrovent) is the oldest and most commonly used anticholinergic bronchodilator. Atrovent prevents bronchospasm for patients with COPD. It is pharmacologically similar to atropine sulphate (see [Chapter 22](#)). It is available as a liquid aerosol for inhalation and as a multidose inhaler; both forms are usually dosed twice daily. Tiotropium bromide monohydrate (Spiriva) is a similar drug but is formulated for once-daily dosing (see Preventing Medication Errors Box). Many patients also benefit from taking both a β_2 -agonist and an anticholinergic drug, with the most popular combination being salbutamol and ipratropium. Although many patients receive the two drugs separately, two combination products are available containing both of these drugs: Combivent (an MDI form) and Teva-Combo Sterinebs® (an inhalation solution).

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Inhalation	5–15 min	1–2 hr	1.6 hr	4–5 hr

PREVENTING MEDICATION ERRORS

Oral Ingestion of Capsules for Inhalation Devices

Some inhalation products use capsules and a device that pierces the capsules to allow the powdered medication to be inhaled with a special inhaler. Two products, Foradil Aerolizer® (formoterol fumarate inhalation powder) and Spiriva HandiHaler® (tiotropium bromide inhalation powder), contain such capsules. Even though these capsules are packaged with inhaler devices, they closely resemble oral capsules. The Institute for Safe Medication Practices Canada has received reports that the capsules have been taken orally by patients, which can potentially result in adverse effects. If the capsules are swallowed instead of taken using the inhalation device, the medication's onset of action may be delayed and its efficacy reduced, and as a result the patient receives inadequate drug delivery.

Xanthine Derivatives

The natural xanthines consist of the plant alkaloids caffeine, theobromine, and theophylline, but only theophylline and caffeine are currently used clinically. There is one synthetic xanthine, aminophylline. Caffeine, which is actually a metabolite of theophylline, has other uses, described later.

Mechanism of Action and Drug Effects

Xanthines cause bronchodilation by increasing the levels of the energy-producing substance cAMP. They do this by competitively inhibiting phosphodiesterase, the enzyme responsible for breaking down cAMP. In patients with COPD, cAMP plays an

integral role in the maintenance of open airways. Higher intracellular levels of cAMP contribute to smooth muscle relaxation and inhibit IgE-induced release of the chemical mediators that drive allergic reactions (histamine, slow-reacting substance of anaphylaxis [SRS-A], others). Theophylline is metabolized to caffeine in the body, whereas aminophylline is metabolized to theophylline. Theophylline and other xanthines also stimulate the CNS, but to a lesser degree than caffeine. Stimulation of the CNS has the beneficial effect of acting directly on the medullary respiratory centre to enhance respiratory drive. In large doses, theophylline may stimulate the cardiovascular system, which results in both an increased force of contraction (positive inotropy) and an increased heart rate (positive chronotropy). The increased force of contraction raises cardiac output and, consequently, blood flow to the kidneys. This action, in combination with the ability of the xanthines to dilate blood vessels in and around the kidney, increases the glomerular filtration rate, which produces a diuretic effect.

Indications

Xanthines are used to dilate the airways in patients with asthma and COPD. They may be used in mild-to-moderate cases of acute asthma and as an adjunct drug in the management of COPD. Xanthines are now de-emphasized as treatment for milder asthma because of their potential for drug interactions and interpatient variability in therapeutic drug levels in the blood. Because of their relatively slow onset of action, xanthines are used more often for the prevention of asthmatic symptoms than for the relief of acute asthma attacks. However, they are also used as adjunct bronchodilators for patients with COPD. Caffeine is used without a prescription as a CNS stimulant, or analeptic (see [Chapter 14](#)), to promote alertness (e.g., for long-duration driving or studying). It is also used as a heart stimulant in infants with bradycardia and for enhancement of respiratory drive in infants in neonatal Critical Care Units. It is not normally used clinically in adults for these purposes, although theoretically it would have similar effects.

Contraindications

Contraindications to therapy with xanthine derivatives include known drug allergy, uncontrolled cardiac dysrhythmias, seizure disorders, hyperthyroidism, and peptic ulcers.

Adverse Effects

The common adverse effects of the xanthine derivatives include nausea, vomiting, and anorexia. In addition, gastroesophageal reflux has been observed to occur during sleep in patients taking these drugs. Cardiac adverse effects include sinus tachycardia, extrasystole, palpitations, and ventricular dysrhythmias. Transient increased urination and hyperglycemia are other possible adverse effects. Overdose and other toxicity of xanthine derivatives are usually treated by the repeated administration of activated charcoal.

Interactions

The use of xanthine derivatives with any of the following drugs causes an increase in its serum level: allopurinol,

cimetidine, macrolide antibiotics (e.g., erythromycin), quinolones (e.g., ciprofloxacin), influenza vaccine, rifampin, and oral contraceptives. Their use with sympathomimetics, or even caffeine, can produce additive heart and CNS stimulation. Rifampin increases the metabolism of theophylline, which results in decreased theophylline levels. St. John's wort (*Hypericum perforatum*) enhances the rate of xanthine drug metabolism; thus, higher dosages of theophylline and other xanthine derivatives may be needed. Cigarette smoking has a similar effect because of the enzyme-inducing effect of nicotine. Interacting foods include charcoal-broiled, high-protein, and low-carbohydrate foods. These substances may reduce serum levels of xanthines through various metabolic mechanisms.

Dosages

For the recommended dosages of selected theophylline salts, refer to the table below.

DRUG PROFILES

theophylline

Theophylline (Theolair®, Uniphyll®) is a common xanthine derivative, although it has fallen out of favour due to its high adverse effect profile. It is available in oral and injectable (as aminophylline) dosage forms. Besides theophylline, which occurs in various salt forms, the other xanthine bronchodilator used clinically for the treatment of bronchoconstriction is aminophylline. Aminophylline is a prodrug of theophylline; it is metabolized to theophylline in the body. Aminophylline is sometimes given intravenously to patients with status asthmaticus who have not responded to fast-acting β -agonists such as epinephrine.

Theophylline has a narrow therapeutic index and the margin of safety above therapeutic doses is small. The beneficial effects of theophylline can be maximized by maintaining levels within a certain target range. If these levels become too high, unwanted adverse effects can occur. If levels become too low, the patient receives little therapeutic benefit. Although the optimal level may vary from patient to patient, most standard references have suggested that the therapeutic range for theophylline blood level is usually 55 to 110 micromol/L. Levels higher than 110 micromol/L are associated with toxic effects. The Canadian Thoracic Society guidelines (Lougheed et al., 2012) recommend that a serum concentration of 28 to 55 micromol/L will reduce adverse effects without loss of therapeutic benefit. Laboratory monitoring of drug blood levels is common to ensure adequate dosage, especially in the hospital setting.

PHARMACOKINETICS:

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Unknown	1–2 hr	7–9 hr	12 hr

Dosages

Theophylline Salts

Drug	Pharmacological Class	Usual Dosage Range	Indications
 theophylline (Theolair, Theo ER®, Uniphyll)	Xanthine-derived bronchodilator	Adults 400–600 mg/day in 1–4 divided doses	Asthma, COPD

NONBRONCHODILATING RESPIRATORY DRUGS

Bronchodilators (β -adrenergic agonists and xanthines) are just one type of drug used to treat asthma and COPD. There are also other drugs that are effective in suppressing underlying causes of some of these respiratory illnesses. These include leukotriene receptor antagonists (montelukast) and corticosteroids (beclomethasone, budesonide, dexamethasone, flunisolide, fluticasone, ciclesonide, triamcinolone). Another drug class known as *mast cell stabilizers* is now rarely used and is no longer included in Canadian Asthma Management Continuum.

Leukotriene Receptor Antagonists

When they became available in the 1990s, the leukotriene receptor antagonists (LTRAs) were the first new class of asthma medications to be introduced in Canada in more than 20 years. Before the development of LTRAs, most asthma treatments focused on relaxing the contraction of bronchial muscles with bronchodilators. More recently, researchers have begun to understand how asthma symptoms are caused by the immune system at the cellular level. A chain reaction starts when a trigger allergen, such as cat hair or dust, initiates a series of chemical reactions in the body. Several substances are produced, including a family of molecules known as *leukotrienes*. In people with asthma, leukotrienes cause inflammation, bronchoconstriction, and mucus production; this, in turn, leads to coughing, wheezing, and shortness of breath.

Mechanism of Action and Drug Effects

LTRA montelukast (Singulair®) acts directly by binding to the D4 leukotriene-receptor subtype (LTD4) in respiratory tract tissues and organs. The drug effects of LTRAs are limited primarily to the lungs. As their class name implies, LTRAs prevent leukotrienes from attaching to receptors located on circulating immune cells (e.g., lymphocytes in the blood) as well as local immune cells within the lungs (e.g., alveolar macrophages); this action alleviates asthma symptoms in the lungs by reducing inflammation. They prevent smooth muscle contraction of the bronchial airways, decrease mucus secretion, and reduce vascular permeability (which reduces edema) through their reduction of leukotriene synthesis. Other effects of LTRAs include prevention of the mobilization and migration of cells such as neutrophils and leukocytes into the lungs; this effect also serves to reduce airway inflammation.

Indications

The LTRAs montelukast are used for the prophylaxis and long-term treatment and prevention of asthma in adults and children. Montelukast is considered safe in children 2 years of age and older. Because it is dosed once daily, montelukast is the most widely used of these drugs and has also been approved for treatment of allergic rhinitis, a condition discussed in [Chapter 37](#). These drugs are not intended for the management of acute asthmatic attacks. Improvement in asthma symptoms with their use is typically seen in about 1 week.

Contraindications

Known drug allergy or other previous adverse drug reaction is the primary contraindication to use of LTRAs. Allergy to povidone, lactose, titanium dioxide, or cellulose derivatives is also important to note, because these are inactive ingredients in these drugs.

Adverse Effects

The adverse effects of LTRAs differ depending on the specific drug. The most common adverse effects of montelukast include headache, nausea, and diarrhea. Furthermore, nightmares have been experienced in both children and adults when taking montelukast. LTRA drugs may also lead to liver dysfunction. For this reason, liver enzyme levels must be monitored regularly in patients taking these drugs, especially early in the course of therapy.

Interactions

Phenobarbital and rifampin, both of which are enzyme inducers, decrease montelukast concentrations. For information on the drugs that interact with Montelukast, see [Table 38.4](#).

Dosages

For recommended dosages of montelukast, refer to the table in the right column.

DRUG PROFILES

Leukotriene receptor antagonists (LTRAs) are used primarily for oral prophylaxis and long-term treatment of asthma. The two drugs currently available are zafirlukast and montelukast. These drugs are not recommended for treatment of acute asthma attacks.

montelukast sodium

Montelukast sodium (Singulair) belongs to the same subcategory of LTRAs as zafirlukast. Montelukast and zafirlukast act by blocking leukotriene D₄ receptors to augment the inflammatory response. Montelukast offers the advantage of being Health Canada approved for use in children 2 years of age and older (a chewable tablet is available for children). It also has fewer adverse effects and drug interactions than zafirlukast. Use of montelukast is contraindicated in patients with a known hypersensitivity to it. It is available only for oral use. Montelukast is reasonably safe to take during pregnancy.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	30 min	3–4 hr	2.7–5 hr	24 hr

Corticosteroids

Corticosteroids, also known as *glucocorticoids*, are either naturally occurring or synthetic drugs used in the treatment of pulmonary diseases because of their anti-inflammatory effects. All have actions similar to those of the natural steroid hormone cortisol, which is chemically the same as the drug hydrocortisone. Synthetic steroids are more commonly used in drug therapy than naturally occurring ones. They can be administered by inhalation, orally, and intravenously (in severe cases of asthma when the drug cannot transfer to the airways because of airway obstruction). Corticosteroids administered by inhalation have an advantage over orally administered corticosteroids in that their action is limited to the topical site in the lungs. This generally limits, although does not completely prevent, systemic effects. The chemical structures of the corticosteroids given by inhalation have also been slightly altered to limit their systemic absorption from the respiratory tract. The corticosteroids administered by inhalation include the following:

- beclomethasone dipropionate (Qvar®)
- budesonide (Pulmicort Nebuamp®, Pulmicort Turbuhaler®, Rhinocort Aqua®, Rhinocort Turbuhaler®)
- ciclesonide (Alvesco®, Omnaris®)

Dosages

Selected Leukotriene Receptor Antagonist

Drug	Pharmacological Class	Usual Dosage Range	Indications
montelukast sodium (Singulair)	Leukotriene-receptor antagonist	<i>Children 2–5 yr</i> PO (chewable tablet): 4 mg daily in evening <i>Children 6–14 yr</i> PO (chewable tablet): 5 mg daily in evening <i>Adults and adolescents over 15 yr</i> PO: 10 mg daily in evening	Prophylaxis and maintenance treatment of asthma Asthma and seasonal allergic rhinitis

PO, oral.

TABLE 38.4 Drug Interactions: Leukotriene Receptor Antagonists

Drug	Interacting Drugs	Mechanism	Result
montelukast sodium (Singulair)	phenobarbital, rifampin	Increased metabolism	Decreased montelukast levels

- fluticasone furoate (Avamys®)
- fluticasone propionate (Flovent Diskus®, Flovent HFA®)
- mometasone (Asmanex Twisthaler®)

The systemic use of corticosteroids was described in [Chapter 34](#). The systemic corticosteroids most commonly used include the following:

- prednisone (oral)
- methylprednisolone (intravenous [IV] or oral)

Mechanism of Action and Drug Effects

Although the exact mechanism of action of the corticosteroids has not been determined, it is conjectured that they have the dual effect of both reducing inflammation and enhancing the activity of β -agonists. The corticosteroids produce their anti-inflammatory effects through a complex sequence of actions. The overall effect is to prevent nonspecific inflammatory processes, including the accumulation of inflammatory mediators as well as altered vascular permeability (which causes edema).

Corticosteroids act by stabilizing the membranes of cells that normally release bronchoconstricting substances. These cells include leukocytes, or white blood cells (WBCs). There are five different kinds of WBCs, each with its own specific characteristics. [Table 38.5](#) summarizes these five types of WBCs, their role in the inflammatory process, and the way in which corticosteroids inhibit their normal actions, combat inflammation, and produce bronchodilation. Inflammatory mediators are released primarily by lymphocytes in the circulation as well as by mast cells and alveolar macrophages. These latter two cell types are stationary inflammatory cells that remain localized in the tissues and organs of the respiratory tract.

Corticosteroids have also been shown to restore or increase the responsiveness of bronchial smooth muscle to β -adrenergic receptor stimulation, which results in more pronounced stimulation of the β_2 -receptors by β -agonist drugs such as salbutamol. It may take several weeks of continuous therapy before the full therapeutic effects of the corticosteroids are felt.

Indications

Inhaled corticosteroids are used for the primary treatment of bronchospastic disorders to control the inflammatory responses that are believed to be the cause of these disorders; they are indicated for persistent asthma. Inhaled corticosteroids are often used concurrently with β -adrenergic agonists. In respiratory illnesses, systemic corticosteroids are generally used only for acute exacerbations, or severe asthma. Their long-term use is associated with adverse effects (see later). The Canadian Thoracic Society's guidelines ([Lougheed et al., 2012](#)), which are currently under review ([Canadian Thoracic Society, 2020](#)), recommend the use of oral prednisone for short periods (usually 3 to 5 days) in children with a recent history of severe exacerbation of asthma and suboptimal response to SABAs during exacerbation, as well as in individuals older than 15 years of age with a history of severe loss of asthma control in the preceding year. When a more pronounced anti-inflammatory effect is needed, however, as in an acute exacerbation of asthma or other COPD, IV corticosteroids (e.g., methylprednisolone) may be used.

Contraindications

Drug allergy is the primary contraindication to corticosteroid use and is usually due to other ingredients in the drug formulation. Corticosteroids are not intended as sole therapy for acute asthma attacks. Inhaled corticosteroids are contraindicated in patients who are hypersensitive to glucocorticoids, in patients whose sputum tests positive for *Candida albicans* organisms, and in patients with systemic fungal infection, as the corticosteroids can suppress the immune system.

Adverse Effects

The main undesirable local effects of typical doses of inhaled corticosteroids include pharyngeal irritation, coughing, dry mouth, and oral fungal infections. Instruct patients to rinse their mouth after the use of an inhaled corticosteroid. Most of the drug effects of inhaled corticosteroids are limited to their topical site of action in the lungs. Because of the chemical

TABLE 38.5 White Blood Cells (Leukocytes)

Specific WBC*	Role in Inflammation	Corticosteroid Effect
Granulocytes		
Neutrophils (65%)	Contain powerful lysosomes (tiny bodies that hold cellular digestive enzymes); release chemicals that destroy invading organisms and also attack other WBCs	Stabilize cell membranes so that inflammation-causing substances are not released
Eosinophils (2–5%)	Function primarily in allergic reactions and in protecting against parasitic infections; ingest inflammatory chemicals and antigen–antibody complexes	Little effect, if any
Basophils (0.5–1%)	Contain histamine, an inflammation-causing substance, and heparin, an anticoagulant	Stabilize cell membranes so that histamine is not released
Agranulocytes		
Lymphocytes (25%)	Two types: T lymphocytes and B lymphocytes; T cells attack infecting microbial or cancerous cells; B cells produce antibodies against specific antigens	Decrease activity of lymphocytes
Monocytes (3–5%)	Produce macrophages, which can migrate out of the bloodstream to such places as mucous membranes, where they are capable of engulfing large bacteria or virus-infected cells	Inhibit macrophage accumulation in already inflamed areas, thus preventing more inflammation

WBC, white blood cell.

*Value in parentheses is the percentage of all leukocytes represented by the given type.

structure of the inhaled dosage forms, there is relatively little systemic absorption of the drugs when they are administered by inhalation at normal therapeutic doses. However, the degree of systemic absorption is more likely to be increased in patients who require higher inhaled doses. When there is significant systemic absorption, which is most likely with high-dose IV or oral administration, corticosteroids can affect any of the organ systems in the body. Some of the possible systemic drug effects include adrenocortical insufficiency, increased susceptibility to infection, fluid and electrolyte disturbances, endocrine effects, CNS effects (e.g., insomnia, nervousness, seizures), and dermatological and connective tissue effects (e.g., brittle skin, bone loss, osteoporosis, Cushing's syndrome; see [Chapter 34](#)).

It is important to remember that when patients are switched to inhaled corticosteroids after receiving systemic corticosteroids, especially at high dosages for an extended period, adrenal suppression (addisonian crisis) may occur if the systemically administered corticosteroid is not tapered slowly. Patient deaths have been reported due to adrenal gland failure in cases when the switch to inhaled corticosteroids was made quickly and the dosage of systemic corticosteroids reduced too abruptly. Prevention of such an occurrence requires careful monitoring with slow tapering of systemic drug dosages. Patients who are dependent on systemic corticosteroids may need up to 1 year of recovery time after discontinuation of systemic therapy. There is evidence that bone growth is suppressed in children and adolescents taking corticosteroids. This suppression is more apparent in children receiving larger systemic (versus inhaled; children on inhaled corticosteroids reach their predicted adult height, but it may take them longer than other children not on inhaled corticosteroid treatment) dosages over long treatment durations. Growth needs to be tracked (e.g., with standardized charts) and medications re-evaluated should growth suppression become evident. In some cases, supplemental growth hormone may be prescribed.

Interactions

Drug interactions are more likely to occur with systemic (versus inhaled) corticosteroids. Corticosteroids may increase serum glucose levels, possibly requiring adjustments in dosages of anti-diabetic drugs. Because of interactions resulting from metabolizing enzymes, they may also raise the blood levels of the immunosuppressants cyclosporine and tacrolimus. Likewise, the antifungal drug itraconazole may reduce clearance of the steroids, whereas phenytoin, phenobarbital, and rifampin may enhance clearance. There is also greater potential for hypokalemia with concurrent use of potassium-depleting diuretics such as hydrochlorothiazide and furosemide.

Dosages

For recommended dosages of selected corticosteroids, refer to the table on p. 629.

DRUG PROFILES

fluticasone propionate

Fluticasone propionate can be administered intranasally (Flonase®; one inhalation in each nostril daily) and by oral inhalation (Flovent Diskus, Flovent HFA; usually one inhalation by

mouth twice daily). The lowest dose of fluticasone required to maintain good asthma control should be used. When a patient's asthma is well controlled, a reduction in the dose of fluticasone should be attempted in order to identify the lowest possible dose required to maintain control; such attempts at dose reduction should be carried out on a regular basis.

Fluticasone is also available in a combination formulation with the bronchodilator salmeterol xinaforte (Advair Diskus®, Advair® Inhalation Aerosol). Advair is one of the most commonly used inhalers and must never be used for acute treatment of asthma.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Inhalation	1–2 weeks	0.5–1hr	24 hr with repeated dosing	Up to 24 hr

methylprednisolone

Methylprednisolone is a systemic corticosteroid available in both oral (Medrol®) and injectable (Solu-Medrol®) forms.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Immediate	30 min	3–4 hr	24–36 hr

Phosphodiesterase-4 Inhibitor

In 2010, Health Canada approved roflumilast (Daxas®), a selective inhibitor of the enzyme phosphodiesterase type 4 (PDE4), the use of which results in decreased inflammation in the lungs. Decreasing inflammation helps to stop the narrowing of airways that occurs in COPD and also prevents excess mucus production from worsening, thus decreasing the frequency of life-threatening COPD exacerbations. It is not intended to treat acute bronchospasm. The most commonly reported adverse effects of roflumilast include nausea, diarrhea, headache, insomnia, dizziness, weight loss, and mental health symptoms such as anxiety and depression.

Monoclonal Antibody Antiasthmatic

Omalizumab (Xolair®) is the newest asthma drug available. It is a monoclonal antibody that selectively binds to the immunoglobulin IgE, which in turn limits the release of mediators of the allergic response. Omalizumab is given by subcutaneous injection and has the potential for producing anaphylaxis. Anaphylaxis can be delayed from 2 hours to 4 days postinjection. Patients receiving omalizumab must be monitored closely for hypersensitivity reactions.

NURSING PROCESS

ASSESSMENT

The net drug effect of β -agonists, xanthine derivatives, anticholinergics, LTRAs, and corticosteroids is improved airflow in airway passages and increased oxygen supply. Thoroughly

Dosages

Selected Corticosteroids

Drug	Pharmacological Class	Usual Dosage Range	Indications
fluticasone propionate (Flonase, Flovent Diskus, Flovent HFA)	Synthetic glucocorticoid	<i>Children 12 mo–4 yr</i> Flovent HFA: 100 mcg daily, bid, using a BABYHALER spacer device with a face mask <i>Children 4–16 yr</i> Flovent HFA, Diskus: 50–200 mcg bid <i>Adults and adolescents over 16 yr</i> Flovent HFA, Diskus: 100–400 mcg daily bid Flovent HFA, 3 strengths available: 50, 125, 250 mcg/actuation Flovent Diskus, inhalation powder, 4 strengths available: 50, 100, 250, 500 mcg/actuation <i>Children 4–11 yr</i> Flonase metered-dose nasal spray: 1–2 sprays (50 mcg/each metered dose) in each nostril bid (max 200 mcg daily)	Asthma (prophylaxis and maintenance treatment)
methylprednisolone (Solu-Medrol injection, Medrol tablets)	Synthetic glucocorticoid	Dose varies as above, but usually 40–120 mg IV over 30 min Oral taper: usually from 24 to 2 mg daily	Status asthmaticus Asthma

IV, Intravenous.

assess for cautions, contraindications, and drug interactions before administering these drugs, and assess the patient's skin colour; temperature; respiration rate, depth, and rhythm; breath sounds; blood pressure; pulse rate; and pulse oximetry readings (to determine oxygen saturation levels). Determine if the patient is having problems with cough, dyspnea, orthopnea, or hypoxia, or has other signs or symptoms of respiratory distress. If a cough is present, assess its character and frequency, the presence or absence of sputum, and the colour of any sputum. Assess the patient for the presence of any of the following: sternal retractions, cyanosis, restlessness, activity intolerance, heart irregularities, palpitations, hypertension, tachycardia, or use of accessory muscles to breathe, indicating significant respiratory compromise. Determine the anterior–posterior diameter of the thorax.

Obtain a complete medication history that includes information about prescription (e.g., questions about possible drug causes of respiratory distress in conjunction with asthma/COPD such as aspirin) and over-the-counter (OTC) drugs, natural health products, and alternative therapies. Also gather information on the use of nebulizers or humidifiers, the use of a home air conditioner, and the type and maintenance of heating and air conditioning systems, as forced-air systems can foster mould and dust mites. Collect information about environmental allergies such as to dust, mould, pollen, or mildew, as well as seasonal allergies and food allergies. Note the characteristics of any respiratory symptoms (e.g., seasonally induced, exercise- or stress-induced) and any family history of respiratory diseases. Identify any environmental exposures, such as to chemicals or irritants, as well as precipitating and alleviating factors for any respiratory symptoms and disease processes. Assess smoking habits, including exposure to second-hand smoke, because smoking exacerbates respiratory symptoms and because nicotine interacts with many respiratory drugs.

Cardiac status may be compromised because of respiratory distress or respiratory illnesses; thus, closely assess the patient's blood pressure, pulse rate, heart sounds, and electrocardiogram, as ordered. Blood gas analysis may be indicated, with attention to the patient's pH, oxygen, carbon dioxide, and serum bicarbonate levels. Assess nail beds for abnormalities (e.g., clubbing, cyanosis) and the area around the lips. Restlessness is often the first sign of hypoxia, so frequent assessment before, during, and after drug treatment is needed. If hypoxia is present, it needs to be reported to the health care provider. If chest radiographs, scans, or magnetic resonance images have been ordered, review the findings. Along with a physical assessment, perform a psychosocial and emotional assessment, because anxiety, stress, and fear may only further compromise the patient's respiratory status and oxygen levels. As well, assess patients' educational level and readiness to learn. Be sure to note the age of the patient because of increased sensitivity to drugs in older adults and children.

With the use of the β -agonists (e.g., salbutamol, salmeterol), cautions, contraindications, and drug interactions associated with these drugs must be noted. A respiratory assessment is needed to assess for allergies to the fluorocarbon propellant in inhaled dosage forms. Assess for contraindications in patients with dysrhythmias and those at risk for stroke. Assess patients' intake of caffeine (e.g., in chocolate, tea, coffee, candy, sodas) and any use of OTC medications containing caffeine (e.g., appetite suppressants, pain relievers). The intake of caffeine is important to determine because of its sympathomimetic effects and possible potentiation of adverse effects along with salbutamol and other β -agonists (e.g., restlessness, tachycardia, tremor, hyperglycemia, vascular headache, hypotension, or hypertension with β_2 drugs). Assess patients' medication history because β -agonists are not to be taken with MAOIs because of the associated enhanced risk for hypertension.

Specifically with the use of anticholinergics, include any history of heart palpitations, GI distress, benign prostatic hyperplasia, urinary retention, or glaucoma because of the adverse effects of these drugs, which can lead to potentiation of these conditions or symptoms. Ipratropium and its aerosol forms have been associated with bronchospasm, so assess patients for any pre-existing problems with the use of MDIs. If a combination product containing both ipratropium and fenoterol hydrobromide or salbutamol is prescribed, perform an assessment appropriate to the use of both of the drugs.

With corticosteroids (also known as *glucocorticoids*), perform a baseline assessment of vital signs, breath sounds, and heart sounds. Assessment for underlying adrenal disorders is crucial because of the adrenal suppression that occurs with the use of these medications. Age is important to consider because corticosteroids may be problematic for pediatric patients if long-term therapy or high dosage amounts are used. The systemic impact of corticosteroids on pediatric patients is suppressed growth (see the Adverse Effects section under Glucocorticoids for further discussion). As with the other drugs in this chapter, awareness of basic information about these drugs, especially their action, is important for safe use and prevention of medication errors. For example, glucocorticoids are used for their anti-inflammatory effects, β -agonists and xanthines for their bronchodilating effects, and anticholinergics for their blockage of cholinergic receptors. Knowing what drugs do and why they are used helps to prevent or decrease medication errors and adverse effects. Significant drug interactions for which to assess, especially with systemic versus inhaled corticosteroids, include antidiabetic drugs, antifungals, phenytoin, phenobarbital, rifampin, and potassium-sparing diuretics. See [Chapter 34](#) for more information on these anti-inflammatory adrenal drugs.

In patients taking xanthine derivatives (e.g., theophylline), identify any contraindications and cautions. Perform a careful cardiovascular assessment, noting heart rate, blood pressure, and any history of cardiac disease; this is important because of the adverse effects of sinus tachycardia and palpitations. GI reflux may also occur with xanthines. Assess bowel patterns and for pre-existing disease such as gastroesophageal reflux or ulcers. Because of possible drug-induced transient urinary frequency, conduct a baseline assessment of urinary patterns. Assessment needs to include the patient's medication history to assess for possible drug interactions such as with allopurinol, cimetidine, erythromycin, ciprofloxacin, oral contraceptives, caffeine, or sympathomimetics. Perform a dietary assessment, including questions about any consumption of a high-carbohydrate, low-protein diet. These dietary practices may lead to decreased theophylline elimination and increased serum theophylline levels, resulting in significant adverse effects in patients. A low-carbohydrate, high-protein diet, and intake of charbroiled meat may increase theophylline elimination and decrease therapeutic serum theophylline levels. Note intake of any caffeine-containing foods, beverages, prescription drugs, OTC drugs, or natural health products because of additional interactions.

SPECIAL POPULATIONS: CHILDREN

Asthma in Children Ages 1 to 5

- The Canadian Thoracic Asthma Clinical Society and the Canadian Paediatric Society jointly developed guidelines for the diagnosis and management of asthma in children 1 to 5 years of age.
- Asthma often begins prior to the age of 6 in children; early diagnosis and management of asthma in this age group is important to reduce both short- and long-term morbidity.
- Preschoolers have the highest rate of emergency room visits and hospitalizations for asthma-like symptoms.
- Wheezing in children under the age of 6 can lead to a reduction in the forced expiratory volume in 1 second (FEV₁) at age 6, which persists into adulthood.
- Guidelines suggested for a diagnosis in this age group are (1) documented wheezing, and (2) improved airflow with therapeutic trial of short-acting β -agonist (SABA) and inhaled corticosteroids.
- Daily long-term inhaled corticosteroids at the lowest dose are recommended first-line management once asthma is diagnosed and control achieved.
- The goal of long-term therapy is to prevent acute exacerbations. The patient should have a written action plan, adhere to the medication regimen, use a spacer with inhaler correctly, and avoid exposure to environmental allergens and irritants that are identified during the evaluation.
- Encourage children to have normal activity levels; they should not limit physical activity to control asthma symptoms.

From Ducharme, F. M., Dell, S. D., Radhakrishnan, D., et al. (2015). Diagnosis and management of asthma in preschoolers: A Canadian Thoracic Society and Canadian Paediatric Society position paper. *Canadian Respiratory Journal*, 22(3), 135–143.

With LTRAs, assess for contraindications, cautions, and drug interactions. Determine liver functioning because of specific concerns about the use of these drugs in patients with altered liver function. As with other medications, older adults are more sensitive to these drugs.

With the PDE4 inhibitors, assess for presenting symptoms as well as any baseline psychiatric issues or disorders. Note that these drugs are not for acute bronchospasms. Omalizumab, a monoclonal antibody antiasthmatic drug, requires additional assessment of known risks associated with certain malignancies; taking a thorough nursing history will help identify any of these risks. Also be sure to assess for signs and symptoms of increased hypersensitivity, as omalizumab is a protein.

◆ NURSING DIAGNOSES

- Inadequate gas exchange as a result of pathophysiological changes caused by respiratory disease
- Fatigue resulting from the disease process and lack of oxygen saturation
- Nonadherence to the medication regimen resulting from undesirable adverse effects of drug therapy

◆ PLANNING

◆ Goals

- Patient will experience improved gas exchange due to improvement in disease process and symptomatology.
- Patient will exhibit improved energy and less fatigue.

- Patient will remain adherent to the medication regimen and to nonpharmacological therapies.

◆ Expected Patient Outcomes

- Patient briefly describes measures to improve gas exchange, such as use of deep breathing, use of medications as described, and avoiding precipitating factors.
 - Patient shows evidence of improved oxygen levels with a blood oxygen saturation level of 95% or higher (depending on pathology).
- Patient is well rested and allows time for frequent rest periods during activities of daily living while minimizing oxygen demands.
- Patient states the importance of taking medication as prescribed, the reasons for not increasing or decreasing the dosage of any drug, and the importance of not stopping drug therapy abruptly, to prevent complications and exacerbations of the disease.
 - Patient takes medication(s) as prescribed to improve oxygenation and prevent exacerbation of symptoms.

◆ IMPLEMENTATION

Nursing interventions that apply to patients with respiratory disease processes (e.g., COPD, asthma, other upper and lower respiratory tract disorders) include patient education and an emphasis on adherence and prevention, in addition to the specific actions resulting from the prescribed drug therapy. Emphasize measures that help to prevent, relieve, or decrease the manifestations of the disease. A resource that provides excellent information as well as photographs and slideshows can be found at <http://www.asthma.ca/>.

Bronchodilators and other respiratory drugs must be given exactly as prescribed and by the prescribed route (e.g., parenterally, orally, by intermittent positive pressure breathing, by inhalation). Demonstrate the proper method for administering the inhaled forms of these drugs to patients (see [Chapter 10](#)), who should then provide return demonstrations. Emphasize the importance of taking only the prescribed dose of β -agonists, anticholinergics, xanthines, LTRAs, or other respiratory drugs because of the possible adverse effects, such as tachycardia, hypertension or hypotension, vascular headaches, heart palpitations, GI distress, urinary retention, gastroesophageal reflux, dysrhythmias, nausea, and dizziness.

MDIs, dry powder inhalers, and nebulizers are popular methods of delivery for respiratory drugs. The use of MDIs often requires coordination to inhale the medication correctly and to obtain approximately 10 to 40% ([Smith & Goldman, 2012](#)) of drug delivery to the lungs. If a second puff of the same drug is ordered, instruct the patient to wait 1 to 2 minutes between puffs. If a second type of inhaled drug is ordered, instruct the patient to wait 2 to 5 minutes between medications or to take as prescribed. Use of a spacer, an external device attached to the MDI for improved drug delivery via enhanced actuation and inhalation coordination, should always be used to increase the amount of drug delivered. For a small child or infant, a mask can be fitted to the spacer. Even small infants can use an MDI

with spacer with effective drug delivery ([DiBlasi, 2015](#)). A dry powder inhaler (Diskus®) is a small, hand-held device that delivers a specific amount of dry micronized powder with each inhaled breath. A nebulizer dosage form delivers an aerosol of small amounts of misted droplets of the drug to the lungs through a small mouthpiece or mask. Although a nebulizer may take longer to deliver the drug to the lungs than any of the types of inhalers, the nebulizer dosage form may be more effective for some patients. When a nebulizer is used, some medications may be combined for administration (e.g., salbutamol and ipratropium). See [Chapter 10](#) for more information. In many agencies, there is a trend to use the MDI method of drug delivery over nebulizers. One Canadian study showed a reduction in hospitalizations and improved cost savings for children with mild-to-moderate asthma who used an MDI over a nebulizer ([Doan, Shefrin, & Johnson, 2011](#)). In addition, the use of nebulizers may increase the risk of pathogen transmission and thus increase the risk of nosocomial infections.

β -Agonists must be taken exactly as prescribed because over-dosage may be life-threatening. Educate patients not to crush or chew oral sustained-release tablets and to take them with food to decrease GI upset. Instructions for inhaled dosage forms are presented in [Chapter 10](#). See [Figure 38.3](#) for instructions on the use of the EpiPen® Auto-Injector. Reassess respiratory status and breath sounds before, during, and after therapy with these drugs to determine therapeutic effectiveness.

Anticholinergic drugs used for respiratory diseases (e.g., ipratropium) are to be taken daily as ordered and with appropriate use of the MDI. See the Patient Teaching Tips for more information on the administration of these drugs. It is important for patients to wait from 1 to 2 minutes (or as prescribed) before inhaling the second dose of the drug to allow for maximal lung penetration. Encourage rinsing of the mouth with water immediately after the use of any inhaled or nebulized drug to help prevent mucosal irritation and dryness. Xanthine derivatives are also to be given exactly as prescribed. If they are to be administered parenterally, determine the correct diluent, compatibility, and rate of administration. Use IV infusion pumps to ensure dosage accuracy and help prevent toxicity. Too rapid an infusion may lead to profound hypotension with possible syncope, tachycardia, seizures, and even cardiac arrest. Oral forms should be taken with food to avoid GI upset. Continue to monitor patients for respiratory status and improvement in baseline condition during drug therapy.

The LTRAs, specifically montelukast and zafirlukast, are given orally. Of most concern are the montelukast chewable tablets, which contain aspartame and approximately 0.842 mg of phenylamine per 5-mg tablet. Some patients may need to avoid using these substances. Emphasize that these drugs are indicated for treatment of chronic asthma, not acute asthma attacks. Stress that these drugs are to be taken as ordered and on a continuous schedule, even if symptoms improve. Encourage an increase in fluid intake, as with all the respiratory drugs, to help in decreasing the viscosity of secretions.

Inhaled corticosteroids (glucocorticoids) are yet another group of drugs that must be used as prescribed, and patients should be given cautions regarding overuse. Advise patients to

take the medication as ordered every day, regardless of whether or not they are feeling better. Often these drugs (e.g., flunisolide) are used as maintenance drugs and are taken twice daily for maximal response. An inhaled β_2 -agonist may be used before the inhaled glucocorticoid to provide bronchodilation before administration of the anti-inflammatory drug. The inhaled bronchodilator is generally taken 2 to 5 minutes (or as ordered) before the corticosteroid aerosol. Stress to the patient the importance of keeping all equipment (inhalers or nebulizers) clean, including cleaning and changing filters (for nebulizers), and maintaining devices in good working condition. Use of a spacer with a MDI inhaler is always indicated because patients can lose 60% of their dose without a spacer. Recommend rinsing of the mouth immediately after use of inhaler or nebulizer dosage forms of corticosteroids to help prevent overgrowth of oral fungi and subsequent development of oral candidiasis (thrush). Children may need a health care provider's order to have these medications on hand at school and during athletic events or physical education. Peak flow meter use is also encouraged among patients of all ages to better regulate disease. A *peak flow meter* is a handheld device used to monitor a patient's ability to breathe out air; readings reflect the airflow through the bronchi and thus the degree of obstruction in the airways. Encourage patients to keep a record of peak flow levels, signs and symptoms of the disease, any improvement, and the occurrence of any adverse effects associated with therapy. In children, use of systemic forms of corticosteroids is of particular concern, because such use may lead to suppression of the hypothalamic–pituitary–adrenal axis and subsequent growth stunting. However, the benefits are considerable when compared with the risks. Inhaled forms are often combined with short-term systemic therapy in children. Continue to monitor every patient's condition during therapy, with a focus on the respiratory, cardiac, and central nervous systems.

With the use of PDE4 inhibitor drugs, educate patients about the importance of reporting any change in psychiatric status to their health care provider immediately. The monoclonal antibody antiasthmatic drug omalizumab is to be taken exactly as ordered. Since it is given as a subcutaneous injection, instruct the patient in self-injection, or alert the patient that frequent visits to a health care provider are necessary to receive the injection. This drug is usually given every 2 to 4 weeks. Omalizumab is not indicated for acute asthma attacks, and it may be used in conjunction with other acute-acting asthma medications. Closely monitor patients for any allergic or hypersensitivity reactions.

◆ EVALUATION

The therapeutic effects of any of the drugs used to treat, prevent, or improve the control of acute or chronic respiratory

symptoms and diseases include the following: decreased dyspnea, wheezing, restlessness, and anxiety; improved respiratory patterns with return to normal rate and quality; improved oxygen saturation levels; improved activity and arterial blood gas levels; improved quality of life; and decreased severity and incidence of respiratory symptoms. The therapeutic effects of bronchodilators (e.g., xanthines, β -agonists) include decreased symptoms and increased ease of breathing. Blood levels of theophylline should be between 55 and 110 micromol/L and need to be frequently monitored. Peak flow meters are easy to use and help reveal early decreases in peak flow caused by bronchospasm. They also aid in monitoring treatment effectiveness. Other respiratory drugs produce medication-specific therapeutic effects. Adverse effects for which to monitor during drug therapy include the following: β -agonists—headache, insomnia, tachycardia, and tremor; anticholinergics—headache, GI distress, urinary retention, and increased intraocular pressure; xanthines—nausea, vomiting, and palpitations; LTRAs—dyspepsia, headaches, and insomnia; and corticosteroids—adrenocortical insufficiency, increased susceptibility to infection, fluid and electrolyte disturbances, and insomnia. With corticosteroids, adrenal suppression may occur when high doses are received for an extended period of time. See the previous discussion for a complete listing of adverse effects.

CASE STUDY

Chronic Obstructive Pulmonary Disease

Hazel is a 73-year-old woman who has had chronic obstructive pulmonary disease (COPD) for approximately 10 years; it was caused by exposure to workplace environmental pollutants and by cigarette smoking. She is now retired and is frequently admitted to the hospital for treatment of her condition. She quit smoking 8 years ago. She is now in the hospital for treatment of an acute exacerbation of her COPD

and a URT infection. The health care provider has ordered the following: ipratropium 2 puffs q3h and salbutamol 2 puffs q3h by MDI; chest physiotherapy bid and prn; levofloxacin 500 mg IV daily; measurement of intake and output; daily weight measurement; assessment of vital signs, with breath sounds q2h and prn until stable; and salbutamol inhaler, 2 puffs q4h per respiratory therapy protocol.

1. What nursing interventions would be most appropriate for helping Hazel conserve energy while enhancing O_2 and CO_2 gas exchange?
2. What is the rationale for the use of salbutamol and ipratropium?
3. What is the rationale for the antibiotic? Be specific.
4. Would Hazel benefit from the use of systemic corticosteroids in the management of this exacerbation?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

PATIENT TEACHING TIPS

- Emphasize to patients that the sequence for the use of multiple inhaled medications is first, the LABA (alone or combined), followed by the long-acting anticholinergic, and last, the corticosteroid. In general, the β -agonist, whether short- or long-acting, opens the airways and allows the corticosteroid and anticholinergic drugs to travel deeper into the lungs for improved therapeutic effect.
- Numerous devices exist for the delivery of respiratory drugs. New devices are constantly being made available. As each device is unique, educate patients on how to operate and maintain them and administer their medication. Provide resources that explain the use of inhalers.
- β -Agonists
 - Educate patients about any potential drug interactions.
 - Encourage patients with asthma or COPD to avoid precipitating events such as exposure to conditions or situations that may lead to bronchoconstriction and worsening of the disorder (e.g., allergens, stress, smoking, air pollutants).
 - Provide instructions about the proper use and care of MDIs, dry powder inhalers, and other such devices. See [Chapter 10](#) for more specific information.
 - Emphasize the importance of not overusing the medication due to the risk of rebound bronchospasm.
- Xanthines
 - Educate patients about the interaction between smoking and xanthines (i.e., smoking decreases the blood concentrations of aminophylline and theophylline). Xanthines also interact with charcoal-broiled foods, and consumption of these may lead to decreased serum levels of xanthine drugs.
 - Educate patients about food and beverage items that contain caffeine (e.g., chocolate, coffee, cola, cocoa, tea), because their consumption can exacerbate CNS stimulation.
 - Encourage patients to take the medication around the clock to maintain steady-state drug levels. Extended-release dosage forms and other oral dosage forms are not to be crushed or chewed. Advise patients that any worsening of adverse effects, such as epigastric pain, nausea, vomiting, tremor, and headache, must be reported immediately.
 - Encourage patients to keep follow-up appointments because of the importance of monitoring therapeutic levels of medications and therapeutic effectiveness.
 - Some patients may need to learn to take their own pulse rate, so demonstrate to them the proper technique.
- Anticholinergics
 - Educate patients that ipratropium is used prophylactically to decrease the frequency and severity of asthma and must be taken as ordered and generally year-round for therapeutic effectiveness.
 - Encourage increased fluid intake unless contraindicated, to decrease the viscosity of secretions and increase the expectoration of sputum.
- When inhaled forms of these drugs (and other respiratory drugs) are used, instruct patients to take the prescribed number of puffs of the inhaler and no more than 2 puffs with one dosing, or as ordered. Educate patients in how to properly use an MDI with or without a spacer, how to use a dry powder inhaler, and how to properly clean and store the equipment (see [Chapter 10](#)). Instruct patients to wait 2 to 5 minutes (or as ordered) before using additional different inhaled medications.
- Leukotriene receptor antagonists
 - Educate the patient about the action and purpose of LTRAs and how they work by preventing leukotriene formation and thus preventing or decreasing inflammation, bronchoconstriction, and mucus production. Emphasize that these drugs are indicated for prevention, not treatment, of acute asthma attacks.
- Corticosteroids (Glucocorticoids)
 - In addition to adhering to the specified dosage and frequency of these drugs, if inhaled forms are used, patients must practise good oral hygiene (i.e., rinsing of the mouth) after the last inhalation. Rinsing the mouth with water is appropriate and necessary to prevent oral fungal infections. Instruct patients in how to keep inhalers clean. Every week, the canister should be removed from the plastic casing and the casing should be washed in warm, soapy water. Once the casing is dry, the canister and mouthpiece may be put back together and the cap applied. Glucocorticoids may predispose patients to oral fungal overgrowth. Provide explicit instructions for mouth care after each use.
 - Instruct patients to keep track of the doses left in each MDI. Many inhalers have built-in counters, but if one does not, the patient can do the following: Divide the number of doses in the canister by the number of puffs used per day to determine the number of days it will last. For example, if the patient takes 2 puffs, 4 times a day, this equals 8 inhalations per day. If there are 200 doses in a canister, dividing 200 by 8 gives the number of days the inhaler will last, 25 days. The MDI may then be marked with the date it will be empty and a refill obtained a few days before that date. Note that using extra doses will alter the refill date. Advise the patient to always check expiration dates.
 - Stress to patients the importance of a written action plan, which is a personalized program developed by the health care provider and patient for managing asthma. Generally, those individuals who use individualized plans have better asthma control. An action plan should outline (1) daily preventive management to maintain control; (2) when and how to adjust reliever and controller therapy to account for loss of control; and (3) clear instructions regarding when to seek urgent medical attention. Adherence to maintenance therapy is a fundamental component of written action plans. In addition, the use of a peak flow meter on a daily basis will assist the patient in recognizing

early changes in expiratory airflow that may be signs of worsening asthma.

- Counsel patients to wear medical alert jewellery at all times and to carry a written or electronic medical record with all diagnoses and a list of medications and allergies. Emergency contact persons and phone numbers should also be listed.
- With the use of intranasal dosage forms, instruct patients on how to clear nasal passages before administration. The patient needs to tilt the head slightly forward, insert the spray tip into one nostril, and point the spray tip toward the inflamed nasal turbinates. Instruct the patient to pump the medication into the nasal passage while sniffing deeply and holding the other nostril closed. This procedure may then be repeated in the other nostril. It is recommended that any unused portion be discarded after 3 months or by the expiration date.
- Educate parents that adherence to inhaled corticosteroids will prevent asthma exacerbations.
- Educate patients that excess levels of systemic corticosteroids may lead to Cushing's syndrome, with symptoms such as moon facies, acne, increased fat pads, and swelling. Although use of inhaled forms helps to minimize this problem, education on the subject remains important to patient safety. As noted previously, the risk of occurrence

of these signs and symptoms is higher when these drugs are given systemically (i.e., orally or parenterally).

- Educate patients about the possibility of Addisonian crisis, which may occur if a systemic corticosteroid is abruptly discontinued. These drugs require weaning prior to discontinuation. Addisonian crisis may be manifested by nausea, shortness of breath, joint pain, weakness, and fatigue. Patients must contact their health care provider immediately if these occur.
- Educate patients about the importance of reporting to a health care provider any weight gain of 1 kg or more in 24 hours or 2.3 kg or more in 1 week.
- Phosphodiesterase-4 inhibitor
 - Emphasize that patients taking roflumilast should report any notable changes in mood or emotions to a health care provider immediately.
- Monoclonal antibody antiasthmatic drugs
 - Omalizumab is used for the treatment of moderate-to-severe asthma and is not for aborting acute asthma attacks. Patients need to provide return demonstrations of subcutaneous injection techniques. Instruct patients to keep medications and needles, syringes, and other equipment out of the reach of children and to use puncture-proof needle waste containers. Each needle is used for only one injection.

KEY POINTS

- The β -agonists stimulate β_1 - and β_2 -receptors.
- Xanthines, such as theophylline, help to relax the smooth muscles of the bronchioles by inhibiting phosphodiesterase. Phosphodiesterase breaks down cAMP, which is needed to relax smooth muscles.
- Corticosteroids (e.g., beclomethasone, dexamethasone, flunisolide, triamcinolone) have many indications and work

by stabilizing the membranes of cells that release harmful bronchoconstricting substances.

- The LTRAs montelukast and zafirlukast are given orally. Their adverse effects include headache, dizziness, insomnia, and dyspepsia.
- Omalizumab, a monoclonal antibody antiasthmatic drug, works by preventing the release of mediators that lead to allergic responses. It is given for preventative purposes.

EXAMINATION REVIEW QUESTIONS

1. A patient who has a history of asthma is experiencing an acute episode of shortness of breath and needs to take a medication for immediate relief. Which medication will the nurse choose for this situation?
 - a. A β -agonist, such as salbutamol
 - b. A leukotriene receptor antagonist, such as montelukast
 - c. A corticosteroid, such as fluticasone
 - d. An anticholinergic, such as ipratropium
2. After a nebulizer treatment with the β -agonist salbutamol, a patient reports feeling a little "shaky," with slight tremors of the hands. The patient's heart rate is 98 beats/min, increased from the pretreatment rate of 88 beats/min. The nurse knows that this reaction is a result of which effect?
 - a. An expected adverse effect of the medication
 - b. An allergic reaction to the medication
 - c. An indication that he has received an overdose of the medication
 - d. An idiosyncratic reaction to the medication
3. A patient has been receiving an aminophylline (xanthine derivative) infusion for 24 hours. The nurse needs to observe for which adverse effect when assessing the patient during the infusion?
 - a. CNS depression
 - b. Sinus tachycardia
 - c. Increased appetite
 - d. Temporary urinary retention
4. During a teaching session for a patient who will be receiving a new prescription for the LTRA montelukast (Singulair), the nurse will tell the patient that the drug has which therapeutic effect?
 - a. Improves the respiratory drive
 - b. Loosens and removes thickened secretions
 - c. Reduces inflammation in the airway
 - d. Stimulates immediate bronchodilation

5. After a patient takes a dose of an inhaled corticosteroid such as fluticasone (Flovent), what is the most important action the patient needs to do next?
 - a. Hold the breath for 60 seconds.
 - b. Rinse out the mouth with water.
 - c. Follow the corticosteroid with a bronchodilator inhaler, if ordered.
 - d. Repeat the dose in 15 minutes if feeling short of breath.
6. The nurse is teaching a patient about the inhaler Advair (salmeterol and fluticasone). Which statements by the patient indicate a correct understanding of this medication? (Select all that apply.)
 - a. "I will rinse my mouth with water after each dose."
 - b. "I need to use this inhaler whenever I feel short of breath but make sure it's not less than 4 hours between doses."
 - c. "This medication is taken twice a day, every 12 hours."
 - d. "I can take this inhaler if I get short of breath while exercising."
 - e. "I will call my doctor if I notice white patches inside my mouth."
7. A patient has been given an MDI of salbutamol and is instructed to take 2 puffs 3 times a day, with doses 6 hours apart. The inhaler contains 200 actuations, but does not have a dose counter. Calculate how many days the inhaler will deliver this ordered dose.
8. The nurse is preparing to administer the elixir form of theophylline to a patient who has a percutaneous endoscopic gastrostomy (PEG) tube. The dose is 240 mg daily, and the medication is available in a concentration of 80 mg/15 mL. How many millilitres of medication will the nurse give per dose?

CRITICAL THINKING ACTIVITIES

1. A patient is taking a xanthine derivative and asks the nurse about drinking coffee with the medication. What is the nurse's best answer?
2. A patient was prescribed an oral LTRA 1 month ago. At today's follow-up appointment, he tells the nurse, "I don't think this pill works. I took it when I was short of breath, but it did not help." What is the priority when the nurse answers this patient's concerns?
3. A 13-year-old is taken to the clinic because he started to have an asthma attack while running outside in the cold air. He carries two MDIs with him: fluticasone and salbutamol. Which inhaler is the priority at this time? Explain your answer.

Acid-Controlling Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Discuss the physiological influence of various pathologies, such as peptic ulcer disease, gastritis, spastic colon, gastroesophageal reflux disease (GERD), and hyperacidic states, on the health of patients and on their gastrointestinal (GI) tracts.
2. Describe the mechanisms of action, indications, cautions, contraindications, drug interactions, adverse effects,
3. Develop a collaborative plan of care that includes all phases of the nursing process for patients receiving acid-controlling drugs.

KEY TERMS

Antacids Basic compounds composed of different combinations of acid-neutralizing ionic salts. (p. 643)

Chief cells Cells in the stomach that secrete the gastric enzyme pepsinogen (a precursor to pepsin). (p. 641)

Gastric glands Secretory glands in the stomach containing the following cell types: parietal, chief, mucous, endocrine, and enterochromaffin. (p. 641)

Gastric hyperacidity The overproduction of stomach acid. (p. 640)

Hydrochloric acid (HCl) An acid secreted by the parietal cells in the lining of the stomach that maintains the environment of the stomach at a pH of 1 to 4. (p. 641)

Mucous cells Cells whose function in the stomach is to secrete mucus that serves as a protective mucous coat against the digestive properties of HCl. Also called *surface epithelial cells*. (p. 641)

Parietal cells Cells in the stomach that produce and secrete HCl. These cells are the primary site of action for many of the drugs used to treat acid-related disorders. (p. 641)

Pepsin An enzyme in the stomach that breaks down proteins. (p. 641)

DRUG PROFILES

antacids, general, p. 644

 cimetidine, p. 646

 famotidine, p. 646

lansoprazole, p. 648

misoprostol, p. 649

 omeprazole (omeprazole magnesium)*, p. 648

pantoprazole, p. 648

ranitidine hydrochloride, p. 646

simethicone, p. 649

 sucralfate, p. 648

 Key drug

* Full generic name is given in parentheses. For the purposes of this text, the more common, shortened name is used.

OVERVIEW

One of the conditions of the stomach requiring drug therapy is hyperacidity, or excessive acid production. Left untreated, this condition can lead to such serious conditions as acid reflux, peptic ulcer disease, esophageal damage, and, potentially, esophageal cancer. Overproduction of stomach acid is also referred to as **gastric hyperacidity**.

HYDROCHLORIC ACID

The stomach secretes many substances with various physiological functions, including the following:

- Hydrochloric acid, an acid that aids digestion and serves as a barrier to infection
- Bicarbonate, a base that is a natural mechanism to prevent hyperacidity

Fig 39.1 The three specific zones of the stomach and the different glands.

- Pepsinogen, an enzymatic precursor to pepsin, an enzyme that digests dietary proteins
- Intrinsic factor, a glycoprotein that facilitates gastric absorption of vitamin B₁₂
- Mucus, which protects the stomach lining from both hydrochloric acid and digestive enzymes
- Prostaglandins, which have a variety of anti-inflammatory and protective functions (see [Chapter 49](#))

The stomach, although one structure, can be divided into three functional areas. Each area is associated with specific glands. These glands are composed of different cells, and these cells secrete different substances. [Fig 39.1](#) shows the three functional areas of the stomach and the distribution of the associated types of stomach glands.

The three primary types of glands in the stomach are the cardiac, gastric, and pyloric glands. These glands are named for their positions in the stomach. The cardiac glands are located around the cardiac sphincter (also known as the *gastroesophageal sphincter*); the gastric glands are in the fundus, also known as the *greater part of the body of the stomach*; and the pyloric glands are in the pyloric region and in the transitional area between the pyloric and the fundic zones.

The **gastric glands** are highly specialized secretory glands composed of several different types of cells: parietal, chief, mucous, endocrine, and enterochromaffin. Each cell secretes a specific substance. The three most important cell types are parietal cells, chief cells, and mucous cells. These cells are depicted in [Fig 39.1](#).

Parietal cells produce and secrete **hydrochloric acid (HCl)**. They are the primary site of action of many of the drugs used to treat acid-related disorders. **Chief cells** secrete pepsinogen, a proenzyme (enzyme precursor) that becomes **pepsin** when activated by exposure to acid. Pepsin breaks down proteins, smaller polypeptides, and amino acids and is therefore referred to as a *proteolytic enzyme*. **Mucous cells** are mucus-secreting cells that are also called *surface epithelial cells*. The secreted mucus serves as a protective coating against the digestive action of HCl and digestive enzymes. These three cell types play an important role in the digestive process. When the balance between these three cells and their secretions is impaired, acid-related diseases can occur. The most harmful of these involve acid hypersecretion and include peptic ulcer disease (PUD) and esophageal cancer. However, the most common acid-related condition is mild to moderate hyperacidity. Many lay terms (e.g., *indigestion*, *sour stomach*, *heartburn*, *acid stomach*) have been used to describe this condition of overproduction of HCl by the parietal cells. Hyperacidity is often associated with gastroesophageal reflux disease (GERD). According to the Canadian Digestive Health Foundation (2019), 5 million Canadians experience GERD symptoms such as heartburn or acid regurgitation a minimum of once a week. GERD is the tendency of excessive and acidic stomach contents to back up, or reflux, into the lower (and even upper) esophagus. Over time, this condition can lead to more serious disorders, such as erosive esophagitis and Barrett's esophagus, a precancerous condition. Therefore, to prevent serious disorders from occurring and to promote patient comfort, GERD is aggressively treated with one or more of the medications described in this section. HCl is secreted by the parietal cells in the lining of the stomach and maintains the environment of the stomach at a pH of 1 to 4. This acidity aids in the proper digestion of food and serves as one of the body's defences against microbial infection via the GI tract. Many substances stimulate HCl secretion by the parietal cells, such as certain foods, including chocolate, caffeine, and alcohol. In moderation, any of these substances is usually not problematic. However, excessive consumption of large, fatty meals or alcohol, as well as emotional stress, may result in the hyperproduction of HCl and lead to hypersecretory disorders such as PUD.

The parietal cell is the primary target for many of the most effective drugs for the treatment of acid-related disorders. A closer look at how the parietal cell receives signals to produce and secrete HCl will enhance understanding of the mechanisms of action of many of the drugs used to treat acid-related disorders. The wall of the parietal cell has three types of receptors: acetylcholine (ACh), histamine, and gastrin. When any one of these is occupied by its corresponding chemical stimulant (ACh, histamine, or gastrin, which can all be considered first messengers), the parietal cell will produce and secrete HCl. [Fig 39.2](#) shows the parietal cell with its three receptors. Once these receptors have become occupied, a second messenger is sent inside the cell. In the case of histamine receptors, occupation results in the production of adenylate cyclase. Adenylate cyclase converts adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP), which provides energy for the

Fig 39.2 Parietal cell stimulation and secretion. ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate.

proton pump. The proton pump, or, more precisely, the hydrogen–potassium–adenosine triphosphatase (ATPase) pump, is a pump for the transport of hydrogen ions located in the parietal cells. The pump requires energy to work. If energy is present, the proton pump will be activated, and the pump will be able to transport hydrogen ions needed to produce HCl.

In the case of both ACh and gastrin receptors, the second messenger that drives the proton pump is not cAMP, but calcium ions. Anticholinergic drugs (see [Chapter 22](#)) such as atropine sulphate block ACh receptors, which results in decreased hydrogen ion secretion from the parietal cells. However, these drugs are no longer used for this purpose and have been superseded by other drug classes discussed in this chapter. There is currently no drug to block the binding of the hormone gastrin to its corresponding receptor on the parietal cell surface.

In 1983, a certain gram-negative spiral bacterium, *Campylobacter pylori*, was isolated from several patients with gastritis. Over the next few years, this bacterium was studied further, and it became implicated in the pathophysiology of PUD. The official name of this bacterium was changed to *Helicobacter pylori* because it was felt to have more characteristics of the *Helicobacter* genus. The prevalence of *H. pylori* as measured by serum antibody tests is approximately 40 to 60% for patients older than 60 years of age and only 10% for those younger than 30 years of age. Although costly to administer, other available tests are the *H. pylori* fecal antigen test and the

carbon 13 urea breath test. The bacterium is found in the GI tracts of approximately 90% of patients with duodenal ulcers and 70% of those with gastric ulcers; however, ulcers can occur without the presence of *H. pylori*. *H. pylori* is also found in many patients who do not have PUD, and its presence is not associated with acute, perforating ulcers. These latter observations suggest that more than one factor is involved in ulceration. Triple therapy includes a 7- to 14-day course of a proton pump inhibitor (discussed later in the chapter) and the antibiotics clarithromycin and either amoxicillin or metronidazole (see Chapters 43 and 44). Quadruple therapy is a combination of a proton pump inhibitor, bismuth subsalicylate (this chapter), and the antibiotics tetracycline and metronidazole (see Chapters 43 and 44). Many different combinations are used, but all incorporate the aforementioned key drugs. Treatment with clarithromycin is the preferred first-line treatment because of high rates of metronidazole resistance. Optimum treatment remains controversial.

Stress-related mucosal damage is an important issue for critically ill patients. Stress ulcer prophylaxis (or therapy to prevent severe GI damage) is undertaken in almost every critically ill patient in a Critical Care Unit (CCU) and for many patients on general medical surgical units. GI lesions are a common finding in CCU patients, especially within the first 24 hours after admission. The etiology and pathophysiology of physiological stress-related mucosal damage is multifactorial and is not fully understood. Factors include decreased blood flow, mucosal

ischemia, hypoperfusion, and reperfusion injury. A common stress ulcer is the Curling ulcer, an acute peptic ulcer of the duodenum that occurs in patients with severe burns that occur when decreased blood volume leads to ischemia and cell necrosis of the gastric mucosa. Although the cause is unknown, a Cushing ulcer can occur after severe head trauma. Procedures performed commonly in critically ill patients, such as passing nasogastric tubes, placing patients on ventilators, and others, predispose patients to bleeding of the GI tract. Coagulopathy, a history of peptic ulcer or GI bleed, sepsis, use of steroids, CCU stay of longer than 1 week, and occult bleeding indicate high risk of GI lesions.

ANTACIDS

Antacids are basic compounds used to neutralize stomach acid. Antacids have been used for centuries in the treatment of patients with acid-related disorders. The ancient Greeks used crushed coral (calcium carbonate) in the first century CE to treat patients with dyspepsia. Antacids were the principal anti-ulcer treatment, along with anticholinergic drugs, until the introduction of histamine-2 (H_2) receptor antagonists in the late 1970s. The use of anticholinergic drugs has fallen out of favour because of poor efficacy and adverse effects. There is a wide variety of commercially available antacids that are over-the-counter (OTC) formulations and are still used extensively. They are inexpensive, available in a variety of dosage forms, and relatively safe, although not without some risk. Antacid tablet forms are slower acting than liquid formulations. They must be chewed thoroughly for effect.

Many formulations of antacids and a variety of combinations are available. Some effervescent antacids contain sodium bicarbonate or baking soda. Alka-Seltzer®, which also contains acetylsalicylic acid, is an example. Bicarbonate reacts with stomach HCl to release carbon dioxide gas that is quickly absorbed but sometimes results in the release of the gas as a burp. In addition, many antacid preparations also contain the antiflatulent (antigas) drug simethicone (see the section, Miscellaneous Acid-Controlling Drugs, p. 648), a surfactant that reduces gas and bloating but has no antacid effect. Some antacids are combined with an alginate, a tasteless substance derived from kelp or seaweed. It is not an antacid. Rather, it creates a physical gel barrier, floating between the gastric acids and the esophagus; the barrier prevents the acid from refluxing into the esophagus. Gaviscon® is one example of an antacid containing alginate sodium. Peppermint is the most common flavouring added to antacids, as it relaxes the lower esophageal sphincter so that gas can be released; however, it should not be used in patients with GERD as stomach acids would flow back into the esophagus.

Many aluminum- and calcium-based antacid formulations include magnesium, which not only contributes to the drug's acid-neutralizing capacity but counteracts the constipating effects of aluminum and calcium. There are multiple salts of calcium, with calcium carbonate being the most commonly used. However, calcium antacids may lead to the development of kidney stones and increased gastric acid secretion. Antacids

containing magnesium must be avoided in patients with kidney failure. Sodium bicarbonate is a highly soluble antacid form with quick onset but a short duration of action.

Mechanism of Action and Drug Effects

Antacids work primarily by neutralizing gastric acidity. They do not prevent the overproduction of acid but instead help to neutralize acid secretions. It is also thought that antacids promote gastric mucosal defensive mechanisms, particularly at lower dosages. They do this by stimulating the secretion of mucus, prostaglandins, and bicarbonate from the cells inside the gastric glands. Mucus serves as a protective barrier against the destructive actions of HCl. Bicarbonate helps buffer the acidity of HCl. Prostaglandins prevent histamine from binding to its corresponding parietal cell receptors, which inhibits the production of adenylate cyclase. Without adenylate cyclase, no cAMP can be formed, and no second messenger is available to activate the proton pump (see Fig 39.2). The primary drug effect of antacids is the reduction of the symptoms associated with various acid-related disorders, such as pain and reflux. A dose of antacid that raises the gastric pH from 1.3 to 1.6 (by only 0.3) reduces gastric acidity by 50%, whereas acidity is reduced by 90% if the pH is raised one entire point (e.g., 1.3 to 2.3). Antacid-associated pain reduction is thought to be a result of base-mediated inhibition of the protein-digesting ability of pepsin, increase in the resistance of the stomach lining to irritation, and increase in the tone of the cardiac sphincter, which reduces reflux from the stomach.

Indications

Antacids are indicated for the acute relief of symptoms associated with peptic ulcer, gastritis, gastric hyperacidity, and reflux.

Contraindications

The only usual contraindication to antacid use is known allergy to a specific drug product. Other contraindications may include severe kidney failure or electrolyte disturbances (because of the potential toxic accumulation of electrolytes in the antacids themselves) and GI obstruction.

Adverse Effects

The adverse effects of the antacids are limited. Magnesium preparations, particularly milk of magnesia, can cause diarrhea. Aluminum- and calcium-containing formulations can result in constipation. Calcium products can also cause kidney stones. Excessive use of any antacid can theoretically result in systemic alkalosis. This adverse effect is more common with sodium bicarbonate than with other formulations. Another adverse effect that is more common with calcium-containing products is rebound hyperacidity, or acid rebound, in which the patient experiences hyperacidity when antacid use is discontinued. Long-term self-medication with antacids may mask symptoms of serious underlying diseases, such as bleeding ulcers or malignancy. Patients with ongoing symptoms need to undergo regular medical evaluations, because additional medications or other interventions may be needed. Box 39.1 lists several specific nursing concerns for patients taking antacids.

BOX 39.1 Nursing Concerns for Patients Taking Antacids

Aluminum, used to reduce gastric acid, binds to phosphate and may lead to hypercalcemia. Early hypercalcemia is characterized by constipation, headache, increased thirst, dry mouth, decreased appetite, irritability, and a metallic taste in the mouth. Later signs and symptoms of hypercalcemia include confusion, drowsiness, a rise in blood pressure, irregular heart rate, nausea, vomiting, and increased urination. Use of aluminum-based antacids may also produce hypophosphatemia, which is characterized by loss of appetite, malaise, muscle weakness, and bone pain. The use of calcium-containing antacids (e.g., calcium carbonate) may lead to milk-alkali syndrome, which is associated with headache, anorexia, nausea, vomiting, and unusual tiredness. Use of sodium bicarbonate may lead to metabolic alkalosis if the drug is misused or used over the long term. Alkalosis is manifested by irritability, muscle twitching, numbness and tingling, cyanosis, slow and shallow respirations, headache, thirst, and nausea. Acid rebound occurs with the discontinuation of antacids that have high acid-neutralizing capacity and with overuse or misuse of antacid therapy. If acid neutralization is sudden and high, the result is an immediate elevation in pH to alkalinity and just as rapid a decline in pH to a more acidic state in the gut.

Interactions

Antacids can cause several drug interactions when administered with other drugs (see Table 39.1). There are four basic mechanisms by which antacids cause interactions:

- *Adsorption* of other drugs to antacids, which reduces the ability of the other drug to be absorbed into the body
- *Chelation*, which is the chemical inactivation of other drugs that produces insoluble complexes
- *Increased stomach pH*, which increases the absorption of basic drugs and decreases the absorption of acidic drugs
- *Increased urinary pH*, which increases the excretion of acidic drugs and decreases the excretion of basic drugs

Most drugs are either weak acids or weak bases. Therefore, pH conditions in both the GI and urinary tracts will affect the extent to which drug molecules are absorbed. Ionized drug molecules are generally more water soluble and thus more likely to be excreted (at the kidney) or not absorbed (from the GI tract). Common examples of drugs whose effects may be chemically enhanced by the presence of antacids (because of pH effects) include benzodiazepines, sulfonyleureas (effects may also be reduced, depending on the drugs involved), sympathomimetics, and valproic acid. More commonly, the presence of antacids reduces the efficacy of interacting drugs by interfering with their GI absorption. Such drugs include allopurinol, tetracycline, thyroid hormones, captopril, corticosteroids, digoxin, histamine antagonists, phenytoin, isoniazid, ketoconazole, methotrexate, nitrofurantoin, phenothiazines, salicylates, and quinolone antibiotics. Advise patients to dose any interacting drugs at least 1 to 2 hours before or after antacids are taken. Significant patient harm may ensue when the quinolone antibiotics (ciprofloxacin, levofloxacin, moxifloxacin) are given with antacids. These antibiotics are administered orally to treat serious infections. Antacids can reduce their absorption by more than 50%. Thus, antacids must be given either 2 hours before or 2 hours after the dose of a quinolone antibiotic.

Dosages

For information on dosages for selected antacid drugs, refer to the table on p. 645.

DRUG PROFILES

antacids, general

There are far too many individual antacid products on the market to mention all formulations. Briefly, OTC antacid formulations are available as capsules, chewable tablets, effervescent granules and tablets, soft chews, powders, suspensions, and plain tablets. This allows patients a variety of options for self-medication. Pharmacokinetic parameters are not normally listed for antacids, but these drugs are generally excreted quickly through the GI tract and the electrolyte homeostatic mechanisms of the kidneys. Antacids are considered safe for use during pregnancy if prolonged administration and high dosages are avoided. It is recommended that pregnant women consult their health care providers before taking an antacid. Many antacids available in Canada are combinations (e.g., aluminum hydroxide, magnesium hydroxide, simethicone). One combination of aluminum hydroxide and magnesium hydroxide also contains a local anaesthetic (Mucaïne®). Aluminum- and sodium-based antacids are often recommended for patients with kidney compromise because these antacids are more easily excreted than are antacids of other categories. Calcium-containing antacids are currently advertised as a source of calcium. Calcium carbonate neutralization will produce gas and possibly belching. For this reason, it may be combined with an antifatulent drug such as simethicone (see the section, Miscellaneous Acid-Controlling Drugs). Calcium carbonate is also available combined with the bisphosphonate etidronate disodium. Magnesium-containing antacids commonly have a laxative effect; magnesium is always combined with other antacids. Both calcium- and magnesium-based antacids are more likely to accumulate to toxic levels in patients with kidney disease and are often avoided in this patient group.

H₂ ANTAGONISTS

H₂ receptor antagonists, also called *H₂ receptor blockers*, are the prototypical acid-secretion antagonists. These drugs reduce but do not completely abolish acid secretion. They have become the most popular drugs for the treatment of many acid-related disorders, including PUD. This can be attributed to their efficacy, excellent safety profile, and acceptance by patients. This class includes cimetidine, ranitidine hydrochloride, famotidine, and nizatidine. There is little difference between the four available H₂ receptor antagonists in terms of efficacy. Ranitidine hydrochloride and famotidine are also available over the counter.

Mechanism of Action and Drug Effects

H₂ receptor antagonists competitively block the H₂ receptor of acid-producing parietal cells. This action makes the cells less responsive not only to histamine but also to the stimulation of ACh and gastrin. This process is shown in Fig 39.2. Up to 90% inhibition of vagal- and gastrin-stimulated acid secretion occurs when histamine is blocked. However, complete inhibition has not been shown. The effect of H₂ antagonists is reduced hydrogen ion secretion from the parietal cells, which results in an increase in the pH of the stomach and relief of many of the symptoms associated with hyperacidity-related conditions.

TABLE 39.1 Antacids: Drug Interactions

Interacting Drug	Mechanism	Result
Benzodiazepines Sulfonylureas Sympathomimetics valproic acid	pH effects	Increased activity of interacting drugs
Allopurinol Tetracycline Thyroid hormones captopril Corticosteroids Digoxin Histamine antagonists Phenytoin Isoniazid Ketoconazole Methotrexate Nitrofurantoin Phenothiazines Raltegravir Salicylates Quinolone antibiotics	Decreased GI absorption	Reduced effects of interacting drugs

Dosages

Selected Antacid Drugs*

Drug	Pharmacological Class	Usual Dosage Range	Indications
aluminum hydroxide and magnesium hydroxide and simethicone (Antacid Plus®, Diovol®, Gelusil®, Maalox Multiaction®)	Combination antacid	<i>Adults</i> PO: 400–2400 mg 3–6×/day	Hyperacidity
calcium carbonate and simethicone (Maalox®, Rolaids®)	Calcium-containing antacid	<i>Adults</i> PO: 0.5–1.5 g prn to a maximum 8000mg/day	Hyperacidity
Carbonic acid calcium salt and magnesium hydroxide (Rolaids®)	Magnesium- and calcium-containing antacid	<i>Adults</i> PO: 400 mg calcium and 84 mg magnesium (1–3 tablets daily)	Hyperacidity

*Many more antacid products are available than appear in this table. Dosages given are approximate dosages of active ingredients; there may be variations among different products and different dosage forms of the same product.

PO, Oral.

Indications

H₂ receptor antagonists have several therapeutic uses, including the treatment of GERD, PUD, and erosive esophagitis; adjunct therapy in the control of upper GI tract bleeding; and treatment of pathological gastric hypersecretory conditions such as Zollinger-Ellison syndrome. This syndrome is one form of hyperchlorhydria, or excessive gastric acidity. H₂ receptor antagonists are commonly used for stress ulcer prophylaxis in critically ill patients. Because of their few adverse effects, these drugs may be administered preoperatively to raise gastric pH.

Contraindications

The only usual contraindication to the use of H₂ antagonists is known drug allergy. Liver and kidney dysfunction are relative contraindications that may warrant dosage reductions. Specific dose limitations and administration guidelines exist for OTC ranitidine and famotidine.

Adverse Effects

The H₂ receptor antagonists have a remarkably low incidence of adverse effects (less than 3% of cases). The four available H₂ antagonists are similar in many respects but have some differences in their adverse effect profiles. Table 39.2 lists the adverse effects associated with these drugs. Central nervous system adverse effects, such as confusion and disorientation, occur in less than 1% of patients taking H₂ receptor antagonists but are sometimes seen in older adults. Be alert for mental health status changes when giving these drugs, especially if they are new to the patient. Cimetidine may induce erectile dysfunction and gynecomastia, as a result of its inhibition of estradiol metabolism and displacement of dihydrotestosterone from peripheral androgen-binding sites. All four H₂ antagonists may increase the secretion of prolactin from the anterior pituitary. Thrombocytopenia has been reported with ranitidine hydrochloride and famotidine.

Interactions

Cimetidine carries a higher risk of drug interactions than the other three H₂ antagonists, particularly in older adults. These interactions may be of clinical importance. Cimetidine binds enzymes of the liver cytochrome P450 microsomal oxidase system. This is a group of enzymes in the liver that metabolize many different drugs. By inhibiting the oxidation (metabolism) of drugs metabolized via this pathway, cimetidine may raise the blood concentrations of such drugs. Ranitidine hydrochloride has only 10 to 20% of the binding action of cimetidine on the P450 system, and nizatidine and famotidine have essentially no effect on it. This interaction has little clinical significance for most drugs; however, significant interactions are more likely to arise with medications that have a narrow therapeutic range, such as theophylline, warfarin sodium, lidocaine, and phenytoin. All H₂ receptor antagonists may inhibit the absorption of certain drugs such as ketoconazole that require an acidic GI environment for gastric absorption. Smoking has been shown to decrease the effectiveness of H₂ receptor antagonists. For optimal results, H₂ receptor antagonists should be taken 1 hour before antacids.

Dosages

For dosage information for the H₂ antagonists, refer to the table on p. 647.

DRUG PROFILES

H₂ receptor antagonists are the prototypical acid-secretion antagonists. These drugs reduce acid secretion. They are among the most commonly used drugs in the world because of their efficacy, some availability over the counter, patient acceptance, and excellent safety profile. However, this drug class has been partially replaced by proton pump inhibitors (see the next section).

cimetidine

Cimetidine was the first drug in this class to be released on the market. It is the prototypical H₂ receptor antagonist. Because of its potential to cause drug interactions and it is an inhibitor of 3 major metabolic pathways CYP1A2, CYP2D6, and CYP3A4, its use has been largely replaced by ranitidine hydrochloride and famotidine. Cimetidine is still used to treat certain allergic reactions.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	60 min	0.75–1.5 hr	2 hr	4–5 hr

ranitidine hydrochloride

Ranitidine hydrochloride (Zantac®) was the second H₂ receptor antagonist introduced. Unlike cimetidine, it is not associated with concerns regarding drug interactions and thus has become the most widely used H₂ receptor antagonist. It is available over the counter. It is also more potent, specific, and longer acting than cimetidine. Administered parenterally, ranitidine can raise gastric pH in 1 hour, and its effects can last for up to 12 hours. It is available in oral and intravenous (IV) forms. Dosing is different for the different forms: oral ranitidine is dosed as 150 mg twice a day or 300 mg at bedtime, whereas the IV form is dosed at 50 mg every 8 hours.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1 hr	2–4 hr	2–3 hr	4–12 hr
IV	Immediate	Less than 15 min	2–3 hr	4–12 hr

famotidine

Famotidine (Pepcid®) was the last H₂ receptor antagonist introduced and, like ranitidine hydrochloride, has minimal drug interaction concerns. It is available in oral and injectable forms. The dosing is the same for both forms.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1.4 hr	1–3 hr	2.6–4 hr	10–12 hr
IV	Immediate	Less than 15 min	2.6–4 hr	10–12 hr

PROTON PUMP INHIBITORS

The newest drugs introduced for the treatment of acid-related disorders are the proton pump inhibitors (PPIs). These include

TABLE 39.2 H₂ Antagonists: Adverse Effects

Body System	Adverse Effects
Cardiovascular	Hypotension (monitor for this effect with intravenous administration)
Central nervous	Headache, lethargy, confusion, depression, hallucinations, slurred speech, agitation
Endocrine	Increased prolactin secretion, gynecomastia (with cimetidine)
Gastrointestinal	Diarrhea, nausea, abdominal cramps
Genitourinary	Impotence, increased blood urea nitrogen and creatinine levels
Hematological	Agranulocytosis, thrombocytopenia, neutropenia, aplastic anemia
Hepatobiliary	Elevated liver enzyme levels, jaundice
Integumentary	Urticaria, rash, alopecia, sweating, flushing, exfoliative dermatitis

Dosages

Selected Histamine-2 (H_2) Antagonists

Drug	Usual Dosage Range	Indications
 cimetidine (generic)	<i>Adults</i>	
	PO: 200 mg bid	Dyspepsia, heartburn
	PO: 300 mg qid or 400 mg bid and at bedtime or 800 mg at bedtime	Ulcers
	PO: 1 600 mg/day divided in 2 to 4 doses	GERD
	PO: 300 mg bid or 400 mg at bedtime	GERD
famotidine (Pepcid, Pepcid AC)		Pathological hypersecretion
	PO: 300 mg tid and at bedtime; do not exceed 2 400 mg/day	Pathological hypersecretion
	<i>Adults</i>	Dyspepsia, heartburn
	PO: 10–20 mg/day bid	
	PO: 40 mg/day at bedtime or 20 mg bid	Ulcers
ranitidine hydrochloride (Zantac)	PO: 20 mg q6h	Pathological hypersecretion
	IV: 20 mg q12h	
	PO: 20–40 mg bid	GERD
	<i>Adults</i>	Dyspepsia, heartburn
	PO: 75 mg bid	
	PO: 150 mg daily bid or 300 mg at bedtime	Ulcers
	PO: 150 mg tid	
	PO: 150 mg qid	Erosive esophagitis

GERD, Gastroesophageal reflux disease; PO, oral; IV, intravenous.

lansoprazole (Prevacid®, Prevacid FasTab®), omeprazole (Losec®, Prilosec®), rabeprazole sodium (Pariet®), pantoprazole sodium (Panto®, Pantoloc®), dexlansoprazole (Dexilant®), and esomeprazole trihydrate (Nexium®). These drugs are more powerful than the H_2 receptor antagonists. The PPIs bind directly to the hydrogen–potassium–ATPase pump mechanism and irreversibly inhibit the action of this enzyme, which results in a total blockage of hydrogen ion secretion from the parietal cells.

Mechanism of Action and Drug Effects

The action of the hydrogen–potassium–ATPase pump is the final step in the acid-secretory process of the parietal cell (see Fig 39.2). If chemical energy is present to run the pump, it will transport hydrogen ions out of the parietal cell, which increases the acid content of the surrounding gastric lumen and lowers the pH. Because hydrogen ions are protons (positively charged particles in atoms), this ion pump is also called the *proton pump*. PPIs bind irreversibly to the proton pump. This inhibition prevents the movement of hydrogen ions out of the parietal cell into the stomach, thereby blocking all gastric acid secretion. The PPIs stop more than 90% of acid secretion over 24 hours, which makes most patients temporarily achlorhydric (without acid). However, food absorption is not affected. For acid secretion to return to normal after a PPI has been stopped, the parietal cell must synthesize new hydrogen–potassium–ATPase. Although there are other proton pumps in the body, hydrogen–potassium–ATPase is structurally and mechanically distinct from other hydrogen-transporting enzymes and appears to exist only in the parietal cells. Thus, the action of PPIs is limited to its effects on gastric acid secretion.

Indications

PPIs are currently indicated as first-line therapy for erosive esophagitis, symptomatic GERD that is poorly responsive to other medical treatment such as therapy with H_2 antagonists, short-term treatment of active duodenal ulcers and active benign gastric ulcers, gastric hypersecretory conditions (e.g., Zollinger-Ellison syndrome), and nonsteroidal anti-inflammatory drug (NSAID)-induced ulcers. They are also used for stress ulcer prophylaxis. Long-term therapeutic uses include maintenance of healing of erosive esophagitis and pathological hypersecretory conditions, including both GERD and Zollinger-Ellison syndrome. All PPIs can be used in combination with antibiotics to treat patients with *H. pylori* infections. The PPIs can be given orally or through a nasogastric or percutaneous enterogastric tube. For example, esomeprazole magnesium dihydrate capsules may be opened, the granules dissolved in 50 mL of water, and the solution given through the tube. Similar tubal administration is listed as an option by the manufacturer for lansoprazole capsules and tablets and omeprazole powder for oral suspension. Consult drug packaging for drug-specific instructions. Be aware of the particle size of the drug once it is in solution and the tube size being used. Several of the PPIs are now also available for IV use.

Contraindications

The only usual contraindication to the use of PPIs is known drug allergy.

Adverse Effects

PPIs are generally well tolerated. The frequency of adverse effects is similar to that for H₂ receptor antagonists. Concerns have arisen over the potential for long-term users of PPIs to develop osteoporosis. Researchers who conducted a Canadian population-based cohort study have cautioned health care providers to be alert to the possibility of an increased risk of acute kidney injury and interstitial nephritis in older patients on PPI therapy (Antoniou, Macdonald, Hollands, et al., 2015). This is thought to be due to the inhibition of stomach acid, and it is speculated that PPIs speed up bone mineral loss. Long-term use of high-dose PPIs has been associated with *Clostridium difficile* infections; risk of wrist, hip, and spine fractures; and pneumonia. Recently, depletion of magnesium was added to the risk profile.

Interactions

Few drug interactions occur with PPIs; however, they may increase serum levels of diazepam and phenytoin. There may be an increased chance of bleeding in patients who are taking both a PPI and warfarin sodium. Other possible interactions include interference with absorption of ketoconazole, ampicillin, iron salts, and digoxin. Sucralfate may delay the absorption of PPIs. Food may decrease absorption of the PPIs, and it is recommended that they be taken on an empty stomach, usually before meals (usually breakfast), as this increases the effectiveness of the drug.

Dosages

For recommended dosages on selected PPIs, refer to the table on p. 649.

DRUG PROFILES

omeprazole magnesium

Omeprazole magnesium (Losec) was the first drug in this breakthrough class of antisecretory drugs. Orally administered PPIs (and H₂ receptor antagonists) often work best when taken 30 to 60 minutes before meals. Omeprazole was the first PPI to become available generically.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	2 hr	0.5–3.5 hrs	0.5–1 hr	3–5 days

lansoprazole

Lansoprazole (Prevacid) is available in a sustained-release capsule and immediate-release tablets. The capsules can be opened and mixed (not crushed) with apple juice for administration via nasogastric tube. Lansoprazole is also available as HP-PAC®, a combination product with amoxicillin and clarithromycin for the treatment of *H. Pylori* infection.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Rapid	1.5–2 hr	1–2 hr	24 hr

pantoprazole sodium

Pantoprazole sodium (Pantoloc, Panto IV) is the only PPI available for IV use. Adding PPIs to endoscopic therapy has become a mainstay of treatment for peptic ulcer bleeding, with current consensus guidelines recommending high-dose IV PPI therapy (IV bolus followed by continuous therapy). IV pantoprazole has been shown to be significantly more effective than the H₂ receptor antagonists ranitidine and famotidine in preventing ulcer rebleeding after endoscopic hemostasis. It was also the first drug to be used as a continuous infusion for the treatment of GI bleeding. It is available as an oral tablet and an enteric-coated tablet.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	2.5 hr	2–2.5 hr	1 hr	>24hrs
IV	End of infusion	End of infusion	1 hr	>24hrs

MISCELLANEOUS ACID-CONTROLLING DRUGS

There are a few other acid-controlling drugs that are unique in their mechanisms and other features. These include sucralfate and misoprostol. They are profiled individually in the following paragraphs. Other antacid drugs include bismuth subsalicylate (Pepto-Bismol®; see Chapter 40) and metoclopramide (see Chapter 41).

DRUG PROFILES

sucralfate

Sucralfate is a drug used as a mucosal protectant in the treatment of active stress ulcerations and in long-term therapy for PUD. Sucralfate acts locally, not systemically, binding directly to the surface of an ulcer. Sucralfate has as its basic structure a sugar, sucrose. Once sucralfate comes into contact with the acid of the stomach, it begins to dissociate into aluminum hydroxide (an antacid) and sulphate anions. The aluminum salt stimulates secretion of both mucus and bicarbonate base. The sulphated sucrose molecules of sucralfate are attracted to and bind to positively charged tissue proteins at the bases of ulcers and erosions, forming a protective barrier that can be thought of as a liquid bandage. By binding to the exposed proteins of ulcers and erosions, sucralfate also limits the access of pepsin. Pepsin is an enzyme that normally breaks down proteins in food but can have the same effect on GI epithelial tissue, either causing ulcers or making them worse. Sucralfate also binds and concentrates epidermal growth factor, present in the gastric tissues, which promotes ulcer healing. In addition, the drug stimulates the gastric secretion of prostaglandin molecules, which serve a mucoprotective function. Despite its many beneficial actions, sucralfate has fallen out of common use because its effects are transient and multiple daily doses (up to four) are therefore needed. It is indicated for stress ulcers, esophageal erosions, and PUD. The only usual contraindication to sucralfate use is known drug allergy. Adverse effects are uncommon but include nausea, constipation, and dry mouth. Only minimal systemic

Dosages

Selected Proton Pump Inhibitors

Drug	Usual Dosage Range	Indications
lansoprazole (Pravacid, Pravacid FasTab)	<i>Adults</i> PO: 30 mg/day	Duodenal ulcer, gastric ulcer, esophagitis
omeprazole magnesium (Losec)	<i>Adults</i> PO: 20–40 mg/day for 4–8 wk PO: 60 mg once daily initially, then titrated and given in single or multiple daily doses, with dosage titration up to a maximum of 120 mg tid	Esophagitis, duodenal ulcer Hypersecretory conditions
pantoprazole sodium (Pantoloc, Panto IV)	<i>Adults</i> PO/IV: 20–80 mg/day depending on indication	GERD, ulcer, stress ulcer prophylaxis

GERD, Gastroesophageal reflux disease; PO, oral; IV, intravenous.

absorption occurs, and the drug is virtually inert. Sucralfate does not display typical pharmacokinetic parameters, and, as such, no pharmacokinetic table is provided. Drug interactions involve mainly physical interference with the absorption of other drugs. This can be alleviated by taking other drugs at least 2 hours ahead of sucralfate. Sucralfate is also best given 1 hour before meals and at bedtime. It can be used during pregnancy and is normally dosed at 1 g orally, 4 times daily.

misoprostol

Misoprostol (generic), a prostaglandin E analogue, has been shown to effectively reduce the incidence of gastric ulcers in patients taking NSAIDs (see [Chapter 49](#)). Prostaglandins have a wide variety of biological activities. They are thought to inhibit gastric acid secretion. They are also believed to protect the gastric mucosa from injury (cytoprotective function), possibly by enhancing the local production of mucus or bicarbonate, by promoting local cell regeneration, and by helping to maintain mucosal blood flow. Use of misoprostol is contraindicated in patients with known drug allergy and in pregnant women or women trying to become pregnant (see below). Adverse effects include headache, GI distress, and vaginal bleeding. There are no major drug interactions, although antacids may reduce drug absorption. Although some studies show that synthetic analogues of prostaglandins promote the healing of duodenal ulcers, to accomplish this, the drugs must be used in dosages that usually produce disturbing adverse effects, such as abdominal cramps and diarrhea. Thus, they are not believed to be as effective as H_2 receptor antagonists and PPIs for this indication. Misoprostol induces uterine contractions and, therefore, has been used for its abortifacient properties. For this reason, it is not to be used during pregnancy. The usual dosage is 200 mcg, 4 times daily with meals, for the duration of NSAID therapy in patients at high potential for ulceration.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	30 min	12 min	20–40 min	3 hrs

simethicone

Simethicone (Ovol®, Pediacol®, Phazyme®) is used to reduce the discomfort of gastric or intestinal gas (flatulence) and aid in its release via the mouth or rectum. It is therefore classified as an antiflatulent drug. Gas commonly appears in the GI tract as a consequence of swallowing air as well as of normal digestive processes. Gas in the upper GI tract is composed of swallowed air and thus consists largely of nitrogen. It is usually expelled from the body by belching. The composition of flatus, however, is determined largely by the dietary intake of carbohydrates and the metabolic activity of the bacteria in the intestines.

Some foods, including legumes (beans) and cruciferous vegetables (e.g., cauliflower, broccoli), are well known for their gas-producing properties. Gas can also result from disorders such as diverticulitis, dyspepsia, peptic ulcers, and spastic or irritable colon; gaseous distention can also occur postoperatively. Simethicone works by altering the elasticity of mucus-coated gas bubbles, which causes them to break into smaller ones. This reduces gas pain and facilitates the expulsion of gas via the mouth or the rectum. Simethicone has no listed adverse effects, drug interactions, or pharmacokinetic parameters. It is available only for oral use. The usual simethicone dosage is 1 to 2 tablets, 4 to 6 times daily, maximum daily dose 500mg/day, as needed. A variety of different OTC products are available.

NURSING PROCESS

ASSESSMENT

Before an acid-controlling drug is given, perform a thorough patient assessment with attention to past and present medical history, with special focus on GI tract-related disorders and signs and symptoms of peptic ulcer disease and GERD. Assess any foods and activities (e.g., smoking, stress) that may increase acid in the GI tract. Assess current bowel patterns, any changes in bowel patterns or GI tract functioning, and GI tract-related pain. Document all findings. Assess results of baseline serum chemistry laboratory tests, as ordered, with specific attention to liver function (e.g., serum ALP, ALT, AST levels) and kidney function (GFR, serum creatinine and BUN levels). As acid-controlling drugs have many interactions, close attention

to all medications a patient is taking is required, and every medication history should include information about prescription drugs, OTC drugs, and natural health products.

Other components of assessment include performing a physical examination and taking a thorough cardiac history, with close attention to any history of heart failure, hypertension, or other heart diseases, and assessing for any presence of edema, fluid or electrolyte imbalances, or kidney disease. One reason it is important to assess for these conditions is that the high sodium content of various antacids may lead to exacerbation of heart problems, kidney dysfunction, and fluid–electrolyte concerns. When antacids are to be used, a medication history is essential regardless of the antacid being used. It is important to note that combination products containing both magnesium and aluminum may have fewer adverse effects than either antacid by itself. For example, aluminum-containing antacids are associated with constipation, whereas magnesium-containing antacids lead to diarrhea. The combination of these antacids is a balancing out of both adverse effects, leading to fewer problems with altered bowel patterns. Calcium-based antacids may also be used, especially as a source of calcium; however, they carry the risks of rebound hyperacidity, milk-alkali syndrome, and changes in systemic pH, especially if a patient has abnormal kidney function (see [Box 39.1](#)). Sodium bicarbonate is generally not recommended as an antacid because of its associated high potential for systemic electrolyte disturbances and alkalosis. The sodium content of sodium bicarbonate is also high, which is problematic for patients who have hypertension, heart failure, or kidney insufficiency.

For patients using H₂ receptor antagonist drugs, assess kidney and liver function as well as level of consciousness because of possible drug-related adverse effects. Older adults are known to react to these drugs with more disorientation and confusion than younger adults. Do not administer drugs such as cimetidine and famotidine simultaneously with antacids. These drugs may be spaced 1 hour apart if both drugs need to be given. In patients taking nizatidine or ranitidine hydrochloride, assess baseline blood chemistry results with attention to levels of BUN, creatinine, bilirubin, ALP, AST, and ALT to document kidney and liver functioning before treatment is initiated. Before administering oral PPIs (e.g., lansoprazole, omeprazole, pantoprazole sodium), assess swallowing capacity because of the size of some of the capsules. Assess patients' medical history with an emphasis on any history of GI tract infections due to decreased acid-mediated antimicrobial protection. Since there are documented concerns about the use of PPIs and the development of osteoporosis, thoroughly assess patients for any history of this disorder. Also assess the length of time patients have been on PPIs as there are long term adverse effects with PPIs (C. difficile diarrhea, vitamin/mineral malabsorption etc.). Drug interactions were discussed previously under PPIs, but important to mention are their interactions with diazepam, phenytoin, warfarin sodium, ampicillin, and iron salts. Always check the patient's medication list before these or any other type of medications are given.

Other GI-related drugs include sucralfate and simethicone. The use of simethicone (an antiflatulent) or sucralfate (an ulcer adherent) requires assessment of the patient's bowel patterns

and bowel sounds. Assess for abdominal distention and rigidity, which may indicate a medical emergency. Treatment of PUD has become focused on the use of antibiotics (to attack the *H. pylori* bacteria), with frequent dosing of other drugs. Inquire also about the presence of any unusual GI tract signs and symptoms.

◆ NURSING DIAGNOSES

- Constipation resulting from the adverse effects of aluminum-containing antacids and other drugs used to treat hyperacidity
- Diarrhea resulting from the adverse effects of magnesium-containing antacids and other drugs used to treat hyperacidity
- Inadequate knowledge as a result of lack of information about antacids, H₂ receptor antagonists, or PPIs, including their use and potential adverse effects

◆ PLANNING

◆ Goals

- Patient will experience minimal to no constipation while using antacids or other acid-controlling drugs.
- Patient will experience minimal to no diarrhea during antacid or acid-controlling medication regimen.
- Patient will demonstrate adequate knowledge about the use of antacid or acid-controlling medications and their expected adverse effects.

◆ Expected Patient Outcomes

- Patient states measures to help prevent and minimize the adverse effect of constipation, including taking the antacid only as directed.
- Patient states measures to help prevent and minimize the adverse effect of diarrhea, such as avoiding magnesium-only antacids, especially milk of magnesia, and taking products that contain a combination of aluminum and magnesium.
- Patient states the purpose of taking antacids, H₂ receptor antagonists, or PPIs for management of gastric hyperacidity.
- Patient describes the various adverse effects associated with antacids, such as diarrhea, constipation, and acid rebound.
- Patient describes the expected adverse effects associated with other acid-controlling drugs, such as constipation, diarrhea, headache, and confusion, and seeks advice from a health care provider if adverse effects worsen or are not relieved after several days.

◆ IMPLEMENTATION

When giving acid-controlling drugs, instruct patients to thoroughly chew chewable tablets and thoroughly shake liquid forms before they are taken. Antacids need to be given with at least 240 mL of water to enhance the absorption of the antacid in the stomach, except for newer forms that are rapidly dissolving drugs. If constipation or diarrhea occurs with single-component drugs, a combination aluminum-and-magnesium-based product may be preferred. Educate patients about the adverse effects

of aluminum-only or magnesium-only products. It is also recommended that antacids be given as ordered but not within 1 to 2 hours of other medications because of the effect of antacids on the absorption of oral medications. Implement this dosing schedule without interrupting the safe dosing of the other medications. Dosing will differ if the health care provider has ordered the drug to be given with antacids. There may be serious harm if quinolone antibiotics are given with antacids because of a 50% reduction in antibiotic absorption. Serious infections may then go unsuccessfully treated due to altered absorption. Antacid overuse or misuse, or the rapid discontinuation of antacids with high acid-neutralizing capacity, may lead to acid rebound. Therefore, antacids should be used only as prescribed or as directed.

Because so many H_2 receptor antagonists and other acid-controlling drugs are now available over the counter, instruct patients about proper medication use (see the Patient Teaching Tips for more information). For example, ranitidine is to be taken 30 to 60 minutes before a meal, and antacids, if also used, need to be taken 1 hour before or after the cimetidine. Famotidine may be given orally without regard to meals or food. Give cimetidine with meals and, if it is administered with antacids, allow 1 to 2 hours before the antacid is given. Dilute IV forms of famotidine or ranitidine hydrochloride with appropriate solutions and infuse over the recommended time frame. With IV H_2 receptor antagonists, hypotension may occur with rapid infusion, so careful monitoring of the infusion and blood pressure is critical to patient safety. Refer to appropriate sources for information on other specific drugs and their IV administration. Monitor patients with diagnoses of ulcers or GI irritation for GI tract bleeding. Report any blood in the stools or the occurrence of black, tarry stools or hematemesis. Listen to bowel sounds and examine the abdomen to monitor for possible complications.

Regarding PPIs, give lansoprazole oral dosage forms as ordered. If a patient has difficulty swallowing these capsules, a capsule may be opened and the granules sprinkled over at least a tablespoon of applesauce, which then must be swallowed immediately. Administer omeprazole before meals and educate patients that the capsule must be taken whole and not crushed, opened, or chewed. Omeprazole may also be given with antacids, if ordered. Always double-check the names and dosages of PPIs to ensure that they are not confused with similarly named drugs. Pantoprazole sodium may be given orally without crushing or splitting of the tablet form. Give IV dosage forms exactly as ordered, using the correct dilutional fluids. Infuse over the recommended time period. Other GI-related drugs, such as simethicone, may also be added to the oral medication protocol with PPIs. Simethicone is

usually well tolerated. It is to be taken after meals and at bedtime. Instruct patients to thoroughly chew chewable tablets or shake suspensions well before use. Sucralfate is usually given 1 hour before meals and at bedtime, and tablets may be crushed or dissolved in water, if needed. Antacids are to be avoided for 30 minutes before or after administration of sucralfate. Misoprostol is to be given with food and is usually ordered to be taken with meals and at bedtime. Suggestions for patient education for all of these drugs are presented in Patient Teaching Tips.

◆ EVALUATION

Therapeutic response to the administration of antacids, H_2 receptor antagonists, PPIs, and other GI-related drugs includes the relief of symptoms associated with peptic ulcer, gastritis, esophagitis, gastric hyperacidity, or hiatal hernia (i.e., decrease in epigastric pain, fullness, and abdominal swelling). Adverse effects for which to monitor include all of those listed for each of the drug categories and range from constipation or diarrhea to nausea, vomiting, abdominal pain, and hypotension. Milk-alkali syndrome, acid rebound, hypercalcemia, and metabolic alkalosis are known complications associated with various antacids; evaluate patients for these adverse effects and document measures taken to prevent or resolve them.

CASE STUDY

Proton Pump Inhibitors

Gurmeet, a 50-year-old lawyer, has self-treated for heartburn for years by drinking large amounts of antacids. She finally made an appointment with her health care provider, who referred her to a gastroenterologist. Her health care provider instructed her to stop taking the antacids.

1. Why did the health care provider ask her to stop taking the antacids?

A few weeks after her initial appointment, Gurmeet had an endoscopy, and it was discovered that she had gastroesophageal reflux disease (GERD) and gastritis secondary to stress-induced hyperacidity. The health care provider prescribed the PPI omeprazole (Prilosec, Losec) 20 mg once a day.

2. For what other conditions will the gastroenterologist test during this diagnostic stage?

3. What is the rationale for the use of PPIs to treat GERD?

4. What patient teaching is important for Gurmeet regarding the PPI?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

PATIENT TEACHING TIPS

- Inform patients that other medications should not be taken within 1 to 2 hours after taking an antacid, unless prescribed, because of antacids' impact on the absorption of many medications in the stomach.
- Advise patients to contact a health care provider immediately if they experience severe or prolonged constipation

or diarrhea, an increase in abdominal pain, abdominal distension, nausea, vomiting, hematemesis, or black and tarry stools (a sign of possible GI tract bleeding).

- If a patient is taking enteric-coated medications, tell the patient that the use of antacids may promote premature dissolution of the enteric coating. Enteric coatings are used to

diminish the stomach upset caused by irritating medications, and if the coating is destroyed early in the stomach, gastric upset may occur.

- Encourage patients to take H₂ receptor antagonists exactly as prescribed. Inform patients that smoking increases the amount of acid produced in the stomach and as such decreases the drug's effectiveness. Advise the patient that H₂ antagonists are not to be taken within 1 hour of antacids.
- Advise patients to take omeprazole and other PPIs before meals. Inform the patient that if lansoprazole is being used, the granules in the capsule may be sprinkled in at least one tablespoon of applesauce if needed.
- Instruct patients to follow the manufacturer's directions when taking simethicone. Chewable forms must always be

chewed thoroughly; liquid preparations need to be shaken thoroughly before administration. Encourage patients experiencing flatulence to avoid problematic foods (e.g., spicy, gas-producing foods) and carbonated beverages.

- Patients taking sucralfate should know that it must be taken on an empty stomach, and that antacids are to be avoided or, if indicated, taken 2 hours before or 1 hour after sucralfate administration.
- For a patient taking the drug regimen for the treatment of *H. pylori* infection, PUD, it is important to emphasize the need to take each drug, including the antibiotics, exactly as prescribed and without fail, to guarantee successful treatment. If treatment protocols are not followed appropriately, the condition will likely recur.

KEY POINTS

- The stomach secretes many substances, including HCl, pepsinogen, mucus, bicarbonate, intrinsic factor, and prostaglandins.
- Parietal cells are responsible for the production of acid.
- In acid-related disorders, there is an impairment of the balance among the substances secreted by the stomach.
- H₂ receptor antagonists are H₂ blockers that bind to and block histamine receptors located on parietal cells. This blocking renders these cells less responsive to stimuli, and thus decreases their acid secretion. Up to 90% inhibition of acid secretion can be achieved with the H₂ receptor antagonists.
- PPIs block the final step in the acid production pathway—the hydrogen–potassium–ATPase pump—and they block all acid secretion.
- Sucralfate is used for the treatment of PUD and stress-related ulcers. It binds to tissue proteins in eroded areas and prevents exposure of the ulcerated area to stomach acid.
- Misoprostol is a synthetic prostaglandin analogue that inhibits gastric acid secretion and is used to prevent NSAID-related ulcers.
- Cautious use of antacids is recommended in patients who have heart failure, hypertension, or other heart diseases or who require sodium restriction, especially if the antacid is high in sodium.
- Many drug interactions occur with acid-controlling drugs due to alteration of oral dosage forms, and so other medications are to be avoided within 1 to 2 hours of taking an antacid. Antacids are sometimes to be avoided when other acid-controlling drugs are taken.
- Magnesium–aluminum combination antacids are used to prevent the adverse effects of constipation and diarrhea. Some of the more serious concerns resulting from antacids include acid rebound, hypercalcemia, milk-alkali syndrome, and metabolic alkalosis.

EXAMINATION REVIEW QUESTIONS

1. A 30-year-old man is taking simethicone for excessive flatus associated with diverticulitis. During a patient teaching session, which statement by the nurse explains the mechanism of action of simethicone?
 - a. "It neutralizes gastric pH, thereby preventing gas."
 - b. "It buffers the effects of pepsin on the gastric wall."
 - c. "It decreases gastric acid secretion and thereby minimizes flatus."
 - d. "It causes mucus-coated gas bubbles to break into smaller ones."
2. When evaluating the medication list of a patient who will be starting therapy with an H₂ receptor antagonist, the nurse is aware that which drug may interact with it?
 - a. codeine sulphate
 - b. penicillin
 - c. ketoconazole
 - d. acetaminophen
3. When administering sucralfate, which action by the nurse is most correct?
 - a. Giving the drug with meals
 - b. Giving the drug on an empty stomach
 - c. Instructing the patient to restrict fluids
 - d. Waiting 30 minutes before administering other drugs
4. A patient with a history of kidney problems is asking for advice about which antacid he should use. The nurse will make which recommendation?
 - a. "Patients with kidney problems cannot use antacids."
 - b. "Aluminum-based antacids are the best choice for you."
 - c. "Calcium-based antacids are the best choice for you."
 - d. "Magnesium-based antacids are the best choice for you."
5. A patient who is taking oral tetracycline complains of heartburn and requests an antacid. Which action by the nurse is correct?
 - a. Give the tetracycline, but delay the antacid for 1 to 2 hours.
 - b. Give the antacid, but delay the tetracycline for at least 4 hours.
 - c. Administer both medications together.
 - d. Explain that the antacid cannot be given while the patient is taking the tetracycline.
6. When the nurse is administering a PPI, which actions by the nurse are correct? (Select all that apply.)

- a. Giving the PPI on an empty stomach
 - b. Giving the PPI with meals
 - c. Making sure the patient does not crush or chew the capsules
 - d. Instructing the patient to open the capsule and chew the contents for best absorption
 - e. Administering the PPI only when the patient reports heartburn
7. The order reads: “Give ranitidine hydrochloride 50 mg in 100 mL normal saline IVPB tid and at bedtime. Infuse over 30 minutes.” The infusion pump can be programmed to deliver only over 60 minutes (mL per hour). The nurse will set the pump to deliver how many mL/hour for each IVPB dose?
8. The nurse is preparing to administer the first dose of misoprostol for a patient who has been diagnosed with a gastric ulcer. What condition would be a contraindication to this medication?
- a. Hypothyroidism
 - b. Type 2 diabetes mellitus
 - c. Pregnancy
 - d. Hypertension

CRITICAL THINKING ACTIVITIES

1. A father brings his 2-month-old infant to the pediatric clinic and says, “He seems to have so much gas! Is there anything that can help?” The pediatrician suggests an infant formulation of simethicone. The father asks, “What does this drug do?” What is the nurse’s best answer?
 2. A patient with a history of decreased renal function tells the nurse, “I have finally found an antacid that gives me great relief!” The nurse checks the antacid’s content and finds that the antacid is a combination of aluminum hydroxide and magnesium hydroxide. What is the nurse’s priority action? Explain your answer.
 3. A patient tells the nurse, “I like taking antacids because they coat my stomach and protect my ulcer.” What is the priority to consider when responding to the patient’s statement?
- For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Antidiarrheal Drugs and Laxatives

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Discuss the anatomy and physiology of the gastrointestinal (GI) tract, including the process of peristalsis.
2. Identify the various factors affecting bowel elimination and bowel patterns.
3. List the various groups of drugs used to treat alterations in bowel elimination, specifically diarrhea and constipation.
4. Discuss the mechanisms of action, indications, cautions, contraindications, drug interactions, dosages, routes of administration, and adverse effects of the various antidiarrheals, probiotics, and laxatives.
5. Develop a collaborative plan of care that includes all phases of the nursing process for patients taking antidiarrheals, probiotics, or laxatives.

KEY TERMS

Antidiarrheal drugs Drugs that prevent or treat diarrhea. (p. 655)

Constipation A condition of abnormally infrequent and difficult passage of feces through the lower GI tract. (p. 657)

Diarrhea The abnormally frequent passage of loose stools. (p. 654)

Irritable bowel syndrome (IBS) A recurring condition of the intestinal tract characterized by bloating, flatulence, and often periods of diarrhea that alternate with periods of constipation. (p. 655)

Laxatives Drugs that promote bowel evacuation, such as by increasing the bulk of the feces, softening the stool, or lubricating the intestinal wall. (p. 657)

DRUG PROFILES

bisacodyl, p. 661

bismuth subsalicylate, p. 656

 diphenoxylate with atropine (diphenoxylate hydrochloride with atropine sulphate)*, p. 656

 docusate sodium, p. 660

 glycerin, p. 661

Lactobacillus, p. 657

 lactulose, p. 661

 loperamide (loperamide hydrochloride)*, p. 656

magnesium salts, p. 661

methylcellulose, p. 660

mineral oil, p. 661

polyethylene glycol (polyethylene glycol 3350)*, p. 661

 psyllium (psyllium hydrophilic mucilloid)*, p. 660

 senna, p. 661

 Key drug

*Full generic name is given in parentheses. For the purposes of this text, the more common, shortened name is used.

OVERVIEW

Diarrhea is the second leading cause of death in children under the age of 5 and is responsible for 525 000 deaths yearly. According to the WHO (2017), there are approximately 1.7 billion cases of childhood diarrheal disease, which is a leading cause of malnutrition. An average adult will experience diarrhea four times per year (Wanke, 2015).

Clostridium difficile is the most notable cause of health care-associated (acute or chronic) diarrhea and is becoming increasingly recognized as a community pathogen that is a significant threat. It is not discussed in this chapter as it is not treated with antidiarrheal drugs or laxatives. The key symptoms of GI disease are abdominal pain, nausea and vomiting, and diarrhea. **Diarrhea** is defined as the passage of stools with abnormally increased frequency, fluidity, and weight, or increased stool water excretion, and consists of three or more loose or liquid stools per day. Acute diarrhea refers to diarrhea of sudden onset in a previously healthy individual. It usually lasts from 3 days to 2 weeks and is self-limiting, resolving without sequelae. Chronic diarrhea lasts for longer than 3 to 4 weeks and is associated with recurrent passage of diarrheal stools, possible fever, nausea, vomiting, weight reduction, and chronic weakness.

The probable cause of diarrhea needs to be taken into consideration when designing a drug regimen to treat it. Causes of acute diarrhea include drugs, bacteria, viruses, nutritional factors,

and protozoa. Causes of chronic diarrhea include tumours, AIDS, diabetes, Crohn's disease, ulcerative colitis, hyperthyroidism, Addison's disease, and **irritable bowel syndrome (IBS)**. Treatment is aimed at decreasing stool frequency, alleviating abdominal cramps, replenishing fluids and electrolytes, and preventing weight loss and nutritional deficits from malabsorption. Often, replacement of fluids is the only treatment needed. Patients with diarrhea associated with a bacterial or parasitic infection must not use antidiarrheal drugs, because this will cause the organism to stay in the body longer and delay recovery.

ANTIDIARRHEALS

Drugs used to treat diarrhea are called **antidiarrheal drugs**. Based on their specific mechanisms of action, they are divided into different groups: adsorbents, antimotility drugs (anticholinergics and opiates), and probiotics (also known as intestinal flora modifiers and bacterial replacement drugs). These classes and the drugs in each class are listed in **Table 40.1**. Antidiarrheal and laxative drugs do not have the classic pharmacokinetics of other drugs, and thus pharmacokinetics tables such as those presented throughout the book are not included in this chapter.

Mechanism of Action and Drug Effects

Antidiarrheal drugs have various mechanisms of action. Adsorbents act by coating the walls of the GI tract. They bind the causative contaminant to their adsorbent surface for elimination from the body through the stool. Adsorption is similar to absorption but differs in that it involves the chemical binding of substances (e.g., ions, bacterial toxins) onto the surface of an adsorbent. In contrast, *absorption* generally refers to the penetration of a substance into the interior structure of the absorbent or the uptake of a substance across a surface (e.g., the absorption of dietary nutrients into the intestinal villi). The adsorbent bismuth subsalicylate is a form of aspirin, or acetylsalicylic acid, and therefore it also has many of the same drug effects as aspirin (see **Chapter 49**). Activated charcoal is not only helpful in coating the walls of the GI tract and adsorbing bacteria but is also useful in cases of overdose because of its drug-binding properties. Activated charcoal should be used only under the supervision of a health care provider. The antilipemic drugs colestipol and cholestyramine (see **Chapter 28**) are anion exchange resins that are sometimes prescribed as antidiarrheal adsorbents and lipid-lowering drugs. Besides binding to diarrhea-causing toxins, they have the additional benefit of decreasing cholesterol levels.

Anticholinergic drugs work to slow peristalsis by reducing the rhythmic contractions and smooth muscle tone of the GI tract; they also have a drying effect and reduce gastric secretions. They are often used in combination with adsorbents and opiates (see later in the chapter). Anticholinergics are discussed in detail in **Chapter 22**. Probiotics are products obtained from bacterial cultures, most commonly *Lactobacillus* organisms, which make up the majority of the body's normal bacterial flora. These organisms are commonly destroyed by antibiotics. Probiotics work by replenishing these bacteria, which help to restore the balance of normal flora and suppress the growth of diarrhea-causing bacteria.

The primary action of opiates (see **Chapter 11**) often results in a decrease in bowel motility. A secondary effect of opiates is the reduction of the pain associated with diarrhea by relief of rectal spasms. Because they increase the transit time of food through the GI tract, they permit longer contact of the intestinal contents with the absorptive surface of the bowel, which increases the absorption of water, electrolytes, and other nutrients from the bowel and reduces stool frequency and net volume.

Indications

Antidiarrheal drugs are indicated for the treatment of diarrhea of various types and levels of severity. Adsorbents are more likely to be used in milder cases, whereas anticholinergics and opiates tend to be used in more severe cases. Probiotics are often helpful in patients with antibiotic-induced diarrhea.

Contraindications

Contraindications to the use of antidiarrheals include known drug allergy, diarrhea caused by bacterial or parasitic infection, and any major acute GI condition, such as intestinal obstruction or colitis, unless the drug is ordered by the patient's health care provider after careful consideration of the specific case.

Adverse Effects

The adverse effects of the antidiarrheals are specific to each drug family. Most of these potential effects are minor and not life-threatening. The major adverse effects of specific drugs in each drug class are listed in **Table 40.2**. Probiotics do not have any listed adverse effects.

Interactions

Many drugs are absorbed from the intestines into the bloodstream, where they are delivered to their respective sites of

TABLE 40.1 Antidiarrheals: Drug Categories and Selected Drugs

Category	Antidiarrheal Drugs
Adsorbents	Activated charcoal, aluminum hydroxide, bismuth subsalicylate, cholestyramine, polycarbophil
Anticholinergics	Atropine sulphate, hyoscyamine
Opiates	Opium tincture, paregoric, codeine phosphate, diphenoxylate, loperamide hydrochloride
Probiotics and intestinal flora modifiers	<i>Lactobacillus acidophilus</i> , <i>Lactobacillus GG</i> , <i>Saccharomyces boulardii</i>

TABLE 40.2 Selected Antidiarrheals: Adverse Effects

Drug	Adverse Effects
bismuth subsalicylate	Increased bleeding time, constipation, dark stools, confusion, tinnitus, metallic taste, black tongue
atropine sulphate	Urinary retention, sexual dysfunction, headache, dizziness, anxiety, drowsiness, bradycardia, hypotension, dry skin, flushing, blurred vision
codeine phosphate, diphenoxylate hydrochloride	Drowsiness, dizziness, lethargy, nausea, vomiting, constipation, hypotension, urinary retention, flushing, respiratory depression
loperamide	dizziness, constipation, abdominal cramps and nausea

action. A number of the antidiarrheals have the potential to alter this normal process, by either increasing or decreasing the absorption of these other drugs.

The adsorbents can decrease the effectiveness of many drugs, primarily by decreasing the absorption of certain drugs. Examples include digoxin, quinidine sulphate, and antihyperglycemic drugs. The oral anticoagulant warfarin sodium (see [Chapter 27](#)) is more likely to cause increased bleeding times or bruising when coadministered with adsorbents. This is thought to be because adsorbents bind to vitamin K, which is needed to make certain clotting factors. Vitamin K is synthesized by the normal bacterial flora in the bowel. The toxic effects of methotrexate are more likely to occur when it is given with adsorbents. The therapeutic effects of the anticholinergic antidiarrheals can be decreased by coadministration with antacids. Taking amantadine hydrochloride, tricyclic antidepressants, monoamine oxidase inhibitors, opioids, or antihistamines can result in increased anticholinergic effects when given with anticholinergics. The opiate antidiarrheals have additive central nervous system (CNS) depressant effects if they are given with CNS depressants, alcohol, opioids, sedative-hypnotics, antipsychotics, and skeletal muscle relaxants.

Bismuth subsalicylate can lead to increased bleeding times and bruising when administered with warfarin sodium, aspirin, or other nonsteroidal anti-inflammatory drugs. It can also cause confusion in older adults. Cholestyramine, when administered with glipizide, can result in decreased hypoglycemic effects. It is important not to give any drug within 2 hours before or 2 hours after cholestyramine as it decreases the absorption of that drug.

Dosages

For dosage information of antidiarrheal drugs, refer to the table on p. 657.

DRUG PROFILES

Drug therapy for diarrhea depends on the specific cause of the diarrhea, if it is known. All antidiarrheals are orally administered drugs available as suspensions, tablets, or capsules. Some antidiarrheals are available over the counter, whereas others require a prescription.

Adsorbents

bismuth subsalicylate

Bismuth subsalicylate is a salicylate by chemical structure. Even though it is available over the counter, it must be used with caution in children and adolescents who have or are recovering from chicken pox or influenza because of the risk of Reye's syndrome (see [Special Populations: Children box](#)). It can also cause all the adverse effects associated with an aspirin-based product (see [Chapter 49](#)). Two alarming but harmless effects of bismuth subsalicylate are temporary darkening of the tongue and the stool. Bismuth subsalicylate is available for oral use.

Anticholinergics

The anticholinergic atropine sulphate is used either alone or in combination with other antidiarrheals to slow GI tract motility. These drugs are referred to as *belladonna alkaloids* and are

discussed in [Chapter 22](#). Their safety margin is not as wide as that of many of the other antidiarrheals, because they can cause serious adverse effects if used inappropriately. For this reason, they are available only by prescription.

Opiates

There are three opiate-related antidiarrheal drugs: codeine sulphate, diphenoxylate hydrochloride with atropine sulphate, and loperamide. The only opiate-related antidiarrheal available as an over-the-counter (OTC) medication is loperamide; all others are prescription-only drugs because of the risks of respiratory depression and dependency associated with opiate use.

diphenoxylate hydrochloride with atropine sulphate

Diphenoxylate hydrochloride with atropine sulphate is available as Lomotil®. Diphenoxylate hydrochloride is a synthetic opiate agonist that is structurally similar to meperidine hydrochloride. It acts on the smooth muscle of the intestinal tract, inhibiting GI motility and excessive GI propulsion. It has little or no analgesic activity; however, because it is an opioid, misuse and chemical dependence can occur. Diphenoxylate hydrochloride is combined with subtherapeutic quantities of atropine sulphate to discourage its use as a recreational opiate drug. The amount of atropine sulphate present in the combination is too small to interfere with the conjugated diphenoxylate. When taken in large doses, however, the combination results in extreme anticholinergic effects (e.g., dry mouth, abdominal pain, tachycardia, blurred vision).

Use of the combination of diphenoxylate hydrochloride and atropine sulphate is contraindicated in patients experiencing diarrhea associated with pseudomembranous colitis or toxigenic bacteria. It is available only for oral use.

loperamide hydrochloride

Loperamide hydrochloride (Imodium®) is a synthetic antidiarrheal that is similar to diphenoxylate hydrochloride. The drug binds to opiate receptors in the intestinal wall; consequently, it inhibits the release of acetylcholine and prostaglandins, thereby reducing peristalsis and increasing intestinal transit time. Loperamide increases the tone of the anal sphincter and, in doing so, reduces incontinence and urgency. Therefore, it inhibits both peristalsis in the intestinal wall and intestinal secretion, thereby decreasing the number of stools and their water content. In addition, fluid and electrolyte loss diminishes. Although the drug exhibits many characteristics of the opiate class, physical dependence has not been reported with the use of loperamide. Because of its safety profile, it is the only opiate antidiarrheal drug available as an OTC medication. It is also available as a combination product with the antifatulent simethicone. Loperamide use is contraindicated in patients with severe ulcerative colitis, pseudomembranous colitis, and acute diarrhea associated with *Escherichia coli*.

Probiotics

Probiotics suppress the growth of diarrhea-causing bacteria commonly depleted by antibiotic-associated diarrhea, and re-establish the normal flora that reside in the intestine. Most commonly, they are bacterial cultures of *Lactobacillus* organisms. Probiotics are often referred to as *intestinal flora modifiers*. Their

SPECIAL POPULATIONS: CHILDREN

Antidiarrheal Preparations

- If diarrhea in infants and children is accompanied by fever, malaise, or abdominal pain, contact a health care provider immediately because of the possibility of excessive fluid and electrolyte loss or possible infection. Dehydration and electrolyte loss occur rapidly in children because of their size and sensitivity to loss of fluid volume and electrolytes through the stool.
- Always contact a health care provider or pharmacist for the proper dosage of antidiarrheals if a child is 6 years of age or younger or if there is any doubt as to proper dosing. Never hesitate to contact a health care provider with any concern or question regarding any medication recommended for a child.
- Bismuth subsalicylate is a salicylate by chemical structure; therefore, it is to be used cautiously in children and adolescents who have been or are recovering from chicken pox or influenza because of the potential for Reye's syndrome (see [Chapter 49](#)) and is contraindicated with a allergy to aspirin.
- Immediately report to a health care provider any abdominal distention, abdominal firmness, abdominal pain, or worsening of or lack of improvement in diarrhea 24 to 48 hours after medication administration. Measurement of the amount of diarrhea by the number of soiled diapers or number of stools per day provides important information.
- Antidiarrheal preparations are always to be used cautiously in children. If symptoms persist or dehydration occurs (possibly evidenced by a lack of tears and decreased urine output), contact the health care provider.
- Always assess children and adolescents for the presence of an eating disorder such as bulimia or anorexia due to the use or misuse of laxatives associated with these conditions.

mechanism of action is not completely understood, but their general benefits are suppression of growth or invasion by pathogenic bacteria, improvement of intestinal barrier function, modulation of the immune system, and modulation of pain perception.

Lactobacillus

The main types of probiotics in foods and supplements are *Lactobacillus* and *Bifidobacteria*. Most products are a combination of acid-producing bacteria prepared in a concentrated, dried culture for oral administration. They are normal inhabitants of the GI tract where, through the fermentation of carbohydrates (which produces lactic acid), they create an unfavourable environment for the overgrowth of harmful fungi and bacteria. *Lactobacillus acidophilus* has been used for more than 75 years for the treatment of uncomplicated diarrhea, particularly that caused by antibiotic therapy that destroys normal intestinal flora. Another commonly used probiotic is *Saccharomyces boulardii*.

LAXATIVES

Laxatives are used for the treatment of **constipation**, which is defined as abnormally infrequent and difficult passage of feces through the lower GI tract. Constipation is a symptom, not a disease; it is a disorder of movement through the colon or rectum that can be caused by a variety of diseases, drugs, or lifestyles. Some of the more common causes of constipation are noted in [Table 40.3](#).

Dosages

Selected Antidiarrheal Drugs

Drug	Pharmacological Class	Usual Dosage Range	Onset of Action
bismuth subsalicylate (Bismuth®, Pepto-Bismol®)	Antimicrobial, antidiarrheal	Doses repeated q30–60 min, not to exceed 8/day; all doses PO <i>Children 3–5 yr*</i> 5 mL or 1/3 tab <i>Children 6–9 yr*</i> 10 mL or 2/3 tab <i>Children 10–12 yr*</i> 15 mL or 1 tab <i>Adults</i> 30 mL or 2 tab	0.5–2 hr
diphenoxylate hydrochloride with atropine sulphate (Lomotil)	Antidiarrheal	<i>Children 4–12 yr</i> PO: 0.3–0.4 mg/kg daily, divided tid–qid <i>Adults</i> PO: 5 mg QID until diarrhea controlled then lowest effective dose (maximum 20 mg diphenoxylate/day)	40–60 min
<i>Lactobacillus acidophilus</i>	Probiotic, dietary supplement	<i>Adults and children over 12 yr</i> PO: 1 cap bid	Unknown
loperamide hydrochloride (Imodium)	Opiate antidiarrheal	<i>Children 2–5 yr</i> PO: 1 mg TID <i>Children 6–12 yr</i> PO: 2 mg bid–tid <i>Adults and children over 12 yr</i> PO: 4 mg followed by 2 mg after each bowel movement (not to exceed 16 mg/day)	1–3 hr

PO, Oral.

*Used with caution in children and teenagers who have or are recovering from chicken pox or influenza because of the risk of Reye's syndrome.

The GI tract is responsible for the digestive process, which involves: (1) ingestion of dietary intake, (2) digestion of dietary intake into basic nutrients, (3) absorption of basic nutrients, and (4) storage and removal of fecal material via defecation (Figure 40.1).

Ingestion→Digestion→Absorption
→Storage and removal

The usual time span between ingestion and defecation is 24 to 36 hours. The last segment of the GI tract, the large intestine (colon), is responsible for: (1) forming the stool by removing excess water from the fecal material, (2) temporarily storing the stool until defecation, and (3) extracting essential vitamins

from the intestinal bacteria (particularly vitamin K). The type of stool depends on the time it spends in the colon and reflects diet, amount of fluid intake, medications, and activity. A common approach to determining the quality of the stool is the use of a stool chart. The colon is 120 to 150 cm long and is separated from the small intestine by the ileocecal valve. The colon extends into the rectum, which terminates at the anus. The rectum is the temporary storage site for the stool, which is composed of water and unabsorbed and indigestible material. Evacuation of the rectal contents is accomplished by bowel movements.

A bowel movement (defecation) is a reflex act that involves both smooth and skeletal muscles. The entry of feces into the rectum stimulates mass peristaltic movement that results in a bowel movement. However, voluntary initiation or inhibition of defecation is also possible via skeletal muscle pathways. Treatment of constipation is individualized, with consideration of the patient's age, concerns, and expectations; duration and severity of constipation; and potential contributing factors. Treatment can be either surgical (this is rare and is limited to extreme cases such as exploratory laparoscopy or bowel resection) or nonsurgical. Nonsurgical treatments can be separated into three broad approaches: dietary (e.g., fibre supplementation), behavioural (e.g., increased physical activity), and pharmacological. The focus in this chapter is on pharmacological treatment. Laxatives are among the most misused OTC medications. Long-term and often inappropriate use of stimulant laxatives may result in laxative dependence, produce damage to the bowel, or lead to previously nonexistent intestinal problems. Apart from the bulk-forming type, laxatives are not to be used for long periods. Based on their mechanisms of action, laxatives are divided into five major groups: bulk-forming, emollient, hyperosmotic, saline, and stimulant. Table 40.4 lists the currently available laxative drugs categorized by drug family. The onset of action of

TABLE 40.3 Causes of Constipation	
Causes	Examples
Adverse drug effects	Analgesics, anticholinergics, iron supplements, aluminum antacids, calcium antacids, opiates, calcium channel blockers
Lifestyle	Poor bowel movement habits: voluntary refusal to defecate resulting in constipation Diet: poor fluid intake and low-fibre diet or excessive consumption of dairy products Physical inactivity: lack of proper exercise, especially in older adults Psychological factors: anxiety, stress, hypochondria
Metabolic and endocrine disorders or conditions	Diabetes mellitus, hypothyroidism, hypercalcemia, hypokalemia, pregnancy
Neurogenic disorders	Autonomic neuropathy, intestinal pseudo-obstruction, multiple sclerosis, spinal cord lesions, Parkinson's disease, stroke

Fig. 40.1 The digestive system. (Source: Patton, K. T., & Thibodeau, G. A. (2014). *Mosby's Handbook of Anatomy and Physiology* (2nd ed.; p. 478). St. Louis, MO: Mosby.)

TABLE 40.4 Laxatives: Drug Categories and Selected Drugs

Category	Laxative Drugs
Bulk forming	psyllium, methylcellulose
Emollient	docusate sodium, mineral oil
Hyperosmotic	polyethylene glycol, lactulose, sorbitol, glycerin
Saline	magnesium sulphate, magnesium phosphate, magnesium citrate
Stimulant	senna, bisacodyl

laxatives is the most important pharmacokinetic feature of these drugs and is listed in the Dosages table on p. 662.

Mechanism of Action and Drug Effects

All laxatives promote bowel movements, but each class of laxative has a different mechanism of action. Laxatives may act by: (1) affecting fecal consistency, (2) increasing fecal movement through the colon, or (3) facilitating defecation through the rectum. Bulk-forming laxatives act in a manner similar to that of the fibre naturally contained in the diet. They absorb water into the intestine, which increases bulk and distends the bowel to initiate reflex bowel activity, thus promoting a bowel movement.

Emollient laxatives are also referred to as *stool softeners* (docusate sodium) and lubricant laxatives (mineral oil). Fecal softeners work by lowering the surface tension of GI fluids, so that more water and fat are absorbed into the stool and the intestines. The lubricant type of emollient laxatives works by lubricating the fecal material and the intestinal wall and preventing absorption of water from the intestines. Instead of being absorbed, this water content in the bowel softens and expands the stool. This promotes bowel distension and reflex peristaltic actions, which ultimately lead to defecation.

Hyperosmotic laxatives work by increasing fecal water content, which results in distention, increased peristalsis, and evacuation. Their site of action is limited to the large intestine. *Saline laxatives* increase osmotic pressure in the small intestine by inhibiting water absorption and increasing both water and electrolyte (salt) secretions from the bowel wall into the bowel lumen. This results in watery stool. Increased distention promotes peristalsis and evacuation. Rectal enemas of sodium phosphate, a saline laxative, produce defecation 2 to 5 minutes after administration.

As the name implies, *stimulant laxatives* stimulate the nerves that innervate the intestines, which results in increased peristalsis. They also increase fluid in the colon, which increases bulk and softens the stool. [Table 40.5](#) summarizes the specific drug effects of the different classes of laxatives.

In 2009, a new class of drugs was approved for the treatment of specific types of constipation as a result of opioid use and bowel resection surgery. These peripherally acting opioid antagonists include methylnaltrexone bromide (Relistor®) and alvimopan (Entereg®). These drugs block entrance of an opioid drug into the bowel cells, thus allowing bowels to function normally, even with continued opioid use. Methylnaltrexone bromide is approved only for advanced illness in palliative patients who have opioid-induced constipation. It is available only as an injection and is given once a

TABLE 40.5 Laxatives: Drug Effects

Drug Effect	Bulk	Emollient	Hyperosmotic	Saline	Stimulant
Increases peristalsis	Y	Y	Y	Y	Y
Causes increased secretion of water and electrolytes in small bowel	Y	Y	N	Y	Y
Inhibits absorption of water in small bowel	Y	Y	N	Y	Y
Increases wall permeability in small bowel	N	Y	N	N	Y
Acts only in large bowel	N	N	Y	N	N
Increases water in fecal mass	Y	Y	Y	Y	Y
Softens fecal mass	Y	Y	Y	Y	Y

day. Alvimopan is indicated to accelerate GI recovery time following partial large or small bowel resection surgery. Alvimopan has yet to be approved by Health Canada; however, it can be accessed through the Special Access Programme in some jurisdictions.

Indications

The following are some of the more common uses of laxatives:

- Facilitation of bowel movements in patients with inactive colon or anorectal disorders
- Reduction of ammonia absorption in hepatic encephalopathic conditions (lactulose only)
- Treatment of drug-induced constipation
- Treatment of constipation associated with pregnancy or the postobstetric period
- Treatment of constipation caused by reduced physical activity or poor dietary habits
- Removal of toxic substances from the body
- Facilitation of defecation in megacolon
- Preparation for colonic diagnostic procedures (e.g., colonoscopy) or surgery (e.g., bowel resection)

See [Table 40.6](#) for specific therapeutic indications for each laxative drug class.

Contraindications

All categories of laxatives share the same general contraindications and precautions, including avoidance in the case of drug allergy and the need for cautious use in the presence of the following: acute surgical abdomen; appendicitis symptoms such as abdominal pain, nausea, and vomiting; fecal impaction (mineral oil enemas excepted); intestinal obstruction; as a weight loss aid; eating disorders, and undiagnosed abdominal pain.

TABLE 40.6 Laxatives: Indications

Category	Indication
Bulk forming	Acute and chronic constipation, irritable bowel syndrome, diverticulosis
Emollient	Acute and chronic constipation, fecal impaction, anorectal conditions requiring facilitation of bowel movements
Hyperosmotic	Chronic constipation, bowel preparation for diagnostic and surgical procedures
Saline	Constipation, bowel preparation for diagnostic and surgical procedures
Stimulant	Acute constipation, bowel preparation for diagnostic and surgical procedures

TABLE 40.7 Laxatives: Adverse Effects

Category	Adverse Effects
Bulk forming	Impaction above strictures, fluid disturbances, electrolyte imbalances, gas formation, esophageal blockage, allergic reaction
Emollient	Skin rashes, decreased absorption of vitamins, lipid pneumonia, electrolyte imbalances
Hyperosmotic	Abdominal bloating, rectal irritation, electrolyte imbalances
Saline	Magnesium toxicity (with kidney insufficiency), electrolyte imbalances, cramping, diarrhea, increased thirst
Stimulant	Nutrient malabsorption, skin rashes, gastric irritation, electrolyte imbalances, discoloured urine, rectal irritation

Adverse Effects

The adverse effects of the various laxative drugs are specific to each group. Most of the adverse effects from laxatives are confined to the intestine; however, the overuse and misuse of laxatives can lead to many unwanted effects that are not expected or designed to occur with appropriate use. The major adverse effects of the laxative drugs are listed in Table 40.7. In addition, laxative dependency may occur when the colon stops reacting to usual doses of laxatives and larger amounts of laxatives are needed to produce bowel movements. Other serious effects may be a stretched or “lazy” colon, colon infection, and irritable bowel syndrome.

Interactions

Laxatives alter intestinal function; therefore, they can interact with other drugs, because many drugs are absorbed in the intestines. Bulk-forming laxatives can decrease the absorption of antibiotics, digoxin, salicylates, tetracyclines, and warfarin sodium. Mineral oil can decrease the absorption of fat-soluble vitamins (A, D, E, and K). Hyperosmotic laxatives can cause increased CNS depression if they are given with barbiturates, general anaesthetics, opioids, or antipsychotics. Oral antibiotics can decrease the effects of lactulose. Stimulant laxatives decrease the absorption of antibiotics, digoxin, nitrofurantoin, salicylates, tetracyclines, and oral anticoagulants.

Dosages

For dosage information on selected laxatives, refer to the table on p. 662.

DRUG PROFILES

Laxatives are used for the treatment of constipation. Such treatment must involve an understanding of the whole patient. Many drugs in the five major groups of laxatives are available as OTC medications, whereas others require a prescription for use. The following profiles describe the prototypical drugs in each of the laxative groups.

Bulk-Forming Laxatives

Bulk-forming laxatives are composed of water-retaining (hydrophilic) natural and synthetic cellulose derivatives. Psyllium is an example of a natural bulk-forming laxative, and methylcellulose is an example of a synthetic cellulose derivative. Bulk-forming drugs increase water absorption, which results in greater total volume (bulk) of the intestinal contents. Bulk-forming laxatives tend to produce normal, formed stools. Their action is limited to the GI tract, so they cause few, if any, systemic effects. However, they need to be taken with liberal amounts of water to prevent esophageal obstruction and fecal impaction. Bulk-forming laxatives are all obtainable over the counter, are among the safest laxatives, and are the only ones that are recommended for long-term use.

methylcellulose

Methylcellulose is a synthetic bulk-forming laxative that attracts water into the intestine and absorbs excess water into the stool, stimulating the intestines and increasing peristalsis. Specific contraindications include GI obstruction and hepatitis. Methylcellulose is an oral drug available in powdered form that provides approximately 2 g of fibre per heaping tablespoon.

psyllium hydrophilic mucilloid

Psyllium hydrophilic mucilloid (Metamucil Preparations®) is a natural bulk-forming laxative obtained from the dried seed of the *Plantago psyllium* plant. It has many of the characteristics of methylcellulose. Psyllium is contraindicated in patients with intestinal obstruction or fecal impaction. Its use is also contraindicated in patients experiencing abdominal pain or nausea and vomiting. Psyllium is available for oral use in powder form.

Emollient Laxatives

Emollient laxatives either directly lubricate the stool and the intestines, as with mineral oil, or act as fecal softeners. By lubricating the fecal material and the intestinal walls, lubricant emollient laxatives prevent water from moving out of the intestines, which softens and expands the stool. Stool softeners (docusate sodium) work by lowering the surface tension of fluids, which allows more water and fat to be absorbed into the stool and the intestines.

docusate sodium

Docusate sodium (Colace®) is a stool-softening emollient laxative that facilitates the passage of water and fats into the fecal mass, which softens the stool. This drug is used to treat constipation, soften fecal impactions, and facilitate easy bowel movements in patients with hemorrhoids and other painful anorectal conditions. They do not cause patients to defecate; they simply soften the stool to ease its passage. Docusate sodium use is contraindicated in patients with intestinal obstruction, fecal impaction, or nausea and vomiting. Please note that Docusate is overall not

therapeutically effective and has been taken off of most hospital formularies. It is still prescribed in community settings.

mineral oil

Mineral oil eases the passage of stool by lubricating the intestines and preventing water from escaping the stool. Mineral oil is the only lubricant laxative in the emollient category. It is a mixture of liquid hydrocarbons derived from petroleum and is most commonly used to treat constipation associated with hard stools or fecal impaction.

Mineral oil use is contraindicated in patients with intestinal obstruction, abdominal pain, or nausea and vomiting. Mineral oil products are available for oral administration and as enemas. Overall, mineral oil is not recommended due to chance of aspiration and lipoid pneumonia.

Hyperosmotic Laxatives

The hyperosmotic laxatives glycerin, lactulose, sorbitol, and polyethylene glycol (PEG) relieve constipation by increasing the water content of feces, which results in distention, peristalsis, and evacuation. They are most commonly used to treat constipation and to evacuate the bowels before diagnostic and surgical procedures.

glycerin

Glycerin promotes bowel movements by increasing osmotic pressure in the intestine, which draws fluid into the colon. Because it is a mild laxative, it is often used in children. Glycerin has properties similar to those of sorbitol, another hyperosmotic laxative. Glycerin use is contraindicated in patients who have shown a hypersensitivity reaction to it. It is available as rectal suppositories for both adults and children.

lactulose

Lactulose is a synthetic derivative of the natural sugar lactose, which is not digested in the stomach or absorbed in the small bowel. It passes unchanged into the large intestine, where it is metabolized. Colonic bacteria digest lactulose to produce lactic acid, formic acid, and acetic acid; this process creates a hyperosmotic environment that draws water into the colon and produces a laxative effect. This drug-induced acidic environment also reduces blood ammonia levels by converting ammonia to ammonium. Ammonium is a water-soluble cation that is trapped in the intestines and cannot be reabsorbed into the systemic circulation. This effect has proved helpful in reducing serum ammonia levels in patients with hepatic encephalopathy. Lactulose use is contraindicated in patients on a low-galactose diet. It is available as a solution for either oral or rectal use.

polyethylene glycol 3350

Polyethylene glycol (PEG 3350[®]) is most commonly used before diagnostic or surgical bowel procedures, because it is a potent laxative that induces total cleansing of the bowel. The 3350 designation refers to the osmolality of the drug. It is usually available in a powdered dosage form that contains a balanced mixture of electrolytes that also helps stimulate bowel evacuation (e.g., Clearlax[®], Colyte[®], Klean-Prep[®], Pegalax[®], PEGLYTE[®], Restoralax[®]). The powder is reconstituted in a large volume of fluid (4 L) that is then gradually drunk by the patient on the

afternoon of the day before the procedure. Use of PEG is contraindicated in patients with GI obstruction, gastric retention, bowel perforation, toxic colitis, toxic megacolon, or ileus.

Diarrhea usually occurs within 30 to 60 minutes after ingestion; complete evacuation and cleansing of the bowel is accomplished within 4 hours. MiraLax[®] is a PEG 3350 product that is available over the counter and can be used daily for constipation in much smaller amounts than those used for total bowel cleansing.

Saline Laxatives

Saline laxatives consist of various magnesium or sodium salts. They increase osmotic pressure and draw water into the colon, producing a watery stool, usually within 3 to 6 hours of ingestion. Oral sodium phosphate-containing products used for bowel evacuation, such as Fleet Phospho-Soda[®], were taken off the market because of concerns about acute phosphate nephropathy.

magnesium hydroxide

The magnesium saline laxative magnesium hydroxide (Phillips' Milk of Magnesia[®]) is an unpleasant-tasting OTC laxative preparation. It is to be used with caution in patients with kidney insufficiency because it can be absorbed enough to cause hypermagnesemia. It is most commonly used to evacuate the bowel rapidly in preparation for endoscopic examination and to help remove unabsorbed poisons from the GI tract.

Use of magnesium hydroxide is contraindicated in patients with kidney disease, abdominal pain, nausea and vomiting, obstruction, acute surgical abdomen, or rectal bleeding. Magnesium hydroxide is available in oral liquid and tablet forms. It is also found in a variety of combination products, such as Dioval[®], Maalox[®], and Pepcid Complete[®]. Other magnesium products are listed in the discussion of saline laxatives earlier in this chapter. Note that magnesium *oxide* is used as a supplement, not as a laxative (see [Chapter 9](#)).

Stimulant Laxatives

Stimulant laxatives induce intestinal peristalsis. In the past, several different stimulant laxatives were available; bisacodyl (Dulcolax[®]) and senna (Senokot[®]) are the remaining stimulants. Their site of action is the entire GI tract. The action of the stimulant laxatives is proportional to the dose. The stimulant class is the most likely of all laxative classes to cause dependence.

bisacodyl

Bisacodyl (Dulcolax) is the most commonly used stimulant laxative. It is available as an oral tablet and rectal suppository. It is used for constipation or for whole bowel evacuation prior to endoscopic examination. It is available over the counter.

senna

Senna (Senokot) is a commonly used OTC stimulant laxative. Senna is obtained from the dried leaves of the *Cassia acutifolia* plant. It may be used for relief of acute constipation or for bowel preparation for surgery or examination. Because of its stimulating action on the GI tract, it may cause abdominal pain. It can produce complete bowel evacuation in 6 to 12 hours. Senna is available orally as tablets and syrup. One product, Senokot-S[®], includes both senna and the stool softener docusate sodium.

Dosages

Selected Laxatives

Drug	Pharmacological Class	Usual Dosage Range	Onset of Action
bisacodyl (Dulcolax)	Stimulant laxative	<i>Children 6–12 yr</i> PO: 5 mg PR: 5 mg suppository <i>Adults and children over 12 yr</i> PO: 5–10 mg PR: 10 mg suppository	Oral: 6–12 hr Rectal: 15–60 min
docusate sodium (Colace)	Stool softener, emollient laxative	<i>Children 3–12 yr*</i> PO: 20–120 mg/day divided <i>Adults</i> PO: 100–200 mg/day divided	1–3 days
glycerin (Glycerin Suppository®)	Hyperosmotic laxative	<i>Children and adults</i> PR only: Insert one adult, child, or infant suppository PR daily–bid prn; attempt to retain 15–30 min; suppository does not have to melt to induce BM	15–30 min
—	Disaccharide, hyperosmotic laxative	<i>Adults†</i> PO: 15–60 mL daily	24 hr
methylcellulose	Bulk-forming laxative	<i>Children 6–11 yr</i> ½ dose of that for adults and children over 12 yr <i>Adults and children over 12 yr</i> PO: 1 heaping teaspoon in 240 mL cold water daily–tid	12–24 hr
polyethylene glycol (Klean-Prep, Pegalax)	Hyperosmolar laxative	<i>Adults</i> PO: 4 L solution, usually evening before procedure; patient needs to fast at least 4 hr before drinking solution	1 hr
psyllium hydrophilic mucilloid (Metamucil Preparations)	Bulk-forming laxative	<i>Children 6–11 yr</i> ½ rounded tsp in water daily–tid <i>Children 12 yr and older/Adult</i> PO: 1 rounded tsp in 240 mL water or juice daily–tid	12–24 hr
senna (Senokot)	Stimulant-irritant laxative	<i>Children 2–5 yr†</i> PO: 2–5 mL at bedtime (max 2.5 mL bid) <i>Children 6–11 yr‡</i> PO (tabs): 1 tab daily (max 2 tabs bid) PO (liquid): 7.5–10 mL daily (max 5 mL bid) <i>Adults and children 12 yr and older</i> PO (tabs): 2–4 tabs daily (max 4 tabs bid) PO (syrup): 15 mL daily (max 30 mL bid)	6–24 hr

PO, oral; PR, rectal.

*Docusate sodium is available in both capsule and liquid forms.

†Rectal route is sometimes used to reverse hepatic coma.

‡There are many dosage forms; consult product labelling if in doubt. Most common dosage forms consist of 187 mg senna in tablet form and 1.7 mg/mL of sennosides in liquid form.

❖ NURSING PROCESS

◆ ASSESSMENT

Before administering antidiarrheal preparations, obtain a thorough history and perform an assessment of bowel patterns, general state of health, any recent illness, and any dietary changes. In the abdominal assessment, include auscultation of bowel sounds in all four quadrants *after* inspection of the entire abdomen but *before* percussion and palpation. Performing auscultation and inspection before percussion prevents any possible stimulation of peristalsis or bowel sounds that would not have otherwise occurred. When the frequency of bowel sounds ranges from 6 to 32 per minute, it is important to describe exactly what is heard and the amount of activity in each of the four quadrants. Terms such as *high-pitched*, *low-pitched*, *gurgling*, or *tinkling* may be used to describe the character or the sounds, whereas activity may be described as *hypoactive* (less than 6 sounds per minute), *normoactive* (between 6 and 32 sounds per minute), or *hyperactive* (more than the normal range). Bowel sounds may also be absent. Perform a thorough abdominal assessment for any patient with GI concerns, including altered bowel status. Note the presence of tenderness, rigidity, changes in contour, bulges, and obvious peristaltic waves across the abdomen. Assess frequency, consistency, amount, colour, and odour (if present) of stools, and document the findings. In addition, it is critical to patient safety and health to be sure that the possibility of *Clostridium difficile* infection or other infectious diarrhea is ruled out. Assess for and document any contraindications, cautions, and drug interactions for all drugs. Report abdominal pain, bloody stools, confirmation of hypoactive to no bowel sounds, or fever to the health care provider immediately. When administering diphenoxylate hydrochloride with atropine sulphate, be wary of overuse because large amounts may result in dry mouth, abdominal pain, tachycardia, and blurred vision. Older adults are more susceptible to fluid and electrolyte depletion associated with diarrhea; therefore, closely assess hydration status for such patients.

Laxative use requires further assessment in addition to the abdominal assessment and bowel pattern history described earlier. For example, focus questions on changes in bowel habits, long-term use of laxatives (because patients may become laxative dependent), and dietary and fluid intake. Assess vital signs, daily weights, intake and output, and fluid and electrolyte levels, and note the presence of any weakness because of the possibility of hypotension and volume or electrolyte depletion (with long-term laxative use). Another important area to assess is that of laxative misuse in older adults as well as in children and adolescents. Specifically, in children and adolescents, assess for eating disorders with concurrent use of laxatives.

The type of laxative and its related mechanism of action dictate specific assessments because of differences in how strongly patients react to the various laxative drugs. Bulk-forming laxatives are often used to treat chronic constipation and have few adverse effects, but a basic abdominal and bowel pattern assessment and related history taking are still needed. Always assess and document contraindications, cautions, and drug interactions.

Prior to the use of hyperosmotic laxatives (e.g., polyethylene glycol, lactulose, sorbitol, glycerin), assess baseline fluid and electrolyte levels to identify any deficits. All of the previously mentioned assessment measures regarding abdominal examination and bowel patterns are also appropriate for these drugs, with additional assessment for the presence of abdominal pain, the degree of peristalsis, and any history of recent abdominal surgery, nausea, vomiting, or weight loss. Older adults react more adversely to hyperosmotic laxatives, so their use in this group is to be avoided.

Saline laxatives (e.g., magnesium hydroxide) are to be used with caution in older adults because of possible dehydration and electrolyte loss. These drugs may also cause magnesium toxicity in those with compromised renal status. Kidney function studies are important to assess in those at risk. Senna and bisacodyl are examples of stimulant laxatives. They may also cause electrolyte imbalances, so baseline electrolyte levels are important to assess and monitor.

◆ NURSING DIAGNOSES

- Constipation as a result of improper or inadequate diet
- Diarrhea as a result of GI irritation from food, bacteria, viruses, or pathology
- Deficit fluid volume due to loss of fluids and electrolytes caused by frequent, loose stools
- Decreased skin integrity caused by frequent, loose stools
- Nutritional deficit due to inadequate dietary intake and loss of appetite

◆ PLANNING

◆ Goals

- Patient will experience minimal constipation.
- Patient will experience minimal diarrhea.
- Patient will remain free from fluid and electrolyte disturbances resulting from changes in bowel patterns and lack of proper management of bowel alterations.

◆ Expected Patient Outcomes

- Patient states measures to manage or prevent constipation such as increasing intake of fluids to 2 to 3 L per day, increasing intake of bulk and fibre (unless contraindicated), and increasing physical activity.
- Patient takes recommended bulk-forming laxatives, stool softeners, as well as other approved laxatives, as prescribed, and follows directions closely.
- Patient states measures to manage and prevent diarrhea such as increasing bulk; avoiding spicy, irritating foods and beverages; and avoiding caffeine.
- Patient takes recommended antidiarrheal preparation as prescribed and instructed, with close attention to following directions on the medication.
- Patient reports to the health care provider any signs and symptoms of fluid and electrolyte loss, such as weakness, lethargy, decreased urinary output, or dizziness.
- Patient implements measures to prevent fluid and electrolyte loss, including nonpharmacological and pharmacological therapies (see above).

◆ IMPLEMENTATION

An effective and well-tolerated bowel protocol is an important component of care. Many agencies have developed specific protocols, requiring the least possible amount of intervention, that may be individualized for specific patients (e.g., increased fibre and fluid intake, rectal stimulation, establishing a daily predictable bowel care time, etc.) followed by pharmacological intervention.

Prior to the use of antidiarrheals, educate patients that the drugs must be taken *exactly* as directions indicate, with strict adherence to the recommended dose, frequency, and duration of treatment. Encourage patients to be aware of fluid intake and any dietary changes that would impact their health status or possibly exacerbate present symptoms. Instruct patients to be aware of the factors precipitating the diarrhea and, if symptoms persist, to contact their health care provider. Document any changes in bowel patterns, weight, intake and output, fluid volume, and mucous membrane status during and after the initiation of treatment, whether for constipation or diarrhea. Inform the patient that bismuth subsalicylate must be taken as directed and that this medication will turn the stool black or grey. If tablets are used, they must be chewed thoroughly before swallowing and with at least 180 mL of fluid. Bismuth subsalicylate is a salicylate-based product and is not to be taken with other salicylates to avoid the risk of toxicity. Encourage parents to check with their children's health care provider before giving bismuth subsalicylate to a child or adolescent with a viral infection, such as chicken pox or influenza, because of the potential for Reye's syndrome (see the Special Populations: Children box).

Diphenoxylate hydrochloride and loperamide may be given without regard to food intake but must be given with adequate fluid. Additionally, advise patients to follow the provided specific directions (e.g., the specific number of tablets recommended by the manufacturer after the first loose stool and the total number of tablets to be taken within a 24-hour period). Maximum amounts are not to be exceeded, and if diarrhea continues or other symptoms occur (e.g., fever, abdominal pain, bloody stools), instruct patients to contact a health care provider immediately. See Patient Teaching Tips for more information.

Probiotics may be recommended for a variety of altered bowel elimination patterns, whether diarrhea or constipation. Probiotics are available in foods and dietary supplements as well as in capsules, tablets, and powder dosage forms. Most of the probiotics are derived from *Lactobacillus* or *Bifidobacterium* bacteria. It is important to educate patients about probiotics and to emphasize their health benefits when administered in the proper amounts. Tell patients to take probiotics exactly as directed. Foods that contain probiotics include yogourt, fermented milk, miso, tempeh, and some juices and soy beverages. Bulk-forming laxatives such as methylcellulose must be administered as specified by the package insert, or as ordered. Methylcellulose is to be taken with at least 240 mL of liquid after the powder form has been thoroughly stirred into it. The fluid must be taken immediately because of a congealing effect; to

avoid choking or swelling of the product in the throat or esophagus, the patient must swallow or receive the drug immediately upon stirring. The medication must never be taken or administered in its dry form. See the Patient Teaching Tips for more information.

Docusate sodium is available in a variety of oral dosage forms (e.g., capsules, tablets, syrups, elixir), and it is recommended to be taken with at least 180 mL of water or other fluid. An additional 1 800 mL to 2 400 mL of water per day is also suggested to help with stool softening. Bisacodyl, if ordered, is best taken on an empty stomach for faster action, and whole tablets must not be chewed or crushed. Advise the patient not to consume milk, antacids, or juices with the dose or within 1 hour of taking the medication. Rectal suppositories, if too soft, may be placed in a medicine cup with ice to harden before insertion. Once the wrapper is removed, apply a water-soluble lubricant to the suppository prior to insertion into the rectum. Use a glove or finger cot on the hand for insertion. For maximal effectiveness, encourage the patient to try to keep the suppository in place by lying still on the left side for at least 15 to 30 minutes to allow the drug to dissolve. Lactulose may be taken with juice, milk, or water to increase palatability. It is important to note that the normal colour of the oral solution is pale yellow. Administer rectal dosage forms as a retention enema with dilution as ordered and instruct the patient to retain for 30 to 60 minutes. For proper insertion of a retention enema, lubricate the tip of the apparatus well and insert it carefully with the nozzle pointed toward the umbilicus of the patient, with the patient lying on the left side. Release the fluid gradually and discontinue administration if the patient experiences severe abdominal pain. If long-term use of the drug is indicated, monitoring of serum electrolyte levels is needed.

Magnesium-based laxatives are generally used only in certain situations because they are potent. Encourage intake of fluids and follow other instructions per the health care provider's order or the package instructions. Refrigeration may help increase the palatability of the oral solution. Emphasize the importance of taking these drugs exactly as prescribed for constipation, with consumption of a sufficient quantity of fluids and careful attention to adverse effects. Instruct the patient to mix a PEG-electrolyte solution with water or flavoured sports drink as directed and to shake well before drinking. Chilled solutions are tolerated better. Rapid drinking of each dose is recommended.

◆ EVALUATION

Therapeutic responses to any of the described medications include an improvement in the GI-related signs and symptoms reported by the patient (e.g., decrease in diarrhea or constipation), return to normal bowel patterns with normal bowel sounds, and absence of abnormal findings from an assessment of the abdomen and bowel patterns. Adverse effects for which to monitor patients vary according to each drug. Use goals and outcome criteria as a means to evaluate the collaborative plan of care related to each problem, whether constipation or diarrhea or both.

CASE STUDY

Long-Term Laxative Use

Gail is a 66-year-old retired teacher. She enjoys good health and exercises three times a week with a senior citizens' group in a supervised arthritis swim class at the local recreation centre. She arrives at the family practice office with reports of "constipation" and says that for the past 3 months she has had only one bowel movement every 3 days instead of one every day. In the assessment of this patient, the nurse discovers that Gail has been taking a stimulant laxative up to twice a day and is now

also feeling "weak." Gail also says that she is experiencing "a lot of tummy cramping."

1. What are at least five questions the nurse should ask Gail? Provide reasons for each question.
2. What types of problems are generally as a result of long-term use of laxatives? Explain your answer.
3. What are some nonpharmacological ways Gail could prevent constipation?
4. What OTC drug is the best choice to help prevent constipation for Gail? Explain your answer.

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

PATIENT TEACHING TIPS

- Instruct patients that antidiarrheals are to be taken exactly as prescribed, with close attention to indicated dosages with warnings of overuse.
- Counsel patients to take antidiarrheal drugs with caution when performing tasks that require mental alertness or precise motor skills until it is clear how the drug actually affects them. Advise patients to immediately report to a health care provider any abdominal distention, firmness or hardness of the abdomen, abdominal pain, worsening (or no improvement) of symptoms, rectal bleeding, unrelieved constipation, fever, nausea, vomiting or other GI-related signs and symptoms, dizziness, muscle weakness, or muscle cramping.
- To help patients with the adverse effect of dry mouth, encourage frequent mouth care, increased fluid intake, or the use of sugarless gum or candy.
- Bismuth subsalicylate may turn the stool tarry black, so warn patients that this may happen. Patients must avoid other drugs containing salicylates while taking bismuth subsalicylate. Always check for cautions and contraindications with this drug, especially for children.
- Patients should increase intake of fluids, preferably water, as well as of green leafy vegetables, fruits, whole grains, and other foods high in fibre to help minimize constipation. Exercise is also beneficial.
- Educate patients that what are normal bowel patterns for one person may not be normal for another. Assess previous normal bowel patterns with the patient.
- Keep all antidiarrheals and laxatives out of the reach of children.
- For patients taking powder forms of methylcellulose, emphasize the need to have the powder thoroughly mixed with at least 180 mL of liquid, which is stirred and then consumed immediately to avoid esophageal or throat obstruction.
- Probiotics are available over the counter in various dosages and under different product names. Advise patients to take them exactly as instructed and to be aware that adverse effects are generally not of concern. Cultured yogourt and cultured milk products provide probiotics.
- Inform patients taking senna to avoid other medications within 1 hour of taking it and that it often takes 6 to 12 hours for the laxative effect to occur.

KEY POINTS

- Diarrhea is a leading cause of morbidity and mortality in developing countries.
- Drugs used to treat diarrhea include adsorbents, anticholinergics, and probiotics.
- Most acute diarrhea is self-limiting, subsiding in 3 days to 2 weeks.
- Fluid and electrolyte replacement is vital while a patient is experiencing diarrhea.
- Encourage patients to check and recheck dosage instructions before taking medications and to note any drug–food and drug–drug interactions.
- Anticholinergics work by decreasing GI peristalsis through their parasympathetic blocking effects. Adverse effects include urinary retention, headache, confusion, dry skin, rash, and blurred vision.
- Adsorbents work by coating the walls of the GI tract. They remain in the intestine and bind the causative bacteria or toxin to the adsorbent surface, so that it can be eliminated from the body through the stool. They may increase bleeding and cause constipation, dark stools, and black tongue.
- Probiotics are used to manage diarrhea and consist of bacterial cultures of *Lactobacillus*. They re-establish normal intestinal flora destroyed by infection or antibiotics and suppress the growth of diarrhea-causing bacteria.
- Opiates are used as antidiarrheals and help to decrease bowel motility, thus permitting longer contact of intestinal contents with the absorptive surface of the bowel. Opiates also help reduce the pain associated with rectal spasms.
- Laxatives, especially osmotic medications, may cause fluid and electrolyte loss.
- Alert patients to the misuse potential of laxatives and the problems associated with their misuse as well as laxative dependency issues.
- Stool softeners and bulk-forming drugs are often preferred to other drug classes in the treatment of constipation because they create fewer problems with fluid and electrolyte loss.

EXAMINATION REVIEW QUESTIONS

1. A patient is being prepared for a colonoscopy. The nurse expects which laxative to be used as preparation for this procedure?
 - a. methylcellulose
 - b. docusate sodium
 - c. PEG 3350
 - d. glycerin
2. The nurse is administering oral methylcellulose and keeps in mind that a potential concern with this drug is which of the following?
 - a. Dehydration
 - b. Tarry stools
 - c. Kidney calculi
 - d. Possible obstruction
3. A 45-year-old woman has been diagnosed with irritable bowel syndrome (IBS) and has numerous bowel movements each day. She has been prescribed loperamide. What are the actions of this drug? Select all that apply.
 - a. Reduces the daily fecal volume
 - b. Increases viscosity and bulk of the bowel movements
 - c. Reduces the loss of fluids and electrolytes associated with watery bowel movements
 - d. Cures the disease process by eliminating the infection causing IBS
 - e. Reduces bowel incontinence and urgency
4. When a nurse teaches a patient about taking bisacodyl tablets, which instruction is correct?
 - a. "Take this medication on an empty stomach."
 - b. "Chew the tablet for quicker onset of action."
 - c. "Take this medication with juice or milk."
 - d. "Take this medication with an antacid if it upsets your stomach."
5. A patient has been receiving long-term antibiotic therapy as part of treatment for an infected leg wound. He tells the nurse that he has had "spells of diarrhea" for the past week. Which medication is most appropriate for him at this time?
 - a. bismuth subsalicylate
 - b. *Lactobacillus acidophilus*
 - c. diphenoxylate hydrochloride with atropine sulphate
 - d. codeine sulphate
6. A parent calls to ask about giving a medication for diarrhea to his 12-year-old child, who is recovering from the flu. The nurse expects the health care provider to recommend which medication?
 - a. bismuth subsalicylate
 - b. *Lactobacillus GG*
 - c. belladonna alkaloid and phenobarbital combination
 - d. loperamide
7. A patient has been instructed to use an OTC form of the bulk-forming laxative methylcellulose to prevent constipation. The nurse will advise the patient of potential adverse effects, including which of the following? (Select all that apply.)
 - a. Fluid and electrolyte disturbances
 - b. Decreased absorption of vitamins
 - c. Gas formation
 - d. Darkened stools
 - e. Discoloured urine
8. A patient has been given a new prescription for loperamide hydrochloride (Imodium), and the nurse is providing education about this medication. Which statement by the patient indicates a need for further education?
 - a. "I will not take a double dose in the afternoon if I forget my morning dose."
 - b. "I should be seeing improvement within a few days."
 - c. "I will call my doctor if I experience severe constipation or bloody diarrhea."
 - d. "This drug will improve symptoms but won't cure my IBS."

CRITICAL THINKING ACTIVITIES

1. The nurse is explaining to a group of older adults the importance of seeking treatment for diarrhea. During your discussion with the group, a member asks, "If I have eaten something 'bad,' does it matter if I take something to stop the diarrhea?" What is the nurse's best response, considering the age of the group?
2. A woman calls the clinic because her 4-month-old daughter, who is your patient, has had diarrhea for approximately 8 hours. What is the nurse's priority action at this time?
3. An 88-year-old patient is undergoing a bowel preparation for colonoscopy. What are the nurse's priorities regarding monitoring the patient during the bowel preparation?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Antiemetic and Antinausea Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Discuss the pathophysiology of nausea and vomiting, including specific precipitating factors and diseases.
2. Identify the various antiemetic and antinausea drugs and their drug classification groupings.
3. Identify the mechanisms of action, indications for use, contraindications, cautions, and drug interactions of the antiemetic and antinausea drugs.
4. Develop a collaborative plan of care that includes all phases of the nursing process for patients taking antiemetic and antinausea drugs.

KEY TERMS

Antiemetic drugs Drugs given to relieve nausea and vomiting. (p. 667)

Chemoreceptor trigger zone (CTZ) The area of the brain that is involved in the sensation of nausea and the action of vomiting. (p. 667)

Emesis The forcible emptying or expulsion of gastric and, occasionally, intestinal contents through the mouth; also called *vomiting*. (p. 667)

Nausea Sensation often leading to the urge to vomit. (p. 663)

Vomiting centre (VC) The area of the brain that is involved in stimulating the physiological events that lead to nausea and vomiting. (p. 667)

DRUG PROFILES

aprepitant, p. 672

doxylamine succinate and pyridoxine hydrochloride, p. 673

metoclopramide (metoclopramide hydrochloride)*, p. 672

ondansetron (ondansetron hydrochloride dihydrate)*, p. 672

prochlorperazine, p. 671

promethazine hydrochloride, p. 671

scopolamine, p. 671

Key drug

* Full generic name is given in parentheses. For the purposes of this text, the more common, shortened name is used.

HIGH ALERT DRUG

promethazine hydrochloride, p. 671

NAUSEA AND VOMITING

Nausea and vomiting are two gastrointestinal (GI) disorders that can not only be extremely unpleasant but can also lead to more serious complications if not treated promptly. **Nausea** is an unpleasant feeling that often precedes vomiting. If nausea does not subside spontaneously or is not relieved by medication,

it can lead to vomiting. Vomiting, which is also called **emesis**, is the forcible emptying or expulsion of gastric and, occasionally, intestinal contents through the mouth. A variety of stimuli can induce nausea and vomiting, including foul odours or tastes, unpleasant sights, irritation of the stomach or intestines, and certain drugs (e.g., antineoplastic drugs, opioids).

The **vomiting centre (VC)** is an area in the brain that is responsible for initiating the physiological events that lead to nausea and vomiting. Neurotransmitter signals are sent to the VC from the **chemoreceptor trigger zone (CTZ)**, another area in the brain involved in the induction of nausea and vomiting. These signals alert these areas of the brain to the existence of nauseating substances (nauseous stimuli) that need to be expelled from the body. Once the CTZ and VC are stimulated, they initiate the events that trigger the vomiting reflex. The neurotransmitters involved in this process and their respective receptors are listed in [Table 41.1](#). The various pathways and the areas of the body that send signals to the vomiting control are illustrated in [Fig 41.1](#). Two specific types of nausea and vomiting, chemotherapy-induced and postoperative, produce much more intense symptoms and are treated much more aggressively than general nausea and vomiting.

ANTIEMETIC AND ANTINAUSEA DRUGS

Drugs used to relieve nausea and vomiting are called **antiemetic drugs**. All antiemetic drugs work at some site in the vomiting

TABLE 41.1 Neurotransmitters Involved in Nausea and Vomiting

Neurotransmitter	Site in the Vomiting Pathway
Acetylcholine (ACh)	VC in brain; vestibular and labyrinth pathways in inner ear
Dopamine (D ₂)	GI and CTZ in brain
Histamine (H ₁)	VC in brain; vestibular and labyrinth pathways in inner ear
Prostaglandins (PGs)	GI
Serotonin (5-HT ₃)	GI; CTZ and VC in brain

ACh, Acetylcholine; CTZ, chemoreceptor trigger zone; D₂, dopamine2 receptor; GI, gastrointestinal; H₁, histamine 1 receptor; 5-HT₃, 5-hydroxytryptamine 3; VC, vomiting centre.

Fig 41.1 Various pathways and areas in the body sending signals to the vomiting centre.

TABLE 41.2 Antiemetic Drugs: Common Drug Categories and Indications

Category	Antiemetic Drugs	Indications
Anticholinergics (ACh blockers)	scopolamine	Motion sickness, secretion reduction before surgery, nausea and vomiting
Antihistamines (H ₁ receptor blockers)	dimenhydrinate, diphenhydramine, meclizine	Motion sickness, nonproductive cough, sedation, rhinitis, allergy symptoms, nausea and vomiting
Antidopaminergics	prochlorperazine hydrochloride, promethazine hydrochloride	Psychotic disorders (mania, schizophrenia, anxiety), intractable hiccups, nausea and vomiting
Prokinetics	metoclopramide hydrochloride	Delayed gastric emptying, gastroesophageal reflux, nausea and vomiting
Serotonin blockers	granisetron hydrochloride, ondansetron hydrochloride	Nausea and vomiting associated with chemotherapy, postoperative nausea and vomiting
Tetrahydrocannabinol	Marihuana	Nausea and vomiting associated with chemotherapy, anorexia associated with weight loss in patients with AIDS and cancer

ACh, acetylcholine.

pathways. There are six categories of antiemetics, with varying mechanisms of action. When drugs from different categories are combined, antiemetic effectiveness is increased because more than one pathway becomes blocked. Some of the more commonly used antiemetics in the various categories are listed in Table 41.2. The sites at which antiemetics work in the vomiting pathway are shown in Fig 41.2.

Mechanism of Action and Drug Effects

Drugs used to prevent or treat nausea and vomiting have many different mechanisms of action. Most work by blocking one of

the vomiting pathways, as shown in Fig 41.2. In doing so, they block the neurological stimulus that induces vomiting. The mechanisms of action of the drugs in the six antiemetic drug categories are summarized in Table 41.3.

Anticholinergic drugs (see Chapter 22) have several uses. As antiemetics, they act by binding to and blocking acetylcholine (ACh) receptors on the vestibular nuclei, which are located deep within the brain. When ACh is prevented from binding to these receptors, nausea-inducing signals originating in this area cannot be transmitted to the CTZ. Anticholinergics also block receptors located in the reticular formation and thus

Fig 41.2 Sites of action of selected antiemetic drugs.

TABLE 41.3 Antiemetic Drugs: Mechanisms of Action

Category	Mechanism of Action
Anticholinergics	Block ACh receptors in the vestibular nuclei and reticular formation
Antihistamines	Block H_1 receptors, thereby preventing ACh from binding to receptors in the vestibular nuclei
Neuroleptics	Block dopamine in the CTZ and may also block ACh
Prokinetics	Block dopamine in the CTZ or stimulate ACh receptors in the GI tract
Serotonin blockers	Block serotonin receptors in the GI tract, CTZ, and VC
Tetrahydrocannabinol	Have inhibitory effects on the reticular formation, thalamus, and cerebral cortex

ACh, Acetylcholine; H_1 , histamine-1; CTZ, chemoreceptor trigger zone; GI, gastrointestinal; VC, vomiting centre.

prevent ACh from binding to these receptors. This then prevents nausea-inducing signals originating in this area from being transmitted to the VC. Anticholinergics also tend to dry GI secretions and reduce smooth muscle spasms; both of these effects are often helpful in reducing acute GI symptoms, including nausea and vomiting.

Antihistamines (histamine-1 [H_1] receptor blockers) act by inhibiting vestibular stimulation in a manner similar to that of anticholinergics. Although they bind primarily to H_1 receptors, they also have potent anticholinergic activity, including antisecretory and antispasmodic effects. Thus, antihistamines (see Chapter 37) prevent cholinergic stimulation in both the vestibular and reticular systems. Nausea and vomiting occur when these systems are stimulated. Note that these drugs are not to be confused with histamine-2 (H_2) receptor blockers used for gastric acid control (see Chapter 39).

Antidopaminergic drugs, although they are traditionally used for their antipsychotic effects (see Chapter 17), also prevent nausea and vomiting by blocking dopamine receptors in the CTZ. Many of the antidopaminergics also have anticholinergic actions similar to those of anticholinergic drugs. In

addition, antidopaminergic drugs calm the central nervous system (CNS).

Prokinetic drugs, in particular metoclopramide, act as antiemetics by blocking dopamine receptors in the CTZ, which desensitizes the CTZ to impulses it receives from the GI tract. Their primary action, however, is to stimulate peristalsis in the GI tract. This action enhances the emptying of stomach contents into the duodenum as well as intestinal movements.

Serotonin blockers work by blocking serotonin receptors located in the GI tract, CTZ, and vomiting centre. There are many subtypes of serotonin receptors, and these receptors are located throughout the body (CNS, smooth muscles, platelets, GI tract). The receptor subtype involved in the mediation of nausea and vomiting is the 5-hydroxytryptamine 3 (5-HT₃) receptor. These receptors are the sites of action for the serotonin blockers such as ondansetron, palonosetron, and granisetron.

Tetrahydrocannabinol (THC), in a drug class by itself, is the major psychoactive substance in marijuana. The drug is occasionally used as an antiemetic because of its inhibitory effects on the reticular formation, thalamus, and cerebral cortex. These

effects cause an alteration in mood and the body's perception of its surroundings, which may be beneficial in relieving nausea and vomiting. There are occasionally unusual cases of nausea and vomiting that respond well to THC; examples include patients being treated for cancer or AIDS who experience nausea and vomiting. In such patients, marijuana may also stimulate the appetite, as nutritional wasting syndromes are common in both diseases. The drug also demonstrates some benefit in controlling the symptoms of glaucoma. The pharmaceutical formulation of THC, dronabinol and nabilone, is available in Canada since the legalization of cannabis on October 17, 2018 ([Health Canada, 2018](#)). As discussed in Chapter 3, the main component responsible for the psychoactive effects is delta-9-tetrahydrocannabinol or THC. Other chemicals such as cannabidiol and cannabidiol possess fewer mood-altering effects. When smoked or ingested, the psychoactive components attach to the cannabinoid receptors in the brain, CB1 and CB2, particularly in the areas involving body movement, memory, and vomiting. Peak effects after smoking marijuana occur in minutes and last for up to 2 hours; when ingested, its effects may linger for hours but the absorption may be unpredictable.

Indications

The therapeutic uses of antiemetic drugs vary depending on their drug category. There are several indications for the drugs in each class. These indications are listed in [Table 41.2](#).

Contraindications

The primary contraindication for all antiemetics is known drug allergy. Other contraindications for specific drugs are mentioned in the drug profiles.

Adverse Effects

Most of the adverse effects of the antiemetics stem from their nonselective blockade of various receptors. Some of the more common adverse effects associated with the various categories of antinausea drugs are listed in [Table 41.4](#).

Interactions

The drug interactions associated with the antiemetic drugs are specific to the individual drug categories. Anticholinergics have additive drying effects when given with antihistamines and antidepressants. Increased CNS effects are seen when antihistamine

TABLE 41.4 Antinausea Drugs: Adverse Effects

Body System	Adverse Effects
Anticholinergics	
Central nervous	Dizziness, drowsiness, disorientation
Cardiovascular	Tachycardia
Ears, eyes, nose, throat	Blurred vision, dilated pupils, dry mouth
Genitourinary	Difficult urination, constipation
Integumentary	Rash, erythema
Antihistamines	
Central nervous	Dizziness, drowsiness, confusion
Ears, eyes, nose, throat	Blurred vision, dilated pupils, dry mouth
Genitourinary	Urinary retention
Antidopaminergics	
Cardiovascular	Orthostatic hypotension, tachycardia
Central nervous	Extrapyramidal symptoms, tardive dyskinesia, headache, drowsiness
Ears, eyes, nose, throat	Blurred vision, dry eyes
Gastrointestinal	Dry mouth, nausea and vomiting, anorexia, diarrhea
Genitourinary	Urinary retention
Prokinetics	
Cardiovascular	Hypotension, supraventricular tachycardia
Central nervous	Sedation, fatigue, restlessness, headache, dystonia
Gastrointestinal	Dry mouth, nausea and vomiting, diarrhea
Serotonin blockers	
Central nervous	Headache
Gastrointestinal	Diarrhea, constipation
Other	Rash, bronchospasm, prolonged QT interval
Tetrahydrocannabinol	
Central nervous	Drowsiness, dizziness, anxiety, confusion, euphoria
Ears, eyes, nose, throat	Visual disturbances
Gastrointestinal	Dry mouth

antiemetics are administered with barbiturates, opioids, hypnotics, tricyclic antidepressants, or alcohol. Increased CNS depression effects are seen when alcohol or other CNS depressants are given together with antidopaminergic drugs. Combining metoclopramide with alcohol can result in additive CNS depression. Anticholinergics and analgesics can block the motility effects of metoclopramide. Serotonin blockers and THC have no significant drug interactions.

Dosages

For dosage information on selected antiemetic drugs, refer to the table on p. 674.

DRUG PROFILES

Antiemetics are used to treat nausea and vomiting in a variety of clinical situations, including chemotherapy-induced and postoperative nausea and vomiting, both of which can be especially difficult to treat. The ultimate goals of antiemetic therapy are minimizing or preventing fluid and electrolyte disturbances and minimizing deterioration of the patient's nutritional status. Most of the antiemetics act by blocking receptors in the CNS, but some work directly in the GI tract. There are six major classes of antiemetic drugs, although there are other drugs that may also be used to treat nausea and vomiting, including corticosteroids such as dexamethasone (see Chapter 34) and anxiolytics such as lorazepam (see Chapter 17). Dexamethasone, lorazepam, and THC are beneficial in treating and preventing nausea and vomiting caused by chemotherapy, especially when used in combination with the serotonin blockers. Lorazepam in particular is often used during chemotherapy because, in addition to its antiemetic effect, it also helps blunt the memory of the nausea and vomiting experience (this is termed “anticipatory nausea and vomiting”).

Anticholinergics

scopolamine

Scopolamine hydrobromide is the primary anticholinergic drug used as an antiemetic. It has potent effects on the vestibular nuclei, which are within the area of the brain that controls balance. Scopolamine hydrobromide works by blocking the binding of ACh to the cholinergic receptors in this region, thereby correcting an imbalance between the neurotransmitters ACh and norepinephrine. Scopolamine hydrobromide is used to treat postoperative nausea and vomiting. Use of the drug is contraindicated in patients with glaucoma due to the pupil dilation effect of the drug, which may alter or increase intraocular pressure. Scopolamine is available in injectable form and as a patch OTC (Transderm V) 1 patch applied to the skin Q72 hours, onset is 4 hours.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IM	30–60 min	1–2 hr	9.5 hr	4–6 hr

Antihistamines

Antihistamine antiemetics are some of the most commonly used and safest antiemetics. Two popular antihistamines are dimenhydrinate (Dinate®, Gravol®, Nauseatol®, others) and diphenhydramine hydrochloride (Aller-Aide®, Allernix®, Benadryl®, others). Many of the antihistamines are available over the counter. Hydroxyzine hydrochloride is used for antiemetic purposes and is available in oral and intramuscular formulations. Hydroxyzine hydrochloride must never be given by the intravenous (IV) route (see the Preventing Medication Errors Box on p. 673). Meclizine hydrochloride, another antihistamine, is no longer being manufactured in Canada.

Antidopaminergic

Prochlorperazine (Prochlorazine®) and promethazine hydrochloride (Histanil®) are the most commonly used antiemetics in the antidopaminergic class. These drugs have antidopaminergic as well as antihistaminergic and anticholinergic properties. Droperidol was one of the most commonly used drugs in the treatment and prevention of postoperative nausea and vomiting for several decades, until Health Canada called for a label warning and required continuous electrocardiographic monitoring with its use. These restrictions were in response to concerns over QT widening and possible ventricular dysrhythmias. Some institutions still use droperidol, whereas others have banned its use. Haloperidol, an antipsychotic, is a dopamine₂-receptor antagonist that may also be used as an antiemetic, although data is limited about this area of use.

prochlorperazine

Prochlorperazine (Prochlorazine), particularly in its injectable form, is used frequently in the hospital setting. This drug is contraindicated in patients with hypersensitivity to phenothiazines, those in a coma, and those who have seizures, encephalopathy, or bone marrow depression. It is available for both injection and oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IM	30–40 min	2–4 hr	6–8 hr	3–4 hr

promethazine

Promethazine (Histanil®) is used in hospitalized patients as an antiemetic. The preferred route is oral or intramuscular. The IV route is not a preferred route but is commonly used. However, extreme care must be taken to avoid accidental intra-arterial injection. If promethazine is inadvertently given intra-arterially instead of intravenously, severe tissue damage, often requiring amputation, can occur. The preferred parenteral route of administration for promethazine hydrochloride injection is by deep intramuscular injection. If administered intravenously, the drug is to be given in a concentration no greater than 25 mg per mL and at a rate not to exceed 25 mg per minute. It is best given in a running IV line at the port furthest from the patient's vein or through a large-bore vein (not a hand or wrist vein). Therapy must be

discontinued immediately if burning or pain occurs with administration. Promethazine is contraindicated in children younger than 2 years of age. Sedation is the most common adverse effect and may be beneficial. Promethazine is not to be given subcutaneously. For more information, see the Preventing Medication Errors box on p. 673. Please note that Promethazine is not used as much clinically because it is a sought after street drug.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IM	20 min	4.4 hr	9–16 hr	2–6 hr

Prokinetics

Prokinetic drugs promote the movement of substances through the GI tract and increase GI motility. The only prokinetic drug that is also used to prevent nausea and vomiting is metoclopramide.

metoclopramide hydrochloride

Metoclopramide hydrochloride (Metonia®, Metoclopramide OMEGA®) is available only by prescription because it can cause some severe adverse effects if not used correctly. Metoclopramide is used for the treatment of delayed gastric emptying and gastroesophageal reflux and also as an antiemetic; specifically, metoclopramide OMEGA is indicated for prophylaxis of postoperative vomiting and vomiting associated with cancer chemotherapeutic regimens that include cisplatin as a component (BC Cancer, 2018). Its use is contraindicated in patients with seizure disorders, pheochromocytoma, breast cancer, or GI obstruction, and in patients with a hypersensitivity to it or to procaine or procainamide hydrochloride. Metoclopramide is available in both oral and parenteral formulations. Extrapyramidal adverse effects can occur with its use, especially in older adults, and older women in particular. In 2011, Health Canada informed health care providers and consumers of updated labelling for metoclopramide regarding its potential to cause the development of tardive dyskinesia with long-term use (longer than 12 weeks).

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	20–60 min	1–2.5 hr	5–6 hr	1–2 hr

Serotonin Blockers

The serotonin blockers are also called *5-HT₃ receptor blockers* because they block the 5-HT₃ receptors in the GI tract, CTZ, and VC. (The chemical name for serotonin is *5-hydroxytryptamine [5-HT]*). Drugs in this class have specific actions, and as a result they have few adverse effects. No significant drug interactions are known to occur with the use of serotonin blockers. These drugs are indicated for the prevention of nausea and vomiting associated with cancer chemotherapy and for the prevention of postoperative or radiation-induced nausea

and vomiting. Currently, there are three drugs in this category: granisetron hydrochloride (Granisetron HCL), palonosetron (Aloxi®), and ondansetron (Zofran®). This class of drugs revolutionized the treatment of nausea and vomiting, especially in patients with cancer and postoperative patients. When used to prevent postoperative nausea and vomiting, a dose is usually given approximately 30 minutes before the end of the surgical procedure. When used to prevent or treat nausea and vomiting associated with cancer treatment, the drug is given in the first 24 to 48 hours of chemotherapy. In 2014, Health Canada issued a warning regarding ondansetron and its associated risk of dysrhythmias; this risk is expected to be greater when it is administered intravenously, with faster rates of infusion and larger doses. Efficacy and tolerance is similar in both older and younger adults; thus, there is no need to alter dosage schedules for older adult patients.

ondansetron hydrochloride dihydrate

Ondansetron hydrochloride dihydrate (Zofran) is the prototypical drug in its class. Approved in 1991, it represented a breakthrough in treating chemotherapy-induced nausea and vomiting and, later, postoperative nausea and vomiting. It is also used for the treatment of hyperemesis gravidarum (nausea and vomiting associated with pregnancy) (Government of Canada, 2016). Its only listed contraindication is known drug allergy. It is available in both oral (tablets, solution, disintegrating tablet) and injectable forms. Doses up to 8 mg can be given by IV push over 2 to 5 minutes. Ondansetron was the first of the serotonin blockers to become available as a generic formulation, which significantly increased its use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	15–30 min	1–1.5 hr	3–6 hr	6–12 hr

tetrahydrocannabinol

THC is the major active substance in marijuana. It may be used for the treatment of nausea and vomiting associated with cancer chemotherapy and to stimulate appetite and weight gain in patients with AIDS.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Inhaled	minutes	Unknown	Unknown	Unknown

Miscellaneous Antinausea Drugs

aprepitant

Aprepitant (Emend®) is the first in a new class of antiemetic drugs, approved in 2007. It is an antagonist of substance P–neurokinin-1 receptors in the brain. In contrast to other antiemetics, this drug has little affinity for 5-HT₃ (serotonin) and

PREVENTING MEDICATION ERRORS

Right Route Is Essential

Two commonly used antiemetic drugs may have serious consequences for patients if they are given via the wrong route.

Hydroxyzine hydrochloride is an antihistamine-class antiemetic that is only to be given either by oral or intramuscular routes. However, as so many other antiemetics are given by the IV route, it may be easy to make the mistake of giving hydroxyzine hydrochloride intravenously. It is important to note that IV, intra-arterial, or subcutaneous administration of hydroxyzine hydrochloride may result in significant tissue damage, thrombosis, and gangrene.

Promethazine hydrochloride (Histantil) is another commonly used antiemetic. The oral and intramuscular routes are the preferred routes of administration for this drug; the IV route, while commonly used, is not the preferred route. If this drug is given intra-arterially, severe tissue damage, possibly leading to amputation, may occur.

These are just two examples that illustrate the importance of the “right route” with drug administration.

dopamine receptors. Studies show that aprepitant augments the antiemetic actions of both ondansetron and the corticosteroid dexamethasone. This drug is specifically indicated for the prevention of nausea and vomiting in highly and moderately emetogenic cancer chemotherapy regimens, including high-dose cisplatin, as well as postoperative nausea and vomiting. Common adverse effects include dizziness, headache, insomnia, and GI discomfort, but these are generally no more common than with other standard antiemetic regimens. Aprepitant may induce the metabolism of warfarin sodium, and the international normalized ratio (INR) needs to be checked before each cycle of aprepitant. The drug may reduce the effectiveness of oral contraceptives. Because aprepitant is a major inhibitor of the cytochrome P450 enzyme system, caution must be used in giving it together with drugs that are primarily metabolized by cytochrome P450 enzyme 3A4, including azole antifungals, clarithromycin, diltiazem, nifedipine, protease inhibitors, and verapamil. It may increase the bioavailability of corticosteroids, including dexamethasone and methylprednisolone, and dosages of these drugs may need to be adjusted by 25 to 50%.

doxylamine succinate and pyridoxine hydrochloride

Doxylamine succinate and pyridoxine hydrochloride (Diclectin®) delayed-release tablets combine the action of two unrelated compounds. Doxylamine succinate, an antihistamine, and pyridoxine hydrochloride (vitamin B6) provide both anti-nausea and antiemetic effects. The drug is indicated for the management of nausea and vomiting during pregnancy. Optimal effects of the drug occur when the drug is given 4 to 6 hours prior to the anticipated onset of symptoms. The delayed action of Diclectin permits the nighttime dose to be effective in the morning hours, when nausea occurs most frequently. The suggested recommended dosage for control of nausea is two tablets at bedtime, one tablet in the morning, and another midafternoon; however, this schedule should be individualized to each patient's requirements. The drug should be slowly tapered when discontinued to prevent return of symptoms.

This drug is contraindicated in patients who are hypersensitive to doxylamine succinate, other ethanolamine derivative antihistamines, pyridoxine hydrochloride, or any nonmedicinal ingredient in the formulation. It is also not recommended for those with a potential for asthmatic attack, patients with narrow angle glaucoma (potential for increased intraocular pressure due to mydriatic effect of drug), stenosing peptic ulcer, pyloroduodenal obstruction, or bladder-neck obstruction, or those who are taking monoamine oxidase inhibitors. It should not be

taken concurrently with other medications or alcohol due to the antihistamine properties of doxylamine. This drug is also prone to misuse. Doxylamine may cause drowsiness as well as vertigo, nervousness, epigastric pain, headaches, palpitations, diarrhea, disorientation, irritability, convulsions, urinary retention, or insomnia. Pyridoxine is a vitamin and as such is well tolerated and has no adverse effects.

NURSING PROCESS

ASSESSMENT

Nurses play a crucial role in the assessment and management of nausea and vomiting. To improve the patient's experience, nurses need to have the necessary instruments available to help them assess each symptom in a timely manner. Early and accurate assessment can promote the development of timely, patient-specific interventions and minimize the symptom experience.

Before any antinausea or antiemetic drug is administered, assess intake and output; examine the skin and mucous membranes, noting turgor and colour; and assess and document capillary refill (normal is less than 5 seconds) to establish baseline hydration status. If laboratory tests are ordered (e.g., serum sodium, potassium, and chloride levels; hemoglobin level and hematocrit; red and white blood cell counts; urinalysis), assess and document the findings to establish baseline levels. Assess for any contraindications or cautions to the use of these drugs and for drug interactions, as well as any allergies. See Natural Health Products: Ginger.

Give the anticholinergic drug scopolamine only after careful assessment of a patient's health history and medication history. This drug is contraindicated in patients with a hypersensitivity to it and in those with glaucoma. If the patient has a history of narrow-angle glaucoma, use another antiemetic or antinausea drug. The same concern regarding use in patients with narrow-angle glaucoma applies to antihistamines; in addition, use antihistamines cautiously in children, who may have severe paradoxical reactions. Older adults may develop agitation, mental confusion, hypotension, and even psychotic-type reactions in response to these drugs. Other medications need to be considered for patients if these reactions occur.

Antidopaminergic drugs such as prochlorperazine are to be used only after cautious assessment for signs and symptoms of dehydration and electrolyte imbalance, through evaluation of skin turgor and of the tongue for the presence of longitudinal furrows. Monitor vital signs, especially blood pressure and pulse rate, due to this drug's adverse effects of orthostatic hypotension and tachycardia. CNS concerns for which to assess include any

Dosages

Selected Antiemetic and Antinausea Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications
Anticholinergics			
scopolamine hydrobromide injection	Anticholinergic, belladonna alkaloid	<i>Children</i> IM, IV, Subcut: 0.006 mg/kg q6h <i>Adults</i> IM, IV, Subcut: 0.3–0.6 mg tid–qid	Antiemetic
Antidopaminergics			
 prochlorperazine (Prochlorazine)	Phenothiazine	<i>Children</i> Dosages vary based on weight and age <i>Adults</i> PO/rectal: 5–10 mg tid–qid IM/IV: 5–10 mg bid–tid	Antiemetic
promethazine hydrochloride (Histanil)	Phenothiazine	<i>Children over 2 yr</i> PO, IM, IV: 6.25–12.5 mg <i>Adults</i> PO, IM, IV: 12.5–25 mg	Antiemetic
Prokinetics			
 metoclopramide hydrochloride (Metonia, metoclopramide OMEGA)	Dopamine antagonist	<i>Children 5–14 yr</i> IV: 1 mg/kg prior to chemo then 0.0375 mg/kg Q6H <i>Adults</i> IV: 1–2 mg/kg (30 min before chemotherapy; repeat q2h × 2 doses, then q3h × 3 doses) IM: 10–20 mg × 1 dose near end of surgery, “usual” hospital dosing for treatment of nausea/vomiting short term is 5–10 mg TID with meals	Chemotherapy antiemetic Chemotherapy antiemetic Prevention of postoperative nausea and vomiting
Serotonin Blockers			
 ondansetron hydrochloride dihydrate (Zofran)	Antiserotonergic	<i>Children 4–12 yr</i> PO: 4 mg tid, after chemotherapy, × up to 5 days IV: 3–5 mg/m ² over 15 min, immediately before chemotherapy, then oral as above <i>Adults</i> PO: 8 mg bid up to 5 days after the initial 24-hr IV dose IV: 8–16 mg over 15 min, given 30 min before chemotherapy, followed by 1 mg/hr continuous infusion up to 24 hr, or one dose of 32 mg over 15 min, given 30 min before chemotherapy PO: 16 mg, 1 hr before surgery IV: 4 mg over 2–5 min × 1 dose (second dose not shown to be effective in patients who fail to respond to first dose)	Chemotherapy antiemetic Chemotherapy antiemetic Prevention and treatment of postoperative nausea

NATURAL HEALTH PRODUCTS

Ginger (*Zingiber officinale*)

Overview

Found naturally in the Asian tropics; now cultivated in other continents, including parts of the United States, and grown commercially in Canada; plant parts used are the rhizome and root; active ingredients include gingerols and gingerdione

Common Uses

Used as an antioxidant; also used for relief of various symptoms such as sore throat, migraine headaches, and nausea and vomiting (including that induced by cancer chemotherapy, morning sickness, and motion sickness); many other varied uses

Adverse Effects

Skin reactions, anorexia, nausea, vomiting

Potential Drug Interactions

Can increase absorption of all oral medications; may theoretically increase bleeding risk with anticoagulants (e.g., warfarin sodium [Coumadin®]) or antiplatelet drugs (e.g., clopidogrel [Plavix®])

Contraindications

Contraindicated in cases of known product allergy; may worsen cholelithiasis (gallstones); anecdotal evidence of abortifacient properties—some clinicians recommend avoiding use during pregnancy

Dosage

Available as a capsule; recommended dosage is 1 to 2 capsules per day or as recommended by a health care provider

abnormal movements at baseline functioning, because these drugs can lead to adverse effects of extrapyramidal symptoms. Contraindications, cautions, and drug interactions for these drugs were discussed earlier. Double-checking the name and mechanism of action is also important, as prochlorperazine may be confused with promethazine hydrochloride.

The prokinetic drug metoclopramide is often reserved for the treatment of nausea and vomiting associated with antineoplastic drug therapy or radiation therapy and for the treatment of GI motility disturbances. Metoclopramide is titrated to maximum benefit and tolerance. If the drug is not effective, add or switch to another dopamine antagonist (e.g., haloperidol). The action of this drug is decreased when it is taken with anticholinergics or opiates; therefore, assess for this interaction. Remember the Health Canada public health advisory regarding adverse reactions with long-term use (see previous discussion).

Give the serotonin blocker granisetron only after assessment of baseline vital signs and determination of age (its safety in children younger than 2 years of age has not been established). Ondansetron requires assessment for the signs and symptoms of dehydration and electrolyte disturbances. Assess skin turgor and examine mucous membranes for dryness and the tongue for longitudinal furrows.

- Potential for injury (falls) resulting from the adverse effects of the antiemetic medications (e.g., sedation and dizziness)
- Potential for reduced fluid volume as a result of nausea and vomiting and limited oral intake

◆ PLANNING

◆ Goals

- Patient will remain free from weakness and dizziness with use of pharmacological and nonpharmacological therapies.
- Patient will regain previous mobility status or maintain stable mobility during drug therapy.
- Patient will remain free from injury during drug therapy with antiemetics.
- Patient will maintain or regain fluid volume balance while undergoing treatment.

◆ Expected Patient Outcomes Criteria

- Patient states specific rationales for reducing nausea and vomiting through use of antiemetic drug therapy as well as specific nondrug measures.
 - Patient states action of a specific antiemetic drug, its specific dosage, and the best time to take the drug; patient also identifies related adverse effects such as sedation, dizziness, and dry mouth.
 - Patient states specific measures to decrease nausea and vomiting, such as avoiding irritating, spicy foods and beverages and possibly avoiding fluids and food until nausea and vomiting subside (but prior to becoming dehydrated).
 - Patient states signs and symptoms of dehydration that should be reported to the health care provider if they occur, such as dry mouth, decrease in urinary output, decreased to no intake of fluids, lethargy, weakness, and dizziness.
- Patient increases physical mobility and activity, with assistance if needed, by 10 to 15 minutes per day with cautious movements, incorporating changing of positions, rising, walking, and performing activities of daily living.
- Patient states measures to implement to prevent injury, such as obtaining assistance while ill, rising slowly, changing positions slowly, taking medications as ordered, and initiating fluid intake once nausea and vomiting subside.
- Patient states measures to implement to prevent further fluid volume deficits, such as consumption of oral fluids (e.g., clear liquids) or chilled gelatin along with medications.

◆ IMPLEMENTATION

Early intervention and prevention (avoiding triggers) are key approaches to managing nausea and vomiting. Nonpharmacological interventions can be used to supplement pharmacological treatment of nausea and vomiting. For example, patients should avoid foods that provoke nausea; avoid spicy, salty, and fatty foods or foods with a strong odour; eat small, frequent, bland meals every 1 to 2 hours; avoid mixing liquids and solid foods (e.g., eat a small portion of food, wait 20 to 30 minutes, then take some liquid); try cool, carbonated drinks, and avoid lying flat after eating.

◆ NURSING DIAGNOSES

- Nausea resulting from disease pathology or adverse effects of specific groups of medications
- Reduced physical mobility as a result of adverse effects (e.g., sedation, lethargy, confusion) of antiemetics

Many agencies follow a best practice algorithm to treat nausea and vomiting. In general, the effectiveness of antiemetic drugs varies among patients. Usually, antiemetics are selected according to etiology (e.g., postoperative, chemotherapy, palliation). If nausea is not controlled, the drug is individually titrated to its full dose (or smallest effective dose without adverse effects). If a drug is inadequate, another drug from another class that targets a different receptor is added. It is usual to add drugs, not substitute drugs, as there may be additive effects. Continuous medication may be more effective. For persistent nausea and vomiting, antiemetics should be prescribed on a regular dosing schedule with a breakthrough dose available. Multiple drug combinations in high doses may be needed. Antiemetics may also be administered prophylactically to prevent nausea resulting from the use of high dose opioids and chemotherapeutic drugs.

Undiluted forms of diphenhydramine hydrochloride must be cautiously administered intravenously, at the recommended rate of 25 mg/min. Intramuscular forms should be administered into large muscles (e.g., gluteus medius), and sites should be rotated if repeated injections are necessary. Promethazine hydrochloride may be given orally without regard to meals; parenteral doses should be given using the proper dilutional solutions and infusion rates. Measure vital signs and monitor patients for extrapyramidal symptoms throughout therapy. Encourage patients to avoid other CNS depressants and alcohol as well as to limit caffeine when this drug is used. Instruct patients taking promethazine to avoid driving and other activities that require mental alertness or precise coordination.

Metoclopramide should be given orally 30 minutes before meals and at bedtime. Infuse IV dosage forms over the recommended time period. For doses in excess of 10 mg, metoclopramide needs to be diluted in 50 mL of either 5% dextrose or 0.9% sodium chloride. Except for prophylaxis of vomiting induced by anticancer drugs, the total daily dosage must not exceed 0.5 mg/kg body weight. Inject the infusion slowly over a 15-minute period and repeat the dose every 2 hours for two doses, and then every 3 hours for three doses. In addition, keep solutions for parenteral dosing for only 24 hours and protect them from light. Metoclopramide should not be given to patients with epilepsy or in combination with any other medications such as phenothiazines that would lead to exacerbation of extrapyramidal reactions. Such reactions should be reported immediately to the health care provider. The development of tardive dyskinesia, an involuntary neurological movement disorder, has been associated with the long-term use of metoclopramide. Monitor for this potential problem and educate patients about it.

Granisetron hydrochloride may be given intravenously or orally. Infuse IV doses over the recommended time frame and dilute as appropriate. A transient taste disorder may occur, especially if the drug is taken with antineoplastic medications, but will diminish

with continued therapy. Encourage the use of various relaxation techniques as complementary therapies. Ondansetron may be given orally, intramuscularly, or intravenously. Inject intramuscular doses into a large muscle mass. IV push is usually given over 2 to 5 minutes and infusions over 15 minutes, as ordered and per manufacturer guidelines. Oral forms are well tolerated regardless of the relation of dosing to meals. Encourage patients to avoid alcohol and other CNS depressants during this therapy and to avoid any activities requiring mental alertness or precise coordination. Antiemetics are usually given 30 to 60 minutes before chemotherapy, depending on the specific drug. Ondansetron is usually given 30 minutes before chemotherapy. Aprepitant is often used in combination with other medications to prevent nausea and vomiting associated with chemotherapy and is given, as ordered, for postoperative nausea and vomiting. The health care provider's orders may indicate other drugs to be administered as well as the timing of the dosage. Oral dosage forms are to be given as ordered.

EVALUATION

The therapeutic effects of antiemetic and antinausea drugs include a decrease in or elimination of nausea and vomiting, and avoidance or elimination of complications such as fluid and electrolyte imbalances and weight loss. Monitor patients for adverse effects such as GI upset, drowsiness, lethargy, weakness, extrapyramidal effects, and orthostatic hypotension, during antiemetic treatment. Laboratory testing (e.g., electrolyte levels, blood urea nitrogen level, urinalysis with specific gravity) may be ordered for evaluation purposes. Defined goals and outcomes may also be used to evaluate therapeutic effectiveness.

CASE STUDY

Nausea Associated With Chemotherapy

Scott, a 65-year-old retired bus driver, has started outpatient chemotherapy for a recent diagnosis of lung cancer. He has recovered well from a right lung lobectomy, the incisions are healing well, and he is now physically and emotionally ready for a 3-month regimen of chemotherapy. The premedication consists of a variety of drugs, including granisetron hydrochloride (Granisetron HCL). Scott has a prescription for oral ondansetron (Zofran) for use at home.

1. What is the mechanism of action of granisetron hydrochloride that makes it effective in the management of chemotherapy-induced nausea and vomiting?
2. What important patient teaching points regarding ondansetron should you emphasize to Scott?
3. After 2 weeks of therapy, the oncologist discontinues the ondansetron because Scott complains that it does nothing to help his nausea and vomiting. A friend suggests the use of marijuana but Scott expresses concern about this strategy. What would you explain to him?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

PATIENT TEACHING TIPS

- Warn patients using an antiemetic or antinausea drug about the adverse effect of drowsiness, and instruct the patient to use caution when performing hazardous tasks or driving while taking these drugs. Caution patients about taking antiemetic or antinausea drugs with alcohol and other CNS depressants because of possible toxicity and exacerbation of CNS depression.
- Educate patients about the possible adverse effects of ondansetron, including headache, which may be relieved with a simple analgesic (e.g., acetaminophen).

KEY POINTS

- Antiemetics help to control vomiting, or emesis, and are also useful in relieving or preventing nausea. Antiemetics are used to prevent motion sickness, reduce secretions before surgery, treat delayed gastric emptying, and prevent postoperative nausea and vomiting. Most of these drugs can cause drowsiness.
- Anticholinergics act by blocking ACh receptors in the vestibular nuclei and reticular formation. This blockade prevents areas in the brain from being activated by nauseous stimuli.
- Antihistamines act by blocking H₁ receptors, which produces the same effect as the anticholinergics do. Antidopaminergic antiemetics block dopamine receptors in the CTZ and may also block ACh receptors. Prokinetic drugs also block dopamine receptors in the CTZ.
- Serotonin blockers (granisetron hydrochloride and ondansetron) may be highly effective antiemetics. They are most commonly used for the prevention of chemotherapy-induced nausea and vomiting.
- Antiemetics are often given 30 to 60 minutes before a chemotherapy drug is administered (time may vary depending on the specific drug) and may also be given during the chemotherapeutic treatment.
- Caution patients taking antiemetic or antinausea drugs that drowsiness and hypotension may occur and to avoid driving and using heavy machinery while taking these medications.

EXAMINATION REVIEW QUESTIONS

1. A 33-year-old patient is in an outpatient cancer centre for his first round of chemotherapy. The nurse knows that which schedule is the most appropriate timing for the IV antiemetic drug?
 - a. 4 hours before the chemotherapy begins
 - b. 30 minutes before the chemotherapy begins
 - c. At the same time as the chemotherapy drugs
 - d. At the first sign of nausea
2. When reviewing the various types of antinausea medications, the nurse recognizes that prokinetic drugs are also used for which disorder?
 - a. Motion sickness
 - b. Vertigo
 - c. Delayed gastric emptying
 - d. GI obstruction
3. A patient who has been receiving chemotherapy tells the nurse that he has been searching the Internet for antinausea remedies and that he found a reference to a product called aprepitant. He wants to know if this drug would help him. What would be the nurse's best answer?
 - a. "This may be a good remedy for you. Let's talk to your health care provider."
 - b. "This drug is used only after other drugs have not worked."
 - c. "This drug is used only to treat severe nausea and vomiting caused by chemotherapy."
 - d. "This drug may not help the more severe nausea symptoms associated with chemotherapy."
4. A patient is asking about using THC. Which statements about dried marihuana therapy are true? (Select all that apply.)
 - a. It is useful for nausea and vomiting as a result of cancer chemotherapy.
 - b. It is approved for the treatment of hyperemesis gravidarum.
 - c. It is useful to help stimulate the appetite in patients with nutritional wasting.
 - d. It may cause extrapyramidal symptoms.
 - e. It may cause drowsiness or euphoria.
5. The order reads: "Give promethazine hydrochloride 12.5 mg IM q4h prn nausea/vomiting." The medication is available in 25-mg/mL vials. How many millilitres will the nurse draw up for this dose?
6. The nurse is providing patient teaching regarding scopolamine transdermal patches (Transderm-Scōp) to a patient who is planning an ocean cruise. Which instruction is most appropriate?
 - a. "Apply the patch the day before travelling."
 - b. "Apply the patch at least 4 hours before travelling."
 - c. "Apply the patch to the shoulder area."
 - d. "Apply the patch to the temple just above the ear."
7. The nurse is reviewing the current medications for a patient who has a new prescription for aprepitant (Emend). Which of these medications may have an interaction with aprepitant? (Select all that apply.)
 - a. digoxin
 - b. warfarin
 - c. Oral contraceptives
 - d. Nonsteroidal anti-inflammatory drugs
 - e. Corticosteroids

CRITICAL THINKING ACTIVITIES

1. A patient who has received chemotherapy with a highly emetogenic drug has orders for both ondansetron (Zofran) and prochlorperazine hydrochloride. Which drug would be the best choice for the nurse to administer for the patient's nausea and vomiting, and how should it be administered for the best possible effects? Explain your answer.
2. The nurse is administering antiemetic drugs to a patient who has been vomiting. What is the priority for assessment at this time? Explain your answer.
3. The nurse has just given an 83-year-old patient a dose of an antinausea drug. Considering this patient's age, what is the nurse's priority action regarding evaluation of the drug's effects?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Nutritional Supplements

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Describe the various pathophysiological processes and disease states that may lead to nutritional deficiencies and require nutritional support.
2. Discuss enteral and parenteral nutrition used to treat the various nutritional deficiencies, including specific ingredients.
3. Describe the nurse's role in the process of initiating and maintaining continuous or intermittent enteral feedings, total parenteral nutrition, and other forms of nutrition.
4. Compare the various enteral feeding tubes, including their specific uses and the special needs of patients requiring this nutritional support.
5. Discuss the mechanisms of action, cautions, contraindications, routes of administration, drug interactions, adverse effects, and complications associated with enteral and parenteral nutrition.
6. Develop a collaborative plan of care that includes all phases of the nursing process for patients receiving enteral and parenteral nutrition.
7. Discuss the various laboratory values as a result of nutritional deficits or altered nutritional status and their impact on monitoring the therapeutic effects of the therapy.

KEY TERMS

Anabolism Metabolism characterized by the conversion of simple substances into the more complex compounds; tissue building. (p. 680)

Casein The principal protein of milk and the basis for curd and cheese. (p. 682)

Catabolism A complex metabolic process in which energy is liberated for use in work, energy storage, or heat production by the destruction of complex substances to form simple compounds. (p. 684)

Dumping syndrome A complex reaction to the rapid entry of concentrated nutrients into the jejunum of the small intestine; most commonly occurs with eating following partial gastrectomy or with enteral feedings that are administered too rapidly into the stomach or jejunum via a feeding tube. The patient may experience nausea, weakness, sweating, palpitations, syncope, sensations of warmth, and diarrhea. (p. 681)

Enteral nutrition The provision of food or nutrients via the gastrointestinal tract, either naturally by eating or through a feeding tube in patients who are unable to eat. (p. 680)

Essential amino acids Those amino acids that cannot be manufactured by the body. (p. 684)

Essential fatty acid deficiency A condition that develops if fatty acids that the body cannot produce are not present in the diet or in nutritional supplements. (p. 685)

Malnutrition Any disorder of undernutrition. (p. 680)

Multivitamin infusion (MVI) A concentrated solution that contains several water- and fat-soluble vitamins and is used as part of an intravenous (parenteral) nutritional source. (p. 685)

Nonessential amino acids Those amino acids that the body can produce without extracting them from dietary intake. (p. 684)

Nutrients Substances that provide nourishment and affect the nutritive and metabolic processes of the body. (p. 680)

Nutritional supplements Oral, enteral, or intravenous preparations used to provide optimal nutrients to meet the body's nutritional needs. (p. 680)

Nutritional support The provision of nutrients orally, enterally, or parenterally for therapeutic reasons. (p. 680)

Parenteral nutrition The administration of nutrients by a route other than through the alimentary canal, such as intravenously. (p. 680)

Pharmaconutrition The science elucidating the role nutrition plays in general health, as well as the key nutrients required by patients who are critically ill. (p. 680)

Semiessential amino acids Those amino acids that can be produced by the body but not in sufficient amounts in infants and children. (p. 685)

Total parenteral nutrition (TPN) The intravenous administration of the total nutrient requirements of patients with gastrointestinal dysfunction, accomplished via peripheral catheters, peripherally inserted central catheters, or central venous catheters. (p. 683)

Whey The thin serum of milk remaining after the casein and fat have been removed; it contains proteins, lactose, water-soluble vitamins, and minerals. (p. 682)

 **DRUG PROFILES**

amino acids, p. 685

carbohydrate formulation, p. 682

protein formulation, p. 682

Key drug

OVERVIEW

Nutrients are dietary products that undergo chemical changes when ingested (and metabolized) and cause tissue to be enhanced and energy to be liberated. Nutrients are required for cell growth and division; enzyme activity; protein, carbohydrate, and fat synthesis; muscle contraction; secretion of hormones (e.g., vasopressin, gastrin); wound repair; immune competence; gut integrity; and numerous other essential cellular functions. Providing for these nutritional needs is known as **nutritional support**. Adequate nutritional support is needed to prevent the breakdown of tissue proteins for use as an energy supply to sustain essential organ systems, which is what occurs during starvation. Malnutrition can decrease organ size and impair the function of organ systems (e.g., cardiac, respiratory, gastrointestinal [GI], liver, kidney). Nutritional support is a means of providing adequate nutrition to meet the body’s nutritional needs.

Pharmaconutrition seeks to understand the ways in which nutrition affects health in general and specifically to understand the key nutrients that are required by patients who are critically ill.

Malnutrition is a condition in which the body’s essential need for nutrients is not met by nutrient intake. The purpose of nutritional support is the successful prevention, recognition, and management of malnutrition. **Nutritional supplements** are dietary products used to provide nutritional support. Nutritional supplement products can be administered to patients in a variety of ways. They vary in the chemical complexity of their carbohydrates, proteins, and fats; electrolytes; vitamins and minerals; as well as in their amounts of these elements and their osmolality. These nutrients may be given in a digested form, a partially digested form, or an undigested form. Nutritional supplements can also be tailored for specific disease states.

Patients’ nutrient requirements vary according to age, sex, weight, level of physical activity, pre-existing medical conditions, nutrition status, and current medical or surgical treatment. Nutritional supplements are classified according to their method of administration as either enteral or parenteral. **Enteral nutrition** is the provision of food or nutrients through the GI tract. **Parenteral nutrition** is the intravenous (IV) administration of nutrients. Its purpose is to promote **anabolism** (tissue building), nitrogen balance, and maintenance or improvement of body weight. It is used when the oral or enteral feeding routes cannot be used (e.g., in postoperative patients or patients who are cachectic from advanced cancer or AIDS). The selection of

either enteral or parenteral nutrition and the specific nutritional composition of the product used depend on the specific patient and the clinical situation. It is important to note that parenteral nutrition orders must be double-checked by two nurses prior to administration to ensure errors do not occur.

ENTERAL NUTRITION

Enteral nutrition is the provision of food or nutrients through the GI tract. The GI tract is the preferred route to deliver nutritional support (Marik, 2014). The most common and least invasive route of administration is the oral route. There are six enteral routes (Table 42.1), and five of these use a feeding tube (Fig 42.1).

Enteral nutrition formulas are designed to meet the basic macronutrient and micronutrient requirements of individuals

TABLE 42.1 Routes of Enteral Nutrition Delivery	
Route	Description
Esophagostomy	Feeding tube surgically inserted into the esophagus
Gastrostomy	Feeding tube surgically inserted directly into the stomach
Jejunostomy	Feeding tube surgically inserted into the jejunum
Nasoduodenal	Feeding tube placed from the nose to the duodenum
Nasojejunal	Feeding tube placed from the nose to the jejunum
Nasogastric	Feeding tube placed from the nose to the stomach
Oral	Nutritional supplements delivered by mouth

Fig 42.1 Tube feeding routes. (Adapted from: Mahan, L. K., Escott-Stump, S., & Raymond, J. L. (2012). *Krause’s food and the nutrition care process* (13th ed.; Fig 14-2). Philadelphia, PA: Saunders.)

BOX 42.1 Enteral Formulations**Elemental Formulations**

Peptamen® Vital® HN	Contents: dipeptides, tripeptides, or crystalline amino acids; glucose oligosaccharides; and vegetable oil or medium-chain triglycerides (MCTs)
Vivonex® Plus	Comments: minimum digestion; residue is minimal
Vivonex® T.E.N.	Indications: partial bowel obstruction, irritable bowel disease, radiation enteritis, bowel fistulas, and short bowel syndrome

Polymeric Formulations

Complete	Contents: complex nutrients (proteins, carbohydrates, and fat)
Ensure® Ensure Plus® Isocal® Osmolite® Portagen® Jevity® Sustacal®	Indications: preferred over elemental formulations for patients with fully functional GI tracts and few specialized nutrient requirements

Modular Formulations

Carbohydrate	Contents: single-nutrient formulas (protein, carbohydrate, or fat)
Moducal® Polycose®	Indications: can be added to a monomeric or polymeric formulation to provide a more individualized nutrient formulation
Fat	
MCT Oil® Microlipid®	
Protein	
Beneprotein® ProMod®	

Altered Amino Acid Formulations

Amin-Aid®	Contents: varying amounts of specific amino acids
Primene® TwoCal® TwoCal® HN Travasol®	Indications: patients with diseases associated with altered metabolic capacities

Formulation for Reduced Glucose Tolerance

Glucerna®	Contents: protein, carbohydrate, fat, sodium, potassium
	Indications: patients with reduced glucose tolerance (e.g., patients with diabetes)

who are unable to meet their nutritional needs orally. Many specialty products have been developed to exhibit specific pharmacological properties, such as immune-enhancing formulas containing arginine, glutamine, nucleotides, and omega-3 fatty acids. Patients who may benefit from feeding tube delivery of nutrients include those with abnormal esophageal or stomach peristalsis, altered anatomy secondary to surgery, depressed

consciousness, or reduced digestive capacity. The enteral route is considered superior to the parenteral route for the administration of nutritional supplements. In patients who are critically ill, such as a patient with burns, early enteral nutrition within at least 24 to 72 hours is recommended. Early enteral nutrition has several advantages, such as protection of intestinal mucosal integrity, reduction of infection, and reduction of morbidity (Shankar, Daphnee, Ramakrishnan, et al., 2015).

Approximately 100 different enteral formulations are available. The enteral supplements have been divided into groups according to the basic characteristics of their formulations; these groups include elemental, polymeric, modular, altered amino acid, and reduced glucose tolerance formulations. These are described in Box 42.1.

Mechanism of Action and Drug Effects

The enteral formula groups provide the basic building blocks for anabolism. Different combinations and amounts of these nutrients are used based on the individual patient's anabolic needs. Enteral nutrition supplies complete dietary needs through the GI tract by the normal oral route or by feeding tube.

Indications

Enteral nutrition can be used to supplement an oral diet that is currently insufficient for a patient's nutrient needs or used alone to meet all the patient's nutrient needs. Box 42.2 lists the main types of enteral nutritional supplements and their indications.

Contraindications

The usual contraindication to any kind of nutritional supplement is known drug allergy to a specific product or a genetic disease that renders a patient unable to metabolize certain types of nutrients.

Adverse Effects

The most common adverse effect of nutritional supplements is GI intolerance, manifesting as diarrhea. Infant nutritional formulations are often associated with allergies and digestive intolerance; other nutritional supplements are most commonly associated with osmotic diarrhea. Rapid feeding or bolus doses can result in **dumping syndrome**, which produces intestinal disturbances. In addition, tube feeding places patients at significant potential for aspiration pneumonia. This is especially true in patients in whom general mobility is compromised.

Interactions

Various nutrients can interact with drugs to produce significant food-drug interactions. With some exceptions, food usually delays the absorption of drugs when administered simultaneously with them. High gastric acid content or prolonged emptying time can result in decreased effects of certain antibiotics (e.g., cephalosporins, erythromycin, penicillins). An increased absorption rate resulting in increased therapeutic effects can be seen when corticosteroids or vitamins A and D are given with nutritional supplements. The antibiotic effects of tetracyclines and quinolones are decreased when they are given with nutritional supplements as a result of physical chemical binding (chelation). These drugs must be given at least 2 hours before or after tube feedings.

BOX 42.2 Enteral Nutrition Supplements: Indications

Complete Nutritional Formulations (i.e., for general nutritional deficiencies)

- Inability to consume or digest normal foods
- Accelerated catabolic status
- Undernourished because of disease

Incomplete Nutritional Formulations (i.e., for specific nutritional deficiencies)

- Genetic metabolic enzyme deficiency
- Liver or kidney impairment

Infant Nutritional Formulations

- Sole nutritional intake for premature and full-term infants
- Supplemental nutritional intake for older infants receiving solid foods
- Supplemental nutrition for breastfed infants

Tube feedings can also reduce the absorption of phenytoin; this reduced absorption can result in seizures. It is recommended that tube feedings be held for at least 2 hours before and after the administration of phenytoin. However, doing so can be problematic because the patient may not receive adequate nutrition if feedings are withheld. This issue is somewhat controversial, and some suggest that the interaction is more theoretical than actual. Thus, some institutions have opted to ignore the possible interaction and monitor phenytoin levels and patient status instead of withholding tube feedings; other institutions continue to withhold the tube feedings when phenytoin is administered. When continuous tube feedings are necessary, patients will often require phenytoin to be administered by IV. It is important to follow institutional protocols when administering enteral feedings when the patient requires phenytoin.

Dosages

Because nutrient requirements vary greatly, dosages are individualized according to patient needs.

DRUG PROFILES

Enteral nutrition can be provided by a variety of supplements. Individual patient characteristics determine the appropriate enteral supplement. The four most commonly used enteral formulations are elemental, polymeric, modular, and altered amino acid.

Elemental Formulations

Elemental formulations are enteral supplements that contain dipeptides, tripeptides, or crystalline amino acids. Minimal digestion is required with elemental formulations. These supplements are indicated in patients with pancreatitis, partial bowel obstruction, irritable bowel disease, radiation enteritis, bowel fistulas, and short bowel syndrome. They are contraindicated in patients who have had hypersensitivity reactions to them. Elemental formulation supplements are available without a prescription.

Polymeric Formulations

Polymeric formulations are enteral supplements that contain complex nutrients derived from proteins, carbohydrates, and fat. The polymeric formulations are some of the most commonly used enteral formulations because they most closely resemble normal dietary intake. They are preferred over elemental formulations in patients who have fully functional GI tracts and have no specialized nutrient needs. Polymeric formulations are less hyperosmolar than elemental formulations and therefore cause fewer GI problems. They are contraindicated in patients who have had hypersensitivity reactions to them. They are available without a prescription.

The commonly used enteral supplement in the polymeric formulation category of enteral nutritional products is Ensure. It is lactose free and is also available in a higher-calorie formula called Ensure Plus. Other polymeric formulations are listed in Box 42.1. These supplements contain complex nutrients such as **casein** (the principal protein of milk) and soy protein for protein; corn syrup and maltodextrins for carbohydrates; and vegetable oil or milk fat for fat. They are available in liquid formulations only.

Modular Formulations

carbohydrate formulation

Moducal and Polycose are examples of commonly used enteral supplements in the carbohydrate modular formulation category. Both are carbohydrate supplements that supply carbohydrates only. They are intended as an addition to monomeric or polymeric formulations to provide a more individualized nutrient mix. They are available in liquid formulations only. These products are available without a prescription and are contraindicated only in patients who have had a hypersensitivity reaction to them.

fat formulation

Microlipid and MCT Oil are the formulations available in the fat category of enteral supplements. Microlipid is a fat supplement supplying only fats. It is a concentrated source of calories and contains 4.5 kcal/mL. These supplements are given to help individualize nutrient formulations. They may be used in patients with malabsorption and other GI disorders and in patients with pancreatitis. They are available in liquid formulations only. These products are obtainable without a prescription and are contraindicated only in patients who have had hypersensitivity reactions to them.

protein formulation

Beneprotein and ProMod are examples of protein modular formulations. They are used to increase patients' protein intake and provide additional proteins. They are derived from a variety of sources, such as **whey**, casein, egg whites, and amino acids. All the available products are dried powders that must be reconstituted with water. They may sometimes be reconstituted by adding them to enteral nutrition formulations that are already in liquid form. They are indicated for patients with increased protein needs. They are contraindicated in patients who have

TABLE 42.2 Peripheral and Total Parenteral Nutrition: Characteristics

Characteristic	Peripheral	Central
Goal of nutritional therapy (total versus supplemental)	Supplemental (total if moderate to low needs)	Total
Length of therapy	Short (fewer than 14 days)	Long (7 days or longer)
Osmolarity	Hyperosmolar (600–900 mOsm/L)	Hyperosmolar (600–900 mOsm/L)
Fluid tolerance	Must be high	Can be fluid restricted
Dextrose	Less than 10%	10–35%
Amino acids	Less than 3%	More than 3–7%
Fats	10–20%	10–20%
Calories/day	Less than 2 000 kcal/day	More than 2 000 kcal/day

had hypersensitivity reactions to them. Protein formulation supplements are available without a prescription.

Altered Amino Acid Formulations

Amin-Aid is one of many amino acid formulation nutritional supplements available. Many of the nutritional supplements in this category are also listed as modular formulations because they can be used as both single-nutrient formulas and as nutritional formulations for patients with genetic errors of metabolism. Specialized amino acid formulations are used most commonly in patients who have metabolic disorders such as phenylketonuria, homocystinuria, or maple syrup urine disease. They are also used to supply nutritional support to patients with such illnesses as kidney impairment, eclampsia, heart failure, or liver failure.

TOTAL PARENTERAL NUTRITION

Parenteral nutrition supplementation (IV administration) is the preferred method for patients who are unable to tolerate and maintain adequate enteral or oral intake. Instead of administration of partially digested nutrients into the GI tract (as in enteral nutrition), vitamins, minerals, amino acids, dextrose, and lipids are administered intravenously directly into the circulatory system. This effectively bypasses the entire GI system, which eliminates the need for absorption, metabolism, and excretion. Parenteral nutrition is also called **total parenteral nutrition (TPN)**.

TPN can supply all the calories, carbohydrates, amino acids, fats, trace elements, vitamins, and minerals needed for growth, weight gain, wound healing, convalescence, immunocompetence, and other health-sustaining functions.

TPN can be administered through either a peripheral vein (usually via an 18-gauge catheter and with less than a 10% solution of dextrose), a peripherally inserted central catheter (PICC), or a central venous catheter. Each route of delivery of TPN has specific requirements and limitations. It is generally accepted that TPN is used only when oral or enteral support is impossible or when the GI absorptive or functional capacity is not sufficient to meet the nutrition needs of the patient. Some of the factors that must be considered in deciding whether to use a peripheral or central route for TPN for a given patient are listed in [Table 42.2](#). For both parenteral and central route for TPN, two nurses must double-check the orders to ensure the appropriate amount of TPN solution is given to the patient.

Peripheral Total Parenteral Nutrition

Peripheral TPN is one route of administration of TPN. A peripheral vein is used to deliver nutrients to the patient's circulatory system. Peripheral TPN is usually a temporary method of nutrition administration. The long-term administration of nutritional supplements via a peripheral vein may lead to phlebitis. It is considered a temporary measure to provide adequate nutrients in patients who have mild deficits or who are restricted from oral intake and have slightly elevated metabolic rates.

Peripheral TPN is valuable in patients who do not have large nutrition needs, can tolerate moderately large fluid loads, and need nutritional supplements only temporarily. Peripheral TPN may be used alone or in combination with oral nutritional supplements to provide the necessary fat, carbohydrate, and protein needed by the patient to maintain health.

Mechanism of Action and Drug Effects

Peripheral TPN provides the basic nutrient building blocks for anabolism. Different combinations and amounts of these supplements are used based on the individual patient's anabolic needs.

Indications

Peripheral TPN is used to provide complete daily nutrition or to administer nutrients to patients who need more nutrients than their current oral intake can supply. It is meant only as a temporary means (less than 2 weeks) of delivering TPN. Circumstances under which patients may benefit from the delivery of peripheral TPN are as follows:

- The patient must undergo a procedure that restricts oral feedings.
- The patient has anorexia caused by radiation or cancer chemotherapy.
- The patient has a GI illness that prevents oral food ingestion.
- The patient has undergone surgery of any type.
- The patient's nutritional deficits are minimal, but oral nutrition will not be reinstated for more than 5 days.

Contraindications

As mentioned previously regarding the enteral nutritional products, the only usual contraindication to nutritional supplements of any kind is known drug allergy to a specific product or a genetic disease that renders a patient unable to assimilate certain types of nutrients.

Adverse Effects

The most severe adverse effect of peripheral TPN is phlebitis, which is vein irritation or inflammation of a vein. If phlebitis is severe and is not treated appropriately, it can lead to the loss of a limb, although this is rare. Another potential adverse effect is fluid overload. Peripheral TPN is limited to solutions with a lower dextrose concentration, generally less than 10%, to avoid sclerosis of the vein. Thus, large volumes are needed to meet a patient's daily nutritional requirements. Some patients, such as those with kidney or heart failure, cannot tolerate large fluid volumes. In these patients, fluid restriction may make it impossible to provide adequate calories through peripheral TPN.

Central Total Parenteral Nutrition

In central TPN, a large central vein is used to deliver nutrients directly into the patient's circulation. Usually, the subclavian or internal jugular vein is used. Central TPN is generally indicated for patients who require nutritional supplements for a prolonged period, usually longer than 7 to 10 days. It can also be used in the home care setting. There are a variety of indications for central TPN. The disadvantages of central TPN are the risks associated with venous catheter insertion and the use and maintenance of the central vein. There is a greater potential for infection, more serious catheter-induced trauma and related events, metabolic alterations, and other technical or mechanical problems than with peripheral TPN.

Mechanism of Action and Drug Effects

TPN is used to supply nutrients to patients who cannot ingest nutrients by mouth and cannot meet required daily nutritional needs by the enteral or peripheral parenteral routes. Like peripheral TPN, central TPN supplies the basic building blocks required for anabolism. It provides the necessary fat, carbohydrate, and protein that the patient needs to maintain health.

Indications

Central TPN delivers total dietary nutrients to patients who require nutritional supplementation. Circumstances under which patients may benefit from the delivery of central TPN include the following:

- The patient has large nutritional requirements (e.g., due to metabolic stress or hypermetabolism).
- The patient needs nutritional support for a prolonged period (longer than 7 to 10 days).
- The patient is unable to tolerate large amounts of fluid.

Contraindications

Central TPN is contraindicated in patients with known allergy to any of its components. Rarely, a patient who is allergic to eggs may have cross-sensitivity to lipid formulations. TPN is used only when the GI tract cannot be used (e.g., in postoperative patients or those who are otherwise unable to eat or digest and absorb nutrients).

TABLE 42.3 Amino Acids: Recommended Daily Dosage Guidelines

HEALTHY		MALNOURISHED OR WITH TRAUMA OR BURN
Adult	Infant or Child	Adult
0.9g/kg	1.5 to 3 g/kg	Up to 2 g/kg

Adverse Effects

The most common adverse effects of central TPN are those associated with the use of the central vein for delivery of the TPN. The risks associated with insertion of the infusion line, as well as the use and maintenance of the central vein for administration of TPN, can create some complications. Central TPN involves greater potential for infection (sepsis), serious catheter-induced trauma and related events such as extravasation of parenteral nutrition solution, and other technical or mechanical problems than are associated with peripheral TPN. Larger and more concentrated volumes of nutritional supplements are being delivered with central TPN, and therefore there is also a greater chance for metabolic complications such as hyperglycemia or hypoglycemia.

Dosages

Dosage requirements vary from patient to patient. Age, sex, weight, and numerous other factors must be considered for proper administration of TPN. Guidelines for amino acids appear in [Table 42.3](#).

DRUG PROFILES

The individual components of peripheral and central TPN are the same. The differences lie in the concentrations and amounts of the components delivered per volume of nutritional supplement. The basic components of peripheral or central TPN are amino acids, carbohydrates, lipids, trace elements, vitamins, fluids, and electrolytes. Most of the electrolyte components are discussed in [Chapter 30](#).

Amino Acids

Amino acids have many roles in the maintenance of normal nutritional status. Their primary role is protein synthesis, or anabolism. Provision of adequate amino acids in nutritional supplements reduces the breakdown of proteins (**catabolism**) and also helps to promote normal growth and wound healing.

Amino acids are commonly classified as essential or nonessential, according to whether they can or cannot be produced by the body. **Nonessential amino acids** are those that the body produces and therefore need not be present in dietary intake. The body is able to manufacture, from nutritional nitrogen sources, all but eight of the available amino acids. **Essential amino acids** are those amino acids that cannot be produced by the body. Therefore, they must be included in daily dietary intake. Amino acids are used as building blocks for protein that is needed for normal growth and development. Two amino acids, histidine

BOX 42.3 Amino Acids: Classification

Essential	Nonessential	Semiessential
Isoleucine	Alanine	Arginine
Leucine	Asparagine	Histidine
Lysine	Aspartic acid	
Methionine	Cysteine	
Phenylalanine	Glutamine	
Threonine	Glutamic acid	
Tryptophan	Glycine	
Valine	Proline	
	Serine	
	Tyrosine	

Fig 42.2 One gram of dextrose, fat, or protein will provide varying amounts of energy as calories.

and arginine, are not manufactured by the body in large enough quantities during rapid growth periods such as infancy or childhood. Thus, they are referred to as **semiessential amino acids**. Box 42.3 lists amino acids according to their categories.

amino acid solutions

Amino acid crystalline solutions (Aminosyn® 5%, 7%, 8.5%, and 10%; Primene® 10%) can be used in either peripheral or central TPN. Amino acids are a source of both protein and calories. They provide 4 kcal/g. The two currently available amino acid solutions differ only in their respective concentrations. The dosage of these solutions varies depending on the patient's weight and requirements. These supplements have no contraindications to their use.

carbohydrates

In nutritional support, carbohydrates are usually supplied to patients through dextrose. Dextrose is normally the greatest source of calories and provides 3.4 kcal/g. However, protein (amino acids) and lipids are also used as calorie sources (Fig 42.2). The concentration of dextrose in TPN is an important consideration. In peripheral TPN, dextrose concentrations are kept below 10% to decrease the possibility of phlebitis. In central TPN, dextrose concentrations can range from 10 to 50% but are commonly 25 to 35%. Because dextrose is a sugar, supplemental insulin may be given simultaneously with nutritional supplements. Use of a balanced nutritional supplement that

Fig 42.3 Lipid emulsions supply essential fatty acids and energy.

contains dextrose and lipids as caloric sources decreases the need for large amounts of insulin.

fat

The average Canadian diet consists of 40% fat. This means that of the total calories supplied, 40% are obtained through fat grams. The ideal diet contains no more than 30% fat. IV fat emulsions serve two functions: they supply essential fatty acids and they are a source of energy or calories. As with the amino acids, certain fatty acids are essential because the body cannot produce them. Linoleic acid cannot be synthesized by the body. It is needed to produce linolenic and arachidonic acid. If these fatty acids are not present in dietary or nutritional supplements, an **essential fatty acid deficiency** may develop. Clinical signs of essential fatty acid deficiency are hair loss, scaly dermatitis, growth retardation, reduced wound healing, decreased platelets, and fatty liver (Fig 42.3).

lipid emulsions

The currently available lipid emulsions are Intralipid®, available as 10%, 20%, or 30% emulsions, and Liposyn® II, available as a 10% emulsion. They differ in fat origin. Intralipid is made from soybean oil, and Liposyn is made from safflower oil.

Lipid emulsions normally deliver 20 to 30% of total daily calories and must not exceed 60% of daily caloric intake. Fat emulsions are most beneficial when combined with dextrose solutions. The use of fat to meet caloric needs prevents potentially harmful conditions such as hyperglycemia, hyperinsulinemia, and hyperosmolality, which can occur when a patient's entire caloric needs are being met solely by dextrose.

Trace Elements

Trace elements are available in individual solutions and in many different combinations. The following are considered trace elements:

- Chromium
- Copper
- Iodine
- Manganese
- Molybdenum
- Selenium
- Zinc

Specific dosages and frequencies depend on the individual patient's requirements, based on the current diet reference and determined by the health care provider. Vitamins and minerals may also be added accordingly. A common multivitamin combination is **multivitamin infusion (MVI)**.

❖ NURSING PROCESS

◆ ASSESSMENT

Perform a thorough nutritional assessment with attention to dietary history, weekly and daily food intakes, weight, and height before initiating any nutritional supplements. Conduct a thorough nursing history and survey of all systems, including questions about any unusual symptoms, possible nutritional concerns, nausea, vomiting, loss of appetite, and weight gain or loss. Focus other questions on past and present medical and health history; history of any difficulties with nutrition, GI absorption, or food intolerance; stressors; and a complete medication profile, including a listing of all prescription drugs, over-the-counter (OTC) drugs, and natural health products. Consultation with a registered dietitian is crucial to help identify the nutrients that are missing in a particular patient's diet. Total body metabolic rate, body mass index, muscle mass, and other variables linked to nutritional status will most likely be assessed and are data that a nutritional consult may provide. Laboratory studies that may need to be assessed include the following: total protein, albumin, blood urea nitrogen (BUN), red blood cell (RBC) count, white blood cell (WBC) count, vitamin B₁₂, hemoglobin (Hgb), and hematocrit. Other laboratory studies may include cholesterol, electrolytes, total lymphocytes, serum transferrin, ferritin, urine creatinine clearance, lipid profile, and urinalysis. All of the described objective and subjective data will help the health care provider, dietitian, and other members of the health care team select the appropriate nutritional supplements for the patient.

Before administering an enteral nutrition supplement that is an elemental formulation, determine if the patient has a history of allergic reaction to any of the contents of the solution. Assess for contraindications and cautions, and document the findings. Of most concern is assessing the patient's heart and kidney status and ensuring that the ingredients and the amount of solution will not be too taxing on these systems. In addition, because these solutions are given either by mouth or via tube feedings (see [Chapter 10](#)), it is important to assess the patient's ability to swallow, and bowel sounds, and to note any nausea or vomiting. Remember that protein-based formulations are to be avoided in patients with allergies to egg whites and whey.

Prior to the implementation of parenteral nutrition, assess for allergies to any of the ordered components of the IV solution and make note of the patient's age and metabolic needs. There are usually multiple combinations of products available; thus, it is important to assess the patient carefully for allergies to essential proteins, amino acids, carbohydrates, trace elements, minerals, vitamins, lipids, high concentrations of dextrose, and any other ingredients present. Assess your knowledge base about parenteral nutrition (including not leaving parenteral nutrition solution out of the fridge for longer than 60 minutes prior to infusion or letting parenteral nutrition hang for greater than 24 hours—12 for lipids, to prevent bacterial growth) and situations that necessitate infusions through a central line, peripherally inserted central lines, or peripherally inserted midline catheters.

Some of the complications of parenteral nutrition include pneumothorax, infection, air emboli or emboli resulting from protein or lipid aggregation (associated with central catheter IV lines), septicemia resulting from the nutrient-rich solutions with an invasive IV route of administration, metabolic imbalances because of the solution or ingredients, and vomiting (seen with lipid administration in parenteral nutrition). Also perform a complete baseline assessment and continuously monitor the following: (1) central line site, including patency, intactness, and appearance; (2) WBC and RBC counts as well as other laboratory values and parameters (listed earlier); (3) vital signs; (4) serum glucose; and (5) heart rhythm with electrocardiogram (ECG) readings (as prescribed).

◆ NURSING DIAGNOSES

- Nutrition less than body requirements, resulting from inability to take in sufficient nutrients
- Diarrhea resulting from a decreased tolerance to enteral feedings and their ingredients
- Potential for infection (sepsis) resulting from parenteral infusions and use of central venous access line

◆ PLANNING

◆ Goals

- Patient will regain normal nutritional status through adequate dietary intake and supplemental feedings or nutrients.
- Patient will remain free from diarrhea as a result of enteral supplementation.
- Patient will remain free from infection during parenteral nutritional supplementation.

◆ Expected Patient Outcomes

- Patient's nutritional status improves with enteral or parenteral nutritional supplementation as prescribed, as evidenced by proportional weight gain, adequate fluid volume status with improved skin turgor, improved urinary output to at least 30 mL/hr, and a return to normal of laboratory values such as total protein, albumin, ferritin, hematocrit, and hemoglobin.
- Patient identifies measures to decrease diarrhea while receiving enteral feedings, such as use of prescribed drugs to decrease motility or use of OTC drugs or natural health products, as ordered.
- Patient states measures to minimize potential for infection at the TPN site (peripheral or central), such as checking the site frequently for redness, swelling, drainage, or abnormal warmth, and reporting these signs as well as fever or chills to the health care provider or home health care nurse immediately.

◆ IMPLEMENTATION

Meeting a patient's nutritional needs relies on the implementation of agency-specific evidence-informed enteral or TPN feeding protocols and interprofessional collaboration, including the

dietitian, nurse, pharmacist, and other health care providers. A health care provider's order must be complete and dated before enteral or total parenteral (peripheral or central) nutrition supplementation is started. In general, monitoring the status of the patient during and after enteral feedings is crucial to safe and prudent nursing care.

It is general practice with nasogastric feeding solutions to check for proper placement and detect gastric residuals to avoid pulmonary aspiration and other complications. A *gastric residual* refers to the volume of fluid remaining in the stomach at a point in time during enteral nutrition feeding. There is a wide range of residual volumes considered (from 150 to 500 mL); these volumes are often used to predict tube-feeding tolerance or pulmonary aspiration risk (Flynn Makic, Rau, & VonRueden, 2013) or to confirm a decision to withhold feedings. According to Flynn Makic and colleagues, there is no evidence to support the use of residual volumes as markers to support withholding feedings or to prevent pulmonary aspiration, and this practice may, in fact, lead to underfeeding. Nonetheless, most agencies recommend checking for placement to ensure that the tube is in the stomach and has not passed through the larynx, through the trachea, and down into the bronchi of the lungs. One method of checking a nasogastric tube's placement involves aspirating fluid from the tube with a syringe and testing the pH to determine the acidity of the fluid. If the aspirate has a pH of 5.5 or lower, the tube is in the correct position. If these checks are not possible, a chest X-ray must be used. Measure gastric residual volumes and document these before each feeding as well as before administration of each medication. When checking gastric residual volumes, stop the tube feeding and then aspirate stomach contents using a syringe connected to the particular tube. If the volume aspirated is more than the volume delivered over the previous 2 hours (of continuous feeding), return the aspirate, hold the feeding, and contact the health care provider while keeping the head of the patient's bed elevated. For intermittent bolus feedings, if the residual amount is more than 50% of the volume previously infused, it is the standard of care to return the aspirate, withhold the feeding, and contact the health care provider. A reduction in the tube feeding volume will probably then be ordered. Always check hospital or facility policy or protocol before the use of enteral feedings, and consistently check and manage residuals during therapy.

Newer tubes for nasogastric and other routes of enteral feeding have smaller diameters and are thinner (5 French to 10 French) and more pliable for better patient tolerance than older tubes. Small-bore tubes are more comfortable but have a greater likelihood of becoming clogged by medications or thick enteral formulations. Small-bore silastic feeding tubes with weighted ends are intended to float in the duodenum. Placement is verified by X-ray. However, the smaller-diameter tubes make gastric aspiration more difficult and their use is not recommended. Depending on agency policy, placement may be checked by auscultation of an air bolus. A forceful air bolus can remove the weighted end.

To prevent clogging of the feeding tube, it is often helpful to flush the tube with 30 mL of lukewarm water (per agency policy), using a gentle, back-and-forth motion with the plunger of the syringe. After instilling the water, if a stubborn clog does not

immediately allow for back-and-forth motion, clamp the tube and let it soak for up to 20 minutes. Acidic juices and carbonated beverages should not be used because they may cause a protein precipitate that will result in further clogging. In addition to regular and consistent warm water flushes, pancreatic enzymes and sodium bicarbonate have been successful in unclogging tubes; however, the best practice to manage clogged feeding tubes is prevention (Fisher & Blalock, 2014). Clog Zapper® is a food-grade powder referred to as an "enzyme cocktail" (with acids, buffers, antibacterial agents, and metal inhibitors) to clear blocked tubes. It is available premeasured and loaded in a ready-to-use system and is approved for use with gastric, jejunal, nasogastric, and nasojejunal tubes. Always follow agency-specific guidelines when using these strategies. Percutaneous enteral gastrostomy (PEG) tubes are also commonly used in many situations but do require surgical insertion by a gastroenterologist and are often inserted procedurally under procedural sedation. Their care includes performing dressing changes during the initial period and then checking for residuals regularly throughout their use. Placement need not be checked, but if it appears that the tube has come out of the opening and is longer than previously noted, stop the infusion and contact the health care provider.

Follow health care provider-ordered enteral feeding infusion rates and concentrations carefully. The patient should be in an upright position for enteral feeds. Usually, the initial rate is 50 mL/hr at one-half strength, but this can be increased per patient tolerance to a rate ordered by the health care provider. More rapid feeding increases the potential for hyperglycemia, dumping syndrome, and diarrhea. Infusion rates of enteral feedings may be adjusted by the health care provider as per the patient's tolerance of the feeding. Keep tube feeding formulas at room temperature and never administer them cold or warm. If all the necessary steps to decrease or prevent diarrhea have been taken and have failed, antidiarrheal medications may be needed. Lactose-free nutritional solutions are available and are recommended for patients who are lactose intolerant. Patients who have lactose intolerance may experience cramping, diarrhea, abdominal bloating, and flatulence with the ingestion of enteral milk-based feedings.

The preparation and administration of enteral medications requires a protocol for safe delivery. Drug absorption depends on the drug's solubility and ability to permeate the intestinal mucosa. The distal end of the feeding tube can be in the stomach, duodenum, or jejunum. Therefore, the position of the distal end should be determined prior to medication administration; consult with the pharmacist to ensure the medication will be properly dissolved and absorbed. The health care provider should always be cautious regarding medication compatibility with tube feeding. In general, the following are safe practices to follow when administering medications via enteral tubes: (1) prepare and administer medications one at a time; (2) open immediate-release gelatin capsules to remove the powder or to crush the solid contents, which are then diluted; (3) further dilute liquid forms of drugs; (4) crush tablets into a fine powder (using a self-contained crushing device to avoid mixing residues from other drugs) and dilute for administration; (5) use purified water for diluting to avoid the presence of chemical

contaminants in tap water; and (6) avoid mixing drugs with the feeding formula—stop the formula and flush with at least 15 mL of purified water, follow with the medication using a clean 30 mL syringe, and flush with an additional 15 mL of purified water. The feeding can be resumed once the medication has been administered.

Assess parenteral nutrition/TPN infusions every hour or per the facility's policies and procedures. Document the status of the entire infusion system and equipment as well as the condition of the patient. The standard of care prior to parenteral nutrition initiation is to examine the patient first and then check the insertion site to confirm insertion site placement, infusion pump, and solution (two nurses are required to confirm solution concentration with the order). It is important to never use a peripheral or central line for anything other than parenteral nutrition or add anything to a parenteral nutrition solution. To prevent infection, change parenteral nutrition tubing every time a new bag is added to the infusion or as per facility policy. It is also recommended that tubing changes occur daily with the beginning of each new infusion. A 1.2-micron filter is used to trap bacteria, including *Pseudomonas* species. Record the patient's temperature every 4 hours, or as ordered, during the infusion, and report any increase in temperature over 37.8°C to the health care provider immediately. Check the patient frequently for signs and symptoms of hyperglycemia, such as polydipsia, polyuria, headache, dehydration, nausea, vomiting, and weakness. Never accelerate infusion rates to increase plasma volume because the rapid increase of dextrose solution may precipitate hyperglycemia and other related complications. Insulin replacement may be needed with the increase in dextrose; therefore, measure serum glucose levels by glucometer (usually every 6 hours) so that hyperglycemia may be immediately recognized and treated.

Hypoglycemia is manifested by cold, clammy skin; dizziness; tachycardia; and tingling of the extremities. Hypoglycemia associated with parenteral nutrition may be prevented by gradual reduction of the IV feeding rate to allow the pancreas time to adapt to changing blood glucose levels. If parenteral nutrition is discontinued abruptly, rebound hypoglycemia may occur. This condition can be prevented by providing infusions of 5 to 10% glucose in situations in which parenteral nutrition must be discontinued immediately. Fluid overload may also occur with parenteral nutrition, manifested by weak pulse, hypertension, tachycardia, confusion, decreased urine output, and pitting edema; this problem may be prevented by maintaining infusion rates as ordered. If signs of fluid overload occur, slow the infusion rate, measure vital signs, contact the health care provider, and remain with the patient until the patient's condition has stabilized. Include auscultation of breath and heart sounds in the patient assessment,

especially if additional therapies that may precipitate fluid overload are administered. Measurement of intake and output is usually indicated when parenteral nutrition is administered (and with enteral supplementation as well). See the [Patient Teaching Tips](#) for more information on the use of nutritional supplements.

EVALUATION

Therapeutic responses to nutritional supplementation include improved well-being, energy, strength, and performance of activities of daily living; an increase in weight; and laboratory test results that reflect improved nutritional status. Specific laboratory values may include some of the following: albumin, total protein, hematocrit, hemoglobin, RBC and WBC counts, electrolyte, blood glucose, and ferritin. Perform ongoing evaluation for adverse effects associated with all enteral or parenteral nutrition infusions during and after therapy, and complete nutritional re-evaluation periodically to ensure that the patient's nutritional needs are met. For outpatients, this may require frequent appointments with a health care provider or monitoring by a home health care nurse. Always refer to goals and outcome criteria to evaluate the effectiveness of therapy.

CASE STUDY

Total Parenteral Nutrition

Lariba, a 28-year-old florist, has been unable to eat due to severe nausea and vomiting as a result of her pregnancy. She is at 13 weeks' gestation and has been admitted to the hospital because of dehydration and her inability to eat. The decision has been made to give her TPN for at least 1 week. After 1 week of therapy, her obstetrician will then decide whether to continue or stop the infusion, based on her response. She will be receiving the TPN infusion via a peripheral IV catheter, with infusion bags that will be changed every 24 hours.

1. Lariba is anxious about this infusion and asks the nurse, "Why is that bag so large? What is in the bag?" How will the nurse answer these questions?
2. The nurse explains to Lariba that her blood glucose levels will need to be monitored while she is receiving the TPN. Lariba begins to cry, saying, "This morning sickness is bad enough, but now I have diabetes too? How can that be?" What is the nurse's best response?
3. What potential complication will the nurse monitor for that can occur with peripherally administered TPN?
4. Before beginning the infusion, the nurse checks the ingredients of the TPN bag. The nurse notices that 20% dextrose is listed in the contents. Will the nurse add this bag to the patient's infusion? Explain your answer.

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

PATIENT TEACHING TIPS

- Patients are often discharged from a facility with the need for various types of tube feedings. In this situation, provide the patient, family members, and caregivers with education, instructions, and demonstrations about daily care of the tube, preparation of tube feedings, and related procedures. Present the education in a way that reflects the learning needs of the patient and those involved in the patient's care.
- Instruct patients, family members, and caregivers about the need for correct placement of the tube, which should be checked prior to each tube feeding if a nasogastric tube is used. Incorrect placement of a nasogastric tube would be manifested by coughing, choking, difficulty speaking, cyanosis, and subsequent respiratory distress. The head of the bed must remain elevated at 30 to 45° during infusions and

for 1 hour afterwards to reduce gastroesophageal reflux and the probability for aspiration; this is more critical with nasogastric tube feedings than with tube feedings by other routes.

- Provide contact names and phone numbers of health care providers, home health care nurses, and other resources to patients, family members, and caregivers so that therapy can be monitored and problems and complications as a result of feeding can be averted. A fever, difficulty breathing, sounds of lung congestion, high amounts of residual, resistance to the flow of the feeding solution, and resistance when checking the residual all require additional monitoring. Appropriate interventions must be implemented, including seeking emergency medical care if needed.
- Patients who are discharged home and are receiving parenteral nutrition will need individualized education as well as support from home health care or related health care services. Practice is critical to acquisition of skills by the patient, family members, or caregivers and must be an integral part of patient education. Before a patient is discharged, explain and demonstrate all procedures for storage, cleansing and care of the site, dressing changes, irrigation of the catheter, pump function and care, and changing of the bag, filters, and tubing; require

return demonstrations by the patient. Advise the patient that parenteral nutrition in the home requires home health care services from a registered nurse to help prevent the complications of infection at the site, sepsis, fever, and pneumonia.

- For patients who normally monitor and log/journal their serum glucose levels, it is important to educate them about the need to check serum glucose levels at home, as ordered by the health care provider if parenteral nutrition or other infused solutions high in dextrose are administered. Thoroughly explain the operation of a glucometer, with specific steps for its use included in a demonstration to the patient, family members, or caregivers. In addition, include and reinforce instructions for self-administration of insulin, if needed.
- Instruct patients to report to their health care provider any signs or symptoms of potential complications of parenteral nutrition, including fever, cough, chest pains, dyspnea, and chills (all of which are indicative of adverse reactions to lipid infusions). Restlessness, nervousness, fainting, and tachycardia are associated with hypoglycemia and must also be reported, as must the occurrence of polyuria, polydipsia, polyphagia, nausea, vomiting, headache, or weakness, which indicate hyperglycemia.

KEY POINTS

- A thorough nutritional assessment and consultation with a registered dietitian are essential to adequate interventions for malnourished patients.
- Various enteral feeding formulations with different nutritional content are available, including some that are lactose free.
- Enteral feedings may result in complications such as hyperglycemia, dumping syndrome, and aspiration of the nutritional supplement.
- Parenteral nutrition supplementation, intravenously administered, is total parenteral nutrition (TPN) or hyperalimentation. TPN may be administered through a central vein.
- TPN is administered through a central venous catheter because of the hyperosmolarity of the substances used and

the need for dilution provided by a larger-diameter vein to prevent venous damage. Parenteral nutrition given through a peripherally inserted central catheter line is another option but uses a solution that has a lower concentration of dextrose and other ingredients.

- Parenteral feedings may result in air embolism, fever, infection, fluid volume overload, hyperglycemia, or hypoglycemia. If they are discontinued abruptly, rebound hypoglycemia may result.
- Cautious and skillful nursing care may prevent or decrease the occurrence of complications associated with enteral or parenteral nutritional supplements.
- Always check the compatibility of putting medications in tube with the pharmacist.

EXAMINATION REVIEW QUESTIONS

1. The nurse is assessing an enteral feeding that is infusing via a nasogastric feeding tube. Which statement about this tube is accurate?
 - a. It is surgically placed into the stomach.
 - b. It is inserted through the nose into the jejunum.
 - c. It is surgically inserted directly into the jejunum.
 - d. It is inserted through the nose into the stomach.
2. When administering total parenteral nutrition (TPN), the nurse is aware that one purpose of IV fat (lipid) emulsions is to provide which nutrient?
 - a. Calories
 - b. Amino acids
 - c. Minerals
 - d. Immunoglobulins
3. The nurse is monitoring a patient who is receiving a TPN infusion and notes that the patient has cold, clammy skin; shows tachycardia; and is reporting feeling dizzy. What is the immediate action of the nurse?
 - a. Stop the TPN infusion.
 - b. Check the patient's blood glucose level.
 - c. Order a stat (immediate) electrocardiogram.
 - d. Obtain an order for blood cultures.
4. A patient has new orders for administration of peripheral TPN. The nurse knows that peripheral parenteral nutrition is most appropriate in which situation?
 - a. Therapy is expected to last more than 14 days.
 - b. Therapy is expected to last fewer than 14 days.
 - c. A dextrose concentration of 20% is needed.
 - d. Nutritional needs are 3 000 kcal/day.

5. During the night shift, a patient's infusion of TPN runs out, the pharmacy is closed, and a new bag of TPN will not be available for about 6 hours. Which action by the nurse would be the most appropriate action at this time?
 - a. Hang a bottle of lipid solution.
 - b. Hang a bag of normal saline.
 - c. Hang a bag of 10% dextrose.
 - d. Call the health care provider for stat TPN orders.
6. The nurse is assessing a patient who is receiving an enteral tube feeding. Which are possible adverse effects associated with enteral feedings? (Select all that apply.)
 - a. Hypoglycemia
 - b. Air embolism
 - c. Aspiration
 - d. Diarrhea
 - e. Infection
7. A patient is receiving a tube feeding via a PEG tube of Glucerna at 50 mL/h. The orders also indicate to check the residual and flush the tubing every 4 hours with 30 mL of water. Calculate the total intake of fluid at the end of a 12-hour shift.
8. The nurse is assessing a newly admitted patient who had been living in his car for several months. Which of these are clinical signs of essential fatty acid deficiency? (Select all that apply.)
 - a. Hair loss
 - b. Wounds with delayed healing
 - c. Increased platelet levels
 - d. Scaly dermatitis
 - e. Excessive bruising

CRITICAL THINKING ACTIVITIES

1. A patient who is receiving enteral nutrition through a PEG tube is experiencing severe diarrhea. What is the nurse's priority action?
 2. A patient has been receiving TPN with a 25% glucose content, and the nurse has just discovered that the central IV access line is clogged. What is of the most immediate concern, and what is the nurse's priority action? Explain your answer.
 3. At the beginning of the morning shift, the nurse is reviewing the medication orders for a patient who is receiving the reduced glucose tolerance formulation Glucerna through a nasogastric feeding tube. The patient has a history of seizures, and a dose of phenytoin (to be given via the tube) is due later in the morning. What is the nurse's priority action?
- For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Antibiotics Part 1: Sulfonamides, Penicillins, Cephalosporins, Macrolides, and Tetracyclines

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Discuss the general principles of antibiotic therapy.
2. Explain how antibiotics work to rid the body of infections.
3. Briefly compare the characteristics and uses of antiseptics and disinfectants.
4. List the most commonly used antiseptics and disinfectants.
5. Discuss any nursing-related considerations associated with the environmental use of antiseptics and disinfectants.
6. Discuss the benefits and risks of antibiotic use with attention to the overuse or misuse of antibiotics and the development of drug resistance.
7. Discuss the concept of superinfection, including its etiology and prevention.
8. Classify various antibiotics by their general category, including sulfonamides, penicillins, cephalosporins, macrolides, and tetracyclines.
9. Discuss the mechanisms of action, indications, cautions, contraindications, routes of administration, and drug interactions for the sulfonamides, penicillins, cephalosporins, macrolides, and tetracyclines.
10. Identify drug-specific adverse effects and toxic effects of each of the antibiotic classes listed earlier, and cite measures to decrease their occurrence.
11. Develop a collaborative plan of care that includes all phases of the nursing process for patients receiving drugs in each of the following classes of antibiotics: sulfonamides, penicillins, cephalosporins, macrolides, and tetracyclines.

KEY TERMS

Antibiotic Having the ability to destroy or interfere with the development of a living organism; most commonly refers to antibacterial drugs. (p. 692)

Antimicrobial stewardship An institutional activity that includes ensuring appropriate selection, dosing, choice of route, and duration of antimicrobial therapy. (p. 695)

Antiseptic One of two types of topical antimicrobial agents; a chemical that inhibits the growth and reproduction of microorganisms without necessarily killing them. Antiseptics are also called *static agents*. (p. 694)

Bactericidal antibiotics that kill bacteria. (p. 698)

Bacteriostatic antibiotics that do not kill bacteria but rather inhibit their growth. (p. 697)

Beta-lactam A broad, major class of antibiotics that includes four subclasses: penicillins, cephalosporins, carbapenems, and monobactams, so named because of the beta-lactam ring that is part of the chemical structure of all drugs in this class. (p. 698)

Beta-lactamase Any of a group of enzymes produced by bacteria that catalyze the chemical opening of the crucial beta-lactam ring structures in beta-lactam antibiotics. (p. 698)

Beta-lactamase inhibitors Medications combined with certain penicillin drugs to block the effect of beta-lactamase enzymes. (p. 698)

Colonization The establishment and growth of microorganisms on skin, open wounds, or mucous membranes or in secretions without causing an infection. (p. 693)

Community-acquired infection An infection that is acquired by a person who has not recently been hospitalized or had a medical procedure (e.g., surgical procedure). (p. 693)

Targeted therapy The administration of antibiotics based on known results of culture and sensitivity testing identifying the pathogen causing infection. (p. 694)

Disinfectant One of two types of topical antimicrobial agents; a chemical applied to nonliving objects to kill microorganisms; also called *cidal agents*. (p. 694)

Empiric therapy The administration of antibiotics based on the health care provider's judgement of the pathogens most likely causing an apparent infection; it involves the presumptive treatment of an infection to avoid treatment delay, before specific culture information has been obtained. (p. 694)

Glucose-6-phosphate dehydrogenase (G6PD) deficiency An inherited disorder in which red blood cells are partially or completely deficient in glucose-6-phosphate dehydrogenase, a crucial enzyme in the metabolism of glucose. (p. 696)

Health care–associated infection An infection acquired during the course of receiving treatment for another condition in a health care facility. The infection is not present or incubating at the time of admission; also known as a *nosocomial infection*. (p. 693)

Host factors that are unique to a particular patient that affect the patient's susceptibility to infection and response to antibiotic drugs; examples include a low neutrophil count or a lack of immunoglobulins in the blood that carry antibodies. (p. 695)

Infections Invasion and multiplication of microorganisms in body tissues. (p. 692)

Microorganisms Microscopic living organisms; also called *microbes*. (p. 692)

Prophylactic antibiotic therapy Antibiotics taken before anticipated exposure to an infectious organism in an effort to prevent the development of infection. (p. 694)

Pseudomembranous colitis A potentially necrotizing inflammatory bowel condition that is often associated with antibiotic therapy; often caused by the bacterium

Clostridium difficile; also called by the more general term *antibiotic-associated colitis*. (p. 695)

Slow acetylation A common genetic host factor in which the rate of metabolism of certain drugs is reduced. (p. 696)

Subtherapeutic Generally refers to blood levels below therapeutic levels due to insufficient dosing. Also refers to antibiotic treatment that is ineffective in treating a given infection. Possible causes include inappropriate drug therapy, insufficient drug dosing, or bacterial drug resistance. (p. 695)

Superinfection (1) An infection occurring during antimicrobial treatment for another infection, resulting from overgrowth of an organism not susceptible to the antibiotic used. (2) A secondary microbial infection that occurs in addition to an earlier primary infection, often because of weakening of the patient's immune system function by the first infection. (p. 695)

Teratogens Substances that can interfere with normal prenatal development and cause one or more developmental abnormalities in the fetus. (p. 696)

Therapeutic Antibiotic therapy that is given in sufficient doses so that the concentration of the drug in the blood or other tissues renders it effective against specific bacterial pathogens. (p. 694)

MICROBIAL INFECTION

Microorganisms are everywhere, both in the external environment and in parts of the internal environment of our bodies. They can be harmful to humans, or they can be beneficial under normal circumstances but can become harmful when conditions are altered in some way. A person is normally able to remain healthy and resistant to infectious **microorganisms** because of the existence of certain host defences. These defences include actual physical barriers, such as intact skin or the ciliated respiratory mucosa, or physiological defences, such as the gastric acid in the stomach or immune factors such as antibodies. Other defences are the phagocytic cells (macrophages and polymorphonuclear neutrophils) that are part of the mononuclear phagocyte system.

Every known, major class of microbes contains organisms that can infect humans. This includes bacteria, viruses, fungi, and protozoa. The focus of this chapter is common bacterial **infections**.

Bacteria may take a number of different shapes. This property of bacteria is called their *morphology* (Fig 43.1), and they are often grouped based on this property. Bacteria may also be grouped according to other common recognizable characteristics. One of the most important ways of categorizing bacteria is on the basis of their response to the *Gram stain* procedure. Bacterial species that stain purple with Gram staining are classified as *gram-positive* organisms. Bacteria that stain red are classified as *gram-negative* organisms. This seemingly simple difference proves to be significant in guiding the choice of **antibiotic** therapy.

Bacterial Morphology Shapes

Fig 43.1 Morphology of bacteria. (Source: Murray, P. R., Rosenthal, K. S., Kobayashi, G. S., et al. (2009). *Medical microbiology* (6th ed.). St. Louis, MO: Mosby.)

Fig 43.2 Gram-positive and gram-negative bacteria. A gram-positive bacterium has a thick layer of peptidoglycan (left). A gram-negative bacterium has a thin peptidoglycan layer and an outer membrane (right). Structures in parentheses are not found in all bacteria. (Source: Murray, P. R., Rosenthal, K. S., Kobayashi, G. S., et al. (2009). *Medical microbiology* (6th ed.). St. Louis, MO: Mosby.)

Gram-positive organisms have a thick cell wall, made of peptidoglycan; they also have a thick outer capsule. Gram-negative organisms have a cell wall structure that is more complex, with a smaller outer capsule, a peptidoglycan layer, and two cell membranes: an outer and inner membrane (Fig 43.2). These differences usually make gram-negative bacterial infections more difficult to treat, because drug molecules have a harder time penetrating the more complex cell walls of gram-negative organisms.

When normal host defences are somehow compromised, a person becomes susceptible to infection. Microorganisms invade and multiply in the body tissues, and if the infective process overwhelms the body's defence system, the infection becomes clinically apparent. The patient usually manifests some of the following classic signs and symptoms of infection: fever, chills, sweating, redness, pain and swelling, fatigue, weight loss, increased white blood cell (WBC) count, and the formation of pus. Not all patients will exhibit signs of the infection; this is especially true in older adults and patients who are immunocompromised.

To help the body and its normal host defences combat an infection, antibiotic therapy is often required. Antibiotics are most effective when their actions are combined with functioning bodily defence mechanisms. Oftentimes, patients will become

colonized with bacteria. Although bacteria are present in open wounds, in secretions, on mucous membranes, or on the skin, such patients do not have any overt signs of infection; in older adults, confusion or altered orientation may be the only indicator. **Colonization** does not require antibiotic treatment. However, it is not uncommon for these colonizations to be treated, which may be one way in which drug-resistant organisms emerge.

Health Care–Associated Infection

A **community-acquired infection** is defined as one that is acquired by a person who has not recently (within the past year) been hospitalized or had a medical procedure (e.g., dialysis, surgery, catheterization). A **health care–associated infection**, previously known as a *nosocomial infection*, is defined as one that a patient acquires during the course of receiving treatment for another condition in a health care facility. The infection was not present or incubating at the time of admission but occurs more than 48 hours after admission. Health care–associated infections are one of the top 10 leading causes of death in Canada. They tend to be more difficult to treat than community-acquired infections because the causative microorganisms have been exposed to strong antibiotics in the past and are the most drug resistant and the most virulent. The particular organisms that cause health care–associated infections have changed over time. Methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant *Enterococcus* (VRE) (see Chapter 44) are currently two of the most important antibiotic-resistant organisms. Other serious pathogens include *Klebsiella*, *Acinetobacter*, and *Pseudomonas aeruginosa*. Most of these microorganisms are now resistant to many of the commonly used antibiotics. Gram-negative bacteria that produce the enzyme beta-lactamase can break down commonly used antibiotics, making it difficult to treat infections with bacteria that produce extended spectrum beta-lactamase (ESBL). Common producers of ESBL are *Escherichia coli* (*E. Coli*) and *Klebsiella pneumoniae*. Carbapenemase-producing *Enterobacteriaceae* (CPE) are resistant to the carbapenems.

Health care–associated infections (HAIs) develop in approximately 1 in 10 children and 1 in 12 adults admitted to a Canadian hospital (Health Canada, 2018). The cost of treating such infections amounts to millions of dollars annually. For example, the total cost to hospitals to treat patients with the “superbug,” MRSA has been estimated between \$42 million and \$59 million annually (Infection Prevention and Control Canada, 2018). The more common types of HAIs are central-line associated bloodstream infections, catheter-associated urinary tract infections, surgical site infections, antimicrobial-resistant organisms (*Clostridium difficile*, MRSA, VRE, carbapenem-resistant gram negative bacteria) and community-acquired infections. Often, patient acquired infections are acquired from various devices, such as mechanical ventilators, IV infusion lines, catheters, and dialysis equipment. Areas of the hospital associated with the greatest risk for acquiring a health care–associated infection are the critical care, dialysis, oncology, transplant, and burn units. This is because the host defences of the patients in these areas are typically compromised, which makes them more vulnerable to infection. Over 70% of health care–associated infections are preventable. The most common mode of transmitting them

TABLE 43.1 Antiseptics Versus Disinfectants

	Antiseptics	Disinfectants
Where used	Living tissue	Nonliving objects
Potency	Lower	Higher
Activity against organisms	Primarily inhibits growth (bacteriostatic)	Kills (bactericidal)

is by direct contact. Handwashing is the single most important activity that health care providers can do to prevent the spread of potentially deadly infections. Because health care–associated infections increase mortality, morbidity, and health care costs, one of Accreditation Canada’s Required Organizational Practices focuses on patient safety, particularly infection control, as a priority area. The 2017 Required Organizational Practices are to identify and track health care–associated infections such as *Clostridium difficile*, surgical site infections, seasonal influenza, noroviruses, or UTIs, as well as other reportable diseases and antibiotic-resistant organisms. Other strategies for reducing health care–associated infections include the use of disinfectants and the use of antiseptics. A **disinfectant** is able to kill organisms and is used only on nonliving objects to destroy organisms that may be present. Disinfectants are sometimes called *cidal agents*. An **antiseptic** generally only inhibits the growth of microorganisms but does not necessarily kill them and is applied exclusively to living tissue. Antiseptics are also called *static agents*. The differences between antiseptics and disinfectants in a clinical sense are summarized in Table 43.1. Topical antimicrobial drugs are discussed further in Chapter 56.

GENERAL PRINCIPLES OF ANTIBIOTIC THERAPY

The selection of antimicrobial drugs requires clinical judgement and detailed knowledge of pharmacological and microbiologic factors. Antibiotics have three general uses: empiric therapy, definitive therapy, and prophylactic or preventative therapy. Antibiotic drug therapy begins with a clinical assessment of the patient to determine whether the patient has the common signs and symptoms of infection. The patient is assessed during and after antibiotic therapy to evaluate the effectiveness of the drug therapy, monitor for adverse drug effects, and make sure the infection is not recurring.

Often, the signs and symptoms of an infection appear long before an organism can be identified. When this happens and the risk of life-threatening or severe complications is high (e.g., suspected acute meningitis), an antibiotic is given to the patient immediately. The antibiotic selected is one that can best kill the microorganisms known to be the most common causes of infection. This is called **empiric therapy**. Before the start of empiric antibiotic therapy, specimens are obtained from suspected areas of infection to be cultured in an attempt to identify a causative organism. It must be emphasized that culture specimens must be obtained before drug therapy is initiated, whenever possible. Otherwise, the presence of antibiotics in the tissues may result in misleading culture results. However, sometimes it is not

possible to obtain a sample (especially sputum) in a reasonable amount of time, and antibiotic therapy is begun without a sample in such situations. If an organism is identified in the laboratory, it is then tested for susceptibility to various antibiotics. The results of these tests can confirm whether the empiric therapy chosen is appropriate for eradicating the organism identified. If not, therapy can be adjusted to optimize its efficacy against the specific infectious organism(s). Once the results of culture and sensitivity testing are available (usually in 48 to 72 hours), the antibiotic therapy is then tailored to treat the identified organism by using the most narrow-spectrum, least toxic drug based on sensitivity results. This is known as **targeted therapy**. Broad-spectrum antibiotics are those that are effective against numerous organisms (gram-positive, gram-negative, and anaerobic). Narrow-spectrum antibiotics are effective against only a few organisms. Once the results of culture and sensitivity testing are available, it is always better to use an antibiotic that targets the specific organism identified (i.e., a narrow-spectrum antibiotic). Overuse of broad-spectrum antibiotics contributes to resistance. The goal of therapy is to use the most narrow-spectrum drug possible, based on sensitivity results.

Antibiotics are also given for prophylaxis. This is often the case when patients are scheduled to undergo a procedure (e.g., surgery) during or after which the likelihood of microbial contamination is high. **Prophylactic antibiotic therapy** is used to prevent an infection. The risk of infection varies depending on the procedure being performed. For example, the risk of infection in a patient undergoing coronary artery bypass surgery (with standard preoperative cleansing of the body) is relatively low, compared with that in a person undergoing intra-abdominal surgery for the treatment of injuries sustained in a motor vehicle crash. In the latter case, the abdominal cavity is likely to be contaminated with bacteria from the gastrointestinal (GI) tract. This would constitute a contaminated or “dirty” surgical field, and thus the likelihood of clinically serious infection would be much higher than in the former case. Antibiotic therapy would likely be required for a longer period after the procedure. To be effective, prophylactic antibiotics need to be given before a procedure, generally 60 minutes before the incision, to ensure adequate tissue penetration. Prevent Surgical Site Infections is a national project of Safer Healthcare Now, the flagship program of the Canadian Patient Safety Institute, which provides hospitals with evidence-informed recommendations on the prioritization and implementation of surgical site infection prevention efforts, including the appropriate use of prophylactic antibiotics. Prophylactic antibiotics prior to dental procedures are recommended only for those at greatest risk of developing infective endocarditis, including individuals with a prosthetic heart valve; a history of infective endocarditis; certain specific, severe congenital heart conditions; or a heart transplant that has developed an issue with a heart valve ([Canadian Dental Association, 2014](#)). Furthermore, prophylaxis is recommended for the above patients who undergo procedures in which gingival tissues are manipulated or that perforate the oral mucosa.

To optimize antibiotic therapy, the patient is continuously monitored for both **therapeutic** efficacy and adverse drug effects. A therapeutic response to antibiotics is one in which there is a decrease in the specific signs and symptoms of

infection compared with baseline findings (e.g., fever, elevated WBC count, redness, inflammation, drainage, pain). Antibiotic therapy is said to be **subtherapeutic** when these signs and symptoms do not improve. This can result from the use of an incorrect route of drug administration, inadequate drainage of an abscess, poor drug penetration to the infected area, insufficient serum levels of the drug, or bacterial resistance to the drug. Antibiotic therapy may result in an allergic or other major adverse reaction to the drug. These reactions can include rash, itching, hives, fever, chills, joint pain, difficulty breathing, or wheezing. Relatively minor adverse drug reactions such as nausea, vomiting, and diarrhea are quite common with antibiotic therapy and are usually not severe enough to require drug discontinuation.

Superinfection can occur when antibiotics reduce or completely eliminate the normal bacterial and fungal flora that are needed to maintain normal function in various organs. When these bacteria or fungi are killed by antibiotics, other bacteria or fungi are permitted to take over and cause infection. Another type of superinfection is the development of a vaginal or pharyngeal *Candida albicans* yeast infection. Antibiotic use is strongly associated with the potential for the development of diarrhea, a common adverse effect. However, antibiotic-acquired diarrhea becomes a serious superinfection when it causes antibiotic-acquired colitis, also known as **pseudomembranous colitis** or simply *C. difficile* infection. This happens because antibiotics disrupt the normal gut flora and can cause an overgrowth of *C. difficile*. The most common symptoms of *C. difficile* colitis are odorous watery diarrhea, abdominal pain, and fever. Whenever a patient who was previously treated with antibiotics develops watery diarrhea, the patient needs to be tested for *C. difficile* infection. If the results are positive, the patient will need to be treated for this serious superinfection. Infections with *C. difficile* are increasingly becoming resistant to standard therapy. For example, an emerging strain of *C. difficile*, NAP/0127, is more virulent than previous strains, with the ability to produce greater quantities of toxins. In addition, it is more resistant to the quinolones.

Yet another type of superinfection occurs when a second infection closely follows the initial infection and comes from an external source (as opposed to normal body flora), which may still be ongoing. A common example is a situation in which a patient who has a viral respiratory infection develops a secondary bacterial infection. This is likely due to weakening of the patient's immune system function by the primary viral infection. Although the viral infection will not respond to antibiotic therapy, antibiotics may be needed to treat the secondary bacterial infection. This situation calls for some diagnostic finesse on the part of the health care provider, who needs to avoid prescribing unnecessary antibiotics for a viral infection. The presence of coloured sputum (e.g., green or yellow) may or may not be a sign of a bacterial superinfection during a viral respiratory illness. Patients will often expect to receive an antibiotic prescription even when they show no signs of a bacterial superinfection. From their perspective, they know they are "sick" and want "some medicine" to expedite their recovery from illness. This expectation can create both diagnostic confusion and an

emotional dilemma for the health care provider. In general, coughs, colds, and sore throats are usually viral. If a fever develops, suspect a bacterial secondary infection. Respiratory tract infections (e.g., otitis media, tonsillitis, pneumonia, bronchitis, sinusitis, pharyngitis, pertussis) are often caused by bacteria.

Over the decades, many easily treatable bacterial infections have become increasingly resistant to antibiotic therapy. One major cause of this phenomenon is the overprescribing of antibiotics, often in the clinical situations described earlier. Antibiotic resistance is now considered one of the world's most pressing public health problems. Another factor that contributes to antibiotic resistance is the tendency of many patients to not complete their antibiotic regimen. Individuals may also take antibiotics purchased abroad or on the Internet, for self-diagnosed illnesses. Patients must be counselled to take the entire course of prescribed antibiotic drugs, even if they feel that they are no longer ill. As part of **Accreditation Canada's Required Organizational Practices (2017)**, institutions that provide inpatient acute care, inpatient cancer care, inpatient rehabilitation, and complex continuing care must have a program in place for **antimicrobial stewardship**. Effective antimicrobial stewardship combined with a comprehensive infection control program will limit the emergence and transmission of antimicrobial-resistant bacteria. "Antimicrobial stewardship programs aim to optimize clinical outcomes related to antimicrobial use while minimizing toxicity and other adverse events as well as reduce antimicrobial resistance in individual patients and in the population by limiting selective pressure on microbial populations through improved prescribing" (Leung, V., Wu, J., Langford, B. J., et al., 2018).

Food-drug and drug-drug interactions are common problems when antibiotics are taken. Both tetracyclines and quinolone antibiotics have a common drug interaction with substances that chelate (e.g., calcium-containing substances such as milk, cheese, and antacids). They also chelate with vitamin/mineral supplements (e.g., iron, magnesium). This is especially important, as will be discussed later, because quinolone antibiotics are used orally to treat serious infections. If they are not absorbed, treatment failure is likely to ensue.

Other important factors that must be understood to use antibiotics appropriately are host-specific factors, or **host factors**. These are factors that pertain specifically to a given patient, and they can have an important impact on the success or failure of antibiotic therapy. Some of these host factors are age, allergy history, kidney and liver function, pregnancy status, genetic characteristics, site of infection, and host defences. Age-related host factors are those that apply to patients at either end of the age spectrum. For example, infants and children may not be able to take certain antibiotics such as tetracyclines, which affect developing teeth or bones; quinolones, which may affect bone or cartilage development in children; and sulfonamides, which may displace bilirubin from albumin and precipitate kernicterus (hyperbilirubinemia) in neonates. The aging process affects the function of organ systems. As individuals age, there is a gradual decline in the function of the kidneys and liver, the organs primarily responsible for metabolizing and eliminating antibiotics. Therefore, depending on an older adult's level

of kidney or liver function, dosage adjustments may be necessary. Pharmacists often play a significant role in evaluating the dosages of antibiotics and other medications to ensure optimal dosing for a patient's level of organ function.

A patient's history of allergic reactions to an antibiotic is important in the selection of the most appropriate antibiotic for that patient. Penicillins and sulfonamides are two broad classes of antibiotics to which many people have allergic anaphylactic reactions. Symptoms of anaphylaxis include flushing; itching; hives; anxiety; fast, irregular pulse; and throat and tongue swelling. The most dangerous reaction is anaphylactic shock, in which a patient can suffocate from drug-induced respiratory arrest. Although this outcome is the most extreme, because it is a possibility, it is of utmost importance to consistently assess patients for drug allergies and document any known allergies clearly in medical records. All reported drug allergies are to be taken seriously and investigated further before making a final decision about administering a given drug. Many patients will say that they are "allergic" to a medication when in fact what they experienced was a common mild adverse effect such as stomach upset or nausea. Patients who report drug allergies need to be asked open-ended questions to elicit descriptions of prior allergic reactions, so that the actual severity of the reaction can be assessed. The most common severe reactions to any medication that need to be noted in the patient's chart include any difficulty breathing; significant rashes, hives, or other skin reactions; and severe GI intolerance. Although some antibiotics are ideally taken on an empty stomach, eating a small amount of food with the medication may be sufficient to help the patient tolerate it and realize its therapeutic benefits.

Pregnancy-related host factors are also important to the selection of appropriate antibiotics because several antibiotics can pass through the placenta and cause harm to the developing fetus. Drugs that cause development abnormalities in the fetus are called **teratogens**. Their use by women who are pregnant can result in birth defects.

Some patients also have certain genetic abnormalities that result in various enzyme deficiencies. These conditions can adversely affect drug actions in the body. Two of the most common examples of such genetic host factors are **glucose-6-phosphate dehydrogenase (G6PD) deficiency** and **slow acetylation**. The administration of antibiotics such as sulfonamides, nitrofurantoin, and dapsone to a person with G6PD deficiency may result in the *hemolysis*, or destruction of red blood cells. Patients who are slow acetylators have a physiological makeup that causes certain drugs to be metabolized more slowly than usual, in a chemical step known as *acetylation*. This can lead to toxicity from drug accumulation (see Chapter 2).

The anatomical site of the infection is an important host factor to consider when deciding not only which antibiotic to use but also the dosage, route of administration, and duration of therapy. Some antibiotics do not penetrate into certain sites of infection, such as the lungs, bone, or abscesses, which can lead to treatment failures.

Consideration of the discussed host factors, as well as drug pharmacokinetics, helps health care providers and pharmacists

to ensure optimal drug selection for each individual patient. Continued patient assessment and proper monitoring of antibiotic therapy increase the likelihood that this therapy will be safe and effective. For example, in patients who are critically ill, their volume of distribution is generally larger, and therefore water-soluble antibiotics require dosage increases; or in serious infections, antibiotics with shorter half-lives (i.e., cloxacillin) require more frequent dosing to endure adequate tissue penetration.

ANTIBIOTICS

Antibiotics are classified into broad categories based on their chemical structures. The common categories are sulfonamides, penicillins, cephalosporins, carbapenems, macrolides, quinolones, aminoglycosides, and tetracyclines. In addition to chemical structure, other characteristics that distinguish classes of drugs include antibacterial spectrum, mechanism of action, potency, toxicity, and pharmacokinetic properties. The four most common mechanisms of antibiotic action are: (1) interference with bacterial cell wall synthesis, (2) interference with protein synthesis, (3) interference with replication of nucleic acids (deoxyribonucleic acid [DNA] and ribonucleic acid [RNA]), and (4) antimetabolite action that disrupts critical metabolic reactions inside the bacterial cell. Fig 43.3 portrays these mechanisms in combating bacterial infections and indicates which mechanisms are used by several major antibiotic classes.

Perhaps the greatest challenge in understanding antimicrobial therapy is remembering the types and species of microorganisms against which a given drug can act. The list of individual microorganisms against which a given drug has activity can be quite extensive and can seem daunting to inexperienced health care providers. Most antimicrobials have activity against only

Fig 43.3 Basic sites of antibiotic activity. DNA, deoxyribonucleic acid; mRNA, messenger ribonucleic acid; RNA, ribonucleic acid. (Source: Murray, P. R., Rosenthal, K. S., Kobayashi, G. S., et al. (2009). *Medical microbiology* (6th ed.). St. Louis, MO: Mosby.)

one *type* of microbe (e.g., bacteria, viruses, fungi, protozoa). However, a few drugs do have activity against more than one class of organisms.

The field of infectious disease treatment is continually evolving, largely because of the continuous emergence of resistant bacterial strains. For this reason, drug indications change frequently, often from year to year, as various bacterial species become resistant to previously effective anti-infective therapy. It is always appropriate to check the most current reference materials or consult with colleagues (e.g., nurses, pharmacists, other health care providers) when questions remain. Pharmacists are excellent resources regarding antibiotics. Many hospitals now have pharmacists who are specially trained in the treatment of infectious diseases.

SULFONAMIDES

Sulfonamides comprise one of the first groups of drugs used as antibiotics. Although there are many compounds in the sulfonamide family, only sulfamethoxazole combined with trimethoprim (a nonsulfonamide antibiotic)—known as Apo-Sulfratrim®, Protrim®, Septra® (available only as an injection), or Teva-Trimel®, and often abbreviated as SMX-TMP—is commonly used in clinical practice. Sulfisoxazole acetyl combined with erythromycin ethylsuccinate (a macrolide antibiotic) is occasionally used in pediatrics. Sulfasalazine, another sulfonamide, is used to treat ulcerative colitis and rheumatoid arthritis but is not used as an antibiotic.

Mechanism of Action and Drug Effects

Sulfonamides do not actually destroy bacteria but inhibit their growth. For this reason, they are considered **bacteriostatic antibiotics**. They inhibit the growth of susceptible bacteria by preventing bacterial synthesis of folic acid. Folic acid is a B-complex vitamin that is required for the proper synthesis of purines, one of the chemical components of nucleic acids (DNA and RNA). Chemical components of folic acid include para-aminobenzoic acid (PABA), pteridine, and glutamic acid. Specifically, in a process known as *competitive inhibition*, sulfonamides compete with PABA for the bacterial enzyme tetrahydropterotic acid synthetase, which incorporates PABA into the folic acid molecule. Because sulfonamides are capable of blocking a specific step in a biosynthetic pathway, they are also considered antimetabolites. Microorganisms that require exogenous folic acid (not synthesized by the bacterium itself) are not affected by sulfonamide antibiotics. Therefore, these drugs do not affect folic acid metabolism in human cells. Trimethoprim, although not a sulfonamide, works via a similar mechanism, inhibiting dihydrofolic acid reduction to tetrahydrofolate, which results in inhibition of the enzymes of the folic acid pathway.

Indications

Sulfonamides have a broad spectrum of antibacterial activity, including activity against both gram-positive and gram-negative organisms. These antibiotics achieve high concentrations in the kidneys, through which they are eliminated. The

combination of these two drugs (in SMX-TMP) allows for a synergistic (see Chapter 2) antibacterial effect. Commonly susceptible organisms include strains of *Enterobacter* species (spp.), *Escherichia coli*, *Klebsiella* spp., *Proteus mirabilis*, *Proteus vulgaris*, and *Staphylococcus aureus*. Unfortunately, however, resistant bacterial strains are a growing problem, as is the case with other antibiotic classes. Results of culture and sensitivity testing help optimize drug selection in individual cases. This combination drug is used for treating respiratory tract infections. However, it is now less effective against streptococci infecting the upper respiratory tract and the pharynx. Another specific use for SMX-TMP is prophylaxis and treatment of opportunistic infections in patients with pneumonia associated with HIV-associated infection, especially infection by *Pneumocystis jirovecii*, a common cause of HIV. SMX-TMP is also a drug of choice for infection caused by the bacterium *Stenotrophomonas maltophilia*. SMX-TMP has become common treatment for outpatient *Staphylococcus* infections, due to the high rate of community-acquired MRSA infections. MRSA and other resistant organisms are discussed in Chapter 44.

Contraindications

Use of sulfonamides is contraindicated in cases of known drug allergy to sulfonamides. Chemically related drugs such as the sulfonylureas (used to treat diabetes; see Chapter 33), thiazide and loop diuretics (see Chapter 29), and carbonic anhydrase inhibitors (see Chapter 29) are generally considered relatively safe in a patient with a sulfonamide allergy. However, the cyclooxygenase-2 inhibitors such as celecoxib (Celebrex®) should not be used (see Chapter 49) in patients with a known sulfonamide allergy. The use of sulfonamides is also contraindicated in pregnant women at term and in infants younger than 2 months of age.

Adverse Effects

Sulfonamide drugs are a common cause of allergic reactions. Patients will sometimes refer to this as “sulfa allergy” or even “sulphur allergy.” Although immediate reactions can occur, sulfonamides typically cause delayed cutaneous reactions. Such reactions frequently begin with fever followed by a rash (morbilliform eruptions, erythema multiforme, Stevens-Johnson syndrome, toxic epidermal necrolysis). If severe allergic reactions occur, the drug should be discontinued. Photosensitivity reactions are another type of skin reaction, induced by exposure to sunlight during sulfonamide drug therapy. In some cases, such reactions can result in severe sunburn. Such reactions are also common with the tetracycline class of antibiotics discussed later in this chapter, as well as with other drug classes, and may occur immediately or have a delayed onset. Other reactions to sulfonamides include mucocutaneous, GI, liver, kidney, and hematological complications, all of which may be fatal in severe cases. It is believed that sulfonamide reactions are immune mediated and involve the production of reactive metabolites in the body. Reported adverse effects to the sulfonamides are listed in Table 43.2.

Interactions

Sulfonamides can have clinically significant interactions with a number of other medications. Sulfonamides may potentiate the hypoglycemic effects of sulfonylureas in diabetes treatment, the toxic effects of phenytoin, and the anticoagulant effects of warfarin sodium, which can lead to hemorrhaging. Sulfonamides may increase the likelihood of cyclosporine-induced nephrotoxicity. Patients receiving any of the above drug combinations may require more frequent monitoring than they would if not taking the combinations.

Dosages

For recommended dosages on selected sulfonamides, refer to the table at the bottom of this column.

DRUG PROFILES

Sulfonamides act by interfering with bacterial synthesis of the essential nutrient folic acid. Most sulfonamide therapy today uses the combination drug sulfamethoxazole/trimethoprim.

sulfamethoxazole/trimethoprim

Sulfamethoxazole/trimethoprim (Apo-Sulfatrim, Protrim, Septra, Teva-Trimel) is a fixed-combination drug product containing a 5:1 ratio of sulfamethoxazole to trimethoprim. It is available in both oral and injectable dosage forms.

PHARMACOKINETICS

Body System	Adverse Effects
Hematological	Agranulocytosis, aplastic anemia, hemolytic anemia, thrombocytopenia
Gastrointestinal	Nausea, vomiting, diarrhea, pancreatitis, hepatotoxicity
Integumentary	Toxic epidermal necrolysis, exfoliative dermatitis, Stevens-Johnson syndrome, photosensitivity
Other	Convulsions, crystalluria, toxic nephrosis, headache, peripheral neuritis, urticaria, cough

Dosages

Selected Sulfonamides and Combination Drug Products

Drug	Pharmacological Class	Usual Dosage Range	Indications
sulfamethoxazole/trimethoprim (Apo-Sulfatrim, Protrim, Septra, Teva-Trimel)	Sulfonamide and folate antimetabolite	<i>Children</i> IV/PO: 5–10 mg/kg/day trimethoprim and 25–50 mg sulfamethoxazole divided bid–qid <i>Adults</i> IV/PO: 160–240 mg trimethoprim and 800–1200 mg sulfamethoxazole bid–qid	Serious systemic infections, <i>Pneumocystis jirovecii</i> , pneumonia

IV, Intravenous; PO, oral.

BETA-LACTAM ANTIBIOTICS

The **beta-lactam** antibiotics are commonly used drugs. They are so called because of the beta-lactam ring that is part of the chemical structure (Fig 43.4). This broad group of drugs includes four major subclasses: penicillins, cephalosporins, carbapenems, and monobactams. They share a common structure and mechanism of action—they inhibit the synthesis of the bacterial peptidoglycan cell wall.

Some bacterial strains produce the enzyme **beta-lactamase**. This enzyme provides a mechanism for bacterial resistance to these antibiotics. The enzyme can break the chemical bond between the carbon (C) and nitrogen (N) atoms in the structure of the beta-lactam ring. When this occurs, all beta-lactam drugs lose their antibacterial efficacy. Because of this, additional drugs known as **beta-lactamase inhibitors** are added to several of the penicillin antibiotics to make the drugs more powerful against beta-lactamase-producing bacterial strains. Each of the four classes of beta-lactam antibiotics is examined in detail in the following sections.

PENICILLINS

The penicillins are a large group of chemically related antibiotics that were first derived from a mould (fungus) often seen on bread or fruit. The penicillins can be divided into four subgroups based on their structure and the spectrum of bacteria they are active against: natural penicillins, penicillinase-resistant penicillins, aminopenicillins, and extended-spectrum penicillins. Examples of antibiotics in each subgroup and a brief description of their characteristics are given in Table 43.3.

Penicillins are **bactericidal antibiotics**, meaning they kill a wide variety of gram-positive and some gram-negative bacteria. However, some bacteria have acquired the capacity to produce beta-lactamases capable of destroying penicillins. These enzymes can inactivate the penicillin molecules by opening the beta-lactam ring. The beta-lactamases that specifically inactivate penicillin molecules are called *penicillinases*. Bacterial strains that produce these drug-inactivating enzymes were a therapeutic obstacle until drugs were synthesized that inhibit these enzymes. Two of these beta-lactamase inhibitors are clavulanic acid (also called *clavulanate*) and tazobactam. These drugs bind with beta-lactamase to prevent the enzyme from breaking down the penicillin molecule, although they are not always effective. The following are examples of currently available combinations of penicillin and beta-lactamase inhibitor:

- amoxicillin trihydrate/clavulanic acid (Amoxi-Clav®, Clavulin®)
- piperacillin/tazobactam sodium

Mechanism of Action and Drug Effects

The mechanism of action of penicillins involves the inhibition of bacterial cell wall synthesis. Once distributed by the patient's bloodstream to infected areas, penicillin molecules slide through bacterial cell walls to get to their site of action. Some penicillins, however, are too large to pass through these openings in the cell walls, and because they cannot get to their site of action, they cannot kill the bacteria. Some bacteria can make the openings in their cell walls small so that the penicillin cannot get through to kill them. The penicillin molecules that do gain entry into the bacterium must then find appropriate binding sites; these are known as *penicillin-binding proteins*. By binding to these proteins, the penicillin molecules interfere with normal cell wall synthesis, causing the formation of defective cell walls that are unstable and easily broken down (see Fig 43.3). Bacterial death usually results from lysis (rupture) of the bacterial cells because of this drug-induced disruption of cell wall structure.

Fig 43.4 Chemical structure of penicillins showing the beta-lactam ring. *R*, variable portion of drug chemical structure.

TABLE 43.3 Classification of Penicillins

Subclass	Generic Drug Names	Description
Natural penicillins	penicillin G, penicillin V	Although many modifications of the original natural (mould-produced) structure have been made, these are the only two in current clinical use—penicillin G is the injectable form for IV or IM use; penicillin V is a PO dosage form (tablet and liquid)
Penicillinase-resistant drugs	cloxacillin sodium	Stable against hydrolysis by most staphylococcal penicillinases (enzymes that normally break down the natural penicillins)
Aminopenicillins	amoxicillin, ampicillin	Have an amino group attached to the basic penicillin structure that enhances their activity against gram-negative bacteria compared with natural penicillins
Extended-spectrum drugs	piperacillin sodium, clavulanic potassium/ticarcillin disodium, piperacillin sodium/tazobactam sodium	Have wider spectra of activity than do all other penicillins

IM, Intramuscular; IV, intravenous; PO, oral.

Indications

Penicillins are indicated for the prevention and treatment of infections caused by susceptible bacteria. The microorganisms most commonly destroyed by penicillins are gram-positive bacteria, including the *Streptococcus* spp., *Enterococcus* spp., and *Staphylococcus* spp. Most natural penicillins have little if any ability to kill gram-negative bacteria. However, the extended-spectrum penicillins have excellent gram-positive, gram-negative, and anaerobic coverage. Because of this, the extended-spectrum penicillins are used to treat many health care-acquired infections, including pneumonia, intra-abdominal infections, and sepsis. Piperacillin/tazobactam sodium is often used as an initial antibiotic when awaiting results of blood cultures.

Contraindications

Penicillins are usually safe and well-tolerated drugs. The only usual contraindication is known drug allergy. It is important to obtain an accurate history regarding the type of reaction that occurs in patients who state they are allergic to penicillins. It is also important to note that, often, drugs are referred to by their trade names, and these don't always end in "cillin" (e.g., Clavulin). Many medication errors have occurred when a penicillin drug called by its trade name is given to a patient with a penicillin allergy.

Adverse Effects

Allergic reactions to penicillin occur in 0.7 to 4% of treatment courses. The most common reactions are urticaria, pruritus, and angioedema. A wide variety of idiosyncratic (unpredictable) drug reactions can occur, such as maculopapular eruptions, eosinophilia, Stevens-Johnson syndrome, and exfoliative dermatitis. Maculopapular rash occurs in approximately 2% of treatment courses with natural penicillin and 5.2 to 9.5% of those with ampicillin. Between 1 and 5 incidents of anaphylaxis occur in every 10 000 cases of penicillin therapy. Severe reactions are much more common with injected than with orally administered penicillin, as is the case with most other antibiotics. Patients who are allergic to penicillins have an increased risk of allergy to other beta-lactam antibiotics. The incidence of cross-reactivity between cephalosporins and penicillins is reported as between 1 and 4%. Patients reporting penicillin allergy need to describe their prior allergic reaction; it is important to document the type of reaction. The decision to treat with cephalosporin therapy in such cases is often a matter of clinical judgement, based on the severity of reported prior reactions to penicillin drugs, the nature of the infection, the drug susceptibility of the infective organism if known, and the availability and patient tolerance of other alternative antibiotics. Generally speaking, only those patients with a history of throat swelling or hives from penicillin should not receive cephalosporins. Some patients may require skin testing and desensitization.

Penicillins are generally well tolerated and are associated with few adverse effects. As with many drugs, the most common adverse effects involve the GI system. Penicillins also disrupt the normal intestinal flora. The IV formulations of some penicillins contain large amounts of sodium or potassium. High doses may cause seizures. IV penicillins are often irritating to veins. It is important to monitor for extravasation or phlebitis and to be aware that pain can occur with infusion, and new sites may be needed. Doses must be

TABLE 43.4 Penicillins: Reported Adverse Effects

Body System	Adverse Effects
Central nervous	Lethargy, anxiety, depression, seizures
Gastrointestinal	Nausea, vomiting, diarrhea, taste alterations, oral candidiasis
Hematological	Anemia, bone marrow depression, granulocytopenia
Metabolic	Hyperkalemia, hyponatremia, alkalosis
Other	Pruritus, hives, rash

adjusted for patients with kidney dysfunction. The most common adverse effects of the penicillins are listed in [Table 43.4](#).

Interactions

Many drugs interact with penicillins; some have positive effects, and others have harmful effects. The most common and clinically significant drug interactions associated with penicillin use are listed in [Table 43.5](#).

Dosages

For dosage information on selected penicillins, refer to the table on p. 701.

DRUG PROFILES

Penicillins are safe antibiotics and can be used during pregnancy if required. Their use is contraindicated in patients with a hypersensitivity to them, but because of their relatively good adverse effects profile, there are otherwise few contraindications to their use.

Natural Penicillins

penicillin G and penicillin V potassium

Penicillin G has three salt forms: benzathine, procaine potassium, and procaine sodium. All of these forms are given by injection, either intravenously or intramuscularly. The benzathine and procaine salts are used as longer-acting intramuscular (IM) injections. They are formulated into a thick, white, pasty material that is designed for prolonged dissolution and absorption from the IM site of injection. Never give these preparations by the IV route, because their consistency is too thick for IV administration; such use can be fatal. The IM formulations can be especially helpful for treating the sexually transmitted infection syphilis because often only one injection is needed. Penicillin G potassium is formulated for IV use. Penicillin V potassium is available only for oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Variable	30–60 min	30 min	4–6 hr
IV	Variable	30 min	24–54 min	4–6 hr

Penicillinase-Resistant Penicillins

cloxacillin sodium

Cloxacillin sodium is the only penicillinase-resistant penicillin currently available in Canada. This penicillinase-resistant penicillin is able to resist breakdown by the penicillin-destroying enzyme (penicillinase) commonly produced by bacteria such as staphylococci. For this reason, this drug may also be referred to as an *antistaphylococcal penicillin*. The chemical structure of cloxacillin features a large, bulky side chain near the beta-lactam ring. This side chain serves as a barrier to the penicillinase enzyme, preventing it from breaking the beta-lactam ring, which would inactivate the drug. There are, however, certain strains of staphylococci, specifically *Staphylococcus aureus*, that are resistant to cloxacillin. Such bacteria require alternative antibiotic regimens. Cloxacillin is available for oral and injectable use. The absorption of oral cloxacillin is significantly affected by food leading to reduced effectiveness of the therapy. For optimum results, this medication should be taken on an empty stomach.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Variable	30–60 min	20–30 min	4–6 hr

Aminopenicillins

There are two aminopenicillins: amoxicillin and ampicillin. They are so named because of the presence of a free amino group ($-NH_2$) in their chemical structure. This structural feature gives aminopenicillins enhanced activity against gram-negative bacteria, against which the natural and penicillinase-resistant penicillins are relatively ineffective. The aminopenicillins are also effective against some gram-positive organisms. Amoxicillin is an analogue of ampicillin.

amoxicillin

Amoxicillin (Amoxil®, Novamoxin®, others) is a commonly prescribed aminopenicillin. Amoxicillin is used to treat infections caused by susceptible organisms in the ears, nose, throat, genitourinary (GU) tract, skin, and skin structures. Pediatric dosages are sometimes higher than those used in the past because of the development of increasingly resistant *Streptococcus pneumoniae* organisms. The traditional adult dosage continues to be adequate in most cases. The drug is available only for oral use and can be given with or without food. It is also available in combination with clavulanic acid (Clavulin).

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	0.5–1 hr	1–2 hr	1–1.5 hr	6–8 hr

Dosages

Selected Penicillins

Drug	Pharmacological Class	Usual Dosage Range	Common Indications
 amoxicillin (Clavulin, Amoxil, Novamoxin, others)	Aminopenicillin	<i>Children</i> PO: 25–100 mg/kg/day divided q 8–12 h depending on age and type of infection <i>Adults</i> PO: 250–500 mg q8h	Otitis media*; sinusitis; various susceptible respiratory, skin, and urinary tract infections
ampicillin (generic)	Aminopenicillin	<i>Children</i> PO/IV/IM: 25–50 mg/kg/day divided q6h (doses up to 300 mg/kg/day may be required for meningitis and other serious infections) <i>Adults</i> PO/IV/IM: 1–12 g/day divided q4–6h	Primarily infection with gram-negative infections such as <i>Shigella</i> , <i>Salmonella</i> , <i>Escherichia</i> , <i>Haemophilus</i> , <i>Proteus</i> , and <i>Neisseria</i> spp.; infection with some gram-positive organisms
cloxacillin sodium (generic only)	Penicillinase-resistant penicillin	<i>Children</i> PO/IM/IV: 25–50 mg/kg/day divided q6h <i>Adults</i> PO/IM/IV: 250–500 mg q6h	Infection with penicillinase-producing staphylococci
penicillin V potassium (Pen VK)	Natural penicillin	<i>Children and adults</i> PO: 125–500 mg (200 000–800 000 units) q6–8h	Primarily infection with gram-positive organisms such as <i>Streptococcus</i> (including <i>Streptococcus pneumoniae</i>)
piperacillin/tazobactam	B- lactam antibiotic	<i>Children</i> 200–350 mg/kg/day divided q6–8h <i>Adults</i> 2.25g–4.5 g q6–8hr (depending on type of infection and renal function)	Pneumonia and skin, gynecological, and abdominal infections caused by gram-negative, gram-positive, and anaerobic bacterial organism

IM, Intramuscular; IV, intravenous; PO, oral; spp., species.

*Children >3 months of age with resistant otitis media may require higher doses such as 80–90 mg/kg/day in divided doses q12h

TABLE 43.5 Penicillins: Drug Interactions

Drug	Mechanism	Result
Aminoglycosides (IV) and clavulanic acid	Additive	More effective killing of bacteria
Methotrexate	Decreased kidney elimination of methotrexate	Increased levels of methotrexate
NSAIDs	Compete for protein binding	More free and active penicillin (may be beneficial)
Oral contraceptives	Uncertain	May decrease efficacy of the contraceptive
probenecid	Competes for elimination	Prolongs the effects of penicillins
rifampin	Inhibition	May inhibit the killing activity of penicillins
warfarin sodium	Reduced vitamin K from gut flora	Enhanced anticoagulant effect of warfarin sodium

IV, Intravenous; NSAIDs, nonsteroidal anti-inflammatory drugs.

ampicillin

Ampicillin is available in two different salt forms: trihydrate and sodium. The different salt forms are administered by different routes. Ampicillin trihydrate is administered orally, whereas ampicillin sodium is given parenterally. This drug is still currently available, although it is used less frequently than in past years because of resistance.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Variable	1–2 hr	1–1.5 hr	4–6 hr
IV	Variable	5 min	1–1.8 hr	6–8 hr

Extended-Spectrum Penicillins

By making a few changes in the basic structure of penicillin, drug developers produced another generation of penicillins that have a wider spectrum of activity than that belonging to either of the other two classes of semisynthetic penicillins (penicillinase-resistant penicillins and aminopenicillins) or to the natural penicillins. Currently, piperacillin sodium is the sole extended-spectrum penicillin available. Piperacillin is available in combination with tazobactam sodium. These beta-lactamase-inhibiting products allow for enhanced multiorganism coverage, especially against anaerobic organisms that are common in intestinal infections and *Pseudomonas* spp., which are common in health care-acquired infections. Piperacillin/tazobactam is commonly used in hospitalized patients with suspected or documented serious infections. Because of its broad spectrum of activity (gram-positive, gram-negative, and anaerobic), it is often used as empiric therapy. This drug is available only by injection.

TABLE 43.6 Cephalosporins: Parenteral and Oral Preparations

FIRST GENERATION		SECOND GENERATION		THIRD GENERATION		FOURTH GENERATION		FIFTH GENERATION

CEPHALOSPORINS

Cephalosporins are semisynthetic antibiotics widely used in clinical practice. They are structurally and pharmacologically related to penicillins. Similar to penicillins, cephalosporins are bactericidal and act by interfering with bacterial cell wall synthesis. They also bind to the same penicillin-binding proteins inside bacteria that were described earlier. Although there are a variety of such proteins, they are collectively referred to as *penicillin-binding* regardless of the type of beta-lactam drug involved.

Cephalosporins can destroy a broad spectrum of bacteria, and this ability is directly related to the chemical changes that have been made to their basic cephalosporin structure. Modifications to this chemical structure by pharmaceutical scientists have given rise to five generations of cephalosporins. Depending on the generation, these drugs may be active against gram-positive, gram-negative, or anaerobic bacteria. They are not active against fungi or viruses. The different drugs of each generation have certain chemical similarities, and thus they can kill similar spectra of bacteria. In general, the level of gram-negative coverage increases with each successive generation. The first-generation drugs have the most gram-positive coverage, and the later generations have the most gram-negative coverage. Anaerobic coverage is found only with the second-generation drugs. Cefepime is the only fourth-generation cephalosporin available in Canada. Ceftaroline fosamil, often referred as the *fifth-generation drug*, has a broad spectrum and covers gram-positive (including MRSA) and gram-negative organisms. The currently available parenteral and oral cephalosporin antibiotics are listed in Table 43.6. As is often the case, injectable drugs produce higher serum concentrations than drugs administered by the oral route and thus are used to treat more serious infections.

The safety profiles and contraindications of the cephalosporins are similar to those of the penicillins. The most commonly reported adverse effects are mild diarrhea, abdominal cramps, rash, pruritus, redness, and edema. Because cephalosporins are chemically similar to penicillins, someone with an allergic reaction to penicillin may also have an allergic reaction to a cephalosporin. This is referred to as *cross-sensitivity*. Investigators have observed that the incidence of cross-sensitivity between penicillins and cephalosporins is between 1 and 4%. However, only those patients who have had a serious anaphylactic reaction to penicillin must not be given cephalosporins. As a class, the cephalosporins are safe and effective antibiotics.

Penicillins and cephalosporins are practically identical in their mechanisms of action, drug effects, therapeutic effects, adverse effects, and drug interactions. For this reason, this information is not repeated for the cephalosporins, and the reader is referred to the pertinent discussion in the section on the penicillin drugs. Cephalosporins of all generations are safe drugs. Their use is contraindicated in patients who have shown a hypersensitivity to them and any patient with a history of life-threatening allergic reaction to penicillins. They are safe to use during pregnancy. Drug interactions are listed in Table 43.7.

Dosages

For the dosage information on selected cephalosporins, refer to the table on p. 705.

DRUG PROFILES

First-Generation Cephalosporins

First-generation cephalosporins are usually active against gram-positive bacteria and have limited activity against gram-negative bacteria. They are available in both parenteral and oral forms. Currently available first-generation cephalosporins include cefazolin and cephalexin.

cefazolin sodium

Cefazolin sodium is a prototypical first-generation cephalosporin. As with all first-generation cephalosporins, it provides excellent coverage against gram-positive bacteria but limited coverage against gram-negative bacteria. It is available only for parenteral use. It is used commonly for surgical prophylaxis and for susceptible staphylococcal infections.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Variable	5 min	1.2–2.5 hr	8 hr

 cephalexin

Cephalexin (Keflex®) is a prototypical oral, first-generation cephalosporin. It also provides excellent coverage against gram-positive bacteria but limited coverage against gram-negative bacteria. It is available only for oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Variable	1 hr	0.6–2 hr	6–8 hr

Second-Generation Cephalosporins

Second-generation cephalosporins have coverage against gram-positive organisms that is similar to that of the first-generation cephalosporins but have enhanced coverage against gram-negative bacteria. Both parenteral and oral formulations are available. Currently available second-generation cephalosporins include cefaclor, cefoxitin, cefuroxime, and cefprozil. These drugs differ slightly in their antibacterial coverage. Cefoxitin is often referred to as a *cephamycin* and has better coverage than the other drugs in this class against various anaerobic bacteria such as *Bacteroides fragilis*, *Peptostreptococcus* spp., and *Clostridium* spp.

 cefoxitin sodium

Cefoxitin sodium is a parenteral second-generation cephalosporin. It provides excellent gram-positive coverage and better gram-negative coverage than the first-generation drugs. Cefoxitin is used for gynecological infections, urinary tract infections, lower respiratory tract infections, bone and joint infections, and soft tissue infections. Normal intestinal flora include gram-positive, gram-negative, and anaerobic bacteria.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Variable	0.5 hr	1 hr	8 hr

cefuroxime sodium

Cefuroxime sodium is the parenteral form of this second-generation cephalosporin. The oral form is a different salt of cefuroxime, cefuroxime axetil (Ceftin®). It has more activity against gram-negative bacteria than first-generation cephalosporins but a narrower spectrum of activity against gram-negative bacteria than third-generation cephalosporins. It differs from the cephamycins such as cefoxitin in that it does not kill anaerobic bacteria. Cefuroxime axetil is a prodrug. It has little antibacterial activity until it is hydrolyzed in the liver to its active cefuroxime form. It is available only for oral use. Cefuroxime sodium is available only in injectable form.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO (cefuroxime axetil)	Variable	2–3 hr	1.3 hr	6–8 hr
IV (cefuroxime sodium)	Variable	30 min	1–2 hr	6–8 hr

Third-Generation Cephalosporins

The available third-generation cephalosporins include cefotaxime sodium, cefixime, cefpodoxime proxetil, ceftazidime, and ceftriaxone. These are the most potent of the three generations of cephalosporins in fighting gram-negative bacteria, but they generally have less activity than first- and second-generation drugs against gram-positive organisms.

Because of specific changes in the basic cephalosporin structure, ceftazidime has significant activity against *Pseudomonas* spp. However, resistance is beginning to limit its usefulness. Cefixime is currently the only third-generation cephalosporins available for oral use. All the other third-generation drugs are available only in parenteral forms.

 ceftriaxone sodium

Ceftriaxone sodium is an extremely long-acting third-generation drug that can be given only once a day in the treatment of most infections. It also has the unique characteristic of being able to pass easily across the blood–brain barrier. For this reason, it is one of the few cephalosporins that is indicated for the treatment of meningitis, an infection of the meninges of the brain and spinal cord. The spectrum of activity of ceftriaxone is similar to that of the other third-generation drug, cefotaxime sodium. It can be given both intravenously and intramuscularly. In some cases of a gonorrhea infection, one IM injection can eradicate the infection when used in combination with a single dose of oral azithromycin. Ceftriaxone is 93 to 96% bound to plasma protein, a proportion higher than that of many of the other cephalosporins. This drug is also unique in that it is metabolized in the intestine after biliary excretion. Ceftriaxone is not given to neonates with hyperbilirubinemia or to patients with severe liver dysfunction. It should not be administered with calcium infusions. This drug is available only for injection.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Variable	1.5–4 hr	4.3–8.7 hr	24 hr

ceftazidime

Ceftazidime (Fortaz®) is a parenterally administered third-generation cephalosporin with activity against difficult-to-treat infections with gram-negative bacteria such as *Pseudomonas* spp. It is the third-generation cephalosporin of choice for many indications because of its excellent spectrum of activity and safety profile; however, resistance is beginning to limit its usefulness, and it is generally given in combination with an aminoglycoside (discussed in Chapter 44). Ceftazidime is available only in injectable form.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV/IM	Variable	1 hr	1–2 hr	8–12 hr

Fourth-Generation Cephalosporins

cefepime hydrochloride

Cefepime hydrochloride (Maxipime®) is the prototypical fourth-generation cephalosporin. Cefepime is a broad-spectrum cephalosporin that most closely resembles ceftazidime in its spectrum of activity. It differs from ceftazidime in that it has increased activity against many *Enterobacter* spp. (gram-negative) as well as gram-positive organisms. Cefepime is indicated for the treatment of uncomplicated and complicated UTIs, uncomplicated skin and skin structure infections, and pneumonia. It is available only in injectable form.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	0.5 hr	0.5–1.5 hr	1–2 hr	8–12 hr

Carbapenems

Carbapenems have the broadest antibacterial action of any antibiotics to date. They are bactericidal and inhibit cell wall synthesis. Because of this broad action, they are often reserved for complicated body cavity and connective tissue infections in acutely ill hospitalized patients. They are also effective against many gram-positive organisms. One hazard of carbapenem use is drug-induced seizure activity, which occurs in a relatively small percentage of patients. However, the risk of seizures can be reduced by proper dosage adjustment in susceptible patients. There is a small risk of cross-sensitivity in patients with penicillin allergies. Only those patients with anaphylactic-type reactions to penicillins must not receive a carbapenem. Currently available carbapenems include imipenem/cilastatin, meropenem, and ertapenem. Carbapenems must be infused over 60 minutes.

imipenem/cilastatin

Imipenem/cilastatin (Primaxin®) is a fixed combination of imipenem, which is a semisynthetic carbapenem antibiotic similar to beta-lactam antibiotics, and cilastatin sodium, an

inhibitor of an enzyme that breaks down imipenem. Imipenem has a wide spectrum of activity against gram-positive and gram-negative aerobic and anaerobic bacteria. Cilastatin sodium is a unique drug in that it inhibits an enzyme in the kidneys called *dihydropeptidase*, which would otherwise quickly break down the imipenem. Cilastatin sodium also blocks the kidney tubular secretion of imipenem, which inhibits imipenem from being excreted from the kidneys, the drug's primary route of excretion.

Imipenem/cilastatin exerts its antibacterial effect by binding to penicillin-binding proteins inside bacteria, which in turn inhibits bacterial cell wall synthesis. Unlike many of the penicillins and cephalosporins, imipenem/cilastatin is resistant to the antibiotic-inhibiting actions of beta-lactamases. Drugs with which it potentially interacts include cyclosporine, ganciclovir, and probenecid, all of which may potentiate the central nervous system (CNS) adverse effects (including seizures) of imipenem. Concurrent use with these drugs should be avoided whenever clinically feasible. The most serious adverse effect associated with imipenem/cilastatin therapy is seizures, which have been reported to occur in up to 1.5% of patients receiving less than 500 mg every 6 hours. In patients receiving higher dosages of the drug (more than 500 mg every 6 hours), however, there is about a 10% incidence of seizures. Seizures are more likely to occur in older adults and in patients with renal disease. Seizures have been associated with all of the carbapenems, but the data suggest that they are less likely to occur with other members of this class than with imipenem/cilastatin.

Imipenem/cilastatin is indicated for the treatment of bone, joint, skin, and soft-tissue infections; bacterial endocarditis caused by *S. aureus*; intra-abdominal bacterial infections; pneumonia; UTIs and pelvic infections; and bacterial septicemia caused by susceptible bacterial organisms. The IM form of imipenem/cilastatin contains lidocaine, and its use is therefore contraindicated in patients with a known drug allergy to lidocaine or related local anaesthetics. All dosage forms contain the same number of milligrams of both imipenem and cilastatin.

meropenem and ertapenem

Meropenem (Merrem®) is the second drug in the carbapenem class of antibiotics. Compared with imipenem/cilastatin, meropenem appears to be somewhat less active against gram-positive organisms, more active against *Enterobacteriaceae*, and equally active against *Pseudomonas aeruginosa*. However, meropenem is the only carbapenem currently indicated for the treatment of bacterial meningitis. Ertapenem (Invanz®) has a spectrum of activity comparable to that of imipenem/cilastatin, although it is not active against *Enterococcus* or *Pseudomonas* spp.

PHARMACOKINETICS (MEROPENEM)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Variable	~1 hr	1 hr	6–8 hr

**DRUG PROFILE****aztreonam**

Aztreonam (Clayston®) powder for aerosol use is the only monobactam antibiotic to be developed thus far. It is a synthetic beta-lactam antibiotic that is active primarily against the aerobic gram-negative bacteria *Pseudomonas aeruginosa*. Aztreonam is a bactericidal antibiotic; it destroys bacteria by inhibiting bacterial cell wall synthesis, which results in lysis. Aztreonam is indicated for the management of cystic fibrosis in patients with chronic pulmonary *Pseudomonas aeruginosa* infections. It is to be used with the Altera® Nebulizer System. Its use is contraindicated in patients with a known drug allergy. The most common adverse effect is a cough. The recommended dosage for both adults and children 6 years of age and older is one single-use vial (75 mg, not based on weight or adjusted for age) of aztreonam reconstituted with a 1 mL ampule of sterile diluent administered 3 times a day for a 28-day course. Each dose should be taken at

least 4 hours apart. Aztreonam is taken in repeated cycles of 28 days on followed by 28 days off. The elimination half-life of the aerosol is 2.1 hours.

MACROLIDES

The macrolides are a large group of antibiotics that first became available in the early 1950s with the introduction of erythromycin. Macrolides are considered bacteriostatic; however, in high enough concentrations, they may be bactericidal to some susceptible bacteria. There are three macrolide antibiotics: azithromycin, clarithromycin, and erythromycin. Azithromycin and clarithromycin are currently the most widely used of the macrolides. Although the spectra of antibacterial activity of azithromycin and clarithromycin are similar to that of erythromycin, the former have longer durations of action, which allows them to be given less often. Azithromycin and clarithromycin produce fewer and milder GI tract adverse effects than erythromycin. Azithromycin is usually

Dosages**Selected Cephalosporins**

Drug	Pharmacological Class	Usual Dosage Range	Indications
cefazolin sodium	First-generation cephalosporin	<i>Children</i> IM/IV: 25–100 mg/kg/day divided q6–8h <i>Adults</i> IM/IV: 250–1 000 mg q6–8h*	Infections due to gram-positive organisms, some penicillinase-producing organisms, and some gram-negative organisms; preoperative and postoperative surgical prophylaxis
cefoxitin sodium	Second-generation cephalosporin	<i>Children</i> IV/IM: 80–160 mg/kg/day divided q4–6h, not to exceed 12 g/day <i>Adults</i> IM/IV: 3–12 g/day, divided q6–8h OR 1–3 g q6–8h; maximum dose 12 g/day	Infections; less coverage of gram-positive organisms, greater coverage of gram-negative and anaerobic organisms
cefuroxime sodium cefuroxime axetil* (Ceftin, tablet form)	Second-generation cephalosporin	<i>Children under 12 yr</i> PO: 20–30 mg/kg/day divided tid–qid IV/IM: 75–100mg/kg/day divided q8h (maximum dose is 6 g/day) <i>Adults and children 12 yr and over</i> PO (tabs): 250–500 mg bid IV/IM: 750–1 500 mg q8h	Comparable to those for cefazolin, and provides more coverage of gram-negative organisms Dose adjustment based on classification of most infections, bone and joint infections, or bacterial meningitis.
ceftazidime pentahydrate (Fortaz)	Third-generation cephalosporin	<i>Children</i> IM/IV: 100–150 mg/kg/day divided q 8–12h <i>Adults</i> IM/IV: 500–2000 mg q8h	Infections; more extensive coverage of gram-negative organisms, including <i>Pseudomonas</i> spp.
ceftriaxone sodium	Third-generation cephalosporin	<i>Children under 12 yr</i> IM/IV: 50–100 mg/kg/day q12–24h <i>Adults and children 12 yr and over</i> IM/IV: 1–2 g q12–24h	Comparable to those for ceftazidime except that it does not cover <i>Pseudomonas</i> spp.
cefepime (Maxipime)	Fourth-generation cephalosporin	<i>Children 2 mo–12 yr</i> IV/IM: 50 mg/kg q8–12h; maximum 2000 mg/dose <i>Adults and children over 12 yr</i> IV/IM: 1–2g q8–12h	Infections; provides more extensive coverage of gram-negative organisms and better gram-positive coverage than third generation, including organisms causing intra-abdominal infections

GI, Gastrointestinal; IM, intramuscular; IV, intravenous; PO, oral; spp., species.

*Cefuroxime axetil is a prodrug for PO use that is hydrolyzed into the active ingredient in the fluids of the GI tract.

*q12h or q24 in patients with severe renal impairment

TABLE 43.7 Cephalosporins: Drug Interactions

Drug	Mechanism	Result
probenecid	Decreased kidney excretion	Increased cephalosporin levels
Oral contraceptives	Enhance oral contraceptive metabolism	Increased risk for unintended pregnancy

dosed over a shorter length of time than many of the erythromycin products. Azithromycin and clarithromycin also exhibit better efficacy in eradicating various bacteria and are capable of better tissue penetration than erythromycin. Because erythromycin has a bitter taste and is quickly degraded by the acidity of the stomach, several salt forms and many dosage formulations were developed to circumvent these problems. Fidaxomicin (Dificid®) is the newest macrolide antibiotic. It is indicated only for the treatment of diarrhea associated with *Clostridium difficile*. The most common adverse effects are nausea, vomiting, and GI bleeding. It is reasonably safe to use during pregnancy. It has minimal absorption and, as such, there are known drug interactions.

Mechanism of Action and Drug Effects

Macrolide antibiotics are bacteriostatic drugs that inhibit protein synthesis by binding reversibly to the 50S ribosomal subunits of susceptible microorganisms. Macrolides are effective in the treatment of a wide range of infections. These include various infections of the upper and lower respiratory tract, skin, and soft tissue caused by some strains of *Streptococcus* and *Haemophilus*; spirochetal infections such as syphilis and Lyme disease; gonorrhea; and *Chlamydia*, *Mycoplasma*, and *Corynebacterium* infections. Gonorrheal infections have become increasingly difficult to treat with macrolide monotherapy, so these drugs are sometimes used in combination with other antibiotics such as cephalosporins. Macrolides are also somewhat unique among antibiotics in that they are especially effective against several bacterial species that often reproduce inside host cells instead of in the bloodstream or interstitial spaces. Common examples of such bacteria, some of which were previously listed, are *Listeria*, *Chlamydia*, *Legionella* (one species of which causes Legionnaire's disease), *Neisseria* (one species of which causes gonorrhea), *Mycoplasma* (one species of which causes "walking pneumonia", common in young adults and community acquired pneumonia) and *Campylobacter*.

Indications

Infections caused by *Streptococcus pyogenes* (group A beta-hemolytic streptococci) are inhibited by macrolides, as are mild to moderate upper and lower respiratory tract infections caused by *Haemophilus influenzae*. Spirochetal infections treated with erythromycin and other macrolides are syphilis and Lyme disease. Various forms of gonorrhea and *Chlamydia* and *Mycoplasma* infections are also susceptible to the effects of macrolides.

A therapeutic effect of erythromycin outside its antibiotic actions is its ability to irritate the GI tract, which stimulates smooth muscle and GI motility. This action may be of benefit to patients who have decreased GI motility, such as delayed gastric emptying in patients with diabetes (known as diabetic gastroparesis). It has also been shown to be helpful in facilitating the passage of feeding

TABLE 43.8 Macrolides: Reported Adverse Effects

Body System	Adverse Effects
Cardiovascular	Palpitations, chest pain, QT prolongation
Central nervous	Headache, dizziness, vertigo
Gastrointestinal	Nausea, hepatotoxicity, heartburn, vomiting, diarrhea, flatulence, cholestatic jaundice, anorexia, abnormal taste
Integumentary	Rash, urticaria, phlebitis at intravenous site
Other	Hearing loss, tinnitus

tubes from the stomach into the small bowel. Azithromycin and clarithromycin are approved for the prevention and treatment of *Mycobacterium avium-intracellulare* complex infections. This is a common opportunistic infection often associated with HIV/AIDS (see Chapter 45). Clarithromycin also has been approved for use in combination with omeprazole for the treatment of patients with active ulcers associated with *Helicobacter pylori* infection.

Contraindications

The only usual contraindication to macrolide use is known drug allergy. Macrolides are often used as alternative drugs for patients with allergies to beta-lactam antibiotics.

Adverse Effects

Erythromycin formulations cause many GI-related adverse effects, especially nausea and vomiting. Azithromycin and clarithromycin seem to be associated with a lower incidence of these GI tract complications. Reported adverse effects are listed in [Table 43.8](#).

Interactions

There are a number of potential drug interactions with the macrolides. The macrolides possess two properties that can cause drug interactions: they are highly protein bound and they are metabolized in the liver. For drugs metabolized in the liver, drug interactions arise from competition between the different drugs for metabolic enzymes, specifically the enzymes known as the *cytochrome P450 complex* (see Chapter 2). Such enzymatic effects generally lead to more pronounced drug interactions than competition for protein binding. The result is a delay in the metabolic clearance of one or more interacting drugs and thus a prolonged and possibly toxic drug effect. Examples of some especially common drugs that compete for liver metabolism with the macrolides, leading to enhanced effects and possible toxicity, are carbamazepine, cyclosporine, theophylline, and warfarin sodium. Therefore, patients must be monitored. Macrolides can also reduce the efficacy of oral contraceptives. Clarithromycin and erythromycin are not to be used with moxifloxacin, pimozone, thioridazine, or other drugs that prolong the QT interval, because malignant dysrhythmias can occur. Concurrent use of simvastatin or lovastatin with clarithromycin or erythromycin is not recommended. Azithromycin is not as prone to such interactions as are the other macrolides because of its minimal effects on the cytochrome P450 enzymes.

Dosages

For dosage information on selected macrolide antibiotics, refer to the table on p. 707.

DRUG PROFILES

Macrolide antibiotics are used to treat a variety of infections, ranging from Lyme disease to Legionnaire's disease. Of the three macrolide drugs currently available, erythromycin has been available for the longest period and has provided the anchor of treatment for various infections for more than four decades. Azithromycin and clarithromycin have fewer adverse effects and better pharmacokinetic profiles than erythromycin.

Macrolide use is contraindicated in patients with known drug allergy. Because macrolides are significantly protein bound and are metabolized in the liver, they may interact with other drugs that are also highly protein bound or hepatically metabolized.

erythromycin

Erythromycin, which has many product names, was for many years the most commonly prescribed macrolide antibiotic; however, other macrolides are now more commonly used. The drug is available in several different salt and dosage forms for oral use that were developed to circumvent some of its chemical drawbacks. A parenteral form is available for IV use. Erythromycin is also available in topical forms for dermatological use (see Chapter 56) and in ophthalmic dosage forms (see Chapter 57). The absorption of oral erythromycin is enhanced if it is taken on an empty stomach, but because of the high incidence of stomach irritation associated with its use, many of its forms are taken with a meal or snack. With delayed-release capsules containing

enteric-coated granules of the drug, maximum blood levels are obtained when administered at least 30 minutes and preferably 2 hours before or after a meal.

azithromycin and clarithromycin

Azithromycin (Zithromax®) and clarithromycin (Biaxin®) are semisynthetic macrolide antibiotics that differ structurally from erythromycin and as a result have advantages over it. These include better adverse effect profiles, including less GI tract irritation, and more favourable pharmacokinetic properties. Both have a similar range of activity that differs only slightly from that of erythromycin. The two drugs are used for the treatment of both upper and lower respiratory tract and skin structure infections.

Azithromycin has excellent tissue penetration, so it can reach high concentrations in infected tissues. It also has a long duration of action, which allows it to be dosed once daily. It is usually given in a regimen of 500 mg on day 1 and then 250 mg per day for 4 days. The drug can be taken with or without food. It is available in oral and injectable forms.

Clarithromycin is given orally, twice daily, in adults and children older than 6 months of age. It can be given with or without food. The immediate-release oral formulations (tablets or oral suspension) are not bioequivalent and are not interchangeable with azithromycin sustained release due to a different pharmacokinetic profile. The extended-release preparation must not be crushed.

Dosages

Selected Macrolides

Drug	Pharmacological Class	Usual Dosage Range	Indications
 azithromycin (Zithromax)	Semisynthetic macrolide	<i>Children</i> PO: 30 mg/kg × 1 dose or 10 mg/kg/day × 3 days or 10 mg/kg × 1 dose, then 5 mg/kg/day × 4 days IV: 10 mg/kg × 1 day then 5 mg/kg/day × 4 days <i>Adults over 16 yr</i> PO: 500 mg × 1 dose, then 250 mg/day × 4 days PO: 500 mg daily × 3 days, or 2 g × 1 dose IV: 500 mg/day	Comparable to those for erythromycin, but especially GU and respiratory tract infections, including MAC infections
 clarithromycin (Biaxin)	Semisynthetic macrolide	<i>Children</i> PO: 7.5 mg/kg/dose BID (max 500 mg/dose) <i>Adults</i> PO: 250–500 mg q12h	Comparable with erythromycin, but especially for infections of the GI and respiratory tracts, including MAC infections
 erythromycin (EES®, Erythro-EC®, many others)	Natural macrolide	<i>Children*</i> 30–100 mg/kg/day divided q6h <i>Adults*</i> PO: 250–500 mg q6h	Infections of respiratory and GI tracts and skin caused by gram-positive, gram-negative, and miscellaneous organisms

GI, Gastrointestinal; GU, genitourinary; IV, intravenous; MAC, *Mycobacterium avium* complex; PO, oral.

*There are many types of dosage forms, and dosages may vary from those listed.

PHARMACOKINETICS (AZITHROMYCIN)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Variable	2.5–4 hr	60–70 hr	several days

PHARMACOKINETICS (CLARITHROMYCIN)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Variable	2–4 hr	3–7 hr	Up to 12 hr

TETRACYCLINES

The tetracyclines are bacteriostatic drugs that inhibit bacterial protein synthesis by binding to the 30S bacterial ribosome. The only available naturally occurring tetracycline is tetracycline hydrochloride. The two semisynthetic tetracyclines are doxycycline hyclate and minocycline hydrochloride. The newest tetracycline antibiotic is tigecycline (Tygacil®). Tigecycline is indicated for complicated infections, intra-abdominal infections, and community-acquired pneumonia. It is effective against many resistant bacteria. However, a warning of increased risk of all-cause mortality in patients treated with tigecycline has been issued; the drug should be used only when other treatments are not available.

Tetracyclines are chemically and pharmacologically similar to one another. The most significant chemical characteristic of these drugs is their ability to bind to (chelate) divalent (Ca^{++} , Mg^{++}) and trivalent (Al^{+++}) metallic ions to form insoluble complexes. Therefore, their coadministration with milk, antacids, or iron salts causes a considerable reduction in the oral absorption of the tetracycline. In addition, their strong affinity for calcium usually precludes their use in children younger than 8 years of age because it can result in significant tooth discoloration. These drugs should also be avoided in pregnant women and nursing mothers. The drugs pass into breast milk, and this can be another route of exposure leading to tooth discoloration in nursing children.

Tetracyclines differ from one another primarily in the following ways:

- **Oral absorption:** All except tigecycline are adequately absorbed, but doxycycline and minocycline hydrochloride have the best absorption.
- **Body tissue penetration:** Doxycycline hyclate and minocycline hydrochloride possess the best penetration potential (brain and cerebrospinal fluid).
- **Half-life and resulting dosage schedule:** Refer to the Dosages table on p. 708 and the pharmacokinetics information in the Drug Profiles section.

Mechanism of Action and Drug Effects

Tetracyclines work by inhibiting protein synthesis in susceptible bacteria. They inhibit the growth of and kill a wide range of *Rickettsia*, *Chlamydia*, and *Mycoplasma* organisms, as well as a variety of gram-negative and gram-positive bacteria (see

Indications). They are also useful in the treatment of spirochetal infections, such as syphilis and Lyme disease, and pelvic inflammatory disease.

Indications

Tetracyclines have a wide range of activity, and all drugs in this class are effective against essentially the same range of microbes. They inhibit the growth of many gram-negative and gram-positive organisms and even that of some protozoa. Traditionally used to treat acne in adolescents and adults, they are also considered the drugs of choice for the treatment of the following infections caused by susceptible organisms:

- *Chlamydia*: lymphogranuloma venereum, psittacosis, and nonspecific endocervical, rectal, and urethral infections
- *Mycoplasma*: Mycoplasma pneumonia
- *Rickettsia*: Q fever, rickettsial pox, Rocky Mountain spotted fever, and typhus
- *Other bacteria*: acne, brucellosis, chancroid, cholera, granuloma inguinale, shigellosis, spirochetal relapsing fever, Lyme disease, *H. pylori* infections associated with peptic ulcer disease (used as part of the treatment regimen), syphilis (used as an alternative drug to treat patients with penicillin allergy); tetracyclines are now unreliable in treating gonorrhea because of resistant bacterial strains.
- *Protozoa*: balantidiasis

Contraindications

The only usual contraindication to the use of tetracyclines is known drug allergy. However, tetracyclines must be avoided by pregnant and nursing women and should not be given to children under the age of 8 years.

Adverse Effects

All tetracyclines cause similar adverse effects. They can cause discoloration of the permanent teeth and tooth enamel hypoplasia in both fetuses and children, and they possibly stunt fetal skeletal development if taken during pregnancy. Other clinically significant undesirable effects include photosensitivity; alteration of the intestinal flora, which can result in diarrhea or vaginal candidiasis; reversible bulging fontanelles in neonates; thrombocytopenia, possible coagulation irregularities, and hemolytic anemia; and exacerbation of systemic lupus erythematosus. Other effects include GI upset, enterocolitis, and maculopapular rash.

Interactions

There are several significant drug interactions associated with the use of tetracyclines. When tetracyclines are taken with antacids, antidiarrheal drugs, dairy products, calcium, enteral feedings, or iron preparations, the oral absorption of the tetracycline is reduced. Tetracyclines can potentiate the effects of oral anticoagulants, which necessitates more frequent monitoring of their anticoagulant effects and possible dose adjustment. They can also antagonize the effects of bactericidal antibiotics and oral contraceptives. In addition, depending on the dosage, they can cause blood urea nitrogen (BUN) levels to be increased.

Dosages

For dosage information on selected tetracyclines, refer to the table on p. 709.

DRUG PROFILES

doxycycline hyclate

Doxycycline hyclate (Aprilon®, Atridox®, Doxycin®, Doxytab®, Periostat®, Vibramycin®) is a semisynthetic tetracycline antibiotic that was made by altering the naturally occurring tetracycline oxytetracycline. Doxycycline is available in Canada in the salt form hyclate. It is useful in the treatment of rickettsial infections, *C. difficile*, chlamydial and mycoplasmal infections, spirochetal infections, and many infections with gram-negative organisms. Doxycycline may also be used as a sclerosing drug in the treatment of pleural effusions. It is available in oral forms. Atridox is a controlled-release sublingual gel.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Variable	1.5–4 hr	18–22 hr	Up to 10–12 hr

tigecycline

Tigecycline (Tygacil) is the newest tetracycline, referred to as a *glycylcycline*. It differs from other tetracyclines in that it is effective against many organisms resistant to others in its class. It is indicated for the treatment of complicated skin and skin structure infections caused by susceptible organisms, including MRSA and vancomycin-sensitive *Enterococcus faecalis*, and for the treatment of complicated intra-abdominal infections. Tigecycline is given by injection only. Nausea and vomiting are the most common adverse effects, occurring in 20 to 30% of patients. Tigecycline should not be used in patients with severe infections such as hospital acquired pneumonia and severe skin infections due to an increased risk of mortality.

Tetracyclines were one of the first classes of antibiotics capable of providing coverage against a broad spectrum of microorganisms. Their use is contraindicated in patients who have had hypersensitivity reactions to them in the past and in women who are lactating. Resistance to one tetracycline implies resistance to all tetracyclines.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Immediate	Immediate after infusion	27 hr	12 hr

NURSING PROCESS

ASSESSMENT

To ensure effective treatment, in general, before the administration of any antibiotic, it is crucial to gather data on a history of, or symptoms indicative of, hypersensitivity or allergic reactions (from mild reactions with rash, pruritus, angioedema, or hives to severe reactions with laryngeal edema, bronchospasm, hypotension, or possible cardiac arrest). Also, determine the patient's age, weight, and baseline vital signs, including body temperature. Examine the results of any laboratory tests that have been ordered, such as liver function studies (AST and ALT levels), kidney function tests (usually GFR, BUN, and creatinine levels), heart function tests (pertinent laboratory tests, electrocardiogram [ECG]), ultrasonography (if indicated), culture and sensitivity tests, and complete blood count (CBC) with hemoglobin/hematocrit (Hgb/Hct) levels and platelet and clotting tests. Assess intake and output measurements, if appropriate, (e.g., urinary output of more than 30 mL/hr or 600 mL/24 hr). Recording a baseline neurological assessment (e.g., history of seizures) is important because of possible CNS adverse effects. Assess bowel sounds and patterns because of potential antibiotic-related GI tract adverse effects. Further assessment needs to include checking for contraindications, cautions, and drug interactions. Obtain a complete list of all medications, including over-the-counter (OTC) drugs and natural health products. Ethnocultural assessment is also important because of the well-documented variations in responses to antibiotics among different racial and ethnic groups, as well as some cultures' common use of folk remedies or alternative therapies to try to alleviate infections. Assess patients' learning preparedness, willingness to learn, and educational level because of the importance of patient education to safe medication administration. Note baseline findings from assessment of the oral mucosa, respiratory tract, GI tract, and GU tract because of the risk of superinfection in these areas. Superinfections are often evidenced by fever, lethargy, oral

Dosages

Selected Tetracyclines

Drug	Pharmacological Class	Usual Dosage Range	Indications
doxycycline hyclate (Aprilon, Atridox, Doxycin, Doxytab, Vibramycin, others)	Tetracycline	Adults PO: 200 mg first day, then 100 mg daily thereafter	Broad antibacterial coverage, including treatment of skin infections and respiratory, GI, and GU tract infections, Lyme disease
tigecycline (Tygacil)	Glycylcycline	Adults IV: 100 mg × 1, then 50 mg q12h	Skin and skin structure infections, MRSA infections, intra-abdominal infections

GI, Gastrointestinal; GU, genitourinary; IV, intravenous; MRSA, methicillin-resistant *Staphylococcus aureus*; PO, oral.

thrush, perineal itching, and other system-related symptoms. Because antibiotic resistance is so prevalent, ask the patient or caregiver questions about long-term use, overuse, or abuse of antibiotics. Assessment information related to each group of antibiotics is presented in the following paragraphs.

For patients taking sulfonamides, a careful assessment for drug allergies to sulfa-type drugs or sulphites, such as the oral sulfonylureas (antihyperglycemic drugs) and thiazide diuretics, is important to patient safety (see previous discussion on sulfonamides). Perform a thorough skin assessment during drug therapy because of the potential for occurrence of the adverse effect of Stevens-Johnson syndrome (see Table 43.2). Assess red blood cell count before beginning sulfonamide therapy because of the possibility of drug-related anemias. With frequent or long-term therapy, assess kidney function because of the potential for drug-related crystalluria. Check the patient's medication and medical history for any manifestations of G6PD and slow acetylation (see Chapter 2).

Before the initiation of therapy with penicillins, because of the high incidence of hypersensitivity, determine if there are drug allergies. Potential drug interactions are presented in Table 43.5. In addition, assess the patient for a history of asthma, sensitivity to multiple allergens, aspirin allergy, and sensitivity to cephalosporins because these are associated with a higher risk for penicillin allergy. If procaine penicillin is to be given, the patient should be assessed for procaine hypersensitivity. Note the results of culture and sensitivity testing as soon as they are available to confirm the appropriateness of therapy. Because of possible CNS and GI adverse effects, complete a thorough neurological, abdominal, and bowel assessment. Especially important for patients with electrolyte disturbances, heart disease, or kidney disease is assessment of serum sodium and potassium levels, primarily because of the high sodium and potassium ion concentrations in some penicillin preparations. For example, penicillin G contains 1.7 mmol of potassium ion per million units and 2 mmol of sodium ion per million units. With these particular preparations, if a patient has heart failure, fluid overload, or cardiac dysrhythmias, a high sodium or potassium level (hyponatremia or hyperkalemia) can lead to exacerbation of these problems. With any dosage forms of the penicillins, it is important to patient safety to assess for the possibility of an immediate, accelerated, or delayed allergic reaction.

Prior to the use of cephalosporins, conduct a thorough assessment of allergies, including allergy to penicillins, because of possible cross-sensitivity. Because of the similarity in their mechanism of action to penicillins, assessment data is also similar. Obtain information about the specific drug, and note the generation of cephalosporins to which it belongs. Each of the drug generations has distinctive adverse effects and complications in addition to commonalities with the other groups.

Carbapenems are used when there are complicated connective tissue infections in acutely ill patients who are hospitalized. Assess patients for a history of seizure activity because of the potential for seizure-type, drug-induced reactions.

With macrolides, assessment of baseline heart function with documentation of vital signs is important because these drugs may lead to palpitations, chest pain, and ECG changes (QT prolongation). Note baseline hearing status because of drug-induced hearing loss and tinnitus. Assess liver function

and determine if there is any history of liver disease due to possible hepatotoxicity and jaundice. Drug interactions have been discussed previously, but special consideration should be given to concurrent use of a macrolide with warfarin sodium, digoxin, or theophylline, resulting in possible toxicity of the latter drugs. Macrolides also reduce the effectiveness of oral contraceptives.

With the use of tetracyclines, as with all antibiotic therapy, carefully assess culture and sensitivity reports. There is concern regarding the use of these drugs in patients younger than 8 years of age because of the problem of permanent mottling and discoloration of the teeth. Use of these drugs in pregnancy may also pose problems for the fetus. Assess for any whitish sore patches on the oral mucosa (due to candidiasis or yeast infection) as well as any vaginal itching, pain, or cottage cheese-like discharge (because of vaginal candidiasis) for early identification and early treatment of superinfections (see previous discussion). Assess for significant drug interactions, including simultaneous use of antacids, antidiarrheal drugs, dairy products, calcium, enteral feedings, and iron preparations. These medications may lead to reduced absorption of the tetracycline. Tetracyclines may also decrease the effectiveness of oral contraceptives. Assess patients taking oral anticoagulants closely due to the possible potentiation of bleeding.

Antiseptics and disinfectants have also been discussed in this chapter.

◆ NURSING DIAGNOSES

- Potential for nonadherence with the treatment regimen as a result of lack of information or inability to pay for and obtain the necessary medication
- Inadequate knowledge as a result of lack of information about the disease process and the medication regimen
- Potential risk for infection as a result of the patient's possible development of a compromised immune status (due to use of sulfonamides)

◆ PLANNING

◆ Goals

- Patient will remain adherent to the antibiotic therapy regimen for the full duration of treatment.
- Patient will demonstrate adequate knowledge about the disease process and related drug therapy.
- Patient will maintain homeostasis and a healthy immune system, as well as remain free from risk for infection.

◆ Expected Patient Outcomes

- Patient describes the rationale for the specific antibiotic therapeutic regimen, associated adverse effects, and measures to decrease these adverse effects.
- Patient takes a specific antibiotic with attention to instructions about whether to take it with meals or increased fluids, as well as foods, medications, and beverages to avoid while on the antibiotic regimen.
- Patient briefly describes the importance to therapeutic effectiveness of taking the antibiotic exactly as prescribed and until the full prescription is taken.

- Patient takes medication exactly as prescribed and for the full time prescribed.
- Patient reports any adverse effects that are unresolved and are of concern, such as jaundice, excessive fatigue, elevated temperature, increase in pain associated with the infection, or severe GI distress, nausea, or diarrhea.
- Patient remains free of elevated WBC counts and maintains temperature, pulse rate, and respiratory rate within normal ranges with negative culture and sensitivity reports.

◆ IMPLEMENTATION

General nursing interventions that apply to antibiotics include the following: (1) Give oral antibiotics within the recommended time frames and with fluids or foods as indicated. (2) All medication is to be taken as ordered, in full, and around the clock to maintain effective blood levels, unless otherwise instructed by the health care provider. (3) Doses are not to be omitted or doubled up. (4) Oral antibiotics are not to be given at the same time as antacids, calcium supplements, iron products, laxatives containing magnesium, or some of the antilipemic drugs (see previous listing of drug interactions). (5) Natural health products are to be used only if they do not interact with the antibiotic. (6) Continuously monitor for hypersensitivity reactions after the initial assessment phase because immediate reactions may not occur for up to 30 minutes, accelerated reactions may occur within 1 to 72 hours, and delayed responses may occur after 72 hours. These reactions are characterized by wheezing; shortness of breath; swelling of the face, tongue, or hands (angioedema); itching; or rash. (7) If there are signs of a possible hypersensitivity reaction, stop the dosage form immediately (if IV, stop the infusion), contact the health care provider, and monitor the patient closely. (8) Results of a culture and sensitivity test must be obtained, if possible, before the first dose of antibiotic is given.

Sulfonamides need to be avoided in patients with G6PD and slow acetylation. Encourage increased intake of fluids (2 000 to 3 000 mL per day) to prevent drug-related crystalluria. Oral dosage forms are to be taken with food to minimize GI upset. Encourage patients to immediately report any of the following to the health care provider: worsening abdominal cramps, stomach pain, diarrhea, hematuria, severe or worsening rash, shortness of breath, or fever. These symptoms may indicate adverse reactions to these drugs; remember that the mucocutaneous, GI, hepatic, and hematologic complications may be fatal.

With penicillins, as with other antibiotics, the natural flora in the GI tract may be killed off by the antibiotic. Unaffected GI bacteria, such as *C. difficile*, may overgrow (see earlier discussion on penicillins for more information). This process may be prevented by the consumption of probiotics, such as products containing *Lactobacillus*; supplements; or cultured dairy products like yogourt, buttermilk, and kefir. Kefir is prepared using milk from sheep, goats, and cows. Soy milk kefir is now also commercially available. Keep in mind the following important points when giving various penicillin formulations: (1) Advise patients to take oral penicillins with at least 180 mL of water. (2) Penicillin V, amoxicillin, and amoxicillin/clavulanate are given with water, 1 hour before or 2 hours after meals to maximize absorption; however, because of GI upset, these medications may need to be taken with a snack or meal. (3) Procaine and benzathine salt penicillins are thick solutions; give them as ordered,

intramuscularly into a large muscle mass, using at least a 21-gauge needle, rotating sites as needed. (4) Reconstitute IM imipenem/cilastatin in sterile saline, with plain lidocaine—as ordered and if the patient has no allergy to it—and give into a large muscle mass. (5) With IV penicillins (e.g., ampicillin), as with any IV therapy, use the proper diluent and infuse the medication over the recommended time. Monitor the IV site frequently for swelling, tenderness, heat, redness, leaking, and pain. Calculate IV rates to deliver the prescribed amount per minute or hour. Change IV sites per facility protocol. (6) Check for compatibilities of IV fluids and drugs prior to infusion. (7) If the patient experiences an anaphylactic reaction to a penicillin (or any drug), give epinephrine and other emergency drugs as ordered, and have supportive treatment (e.g., oxygen) available at all times.

Orally administered cephalosporins may be given with food to decrease GI upset. Alcohol and alcohol-containing products are to be used with caution because of the potentiation of a disulfiram-like reaction, known as *acute alcohol intolerance*. Although uncommon, acute alcohol intolerance is associated with the cephalosporin, ceftriazone. Symptoms that may occur include stomach cramping, nausea, vomiting, headache, diaphoresis, pruritus, and hypotension. With the newer cephalosporins, as with many drug groups, check the drug names carefully to ensure patient safety because many drug names sound alike, and this can lead to medication errors.

Macrolides need to be administered with the same precautions as those used for other antibiotics. Macrolides are not to be given with or immediately before or after fruit juices to avoid interactions with the drug. Inform the patient about the many possible drug interactions (discussed previously), including those with OTC drugs and natural health products. Encourage patients to report any of the following to their health care provider immediately: chest pain, palpitations, dizziness, jaundice, rash, or hearing loss.

Tetracyclines cause photosensitivity, so advise patients to take precautions to avoid sun exposure and avoid tanning bed use. Encourage patients to take oral doses with at least 240 mL of fluids as well as food to minimize GI upset. However, warn patients *not* to take tetracyclines with calcium, magnesium, or iron. These chemicals chelate, or bind, with the tetracycline, leading to a significant reduction in the oral absorption, and thus the effectiveness, of this group of antibiotics. Therefore, concurrent use of dairy products, antacids, or iron needs to be avoided. Patients may consume these interacting foods and drugs 2 hours before or 3 hours after the tetracycline to avoid this interaction. Remember that tetracyclines can cause discoloration of the permanent teeth and tooth enamel in fetuses and children. They may also retard fetal skeletal growth if taken during pregnancy. Continuously monitor for diarrhea or vaginal yeast infections due to altered intestinal or vaginal flora.

◆ EVALUATION

Include monitoring of goals, outcome criteria, therapeutic effects, and adverse effects in the evaluation. Therapeutic effects of antibiotics include a decrease in the signs and symptoms of infection; a return to normal vital signs, including temperature; negative results on culture and sensitivity tests; normal results for CBC; and improved appetite, energy level, and sense of well-being. Evaluation for adverse effects includes monitoring for specific drug-related adverse effects (see each drug profile).

CASE STUDY

Antibiotic Therapy

Rahul has been a resident of a complex continuing care facility since experiencing a left-sided stroke, 5 years ago. Currently, his cardiovascular status and cerebrovascular status are stable. However, he has had a productive cough and a low-grade fever for 2 days. After physical assessment and chest radiographic examination, the health care provider diagnosed him with pneumonia of the left lower lobe of the lung. The health care provider orders IV piperacillin/tazobactam sodium, 2.25 g every 8

hours, and oral theophylline, 300 mg every 12 hours. Rahul also takes warfarin sodium, 2 mg every evening. Maalox® 30 mL has been ordered as needed for GI upset and oral ibuprofen 400 mg to be given, as needed, for pain.

1. Explain the rationale behind the use of tazobactam sodium with piperacillin.
2. What assessments does the nurse need to undertake prior to starting the antibiotic?
3. What concerns or drug interactions should the nurse be aware of with the use of piperacillin/tazobactam and the other medications ordered for Rahul?
4. What parameters should be monitored to determine whether piperacillin/tazobactam is working? Explain your answer.

PATIENT TEACHING TIPS

- Provide patients with a list of foods and beverages that may interact negatively with antibiotics, such as alcohol, acidic fruit juices, and dairy products.
- Advise patients to report severe adverse effects to their health care providers and to keep any follow-up visits so that the effectiveness of therapy may be monitored. Laboratory tests (e.g., CBC) may also be performed at these visits.
- Foods that may help prevent superinfections (e.g., vaginal yeast infections) include yogourt, buttermilk, and kefir. Probiotic yogourt is now available for re-establishing the natural flora of the GI tract.
- Educate patients who are taking oral contraceptives for birth control about interactions between them and certain antibiotics; the effectiveness of oral contraceptives may be decreased with certain antibiotics. Reliable backup methods of contraception must be used in addition to oral contraceptives, during antibiotic use.
- Recommend that patients wear medical alert jewellery if they have any drug allergies, especially if these are anaphylactic in nature. It is recommended that patients keep drug allergy information and a listing of medical diagnoses and medications on their person at all times.
- Sulfonamides are to be taken with plenty of fluids (2 000 to 3 000 mL per day), with food, to decrease GI effects.
- Penicillins are to be taken exactly as prescribed for the full duration indicated, as with all antibiotics. Doses are to be spaced at regularly scheduled intervals. Instruct patients to take oral dosage forms with water, avoiding the following: caffeine-containing beverages, citrus fruit, colas, fruit juices, and tomato juice (which decrease the effectiveness of the antibiotic). If a patient must take a penicillin drug four times a day, encourage the patient to set up a reminder system (with cell phone alarms or a watch) so that blood levels remain steady.
- Advise patients taking cephalosporins to report any unresolved GI upset, such as diarrhea and nausea, and to avoid alcohol.
- Warn patients taking tetracyclines to avoid exposure to tanning beds and direct sunlight or to use sunscreen and wear protective clothing because of drug-related photosensitivity. Photosensitive effects may be noticed from within a few minutes to hours after taking the drug and may last up to several days after the drug has been discontinued.
- Instruct patients taking macrolides to take the specific drug as directed, and check for interactions with other drugs being taken at the same time, especially interactions between erythromycin and other medications. For some drugs in this class (e.g., azithromycin), newer dosage forms are available in 3-day and 1-day dose packs rather than 5-day dose packs. Always be sure that patients know the proper dosages and instructions for the drugs they are taking.

KEY POINTS

- Antibiotics are either bacteriostatic or bactericidal. Bacteriostatic antibiotics inhibit the growth of bacteria but do not directly kill them. Bactericidal antibiotics directly kill the bacteria.
- Most antibiotics work by inhibiting bacterial cell wall synthesis in some way. Bacteria have survived over the ages because they can adapt to their surroundings. If a bacterium's environment includes an antibiotic, over time it can mutate in such a way that it can survive an attack by the antibiotic. The production of beta-lactamases is one way in which bacteria can fend off the effects of antibiotics.
- Be aware of the most common adverse effects of antibiotics, which include nausea, vomiting, and diarrhea. Inform patients that antibiotics should be taken for the prescribed length of time.
- Each class of antibiotics is associated with specific cautions, contraindications, drug interactions, and adverse effects that must be carefully assessed for and monitored.
- Because normally occurring bacteria are killed during antibiotic therapy, superinfections may arise during treatment. These may be manifested by the following signs and symptoms: fever, perineal itching, oral lesions, vaginal irritation and discharge, cough, and lethargy.

EXAMINATION REVIEW QUESTIONS

- The nurse is caring for a patient who is scheduled for colorectal surgery the next day. The patient does not have sepsis, WBC count is normal, and the patient is afebrile and otherwise presents in good health. The health care provider orders the nurse to administer an antibiotic on call, prior to the patient going for surgery. Identify the rationale for why the nurse understands that the antibiotic is to be administered prior to surgery.
 - To provide empiric therapy
 - To provide prophylactic therapy
 - To treat for a superinfection
 - To reduce the number of resistant organisms
- An adolescent patient is taking a tetracycline drug as part of treatment for severe acne. Which of the following statements should the nurse teach this patient about drug-related precautions when taking tetracycline?
 - When the acne clears up, the medication may be discontinued.
 - This medication needs to be taken with antacids to reduce GI upset.
 - The patient needs to use sunscreen or avoid exposure to sunlight, because this drug may cause photosensitivity.
 - The teeth should be observed closely for signs of mottling or other colour changes.
- The nurse is caring for a newly admitted patient who reports a penicillin allergy. The health care provider has ordered a second-generation cephalosporin as part of therapy. Which of the following would be the most appropriate nursing action?
 - Call the health care provider to clarify the order because of the patient's allergy.
 - Ask the pharmacy to change the order to a first-generation cephalosporin.
 - Give the medication and monitor for adverse effects.
 - Administer the drug with a nonsteroidal anti-inflammatory drug to reduce adverse effects.
- The nurse is caring for a client who has been ordered an oral macrolide such as erythromycin. Which of the following would be the most important information by the nurse to provide to the patient during teaching?
 - If GI upset occurs, the drug will have to be stopped.
 - The drug needs to be taken with an antacid to avoid GI problems.
 - The patient needs to take each dose with a sip of water.
 - The patient may take the drug with a small snack to reduce GI irritation.
- A female client has been taking an antibiotic for a urinary tract infection (UTI) and calls the health care provider to report severe vaginal itching. The patient explains that she has also noticed a thick, whitish vaginal discharge. Which of the following would explain the patient's clinical manifestations?
 - This is an expected response to antibiotic therapy.
 - The UTI has become worse instead of better.
 - A superinfection has developed.
 - The UTI is resistant to the antibiotic.
- The nurse is reviewing orders for wound care, which include use of an antiseptic. Which statements best describe the use of antiseptics? (Select all that apply.)
 - Antiseptics are appropriate for use on living tissue.
 - Antiseptics work by sterilizing the surface of the wound.
 - Antiseptics are applied to nonliving objects to kill microorganisms.
 - The patient's allergies must be assessed before using the antiseptic.
 - Antiseptics are used to inhibit the growth of microorganisms on the wound surface.
- The order for a child reads: "Give cefoxitin 160 mg/kg/day, IVPB, divided into doses given every 6 hours." The child weighs 55 lb. How much will the patient receive each day? For each dose?
- The nurse is reviewing the orders for a patient who has been admitted for treatment of pneumonia. The antibiotic orders include an order for doxycycline. However, when the patient is asked about his allergies, he lists "doxycycline" as one of his allergies. What is the nurse's first action at this time?
 - Call the prescriber to clarify the order because of the patient's allergy.
 - Ask the patient to explain what happened when he had the allergic reaction.
 - Ask the pharmacy to order a different antibiotic.
 - Administer the drug with an antihistamine to reduce adverse effects.

CRITICAL THINKING ACTIVITIES

- The nurse is reviewing a patient's medications that are due this morning and notes the following orders:
doxycycline, 200 mg, PO every morning
Multivitamin with iron, 1 tablet, PO every morning
Maalox, 30 mL, PO, twice a day
What is the priority action when considering whether these medications can be given together?
 - The nurse is reviewing the orders for a patient who has been admitted for treatment of pneumonia. The antibiotic orders include an order for penicillin. However, when the patient is asked about his allergies, he lists "penicillin" as one of his allergies. What will be the next action of the nurse?
 - A 79-year-old patient has been admitted for treatment of osteomyelitis. His orders include IV imipenem/cilastatin, oral lisinopril, oral phenytoin sodium, and a prn order for acetaminophen for a temperature over 38.3°C or for pain. The nurse is reviewing the patient's history and new orders. After reviewing the orders, what is the first action the nurse will take?
- For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Antibiotics Part 2: Aminoglycosides, Fluoroquinolones, and Other Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Apply the general principles of antibiotic therapy and all of the antibiotics covered previously in [Chapter 43](#), in preparation for discussion of the following antibiotics or antibiotics classes: aminoglycosides, quinolones, clindamycin, metronidazole, nitrofurantoin, vancomycin hydrochloride, and several other miscellaneous antibiotics.
2. Describe the advantages and disadvantages associated with the use of antibiotics, including overuse and misuse of antibiotics, development of drug resistance, superinfections, and antibiotic-associated colitis.
3. Discuss the indications, cautions, contraindications, mechanisms of action, adverse effects, toxic effects, routes of administration, and drug interactions for the aminoglycosides, fluoroquinolones, clindamycin, metronidazole, nitrofurantoin, vancomycin hydrochloride, and miscellaneous antibiotics.
4. Develop a collaborative plan of care that includes all phases of the nursing process for the patient receiving antibiotics.

KEY TERMS

Concentration-dependent killing A property of some antibiotics, especially aminoglycosides, whereby achieving high plasma drug concentration, even briefly, results in the most effective bacterial kill (compare *time-dependent killing*). (p. 717)

Extended-spectrum beta-lactamases (ESBLs) A group of beta-lactamase enzymes produced by some organisms that make the organism resistant to all beta-lactam antibiotics (penicillins and cephalosporins) and aztreonam. Patients who are infected by such organisms must be in contact isolation; proper handwashing is key to preventing the spread of these organisms. (p. 716)

***Klebsiella pneumoniae* carbapenemase (KPC)** An enzyme first found in isolates of the bacterium *Klebsiella pneumoniae* that renders the organism resistant to all carbapenem antibiotics as well as beta-lactam antibiotics and monobactams. Such organisms produce a serious resistant infection. (p. 716)

Methicillin-resistant *Staphylococcus aureus* (MRSA) A strain of *Staphylococcus aureus* that is resistant to the beta-lactamase penicillin known as *methicillin*. Originally, the abbreviation MRSA referred exclusively to methicillin-resistant *S. aureus*. It is now used more commonly to refer to strains of *S. aureus* that are resistant to several drug classes, and therefore, depending on the context or health facility, it may also stand for *multidrug-resistant S. aureus*. (p. 716)

Minimum inhibitory concentration (MIC) A laboratory measurement of the lowest concentration of a drug needed to kill a certain standardized amount of bacteria. (p. 717)

Multidrug-resistant organisms Bacteria that are resistant to one or more classes of antimicrobial drugs. These

include multidrug-resistant *Staphylococcus aureus*, extended-spectrum beta-lactamase-producing organisms, and *Klebsiella pneumoniae* carbapenemase-producing organisms. (p. 716)

Nephrotoxicity Toxicity to the kidneys, often drug induced and manifesting in compromised kidney function; usually reversible upon withdrawal of the offending drug. (p. 711)

Ototoxicity Toxicity to the ears, often drug induced and manifesting as varying degrees of hearing loss that is likely to be permanent. (p. 717)

Peak The highest concentration of a drug in the patient's bloodstream. (p. 717)

Postantibiotic effect (PAE) A period of continued bacterial suppression that occurs after brief exposure to certain antibiotic drug classes, especially aminoglycosides (discussed in this chapter) and carbapenems (see [Chapter 43](#)). The mechanism of this effect is uncertain. (p. 717)

Pseudomembranous colitis A necrotizing, inflammatory bowel condition that is often associated with antibiotic therapy. Some antibiotics (e.g., clindamycin) are more likely to produce it than others. More commonly referred to as *antibiotic-associated colitis* or *Clostridium difficile* diarrhea or *C. difficile* infection. (p. 722)

Synergistic effect Drug interaction in which the bacterial killing effect of two antibiotics given together is greater than the sum of the individual effects of the same drugs given alone. (p. 717)

Therapeutic drug monitoring Ongoing monitoring of plasma drug concentrations and dosage adjustment based on these values as well as on other laboratory indicators such as kidney and liver function tests; this monitoring is often

carried out by a pharmacist in collaboration with medical, nursing, and laboratory staff. (p. 716)

Time-dependent killing A property of most antibiotic classes whereby prolonged high plasma drug concentrations are required for effective bacterial kill (compare *concentration-dependent killing*). (p. 717)

Trough The lowest concentration of a drug in the patient's bloodstream. (p. 717)

Vancomycin-resistant *Enterococcus* (VRE) *Enterococcus* species that are resistant to beta-lactam antibiotics and vancomycin. Most commonly refers to *Enterococcus faecium*. (p. 716)

DRUG PROFILES

* Full generic name is given in parentheses. For the purposes of this text, the more common, shortened name is used.

OVERVIEW

This chapter is a continuation of [Chapter 43](#) and focuses on additional classes of antibiotics used for more serious and harder-to-treat infections. Many of the drugs discussed in this chapter are administered by the *parenteral* (injection) route only, a route generally reserved for treating more clinically serious infections in the hospital setting. Also included in this chapter are miscellaneous drugs that are unique in their class, as well as newer drugs and drug classes. This chapter also focuses on multidrug-resistant organisms, specifically **methicillin-resistant *Staphylococcus aureus* (MRSA)**, **vancomycin-resistant *Enterococcus* (VRE)**, organisms producing **extended-spectrum beta-lactamases (ESBLs)**, and organisms producing ***Klebsiella pneumoniae* carbapenemase (KPC)**.

Organisms that are resistant to one or more classes of antimicrobial drugs are referred to as **multidrug-resistant organisms**. These include MRSA, VRE, and ESBL- and KPC-producing organisms. MRSA has been around for many years, and, fortunately, new antibiotics have been developed to treat it. However, the threat of MRSA becoming resistant to all currently available antibiotics is all too real. MRSA is no longer seen just in hospitals; it has spread to the community setting, and approximately 50% of staphylococcal infections contracted in the community involve MRSA, depending on location; local community and hospital MRSA strains vary. VRE is usually seen in urinary tract infections. Some newer antibiotics have been developed to successfully treat VRE as well as MRSA.

Unfortunately, ESBL- and KPC-producing bacteria are the newest players in this saga. Organisms that produce ESBL are resistant to all beta-lactam antibiotics and aztreonam and can be treated only with carbapenems or sometimes quinolones. In the noble effort to treat infection with ESBL-producing organisms, the use of carbapenems has increased, and unfortunately, in response, bacteria have created a new means of resistance, namely, the ability to produce KPC. When patients become infected with KPC-producing bacteria, there are only two known antibiotics that can be used—tigecycline and colistimethate sodium. Reports of resistance to these antibiotics have been described; such resistance leaves patients with the infection untreatable. Multidrug-resistant organisms are one of the world's top health problems. When patients become infected with such organisms, they must be placed in contact isolation. VRE is no longer isolated in hospitals, whereas MRSA is isolated, although the two are often isolated together. Refer to institutional policies regarding isolation precautions.

Many hospitals are placing all patients infected with KPC-producing bacteria in one area, and some hospitals have been shut down due to this organism. Proper handwashing is of the utmost importance. These organisms are spread by contact, so all health care providers must wash their hands before and after all patient contact. Some research indicates that patterns of antibiotic resistance for a certain class of antibiotics are influenced by the prescription of antibiotics in other classes that were previously assumed to be unrelated.

AMINOGLYCOSIDES

The aminoglycosides are a group of natural and semisynthetic antibiotics that are classified as bactericidal drugs (see [Chapter 43](#)). They are potent antibiotics, which makes them the drugs of choice for the treatment of virulent infections. The aminoglycoside antibiotics available for clinical use are listed in [Table 44.1](#). These drugs can be given by several different routes, but they are not given orally because of their poor oral absorption.

The three aminoglycosides most commonly used for the treatment of systemic infections are gentamicin, tobramycin, and amikacin. Serum levels of these drugs are routinely monitored. Dosages are adjusted to maintain optimal levels that maximize drug efficacy and minimize the risk for toxicity. This process is known as **therapeutic drug monitoring**. Aminoglycoside therapy is monitored in this way because of the nephrotoxicity and ototoxicity associated with the use of aminoglycosides. Most commonly, dosing is adjusted to the patient's level of kidney function, based on estimates of creatinine clearance calculated from serum creatinine values. This task is often carried out by a hospital pharmacist, consulting for the health care provider. Not

TABLE 44.1 Desired Traditional Serum Drug Levels of the Aminoglycoside Antibiotics

Serum Drug Levels	PEAK		TROUGH	
	Multiple-Daily Dosing*	Once-Daily Dosing	Multi-Daily Dosing	Once-Daily Dosing
amikacin	20–30 mg/L [†]	Usually not measured	5–10 mg/L	Less than 10 mg/L
gentamicin and tobramycin	5–10 mg/L	Usually not measured	< 2 mg/L	<1 mg/L

*q8h or q12h.

[†]mcg = microgram; note that one microgram = 1/1 000 (one thousandth) of a milligram or 1/1 000 000 (one millionth) of a gram. Also note that *microgram* is abbreviated *mcg*, whereas *milligram* is abbreviated *mg*.

only are serum levels measured to prevent toxicity, but it has been shown that for the aminoglycosides to be effective, the serum level needs to be at least eight times higher than the **minimum inhibitory concentration (MIC)**. The MIC for any antibiotic is a measure of the lowest concentration of drug needed to kill a standard amount of bacteria. This value is determined in vitro (in the laboratory) for each drug. It has been shown that other classes of antibiotics, such as beta-lactams, work on **time-dependent killing**, that is, the amount of time the drug is above the MIC is critical for maximal bacterial kill. However, aminoglycosides work primarily through **concentration-dependent killing**; that is, achieving a drug plasma concentration that is a certain level above the MIC, even for a brief period of time, results in the most effective bacterial kill. For this reason, although these drugs were originally given in three daily intravenous (IV) doses, the current predominant practice is once-daily aminoglycoside dosing in combination with other antibiotics for synergistic effects. Dosages of 5 to 7 mg/kg/day are used. Once-daily dosing provides a sufficient plasma drug concentration for bacterial kill, along with equal or lower risk for toxicity compared with multiple daily dosage regimens. Use of a once-daily regimen instead of the traditional three times daily regimen also reduces the nursing care time required and often allows for outpatient or even home-based aminoglycoside drug therapy.

Peak (highest) drug levels for once-daily regimens are usually not measured (this may vary among agencies) as it is assumed that the peak level for a single daily dose will be short lived and will drop within a reasonable time frame. However, **trough** (lowest) levels are routinely measured to ensure adequate renal clearance of the drug and avoid toxicity. For dosage information on selected aminoglycosides, see the table on p. 719. Dosage regimens and ranges for serum levels may vary for different institutions.

With once-daily dosing, the blood sample for trough measurement is drawn 30 minutes prior to the next dose administration. The therapeutic goal is a trough concentration at or below 1 mcg/mL (which is considered undetectable). Trough levels above 2 mcg/mL are associated with greater risk for both ototoxicity and nephrotoxicity. **Ototoxicity** (toxicity to the ears) often manifests as some degree of temporary or permanent hearing loss. **Nephrotoxicity** (toxicity to the kidneys) manifests as varying degrees of reduced kidney function. This risk is generally indicated by laboratory test results such as serum creatinine level. A rising serum creatinine level suggests reduced creatinine clearance by the kidneys and is indicative of declining renal function. Trough levels are normally monitored initially and then once every 5 to 7 days until drug therapy is discontinued. The patient's serum creatinine level is measured

at least every 3 days as an index of renal function, and drug dosages are adjusted as needed for any changes in renal function.

Traditional dosing of aminoglycosides (i.e., three times a day) can still be used. When an aminoglycoside is given in this manner, both peak and trough levels are measured. Samples for measurement of peak levels are drawn 30 minutes after a 30-minute infusion has ended, and samples for measurement of trough levels are drawn just before the next dose. The health care provider can adjust the dose based on a pharmacokinetic evaluation of these levels. When the drug is given in the traditional manner, the desired peak levels vary depending on the type of organism and the site of infection. Higher levels are needed when treating pneumonia than when treating a urinary tract infection—because aminoglycosides are eliminated by the kidney, the drug concentrates in the urine, so lower dosages can be used to treat urinary tract infections. Regardless of the infection being treated, however, it is desirable to keep the trough levels below 2 mcg/mL. [Table 44.1](#) lists the traditional desired drug levels for these drugs.

Mechanism of Action and Drug Effects

Aminoglycosides work in a way that is similar to that of tetracyclines, in that they bind to ribosomes, specifically the 30S ribosome, thereby preventing protein synthesis in bacteria (see [Chapter 43](#), Figure 43.3). Aminoglycosides are most often used in combination with other antibiotics such as beta-lactams or vancomycin in the treatment of various infections because the combined effect of the two antibiotics is greater than the sum of the effects of either drug acting separately. This is known as a **synergistic effect**. When aminoglycosides are used in combination with beta-lactam antibiotics (i.e., penicillins, cephalosporins, and monobactams [see [Chapter 43](#)]), the beta-lactam antibiotic is given first. This is because beta-lactams break down the cell wall of the bacteria and allow the aminoglycoside to gain access to the ribosomes where they work. Aminoglycosides also have a property known as **postantibiotic effect (PAE)**. PAE is a period of continued bacterial growth suppression that occurs *after* short-term antibiotic exposure, as in once-daily aminoglycoside dosing (see earlier). Carbapenems are another antibiotic class with a PAE. The PAE is enhanced with higher peak drug concentrations and concurrent use of beta-lactam antibiotics.

As is the case with most antibiotic drug classes, various bacterial mechanisms of resistance to aminoglycosides have emerged among gram-positive and gram-negative species that were previously more susceptible to these drugs. The prevalence and intensity of such resistance varies for the specific drugs, organisms, patient populations, disease states, and geographic prescribing patterns.

Indications

The toxicity associated with aminoglycosides limits their use to treatment of serious gram-negative infections and specific conditions involving gram-positive cocci, in which case gentamicin is usually given in combination with a penicillin. Gram-negative infections commonly treated with aminoglycosides include *Pseudomonas* spp. and several organisms belonging to the Enterobacteriaceae family (facultatively anaerobic gram-negative rods), including *Escherichia coli*, *Proteus* spp., *Klebsiella* spp., and *Serratia* spp. Such infections are often treated with a suitable aminoglycoside and an extended-spectrum penicillin, third-generation cephalosporin, or carbapenem. Gram-positive infections treated with aminoglycosides may include *Enterococcus* spp., *S. aureus*, and bacterial endocarditis, which is usually streptococcal in origin. A regimen of once daily doses is more common when treating gram-positive infections because this often enhances synergy with other antibiotics used. Aminoglycosides are never used alone to treat gram-positive infections. Aminoglycosides are also used for prophylaxis in procedures involving the gastrointestinal (GI) or genitourinary (GU) tract because such procedures carry a high risk for enterococcal bacteremia. They are also commonly given in combination with either ampicillin or vancomycin (for penicillin-allergic patients) for surgical patients with a history of valvular heart disease because diseased heart valves are more prone to enterococcal infection.

Aminoglycosides are to be administered with caution in neonates, whether premature or full term; because of the immaturity of the kidneys in newborns, prolonged actions of the aminoglycosides and a greater risk for toxicities may result. Serious infections in children for which aminoglycosides are used include pneumonia, meningitis, and urinary tract infections. Drug selection for both children and adults is based on the susceptibility of the causative organism. Refer to [Table 44.2](#) for more information on the antibacterial spectra of specific aminoglycosides. A few aminoglycosides have more specific indications. Streptomycin sulphate is active against *Mycobacterium* spp. (see [Chapter 46](#)),

whereas paromomycin sulphate is used to treat amebic dysentery, a protozoal intestinal disease (see [Chapter 48](#)). Aminoglycosides are inactive against fungi, viruses, and most anaerobic bacteria.

Contraindications

The only usual contraindication for aminoglycosides is known drug allergy. However, they have been shown to cross the placenta and cause fetal harm when administered to pregnant women. There have been several case reports of total irreversible bilateral congenital deafness in the children of women who received aminoglycosides during pregnancy. Therefore, aminoglycosides should be used in pregnant women only in the event of life-threatening infections when safer drugs are ineffective. These drugs are also distributed in breast milk. They should not be used by women who are lactating, to avoid the risk of drug toxicity in nursing infants.

Adverse Effects

Aminoglycosides are potent antibiotics and are capable of potentially serious toxicities, particularly to the kidneys (nephrotoxicity) and the ears (ototoxicity), in which they can affect hearing and balance functions. Duration of drug therapy needs to be as short as possible, based on sound clinical judgement and monitoring of the patient's progress. Nephrotoxicity typically occurs in 5 to 25% of patients and is usually manifested by urinary casts (visible remnants of destroyed kidney cells), proteinuria, and increased blood urea nitrogen (BUN) and serum creatinine levels. It is usually reversible, but patients' kidney function tests should be monitored throughout therapy. In contrast, ototoxicity is less common, occurring in 3 to 14% of patients, and often is not reversible. It can result in varying degrees of permanent hearing loss, depending on the dosage and duration of drug therapy. It is believed to result from injury to the eighth cranial nerve (CN VIII, also called the *vestibulocochlear nerve*) and involves both cochlear damage (hearing loss) and vestibular damage (disrupted sense of balance). Other less common effects include headache, paresthesia, vertigo, skin rash, fever, overgrowth of nonsusceptible organisms, and neuromuscular paralysis (very rare and reversible). The risk for these toxicities is greatest in patients with pre-existing kidney impairment, patients already receiving other renally toxic drugs, and patients receiving high-dose or prolonged aminoglycoside therapy.

Interactions

The risk for nephrotoxicity can be increased with concurrent use of other nephrotoxic drugs, such as vancomycin hydrochloride, cyclosporine, and amphotericin B. Concurrent use with loop diuretics increases the risk for ototoxicity. In addition, because aminoglycosides also kill normal intestinal bacterial flora, they also reduce the amount of vitamin K produced by these gut bacteria. These normal flora serve to balance the effects of oral anticoagulants such as warfarin sodium (Coumadin®). Therefore, aminoglycosides can potentiate warfarin sodium toxicity. Concurrent use with neuromuscular blocking drugs may prolong the duration of action of the neuromuscular blockade.

Dosages

For dosage information on selected aminoglycosides, refer to the table on p. 719.

TABLE 44.2 Aminoglycosides: Comparative Spectra of Antimicrobial Activity

Aminoglycoside	Spectrum
amikacin sulphate	<i>Acinetobacter</i> spp., <i>Enterobacter aerogenes</i> , <i>Escherichia coli</i> , <i>Klebsiella pneumoniae</i> , <i>Proteus</i> spp., <i>Providencia</i> spp., <i>Pseudomonas</i> spp., <i>Serratia</i> spp., <i>Staphylococcus</i>
gentamicin sulphate	<i>E. aerogenes</i> , <i>E. coli</i> , <i>K. pneumoniae</i> , <i>Proteus</i> spp., <i>Pseudomonas</i> spp., <i>Salmonella</i> spp., <i>Serratia</i> spp. (nonpigmented), <i>Shigella</i> spp.
neomycin sulphate	Used as a topical antibacterial
paromomycin sulphate	Amebic dysentery
streptomycin sulphate	<i>Klebsiella granulomatis</i> (granuloma inguinale), <i>Yersinia pestis</i> (plague), <i>Francisella tularensis</i> (tularemia), <i>Mycobacterium tuberculosis</i> (tuberculosis), <i>Streptococcus</i> spp. (nonhemolytic endocarditis)
tobramycin sulphate	<i>Citrobacter</i> spp., <i>Enterobacter</i> spp., <i>E. coli</i> , <i>Klebsiella</i> spp., <i>Proteus</i> spp., <i>Providencia</i> spp., <i>P. aeruginosa</i> , <i>Serratia</i> spp.

Dosages

Selected Aminoglycosides

Drug	Usual Dosage Range	Indications
amikacin sulphate (generic)	Neonates/Children/Adults IM/IV: 15 mg/kg/day divided bid-tid, administered over 30–60 min	Primarily gentamicin- and tobramycin-resistant gram-negative infections along with severe staphylococcal infections
 gentamicin sulphate (generic)	Neonates/Children/Adolescents IM/IV: 2.5 mg/kg/dose q8h	Primarily gram-negative infections along with severe staphylococcal infections
tobramycin (generic)	Adults IM/IV: 5–7 mg/kg q 24 h (once daily dosing); 2 mg/kg/dose with dosing interval dependent on renal function (CrCl) classified as traditional or multiple daily dosing	

IM, intramuscular; IV, intravenous.

DRUG PROFILES

Historically, aminoglycoside antibiotics were used primarily to treat gram-negative infections. However, they are now used as a synergistic drug in the treatment of gram-positive infections as well. They are normally given intravenously or intramuscularly, but neomycin is administered only topically. Topical dosage forms of both gentamicin and tobramycin are available for dermatological (see [Chapter 56](#)) and ophthalmic (see [Chapter 57](#)) use. Currently available aminoglycosides include amikacin, gentamicin, paromomycin sulphate, streptomycin sulphate, and tobramycin. The variations in the suffixes of some of the drug names, in particular–mycin versus–micin, denote different bacterial origins of the aminoglycosides.

amikacin sulphate

Amikacin sulphate is a semisynthetic aminoglycoside antibiotic that is often used for infections that are resistant to gentamicin or tobramycin. It is available only in injectable form.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Variable	1 hr	2–3 hr	8–12 hr
IM	Variable	30 min–2 hr	2–3 hr	8–12 hr

gentamicin sulphate

Gentamicin sulphate is the most commonly used aminoglycoside in clinical practice today. It is usually administered intramuscularly (according to the Health Canada monograph). The IV route is recommended for special indications when the intramuscular (IM) route is not feasible, such as in patients in shock, with severe burns, with hemorrhagic disorders or receiving anticoagulants, or with low muscle mass. The dosage is the

same for both routes. It is indicated for the treatment of infection with several susceptible gram-positive and gram-negative bacteria. Gentamicin is available in several dosage forms, including injections, topical ointments, and ophthalmic drops and ointments.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Variable	30 min	2–3 hr	Up to 24 hr
IM	Variable	30–90 min	2–3 hr	Up to 24 hr

tobramycin

Tobramycin's dosages, routes of IV administration, and indications are comparable to those of gentamicin for generalized infections. In addition, it is commonly used to treat recurrent pulmonary infections in patients with cystic fibrosis, by both injectable parenteral and inhaled dosing. When used by inhalation, it goes by the trade name of TOBI. It is also available in topical and ophthalmic dosage forms.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Variable	30 min	2–3 hr	Up to 24 hr
IM	Variable	30–90 min	2–3 hr	Up to 24 hr

QUINOLONES

Quinolones, sometimes referred to as *fluoroquinolones*, are potent, bactericidal, broad-spectrum antibiotics. Currently available quinolone antibiotics include norfloxacin hydrochloride, ciprofloxacin, levofloxacin, ofloxacin, and moxifloxacin hydrochloride. With the exception of norfloxacin hydrochloride, these antibiotics have excellent oral absorption—in most cases, comparable to that of IV injection.

Mechanism of Action and Drug Effects

Quinolone antibiotics destroy bacteria by altering their deoxyribonucleic acid (DNA) (see [Chapter 43](#), Figure 43.3). They accomplish this by interfering with the bacterial enzymes DNA gyrase and topoisomerase IV. Quinolones do not inhibit the production of human DNA.

The quinolones kill susceptible strains of mostly gram-negative and some gram-positive organisms. Some quinolones are also believed to diffuse into and concentrate themselves in human neutrophils, killing bacteria such as *S. aureus*, *Serratia marcescens*, and *Mycobacterium fortuitum* that sometimes accumulate in these cells. Bacterial resistance to quinolone antibiotics has been identified among several bacterial species, including *Pseudomonas aeruginosa*, *S. aureus*, *Pneumococcus* spp., *Enterococcus* spp., and the broad Enterobacteriaceae family that includes *E. coli*.

Indications

Quinolones are active against a wide variety of gram-negative and selected gram-positive bacteria. Most are excreted primarily by the kidneys as unchanged drug. This characteristic, together with the fact that they have extensive gram-negative coverage, makes them suitable for treating complicated urinary tract infections. They are also commonly used to treat respiratory, skin, GI, bone, and joint infections.

Ciprofloxacin (Cipro®) was the first quinolone to experience widespread use. Resistance was soon seen in *Pseudomonas* and some *Streptococcus* spp. Ciprofloxacin and levofloxacin are available both orally and by injection and are both available in generic form, which means that they cost significantly less than brand name quinolones. Levofloxacin (Levaquin®) is somewhat more active than ciprofloxacin against gram-positive organisms such as *S. pneumoniae*, including penicillin-resistant strains, as well as *Enterococcus* and *S. aureus*. Moxifloxacin hydrochloride is also effective against *S. pneumoniae* as well as some strains of *S. aureus* and enterococci. However, MRSA and VRE are generally also resistant to moxifloxacin hydrochloride. The activity of moxifloxacin hydrochloride against many enteric gram-negative bacteria and *P. aeruginosa* is similar to that of levofloxacin and less than that of ciprofloxacin. Moxifloxacin hydrochloride often has stronger anaerobic bacterial coverage. Norfloxacin hydrochloride has limited oral absorption and is available only in oral form, so its use is limited to GU infections. Quinolones may be combined with aminoglycosides to treat *P. aeruginosa* infections; step-down to monotherapy is recommended once susceptibility results are confirmed. The use of quinolones in prepubescent children is not generally recommended because these drugs have been shown to affect cartilage development in laboratory animals. However, more recent evidence suggests that judicious use in children might be less of a risk than previously thought, and in fact these drugs are used commonly in children with cystic fibrosis. Box 44.1 lists selected microbes commonly susceptible to quinolone therapy in general, but there is some variation in spectra among drugs. Table 44.3 gives common indications for individual drugs.

Contraindications

The only true contraindication to quinolones is known drug allergy.

BOX 44.1 Overview of Quinolone-Susceptible Microbial Spectra

- Gram-positive: *Streptococcus* (including *S. pneumoniae*), *Staphylococcus*, *Enterococcus*, *Listeria monocytogenes*
- Gram-negative: *Neisseria gonorrhea*, *N. meningitidis*, *Haemophilus influenzae*, *H. parainfluenzae*, Enterobacteriaceae (including *Escherichia coli*, *Enterobacter*, *Klebsiella*, *Proteus mirabilis*, *Salmonella*, *Shigella*), Acinetobacter, *Pseudomonas aeruginosa*, *Pasteurella multocida*, *Legionella*, *Mycoplasma pneumoniae*, Chlamydia
- Anaerobes: *Bacteroides fragilis*, *Peptococcus*, *Peptostreptococcus* (moxifloxacin hydrochloride is strongest)
- Other: *Rickettsia* (ciprofloxacin only)

Adverse Effects

Quinolones are capable of causing a variety of adverse effects, the most common of which are listed in Table 44.4. Bacterial overgrowth is another possible complication of quinolone therapy, but this is more commonly associated with long-term use. More worrisome is a heart effect that involves prolongation of the QT interval on the electrocardiogram (ECG). Dangerous cardiac dysrhythmias are more likely to occur when quinolones are taken by patients who are also receiving class Ia and class III antidysrhythmic drugs, such as disopyramide and amiodarone hydrochloride. For this reason, such drug combinations are best avoided. A labelling warning is required by Health Canada for all quinolones because of the increased risk of tendinitis and tendon rupture with use of these drugs. The Achilles tendon is most affected in 95% of all cases, likely as a result of the weight-bearing role of the tendon (Lewis & Cook, 2014). Health Canada continues to work with manufactures to update safety information related to the potential risk during the use of fluoroquinolones (Health Canada, 2017). This effect is more common in older adults, patients with kidney failure, and those on concurrent glucocorticoid therapy (e.g., prednisone). In addition, a second labelling warning was required concerning worsening symptoms such as muscle weakness and breathing difficulties in patients with myasthenia gravis.

TABLE 44.3 Quinolones: Common Indications for Specific Drugs

Generic Name (Brand Name)	Common Indications
ciprofloxacin (generic)*	Respiratory, skin and soft tissue, urinary tract, prostate, intra-abdominal, bone and joint infections; infectious diarrhea; meningococcal carriers; typhoid fever; uncomplicated gonorrhea
levofloxacin (Levaquin®)	Respiratory and urinary tract infections; skin and skin structure infections
moxifloxacin hydrochloride (Avelox®)	Respiratory and skin infections; intra-abdominal infections; community-acquired pneumonia
norfloxacin (Apo-Norfloxx®)	Urinary tract infections; sexually transmitted infections

*antibacterial spectrum: extensive gram negative and selected gram positive coverage

TABLE 44.4 Quinolones: Reported Adverse Effects

Body System	Adverse Effects
Central nervous	Headache, dizziness, insomnia, depression, restlessness, convulsions
Gastrointestinal	Nausea, constipation, increased AST and ALT levels, flatulence, heartburn, vomiting, diarrhea, oral candidiasis, dysphagia
Integumentary	Rash, pruritus, urticaria, flushing
Other	Ruptured tendons and tendonitis, worsening myasthenia gravis symptoms, fever, chills, blurred vision, phototoxicity, tinnitus

ALT, Alanine aminotransferase; AST, aspartate aminotransferase.

Central nervous system (CNS) stimulation in the form of seizures has been reported. Slow infusion of a dilute solution into a large vein will minimize patient discomfort and reduce the risk of venous irritation.

Interactions

There are several drugs that interact with quinolones. Their concurrent use with antacids, calcium, magnesium, iron, zinc preparations, or sucralfate causes a reduction in the oral absorption of the quinolone. Patients need to take the interacting drugs at least 1 hour before or after taking quinolones. Dairy products also reduce the absorption of quinolones and should be separated as stated previously for interacting drugs. Enteral tube feedings can also reduce the absorption of quinolones. Probenecid can reduce kidney excretion of quinolones. Nitrofurantoin (discussed later in this chapter) can antagonize the antibacterial activity of quinolones, and oral anticoagulants are to be used with caution in patients receiving quinolones because of the antibiotic-induced alteration of the intestinal flora, which affects vitamin K synthesis.

Dosages

For dosage information on selected fluoroquinolones, refer to the table on p. 724.

Dosages

Selected Quinolones

Drug	Pharmacological Class	Usual Dosage Range	Indications
 ciprofloxacin hydrochloride	Fluoroquinolone	Adults* IV: 200–400 mg q8–12h PO: 250–750 mg q12h	Broad gram-positive and gram-negative coverage for infections throughout the body
levofloxacin (Levaquin)		Adults only IV/PO: 250–750 mg once daily	Various susceptible bacterial infections

IV, Intravenous; PO, oral.

*Not normally recommended for children under 18 years because of adverse musculoskeletal effects shown in studies of immature animals.

DRUG PROFILES

Two of the most commonly prescribed quinolones are ciprofloxacin and levofloxacin. Dosage information appears in the designated Dosages table on p. 724.

ciprofloxacin hydrochloride

Ciprofloxacin hydrochloride was one of the first of the broad-coverage, potent quinolones to become available. It was first marketed in an oral form and is now available in injectable, ophthalmic (see [Chapter 57](#)), otic (see [Chapter 58](#)), and inhalation (TOBI) formulations. Because of its excellent bioavailability, it can work orally as well as many IV antibiotics.

It is capable of killing a wide range of gram-negative bacteria and is effective against traditionally difficult-to-kill gram-negative bacteria such as *Pseudomonas*. Some anaerobic bacteria as well as atypical organisms such as *Chlamydia*, *Mycoplasma*, and *Mycobacterium* can also be killed by ciprofloxacin.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	30 min	1 hr	3–4.8 hr	Up to 12 hr
PO	Variable	1–2 hr	3–4.8 hr	Up to 12 hr

levofloxacin

Levofloxacin (Levaquin) is one of the most widely used quinolones. It has a broad spectrum of activity similar to that of ciprofloxacin, but it has the advantage of once-daily dosing, as does gatifloxacin. Levofloxacin is available in both oral and injectable forms.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Variable	1–2 hr	6–8 hr	Up to 24 hr
PO	Variable	2 hr	6–8 hr	Up to 24 hr

DRUG PROFILES

Miscellaneous Antibiotics

There are a number of antibiotics that do not fit into any of the previously described broad categories. Most have somewhat unique indications or are especially preferred for a particular type of infection. Although they may not be used as commonly as drugs from the other major classes, they are still of clinical importance. Several of these drugs are described individually in the following drug profiles. For dosage information on these drugs, refer to the table on p. 724.

clindamycin

Clindamycin (Dalacin C®) is a semisynthetic antibiotic. Clindamycin can be either bactericidal or bacteriostatic (see [Chapter 43](#)), depending on the concentration of the drug at the site of infection and on the infecting bacteria. It inhibits protein synthesis in bacteria (see [Chapter 43](#), Figure 43.3). Clindamycin is indicated for the treatment of chronic bone infections, GU tract infections, intra-abdominal infections, anaerobic pneumonia, septicemia caused by streptococci and staphylococci, used topically in the treatment of acne, and serious skin and soft-tissue infections caused by susceptible bacteria. Most gram-positive bacteria, including *Staphylococci*, *Streptococci*, and *Pneumococci*, are susceptible to clindamycin's actions. It also has the advantage of being active against several anaerobic organisms and is most often used for this purpose. However,

resistant strains of gram-positive, gram-negative, and anaerobic organisms do occur. All Enterobacteriaceae strains are resistant to clindamycin. Clindamycin is contraindicated in patients with a known hypersensitivity to it, those with ulcerative colitis or enteritis, and infants younger than 1 month of age. GI tract adverse effects are the most common ones and include nausea, vomiting, abdominal pain, diarrhea, pseudomembranous colitis, and anorexia.

Pseudomembranous colitis (also known as *antibiotic-associated colitis*, *C. difficile* diarrhea, or *C. difficile* infection) is a necrotizing inflammatory bowel condition that is often associated with antibiotic therapy, especially clindamycin therapy. Clindamycin is available in oral, injectable, and topical (see Chapter 56) forms.

Clindamycin is also known to have some neuromuscular blocking properties that may enhance the action of neuromuscular drugs used in perioperative and critical care settings, such as vecuronium bromide (see Chapter 12). Patients receiving both drugs need to be monitored for excessive neuromuscular blockade and respiratory paralysis, and appropriate ventilatory support should be provided as needed.

PHARMACOKINETICS				
Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	30 min	45 min	2–3 hr	6 hr
IM/IV	Variable	IM: 3 hr IV: 10–45 min	2–3 hr	IM: 8–12 hr

linezolid

Linezolid (Zyvoxam®) is the first antibacterial drug in a new class of antibiotics known as oxazolidinones. This drug acts by inhibiting bacterial protein synthesis. This drug is bacteriostatic against enterococcus and staphylococcus and bactericidal against streptococci. Linezolid was originally developed to treat infections associated with VRE *faecium*, more commonly referred to as VRE. VRE is a notoriously difficult infection to treat and often occurs as a health care–associated infection. Linezolid has also received approval for the treatment of health care–associated pneumonia; complicated skin and skin structure infections, including cases caused by MRSA; and gram-positive infections in infants and children. MRSA is a virulent organism. However, methicillin, a penicillinase-resistant penicillin, has been removed from the Canadian market. Nonetheless, MRSA is still the term used, although oxacillin is now the test drug for this organism. To confuse things even further, oxacillin is rarely used for therapy, and oral linezolid is the most commonly used drug for methicillin-susceptible *S. aureus*. Linezolid is approved for treatment of community-acquired pneumonia and uncomplicated skin and skin structure infections.

The most commonly reported adverse effects attributed to linezolid are headache, nausea, diarrhea, and vomiting. It has also been shown to decrease platelet count. It is contraindicated in patients with a known hypersensitivity to it. It is available in oral and injectable forms. It has excellent oral absorption,

which allows patients to continue oral therapy at home for serious infections that would otherwise require hospitalization. Linezolid has the potential to strengthen the vasopressor (prohypertensive) effects of vasopressive drugs (see Chapter 19) such as dopamine, by an unclear mechanism. Also, there have been postmarketing case reports of this drug causing serotonin syndrome when used concurrently with serotonergic drugs such as the selective-serotonin reuptake inhibitor (SSRI) antidepressants (see Chapter 17). It is recommended that the SSRI be stopped while the patient is receiving linezolid therapy; however, oftentimes this is not realistic, and patients must be watched carefully for signs of serotonin syndrome. Finally, tyramine-containing foods, such as wine, aged cheese, soy sauce, smoked meats or fish, and sauerkraut, can interact with linezolid to raise blood pressure.

PHARMACOKINETICS				
Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Variable	1–2 hr	5 hr	12 hr
IV	Variable	Immediate	6–7 hr	8–12 hr

 metronidazole

Metronidazole (Flagyl®) is an antimicrobial drug of the class nitroimidazole. It has good activity against anaerobic organisms and is widely used for intra-abdominal and gynecological infections caused by such organisms. Examples of the anaerobes against which it is active include *Peptostreptococcus* spp., *Bacteroides* spp., and *Clostridium* spp. Metronidazole is also indicated for treatment of protozoal infections such as amebiasis and trichomoniasis (see Chapter 48). It works by interfering with microbial DNA synthesis, and in this regard, it is similar to the quinolones (see Chapter 43, Figure 43.3). It is used orally to treat antibiotic-associated colitis; however, resistance has been noted. Oral metronidazole is the treatment of choice in initial occurrence and the first recurrence of mild to moderate cases of *C. difficile* colitis in children (D’Ostroph & So, 2017). Children presenting with a severe case or a second recurrence of *C. difficile* infections should be treated with oral vancomycin. Metronidazole is contraindicated in cases of known drug allergy. It is available in oral forms. The drug is not recommended for use during the first trimester of pregnancy. Adverse effects include dizziness, headache, GI discomfort, nasal congestion, and reversible neutropenia and thrombocytopenia. Drug interactions include acute alcohol intolerance when it is taken with alcoholic beverages, due to the accumulation of acetaldehyde, the principal alcohol metabolite. Patients must avoid alcohol for 24 hours before initiation of therapy and for at least 36 hours after the last dose of metronidazole. Metronidazole may also increase the toxicity of lithium, benzodiazepines, cyclosporine, calcium channel blockers, antidepressants (e.g., venlafaxine hydrochloride), warfarin sodium, and other drugs. In contrast, phenytoin and phenobarbital may reduce the effects of metronidazole. These interactions occur because of various enzymatic effects

involving the cytochrome P450 liver enzymes that result in altered metabolism when these drugs are taken concurrently with metronidazole.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Variable	1–2 hr	8 hr	Unknown
IV	Variable	1 hr	8 hr	Unknown

nitrofurantoin

Nitrofurantoin (Furantoin®, MacroBID®) is an antibiotic drug of the class nitrofuran. It is indicated primarily for urinary tract infections caused by *E. coli*, *S. aureus*, *Klebsiella* spp., and *Enterobacter* spp. It works by interfering with the activity of enzymes that regulate bacterial carbohydrate metabolism and by disrupting bacterial cell wall formation. It is contraindicated in cases of drug allergy and significant kidney function impairment because the drug concentrates in the urine. This drug should not be used for more complicated urinary tract infections, like pyelonephritis, as it does not reach sufficient concentrations in the kidney. The drug is available only for oral use and is taken with food or milk to minimize gastric upset. Adverse effects include GI discomfort, dizziness, headache, skin reactions (mild to severe reactions have been reported), blood dyscrasias, ECG changes, possibly irreversible peripheral neuropathy, and hepatotoxicity. Although hepatotoxicity is rare, it is often fatal. Interacting drugs are few and include probenecid, which can reduce kidney excretion of nitrofurantoin, and antacids, which can reduce the extent of its GI absorption. The dose must be reduced for older adult patients and those with decreased renal function. Another drug that is approved for urinary tract infections is fosfomycin tromethamine (Monurol®). It is given as a one-time dose and maintains high concentrations in the urine for up to 48 hours.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	2.5–4.5 hr	30 min	0.5–1 hr	5–8 hr

quinupristin/dalfopristin

Quinupristin and dalfopristin (Synercid®) are two streptogramin antibacterials marketed in a 30:70 combination. The combination drug is approved for IV treatment of bacteremia and life-threatening infection caused by VRE and for treatment of complicated skin and skin structure infections caused by *S. aureus* and *S. pyogenes*, including MRSA. This drug combination is available through the Special Access Programme, Health Canada.

Common adverse effects are arthralgias and myalgias, which may become severe. Adverse effects related to the infusion site, including pain, inflammation, edema, and thrombophlebitis, have developed in approximately 75% of patients treated through a peripheral IV line. The drug is contraindicated in patients with a known hypersensitivity to it. Drug interactions

are limited; the most serious being potential increase in levels of cyclosporine. The drug is available only in injectable form. Quinupristin/dalfopristin must be infused with 5% dextrose in water (D₅W) only and cannot be mixed with saline or heparin sodium, including heparinized flushes.

PHARMACOKINETICS (QUINUPRISTIN/DALFOPRISTIN)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	1–2 hr	3–4 hr	1–3 hr	8–12 hr

vancomycin hydrochloride

Vancomycin hydrochloride (Vancocin®) is a natural bactericidal antibiotic that is structurally unrelated to any other commercially available antibiotics. It destroys bacteria by binding to the bacterial cell wall, producing immediate inhibition of cell wall synthesis and death (see Chapter 43, Figure 43.3). This mechanism differs from that of beta-lactam antibiotics.

Vancomycin hydrochloride is the antibiotic of choice for the treatment of MRSA infection and infections caused by many other gram-positive bacteria. It is not active against gram-negative bacteria, fungi, or yeast. Oral vancomycin is indicated for the treatment of antibiotic-induced colitis (*C. difficile*) and for the treatment of staphylococcal enterocolitis. Because the oral formulation is poorly absorbed from the GI tract, it is used for its local effects on the surface of the GI tract. The parenteral form is indicated for the treatment of bone and joint infections and bacterial bloodstream infections caused by *Staphylococcus* spp. Resistance to vancomycin hydrochloride has been noted with increasing frequency in patients with infections caused by *Enterococcus* organisms. These strains have been isolated most often from GI tract infections but have also been isolated from skin, soft tissue, and bloodstream infections. Federal, provincial, territorial, and institution guidelines are available for the management and treatment of MRSA, VRE, *C. difficile*, and other superinfections.

Vancomycin hydrochloride is contraindicated in patients with known hypersensitivity to it. Because it is excreted rapidly by the kidneys, it should be used with caution in those with pre-existing kidney dysfunction, as blood levels can increase markedly, and with that, the risk of toxicity. Another adverse effect, nephrotoxicity, is more likely to occur with concurrent therapy with other nephrotoxic drugs such as aminoglycosides, cyclosporine, and contrast media used for CT scans. Vancomycin can also cause additive neuromuscular blocking effects in patients receiving neuromuscular blockers. Ototoxicity has occurred with serum levels above 80 mcg/mL, particularly in older adults. If the levels are too low (less than 5 mg/mL), the dosage may be subtherapeutic, with reduced antibacterial efficacy. Another common adverse effect that is bothersome but usually not harmful is known as *red man syndrome*. This syndrome is characterized by flushing, erythema, or itching of the head, face, neck, and upper trunk area. It is most commonly seen when the drug is infused too rapidly. It can usually be alleviated by giving the infusion of the dose over at least 1 hour. Rapid infusions

may also cause hypotension. Pains and muscle spasms in the back and chest may occur, as well as dyspnea. Optimal blood levels of vancomycin hydrochloride are a peak level of 18 to 50 mcg/mL and a trough level of 10 to 20 mcg/mL. Measurement of peak levels is no longer routinely recommended, and only trough levels are commonly monitored. There is a lack of clear evidence that nephrotoxicity and ototoxicity associated with vancomycin hydrochloride are prevented by adherence to specific concentration ranges. Vancomycin hydrochloride is poorly absorbed orally and is distributed slowly into peripheral tissues, so toxicity does not occur with oral doses. Blood samples for measurement of trough levels are drawn immediately before administration of the next dose. Because of the increase in resistant organisms, many clinicians use a trough level of 15 to 20 mcg/mL as their goal. Vancomycin hydrochloride is available in both oral and injectable forms. It is strongly recommended to consult a clinical pharmacist for all dosing recommendations as this drug also requires therapeutic drug monitoring.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Variable	1 hr	4–6 hr	Up to 24 hr; longer in those with kidney dysfunction

colistimethate sodium

Colistimethate sodium (Coly-Mycin®) is a polypeptide antibiotic that penetrates and disrupts the bacterial membrane of susceptible strains of gram-negative bacteria. It is an old drug that fell out of clinical use when newer, less toxic drugs became available. Unfortunately, due to the emergence of infections with KPC-producing organisms, it is now being used again, often as one

Dosages

Selected Miscellaneous Antibiotics

Drug	Pharmacological Class	Usual Dosage Range	Indications
 clindamycin (Dalacin C)	Lincosamide	<i>Neonates under 1 mo</i> IM/IV: 5 mg/kg bid–tid <i>Children older than 1 mo</i> IM/IV: 20–40 mg/day, divided tid–qid PO: 8–20 mg/kg/day divided tid–qid <i>Adults</i> IM/IV: 600–2 700 mg/day, divided bid–qid PO: 150–450 mg q6h	Anaerobes; streptococcal and staphylococcal infections of bone, skin, respiratory, and GU tract
colistimethate sodium (Coly-Mycin)	Polypeptide	<i>Adults</i> IV: 2.5–5 mg/kg/day; divided bid–qid; infuse over 3–5 min	Treatment of KPC-producing organisms
linezolid (Zyvoxam)	Oxazolidinone	<i>Adults only</i> IV/PO: 400–600 mg q12h	VRE; skin and respiratory infections caused by <i>Staphylococcus</i> and <i>Streptococcus</i> spp.
 metronidazole (Flagyl)	Nitroimidazole	<i>Children</i> PO: 15–50 mg/kg/day divided tid <i>Adults</i> PO: 250–700 mg, divided bid–tid	Primarily anaerobic and gram-negative infections of abdominal cavity, skin, bone, and respiratory, and GU tracts
nitrofurantoin (Furantoin, MacroBID)	Nitrofuran	<i>Children/Adults</i> PO: 100 mg bid	Primarily UTIs caused by gram-negative organisms and <i>Staphylococcus aureus</i>
quinupristin/dalfopristin* (Synercid)	Streptogramins	<i>Children/Adults</i> IV: 7.5 mg/kg q8–12h	VRE; skin infections caused by streptococcal and staphylococcal infections
 vancomycin (Vancocin)	Tricyclic glycopeptide	<i>Neonates, Infants, and Children</i> IV: 10–15 mg/kg q6–12h PO: 40 mg/kg <i>Adults</i> IV: 500–3000 mg q8–48h (depending on renal function and dosing weight) PO: 125–500 mg tid–qid	Severe staphylococcal infections, including MRSA; other serious gram-positive infections, including <i>Streptococcus</i> spp.

GU, Genitourinary; IM, intramuscular; IV, intravenous; MRSA, methicillin-resistant *S. aureus*; PO, oral; spp., species; UTIs, urinary tract infections; VRE, vancomycin-resistant *Enterococcus*.

*Available through Special Access Programme, Health Canada.

of the only drugs available to treat KPC. Colistimethate sodium is available for IV, IM, and inhalational administration, commonly used in multi-drug resistant ventilator-associated pneumonias. It has serious adverse effects, including kidney failure and neurotoxic effects such as paresthesia, numbness, tingling, vertigo, dizziness, and impairment of speech. Colistimethate sodium crosses the placenta and needs to be used with caution in pregnant women. Colistimethate sodium is infused over 3 to 5 minutes.

❖ NURSING PROCESS

◆ ASSESSMENT

Many of the antibiotics discussed in this chapter, in contrast to those in [Chapter 43](#), are the types of drugs that are often reserved for the treatment of more virulent infections and are mainly administered by parenteral routes; thus, they demand more skillful and thorough assessment of the patient and the specific drug. These antibiotics all require a crucial assessment on a history of or symptoms indicative of hypersensitivity or allergic reactions, with symptoms ranging from mild reactions with angioedema, rash, pruritus, or hives to severe reactions with laryngeal edema, bronchospasm, or possible cardiac arrest. Further assessment associated with these groups of antibiotics in general includes conducting a nursing physical examination and recording age, weight, and baseline vital sign values. Diagnostic and laboratory tests that may be ordered include some of the following: (1) AST and ALT levels (for assessing liver function); (2) urinalysis (glomerular filtration rate [GFR], BUN, and serum creatinine levels; for assessing kidney function); (3) ECG, echocardiogram, ultrasonography, and cardiac enzyme levels (for assessing cardiac function); (4) culture and sensitivity of the infected tissue or blood samples for assessing sensitivity of the bacteria to the antibiotic; (5) white blood cell (WBC) count, hemoglobin level, hematocrit, red blood cell (RBC) count, platelet count, and clotting values for baseline blood count levels. In the baseline neurological assessment, note sensory and motor intactness and assessment of any alterations in neurological functioning—for example, altered sensorium and level of consciousness—because of the potential for CNS adverse effects. Baseline abdominal and GI assessments are important, with a focus on bowel patterns and bowel sounds because of possible GI adverse effects. Note contraindications, cautions, and drug interactions, and obtain a complete list of the patient's medications, including over-the-counter drugs and natural health products. Perform an ethnocultural assessment because of the various responses of certain racial and ethnic groups to specific drugs as well as the potential use of alternative healing practices.

With any antibiotic, assess for superinfection, or a secondary infection that occurs with the destruction of normal flora during antibiotic therapy (see [Chapter 43](#)). Fungal superinfections may be evaluated by creamy white mouth lesions, fever, lethargy, or perineal itching. Assess the patient's immune system status and overall condition because if there is an immune deficiency (e.g., in patients with cancer, autoimmune disorders such as systemic lupus erythematosus, AIDS, and any chronic illness), the patient's ability to physically resist infection may be diminished. Antibiotic resistance is a continual concern with antibiotic drug therapy, especially in children and in patients being treated in large health care institutions and long-term care facilities. Consider this possibility of resistance to certain antibiotics when assessing patients for symptoms of infection and superinfection. With aminoglycosides, assess for hypersensitivity and pre-existing conditions. Obtain a list of all medications the patient is taking because of the many cautions, contraindications, and drug interactions associated with these drugs.

The aminoglycosides are known for their ototoxicity and nephrotoxicity; therefore, if deemed appropriate, perform baseline hearing tests and assessment of vestibular function. There is an increased risk for nephrotoxicity with the use of other nephrotoxic drugs, such as cyclosporine and the IV contrast used for CT scans. For patients requiring a CT scan with contrast who are also on a nephrotoxic medication, alert the health care provider to the situation so that the dose may be adjusted and additional fluids or medications ordered. As well, perform kidney function studies (BUN level, urinalysis, and serum and urine creatinine levels) ordered, and document all results. If kidney baseline functioning is decreased, the health care provider may need to adjust the dosage amounts because of the risk of nephrotoxicity.

Complete a thorough neuromuscular assessment because of the possibility for drug-related neurotoxicity and higher risk for complications in those with impaired neurological functioning. For example, patients with myasthenia gravis or Parkinson's disease may experience worsening of muscle weakness because of the drug's neuromuscular blockade. Neonates (because of the immaturity of the nervous and kidney systems) and older adults (because of decreased neurological and kidney functioning) are also at highest risk for nephrotoxicity, neurotoxicity, and ototoxicity and require careful assessment before and during drug therapy. Assess hydration status. The toxicities of these drugs are greater in those with pre-existing renal impairment, those receiving other nephrotoxic drugs, and in those patients taking the aminoglycoside for a long period of time or on high-dose therapy.

Quinolones, such as ciprofloxacin, require careful assessment for pre-existing CNS conditions (e.g., seizure disorders or stroke) that may be exacerbated with the concurrent use of these drugs. Assess for a cardiac history, and note if the patient is taking certain antidysrhythmics because of the potential for dangerous cardiac irregularities. Significant drug interactions include antacids, iron, zinc preparations, and sucralfate, as they affect the absorption of the quinolone. Oral anticoagulants also interact with and alter the antibacterial activity of quinolones (see previous discussion).

If clindamycin is being used, assess for hypersensitivity to the drug or related compounds. Clindamycin is not to be used in patients with ulcerative colitis or in those younger than 1 month of age. Perform a thorough assessment of GI disorders because of the possibility of drug-induced pseudomembranous colitis, vomiting, and diarrhea (see previous discussion). Assess bowel sounds as well as bowel patterns prior to giving this drug. Preoperatively, or if patients are in an intensive care setting and receiving clindamycin, assess for the concurrent use of neuromuscular blocking drugs because of clindamycin's excessive blockade of neuromuscular functioning and respiratory paralysis. These patients, if in need of clindamycin, would need ventilator support.

Linezolid is used to treat health care-associated infections, pneumonia, and complicated skin infections, including MRSA. Use of methicillin (removed from the market) and oxacillin are no longer options for treatment, so this drug offers another pharmacotherapeutic option. Assess for the concurrent use of serotonergic drugs (e.g., SSRIs [anti-depressants]) because of drug-induced serotonin syndrome (see Chapter 17). Additionally, assess for intake of tyramine-containing foods (e.g., wine, aged cheese, soy sauce, and smoked fish or meat) because of the risk of elevated blood pressure.

Assess patients taking metronidazole for allergy to the drug and to other nitroimidazole derivatives. As with all medications, assess for contraindications, cautions, and drug interactions, and document the findings (see previous discussion). It is important for patient safety to review culture and sensitivity reports before therapy is initiated. However, it may be necessary to start the medication regimen (due to clinical presentation) prior to results being obtained and then change medications as dictated by the culture and sensitivity results. Baseline assessments are needed of the neurological system (noting any dizziness, numbness, tingling, and other sensory or motor abnormalities), GI system (checking bowel sounds, bowel problems and patterns), and GU system (documenting urinary patterns, colour of urine, and intake and output). Inquire about alcohol intake because of the interaction of alcohol with the drug and subsequent acute alcohol intolerance. Assess for potential drug interactions, such as with benzodiazepines, calcium channel blockers, various antidepressants, and warfarin.

Assessment of drug allergies is important with the use of nitrofurantoin. It is also important to assess kidney and liver function due to the possibility of hepatotoxic adverse effects as well as the need for a decrease in dosage amounts in older adults with kidney function impairment (creatinine clearance less than 60 mL/min). Complete a baseline assessment of any sensory or motor problems because of the possible adverse effect of peripheral neuropathy, which may be irreversible. Assess the patient's skin colour, turgor, intactness, and the presence of rash due to the possibility of drug-related, mild to severe skin reactions. With quinupristin/dalfopristin, assess vital signs as well as for any muscular aches and pains due to drug-induced arthralgia and myalgia.

For patients taking vancomycin, ask questions about other medications the patient is taking, especially drugs that are nephrotoxic or ototoxic. Assess the patient for a history of

pre-existing kidney disease or hearing loss due to the possibility of nephrotoxicity or ototoxicity. Note the baseline hearing status because of the risk of hearing loss. Part of the health care provider's order will be to order trough levels of vancomycin. These labs will be drawn immediately before the next dose. Assessment of these levels is important to patient safety. Peak levels are used to calculate the exact dose that the patient needs to maintain therapeutic levels. It is important to assess the colour of the patient's skin because of the risk for red man syndrome. This syndrome is bothersome but usually not harmful, and is characterized by flushing of the face, head, neck, and upper trunk areas. Red man syndrome is seen when infusions are administered too rapidly, so always assess and monitor IV rates to be sure the drug is administered over at least 1 hour. Assess vital signs with attention to blood pressure because infusions that are too rapid may precipitate hypotension. Phlebitis may also occur, so assess for localized redness and swelling and pain or burning along the length of the vein. Because of multiple drug and diluent incompatibilities, as with several of the other parenteral antibiotics mentioned previously in this chapter, always assess for potential fluid and medication interactions.

With the emergence of multidrug-resistant organisms (e.g., MRSA, VRE, and ESBL- and KPC-producing organisms), ensure that proper handwashing techniques are used by health care providers and caregivers.

CASE STUDY

Vancomycin

Greg, a 45-year-old graphic artist with paraplegia, is being treated for an infected stage IV sacral pressure ulcer. The wound cultures have indicated the presence of multidrug-resistant *Staphylococcus aureus* (MRSA). The health care provider has ordered IV vancomycin to be given every 12 hours, application of dressings (twice a day) as part of the treatment, as well as a referral to the enterostomal therapist. In addition, Greg is placed on contact precautions because of the MRSA.

1. What will you assess before starting the vancomycin infusion?
2. Two days later, Greg reports feeling "hot" and itchy in his face and neck, and these areas are flushed. What do you suspect is happening?
3. What can you do to minimize complications during vancomycin infusions?
4. The health care provider orders measurement of vancomycin blood levels. What is the therapeutic goal when vancomycin levels are monitored?
5. What is the single best action you can take to prevent the spread of Greg's MRSA infection?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

NURSING DIAGNOSES

- Inadequate knowledge as a result of lack of information and experience with the medication regimen
- Potential risk for infection as a result of the patient's compromised immune status before and during treatment
- Potential risk for injury (compromised organ function) as a result of adverse effects of medications (e.g., ototoxicity and nephrotoxicity) and weakened physical state

◆ PLANNING

◆ Goals

- Patient will demonstrate adequate knowledge base about the antibiotic therapeutic regimen.
- Patient will remain free from infection and have improved immune status during antibiotic therapy.
- Patient will remain free from injury.

◆ Expected Patient Outcomes

- Patient states action and rationale for use of antibiotic therapy.
 - Patient understands the need to take the antibiotic exactly as ordered and for the duration of therapy.
- Patient experiences an increased sense of well-being and improved immune status while taking antibiotics.
 - Patient remains without fever, pain, and malaise.
 - Patient experiences increased comfort and improved energy levels.
 - Patient experiences minimal adverse effects of antibiotic therapy.
- Patient remains free from injury in regard to adverse effects, such as minimal to no problems with GI upset, diarrhea, nausea, or hearing loss.
 - Patient states measures to minimize adverse effects associated with antibiotic therapy, such as taking medications with yogurt, increasing fluids, eating well-balanced meals, and following instructions associated with safe use of the specific antibiotic.

◆ IMPLEMENTATION

Aminoglycosides, as well as any antibiotics, need to be given exactly as ordered and with adequate hydration. Encourage fluid intake up to 3000 mL/24 hours unless contraindicated. A culture and sensitivity test must be carried out, if possible, before the first dose of antibiotic. It is also important to identify the source of the infection, if possible. Parenteral dosage forms are most commonly used. Because of the potential for nephrotoxicity and ototoxicity, determine and monitor the patient's kidney function during therapy and possible hearing loss. Dosing is adjusted based on estimates of creatinine clearance calculated from the patient's serum creatinine level. This measurement assists in keeping a close watch on the patient's kidney function and thus helps to prevent toxicity. Also monitor BUN levels and GFR during therapy. Timing between doses and amount of drug are usually individualized. Alteration in auditory, vestibular, or kidney function may indicate the need for a possible dosage adjustment or withdrawal of the drug. Consumption of yogurt or buttermilk may help prevent antibiotic-induced superinfections (see [Chapter 43](#)).

With aminoglycosides, instruct the patient to report to the health care provider any changes in hearing, ringing in the ears (tinnitus), or a full feeling in the ears. Nausea, vomiting with motion, ataxia, nystagmus, or dizziness should also be reported immediately and may indicate problems with the vestibular nerve. With ophthalmic dosage forms, redness, burning,

and itching of the eyes may indicate an adverse reaction, and redness over the skin area may indicate an adverse reaction to topical forms. IM sites should be checked for induration. If noted, report it immediately to the health care provider, and do not reuse the site. Monitor IV sites for heat, swelling, redness, pain, or red streaking over the vein (sign of phlebitis), and initiate measures as per institutional protocol or policy. Keep in mind the following special considerations for gentamicin: (1) IM: Give deeply and slowly into muscle mass (ventrogluteal) to minimize discomfort; and (2) IV: Check for incompatibilities with other drugs, and give only clear or slightly yellow solutions that have been diluted with either normal saline (NS) or D₅W, infusing at the correct rate.

Quinolones, as with any self-administered antibiotics, are to be taken exactly as prescribed and for the full course of treatment. Instruct the patient not to take these medications with antacids, iron, zinc preparations, multivitamins, or sucralfate because the absorption of the antibiotic will be decreased. Instruct patients who need to take calcium or magnesium to take it 1 hour before or after the quinolone. Encouraging fluids is recommended, unless contraindicated. See Patient Teaching Tips for more information.

With clindamycin, instruct the patient to take the medication as ordered. Oral dosage forms are to be taken with 240 mL of water or other fluid. With topical forms, advise patients to avoid the simultaneous use of peeling or abrasive acne products, soaps, or alcohol-containing cosmetics to prevent cumulative effects; however, some products combine clindamycin with anti-acne medications (e.g., Benzaclin Topical Gel®). Topical forms are to be applied in a thin layer to the affected area. Infuse IV dosage forms by piggyback technique and as ordered. Most resources state *never* to give these drugs via parenteral IV push. Dilute doses of the drug, and infuse per manufacturer guidelines. IV infusion that is too rapid can lead to severe hypotension and possible cardiac arrest. Give IM dosage forms deep into a large muscle mass (see [Chapter 10](#)).

Linezolid is generally given orally or intravenously, which makes it advantageous for those requiring an antibiotic with a spectrum similar to vancomycin for an extended period or on an outpatient basis. Oral dosages are to be evenly spaced around the clock, as ordered, and given with food or milk to decrease the possibility of GI upset. Oral suspension forms must be given within 21 days of reconstitution. Protect IV doses from light, and infuse over 30 to 120 minutes; do not mix with any other medication. Foods that may increase blood pressure while taking linezolid need to be avoided; these include aged cheeses, wine, soy sauce, smoked meats or fish, and sauerkraut, due to their tyramine content (see [Chapter 17](#)).

Oral forms of metronidazole need to be given with food or meals to decrease GI upset. Educate patients not to chew extended-release dosages. It is recommended that intravaginal doses be administered at bedtime. Topical creams, ointments, or lotions are to be applied thinly to the affected area. An applicator should be used for intravaginal dosages. Gloves are worn to protect the hands from unnecessary exposure to medication and as part of standard precautions/routine practices. Do not apply topical forms close to the eyes, to avoid irritation. Store at

room temperature IV dosage forms that are supplied in a ready-to-use infusion bag.

Nitrofurantoin is available in oral forms and must be given with sufficient fluids, food, or milk to reduce GI upset. To help prevent tooth staining and GI upset, do not crush tablets. Because of the risk for superinfection, hepatotoxicity, and peripheral neuropathy (which may be irreversible), closely monitor for signs and symptoms of these adverse effects and document the findings. Be aware that jaundice, itching, rash, and liver enlargement may indicate toxic effects to the liver, whereas numbness and tingling may occur with peripheral neuropathy. Inform the patient nitrofurantoin may turn urine a dark brown color during therapy.

For quinupristin/dalfopristin, only IV dosage forms are available. Reconstitute the drug using only D₅W. Use a gentle swirling action instead of shaking to mix the drug (to help minimize foaming). A diluted infusion bag of the drug is stable for up to 6 hours, or, if refrigerated, 54 hours. It is important to know these characteristics to help prevent untoward complications. Infusions are generally given over at least 60 minutes. Implement the same measures as with other antibiotics, to monitor for superinfection.

Vancomycin may be used orally but is poorly absorbed by this route and is used only to treat microbes in the GI tract (e.g., staphylococcal enterocolitis, *C. difficile*). Parenteral dosage forms must be used to treat infection outside of the intima of the GI tract. Reconstitute IV dosage forms as recommended (e.g., with either D₅W or NS) and infuse over at least 60 minutes. Too rapid an infusion of vancomycin or administration by IV push may lead to severe hypotension and red man syndrome. Extravasation may cause local skin irritation and damage, so frequently monitor the infusion and, in particular, the IV site. Constant monitoring for drug-related neurotoxicity, nephrotoxicity, ototoxicity, and superinfection remain crucial to patient safety. In addition, adequate hydration (at least 2 litres of fluids every 24 hours unless contraindicated) is important to prevent nephrotoxicity. Trough levels need to be ordered prior to the third or fourth dose; peak levels are no longer used (see the previous discussion for more information).

Because of the significant issue of multidrug-resistant organisms, encourage patients and family members not to abuse or overuse antibiotics and to report immediately to the health care provider any signs or symptoms of an infection that is not resolving or responding to antibiotic therapy. Regardless of drug management, in today's health care settings (e.g., acute and long-term facilities, medical offices, urgent care centres or walk-in clinics, emergency departments) as well as in the home setting and abroad, teach and demonstrate proper and thorough handwashing technique. The Centers for Disease Control and Prevention (CDC) and Health Canada recommend the following as the proper handwashing technique: Wash hands with warm running water and soap; lather well by rubbing hands vigorously for at least 15 to 20 seconds; pay attention to the wrist area, backs of the hands, areas between the fingers, and under the fingernails; and rinse well. Allow the water to run while drying hands with a paper towel and then use a dry paper towel as a barrier between the faucet and clean hands while turning off the water. If soap and water are not available and hands are not visibly soiled, gel hand sanitizers or alcohol-based hand wipes containing at least 60% ethyl alcohol or isopropanol may be used. Once the gel is applied and all surfaces covered, rub hands until gel is dry and do not towel gel off.

◆ EVALUATION

Once antibiotic therapy has been initiated, evaluation that is focused on goals, outcome criteria, therapeutic effects, and adverse effects must be ongoing. Ask patients to report any decrease in symptoms (e.g., associated with infection). Therapeutic goals include a return to normal of all blood counts and vital signs; negative results of culture and sensitivity testing; and improved appetite, energy level, and sense of well-being. Signs and symptoms of the infection will begin to resolve once therapeutic levels of antibiotics are achieved. Another aspect of evaluation is monitoring for adverse effects of therapy such as superinfections, antibiotic-associated colitis, nephrotoxicity, ototoxicity, neurotoxicity, hepatotoxicity, and other drug-specific adverse effects.

PATIENT TEACHING TIPS

- Aminoglycosides
 - Educate patients about the drug, its purpose, and its adverse effects, including the risk of hearing loss, which may occur after completion of therapy. Advise them to report any change in hearing to the health care provider.
 - Patients should be informed of the importance of drinking up to 3 000 mL/24 hours of fluids, unless contraindicated, with any medication but especially with antibiotics, to maximize absorption of oral doses, minimize some of the adverse effects, and ensure adequate hydration.
 - Instruct patients to report to the health care provider any persistent headache, nausea, or vertigo. Educate them about the signs and symptoms of superinfection,

such as diarrhea, vaginal discharge, stomatitis, loose and foul-smelling stools, or cough.

- Quinolones
 - Educate patients about the importance of avoiding exposure to sun and tanning beds because of the risk of photosensitivity with these drugs. Recommend the use of sunglasses and sunscreen protection.
 - Advise patients to report to the health care provider any headache, dizziness, restlessness, diarrhea, vomiting, oral candidiasis, flushing of the face, or inflammation of the tendons.
 - Educate patients taking quinolones about drug interactions that may occur with the following drugs: calcium, magnesium, probenecid, nitrofurantoin, oral anticoagulants, iron,

sucralfate, and zinc preparations. Instruct them to take calcium and magnesium supplements at least 1 hour before or after taking the quinolone. Probenecid may reduce the excretion of the antibiotic and cause toxicity. Since quinolones may alter the intestinal flora and thus vitamin K synthesis, oral anticoagulants must be used with caution in patients taking these antibiotics.

- Instruct patients taking ciprofloxacin or levofloxacin, both quinolones, to take the drug exactly as ordered.
- Clindamycin
 - Instruct patients not to use topical forms of clindamycin near the eyes or near any abraded areas to avoid irritation.
 - When vaginal dosage forms are used, patients need to be advised not to engage in sexual intercourse for the duration of the therapy. The full course of antibiotics is to be taken as ordered to obtain maximal therapeutic benefit.
 - Instruct patients that, if topical dosage forms get into the eyes accidentally, they should rinse the eyes immediately with copious amounts of cool tap water.
- Linezolid
 - Instruct patients to continue therapy for the full prescribed length of treatment (as with all antibiotics).
 - Educate patients to avoid tyramine-containing foods (e.g., red wine, aged cheeses) while taking the drug.
 - Instruct patients to report to the health care provider any severe abdominal pain, fever, severe diarrhea, or worsening of signs and symptoms of infection.

- Metronidazole
 - Caution patients taking metronidazole to avoid alcohol and any alcohol-containing products (e.g., cough preparations and elixirs) while taking the drug because of the risk for a disulfiram-like reaction (e.g., severe vomiting).
 - Educate patients about the purpose of the drug, because this knowledge is crucial to achieving therapeutic effects and preventing adverse effects.
- Nitrofurantoin
 - Advise patients to report to the health care provider any abdominal cramping, dizziness, severe skin reactions, or jaundice.
- Vancomycin
 - Instruct patients to report any changes in hearing, such as ringing in the ears or a feeling of fullness in the ears. Any nausea, vomiting, unsteady gait, dizziness, generalized tingling (usually after IV dosing), chills, fever, rash, or hives must also be reported. Monitor for symptoms of Red Man Syndrome such as redness, rash, itching, or feeling hot, and report to a healthcare provider.
 - Monitor serum drug levels throughout therapy; this monitoring is key to prevention of toxicity. Trough levels are usually monitored throughout therapy. Stress to patients that follow-up appointments are important for monitoring serum drug levels and identifying possible toxic effects.

KEY POINTS

- Over the years, bacteria have developed enzymes and mechanisms to interact with antibiotics and render the antibiotic ineffective. Multidrug resistance is a significant health issue, and such resistant organisms include ESBL- and KPC-producing bacteria, MRSA, and VRE.
- The aminoglycosides are a group of natural and semisynthetic antibiotics that are classified as bactericidal drugs; they are extremely potent and are capable of potentially serious toxicities (e.g., nephrotoxicity, ototoxicity).
- Quinolones are extremely potent, bactericidal, broad-spectrum antibiotics and include norfloxacin hydrochloride, ciprofloxacin, levofloxacin, and moxifloxacin hydrochloride.
- Clindamycin is a semisynthetic derivative of lincomycin, an older antibiotic.
- Linezolid is an antibacterial drug used to treat infections associated with VRE *faecium*, more commonly referred to as VRE. VRE is a difficult infection to treat and often occurs as a health care–associated infection.
- Metronidazole (Flagyl) is an antimicrobial drug of the class nitroimidazole. It has good activity against anaerobic organisms and is widely used to treat intra-abdominal and gynecological infections; it is also used to treat protozoal infections (e.g., amebiasis, trichomoniasis).
- Nitrofurantoin (MacroBID) is an antibiotic drug of the class nitrofuran. It is indicated primarily to treat urinary tract infections caused by *E. coli*, *S. aureus*, *Klebsiella* spp., and *Enterobacter* spp.
- Quinupristin/dalfopristin (Synercid) are two streptogramin antibacterials approved for IV treatment of bacteremia and life-threatening infection caused by VRE and for treatment of complicated skin and skin-structure infections caused by *S. aureus* and *S. pyogenes*.
- Use of the antibiotics in this chapter requires assessment for any history of or current symptoms indicative of hypersensitivity or allergic reactions (from mild reactions with rash, pruritus, and hives to severe reactions with laryngeal edema, bronchospasms, hypotension, and possible cardiac arrest).
- With the use of any antibiotic, it is important to assess for superinfection, or a secondary infection that occurs with the destruction of normal flora during antibiotic therapy. Superinfections may occur in the mouth, respiratory tract, GI tract, or GU tract, or on the skin. Fungal infections are evidenced by fever, lethargy, perineal itching, and other anatomically related symptoms.

EXAMINATION REVIEW QUESTIONS

- The nurse is assessing a woman who is receiving an antibiotic for community-acquired pneumonia. The patient complains of perineal itching and a thick, white vaginal discharge. Which of the following would the nurse suspect is the primary problem?
 - Resistance to the antibiotic
 - An adverse effect of the antibiotic
 - A superinfection
 - An allergic reaction
- The nurse is reviewing a patient's medication list. The patient has been admitted for treatment of an infected leg ulcer and will be started on IV linezolid. Which of the following medications, if listed in the medication list with linezolid, would be most concerning for the nurse?
 - Beta-blocker
 - Oral anticoagulant
 - Selective serotonin reuptake inhibitor (SSRI) antidepressant
 - Thyroid replacement hormone
- The nurse is caring for a client who has been administered vancomycin. Which of the following would be a priority assessment for the nurse prior to administering the vancomycin?
 - Kidney function
 - WBC count
 - Liver function
 - Platelet count
- During therapy with an IV aminoglycoside, the patient calls the nurse and says, "I am hearing some odd sounds, like ringing, in my ears." Which of the following would be the nurse's priority action at this time?
 - Reassure the patient that these are expected adverse effects.
 - Reduce the rate of the IV infusion.
 - Increase the rate of the IV infusion.
 - Stop the infusion immediately.
- The nurse is caring for a client who has been ordered IV quinolones. Which of the following would the nurse be concerned about with a serious drug-to-drug interaction?
 - Selective serotonin reuptake inhibitor (SSRI) antidepressants
 - Nonsteroidal anti-inflammatory drugs (NSAIDs)
 - Oral anticoagulants
 - Antihypertensives
- The nurse is administering an IV aminoglycoside to a patient who has had gastrointestinal surgery. Which of the following nursing measures would be most appropriate? (Select all that apply.)
 - Report a trough drug level of 0.8 mcg/mL, and hold the drug.
 - Enforce a strict fluid restriction.
 - Monitor serum creatinine levels.
 - Instruct the patient to report dizziness or a feeling of fullness in the ears.
 - Warn the patient that the urine may turn a darker colour.
- The order reads: "Give vancomycin, 1 250 mg in 250 mL NS, IVPB, every 12 hours. Infuse over 90 minutes." The nurse will set the infusion pump to what setting for mL/hour?

CRITICAL THINKING ACTIVITIES

- A patient who has been receiving IV doses of metronidazole has been discharged and will continue therapy with oral doses of this medication. The patient remarks, "I'm so glad to be going home. Our annual office party is tomorrow night, and I've been looking forward to it all year long." What is the priority when teaching the patient regarding this drug?
 - A patient has been receiving therapy with the aminoglycoside tobramycin, and the nurse notes that the patient's latest trough drug level was 3 mcg/mL. This drug is given daily, and the next dose is to be administered now. Based on this trough drug level, what is the nurse's priority action? Explain your answer.
 - A patient has a urinary tract infection caused by *Pseudomonas* spp. Two antibiotics have been ordered, both due at 0900 hr:
 - gentamicin, 300 mg, intravenously, daily (due at 0900 hr), infuse over 60 minutes
 - ceftazidime, 500 mg intravenously, every 12 hours (due at 0900 hr and 2100 hr), infuse over 30 minutes
 Which antibiotic should the nurse infuse first? Explain your answer.
- For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Antiviral Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Discuss the effects of the immune system, paying attention to the different types of immunity.
2. Discuss the effects of viruses in the human body.
3. List specific drugs categorized as non-HIV antivirals and HIV antivirals or antiretrovirals.
4. Discuss the process of immunosuppression in patients with viral infections, specifically those with HIV infection.
5. Describe the stages of HIV/AIDS and various drugs used to manage the illness.
6. Discuss the mechanism of action, indications, contraindications, cautions, routes, adverse effects, and toxic effects of the various non-HIV and HIV antiviral drugs.
7. Develop a collaborative plan of care that includes all phases of the nursing process for patients receiving non-HIV and HIV antiviral drugs.

KEY TERMS

Acquired immune deficiency syndrome (AIDS) Infection caused by the human immunodeficiency virus (HIV), which weakens the host's immune system, giving rise to opportunistic infections. (p. 732)

Antibodies Immunoglobulin molecules that have an antigen-specific amino acid sequence and are produced by the humoral immune system (antibodies produced from B lymphocytes) in response to exposure to a specific antigen, the purpose of which is to attack and destroy molecules of this antigen. (p. 733)

Antigen A substance, usually a protein, that is foreign to a host and causes the formation of an antibody and reacts specifically with that antibody. Examples of antigens include bacterial exotoxins, viruses, and allergens. An allergen (e.g., dust, pollen, mould) is a specific type of antigen that causes allergic reactions (see Chapter 37). (p. 733)

Antiretroviral drugs A more specific term for antiviral drugs that work against retroviruses such as HIV. (p. 734)

Antiviral drugs Drugs that destroy viruses, either directly or indirectly, by suppressing their replication. (p. 734)

Cell-mediated immunity (CMI) One of two major parts of the immune system. CMI consists of nonspecific immune responses mediated primarily by T lymphocytes (T cells) and other immune system cells (e.g., monocytes, macrophages, neutrophils) but not antibody-producing cells (B lymphocytes). (p. 733)

Deoxyribonucleic acid (DNA) A nucleic acid composed of nucleotide units that contain molecules of the sugar deoxyribose, phosphate groups, and purine and pyrimidine bases. DNA molecules transmit genetic information and are found primarily in the nuclei of cells. (Compare with *ribonucleic acid [RNA]*). (p. 732)

Fusion The process by which viruses attach themselves to, or fuse with, the cell membranes of host cells, in preparation for infecting the cell for purposes of viral replication. (p. 732)

Genome The complete set of genetic material of any organism. The genome may consist of multiple chromosomes (groups of DNA or RNA molecules) in higher organisms; a single chromosome, as in bacteria; or one or two DNA or RNA molecules, as in viruses. (p. 732)

Herpesviruses Several different types of viruses belonging to the family Herpesviridae that cause various forms of herpes infection. (p. 733)

Host Any organism that is infected with a microorganism, such as bacteria or viruses. (p. 732)

Human immunodeficiency virus (HIV) The retrovirus that causes AIDS. (p. 732)

Humoral immunity One of two major parts of the immune system. Humoral immunity consists of specific immune responses in the form of antigen-specific antibodies produced from B lymphocytes (B cells). (p. 733)

Immunoglobulins Glycoproteins produced and used by the humoral immune system to attack and kill any substance (antigen) that is foreign to the body. An immunoglobulin with an antigen-specific amino acid sequence is called an *antibody* and is able to recognize and inactivate molecules of a specific antigen. (Also called *immune globulins*.) (p. 734)

Influenza viruses Viruses that cause influenza, an acute viral infection of the respiratory tract. There are three types of influenza virus: A, B, and C. Currently, medications are available to treat only types A and B. (p. 734)

Nucleic acids Complex biomolecules, including DNA and RNA, that contain the genetic material of all living organisms, which is passed to future generations during reproduction. (p. 732)

Nucleoside A structural component of nucleic acid molecules (DNA or RNA) that consists of a purine or pyrimidine base attached to a sugar molecule. (p. 734)

Nucleotide A nucleoside that is attached to a phosphate unit, which makes up the side chain “backbone” of a DNA or a RNA molecule. (p. 734)

Opportunistic infections Infections caused by any type of microorganism that occurs in an immunocompromised host but normally would not occur in an immunocompetent host. (p. 734)

Protease An enzyme that breaks down the amino acid structure of protein molecules by chemically cleaving the peptide bonds that link together the individual amino acids. (p. 740)

Replication Any process of duplication or reproduction, such as that involved in the duplication of nucleic acid molecules (DNA or RNA) during the reproduction processes of all

living organisms; most commonly describes the entire process of viral reproduction, which occurs only inside the cells of an infected host organism. (p. 732)

Retroviruses Viruses belonging to the family Retroviridae.

These viruses contain RNA (as opposed to DNA) as their genome and replicate using the enzyme reverse transcriptase. Currently, the most clinically significant retrovirus is HIV. (p. 733)

Reverse transcriptase An RNA-directed DNA polymerase enzyme. Reverse transcriptase promotes the synthesis of a DNA molecule from an RNA molecule, which is the reverse of the usual process. HIV replicates in this manner. (p. 739)

Ribonucleic acid (RNA) A nucleic acid composed of nucleotide units that contain molecules of the sugar ribose, phosphate groups, and purine and pyrimidine bases. RNA molecules transmit genetic information and are found in both the nuclei and cytoplasm of cells. (Compare with *deoxyribonucleic acid [DNA]*.) (p. 732)

Virion A mature virus particle. (p. 732)

Viruses The smallest known class of microorganisms; viruses can replicate only inside host cells. (p. 732)

* Full generic name is given in parentheses. For the purposes of this text, the more common, shortened name is used.

GENERAL PRINCIPLES OF VIROLOGY

Viruses are tiny microorganisms, usually many times smaller than bacteria. Unlike bacteria, viruses can replicate only inside the cells of their **host**. In this respect, all viruses are obligate intracellular parasites. It must be emphasized that viruses are not cells per se, but instead are particles that infect and replicate inside cells. A mature virus particle is known as a **virion**. Compared with other organisms, virions have a relatively simple structure that consists of the genome, the capsid, and the envelope. The **genome** is the inner core of the virion and is

composed of single- or double-stranded **deoxyribonucleic acid (DNA)** or **ribonucleic acid (RNA)** molecules, but not both.

Viruses are the simplest of all organisms. The cells of more complex organisms have much larger strands of **nucleic acids**, or multiple strands, which make up chromosomes. The viral capsid is a protein coat that surrounds and protects the genome. It also plays a role in the **fusion** between virions and host cells. Fusion occurs when virions attach themselves to host cells in preparation for infecting the cells. The envelope is the outermost layer of the virion and is present in some, but not all, viruses. It has a lipoprotein structure containing viral antigens that are often chemically specific for various proteins on the surface of the host cell membranes. This biochemical specificity, when present, also facilitates the fusion process. The **human immunodeficiency virus (HIV)**, which causes **acquired immune deficiency syndrome (AIDS)**, functions in this manner.

Viruses can enter the body through at least four routes: by inhalation through the respiratory tract, by ingestion via the gastrointestinal (GI) tract, via the placenta from mother to infant, and through inoculation via skin or mucous membranes. Inoculation occurs in several ways, including sexual contact, blood transfusions, sharing of syringes or needles, organ transplants, or bites (including human, animal, insect, spider, and others). Once inside the body, the virus particles, or virions, begin to attach themselves to the outer membranes of host cells (cell membranes or plasma membranes), as illustrated in **Figure 45.1**.

The viral genome then passes through the plasma membrane into the cytoplasm of the host cell. It later enters the cell nucleus, where the **replication** process begins. The virion may use its own or the host's enzymes (or both) to direct the replication process. In the host cell nucleus, the viral genome uses the cell's genetic material (the nucleic acids RNA and DNA) to synthesize viral nucleic acids and proteins. These are then used

Fig. 45.1 Virus replication. Some viruses integrate into host chromosomes and enter a period of latency. *mRNA*, messenger RNA. (Modified from Brody, T. M., Larner, J., & Minneman, K. P. (2010). *Human pharmacology: Molecular to clinical* (5th ed.). St. Louis, MO: Mosby.)

to construct complete new virions. These new virions then exit the infected host cell by budding through the plasma membrane and go on to infect other host cells, where the replication process continues. The changes in the cell associated with viral replication are known as the *cytopathic effect* and usually result in the destruction of the host cell. Repeated over time, host cell destruction gives rise to the pathological effects of the virus, which can eventually impair or kill the host organism.

Although this cytopathic effect is the most common outcome, there are other possible outcomes of viral infection. One is viral transformation, which involves mutation of the host cell DNA or RNA and can result in malignant (cancerous) host cells. Viruses that can induce cancer in this way are known as *oncogenic viruses*. More common is latent, or dormant, infection, in which the virions remain inside host cells but do not actively replicate to any significant degree. For example, HIV infection may have a dormant phase of 10 years or more before giving rise to AIDS in an infected person. HIV infection is discussed in greater detail later in this chapter, in the section on retroviruses.

Viruses are widespread in the environment, and most viral infections may not be noticed before they are eliminated by the host's immune system. These are referred to as "silent" viral infections. Although the host's immune system acts to neutralize viral infection, it can become overwhelmed, depending on how virulent the virus is and how rapidly it replicates inside host cells. In most cases, however, a person's immune system is able to arrest and eliminate the virus. Host immune responses to viral infections are classified as either nonspecific or specific. Nonspecific immune responses include phagocytosis (the process of engulfing and killing) of viral particles by leukocytes such as neutrophils, macrophages, monocytes, and T lymphocytes (T cells). Another nonspecific immune response is the release of cytokines from these leukocytes. Cytokines are biochemical substances (e.g., histamine, tumour necrosis

factor) that stimulate other protective immune functions. In addition, these activated immune system cells may also phagocytize infected host cells to curb the growth and spread of infection. These types of immune responses are collectively referred to as **cell-mediated immunity (CMI)**. CMI is non-specific in the sense that it does not involve **antibodies** that are specific for a given **antigen**. In contrast, specific immune responses include the production of antibodies from B lymphocytes (B cells). This type of immune response is called **humoral immunity**. Immune system function is discussed in more detail in Chapters 50 and 51.

OVERVIEW OF VIRAL ILLNESSES AND THEIR TREATMENT

There are at least six classes of DNA viruses and at least 14 classes of RNA viruses that are known to infect humans. Some of the more prominent viral illnesses include smallpox (poxviruses), sore throat and conjunctivitis (adenoviruses), warts (papovaviruses), influenza (orthomyxoviruses), respiratory infections (coronaviruses, rhinoviruses), gastroenteritis (rotaviruses, Norwalk-like viruses), HIV/AIDS (retroviruses), herpes (**herpesviruses**), and hepatitis (hepadnaviruses). Effective drug therapy is currently available for only a relatively small number of active viral infections. The drug therapy for hepatitis is discussed further in Chapter 54. HIV belongs to the relatively unique viral class known as **retroviruses** and is discussed in a separate section of this chapter.

Fortunately, many viral illnesses are survivable (e.g., chicken pox), albeit bothersome and uncomfortable. The incidence of some of these illnesses has been reduced by the development of effective vaccines (e.g., vaccines for polio, smallpox, measles, chicken pox). Vaccines are discussed in more detail in Chapter 51. However, many other viral illnesses are either fatal or have

much more severe long-term outcomes (e.g., hepatitis, HIV infection). At the time of this text's publication, development of treatments and vaccines for COVID-19 is in progress.

Antiviral drugs are chemicals that kill or suppress viruses by either destroying virions or inhibiting their ability to replicate. The body's immune system has a better chance of controlling or eliminating a viral infection when the ability of the virus to replicate itself is suppressed. Drugs that destroy virions include disinfectants and immunoglobulins. Disinfectants such as povidone-iodine (Ovadine®) are virucides and are commonly used to disinfect medical equipment, as well as parts of the body during invasive procedures.

Immunoglobulins are concentrated antibodies that can attack and destroy viruses. They are isolated and pooled from human or animal blood. Their activity may be either nonspecific (e.g., human gamma globulin) or specific (e.g., rabies immunoglobulin, varicella-zoster immunoglobulin). Although such substances can technically be considered antiviral drugs, they are more commonly thought of as immunizing drugs and are therefore discussed in more detail in Chapter 51. A few antiviral drugs, such as interferons, stimulate the body's immune system to kill the virions directly. These drugs are discussed in Chapter 54.

The current antiviral drugs are all synthetic compounds that work indirectly by inhibiting viral replication as opposed to directly destroying mature virions. Relatively few of the known viruses can be controlled by current drug therapy. Some of the viruses in this group are the following:

- Cytomegalovirus (CMV)
- Hepatitis viruses
- Herpes viruses
- HIV
- **Influenza viruses** ("flu" viruses)
- Respiratory syncytial virus (RSV)

Active viral infections are usually more difficult to eradicate than those caused by bacteria. One reason is that viruses replicate only inside host cells rather than independently in the bloodstream or in other tissues. Most antiviral drugs must therefore enter these cells to disrupt viral replication. The need to develop antiviral drugs that are not overly toxic to host cells is one reason that there are relatively few effective antiviral medications on the market. However, the HIV/AIDS pandemic that began in the early 1980s strongly boosted antiviral drug research. This research has increased the number of available antiviral drugs to treat HIV and other viral infections such as influenza, CMV infection, and varicella-zoster virus (VZV) infection. Many drugs for the treatment of HIV are approved by Health Canada via an accelerated process, which means that they are approved faster than other drugs because of the nature of the illness. Given the rapid addition of HIV drugs to the market, it is beyond the scope of this book to list every available drug.

Another reason viral illnesses are difficult to treat is that the virus has often replicated itself many thousands or possibly millions of times before symptoms of illness appear. Therefore, one goal in the field of infectious disease is to be able to diagnose viral illnesses before an infecting virus has undergone

widespread replication in a human host. This would theoretically allow the dual benefit of both early drug therapy and easier elimination of the virus by the host's immune system. This has happened to some degree with HIV infection, with relatively early diagnosis made possible by blood tests to screen for HIV antibodies. Of course, the patient must also be alert to the need to seek medical care before serious illness develops. Recall that for a virus to replicate, virions must first attach themselves to host cell membranes in a process known as *fusion*. Once inside the cell, the viral genome makes nucleic acids and proteins, which are then used to build new viral particles, or virions (see [Figure 45.1](#)). All virions contain a genome that consists of either DNA or RNA, but not both. Antiviral drugs inhibit this replication in various ways. Most antiviral drugs enter the same cells that the viruses enter. Once inside, these antiviral drugs interfere with viral nucleic acid synthesis. Other antiviral drugs work by preventing the fusion process.

The best responses to antiviral drug therapy are usually seen in patients with competent immune systems. The immune system can work synergistically with the drug to eliminate or effectively suppress viral activity. Patients who are immunocompromised are at greater risk for **opportunistic infections**, which are infections caused by organisms that would not normally harm an immunocompetent person. The most common examples of immunocompromised patients are patients with cancer, organ transplant recipients, and patients with AIDS. These patients are prone to frequent and often severe opportunistic infections of many types, including those caused by other non-HIV viruses, bacteria, fungi, and protozoans. Such infections often require long-term prophylactic anti-infective drug therapy to control the infection and prevent recurrence because of compromised host immune functions.

Recall that there are two types of nucleic acids found in living organisms: DNA and RNA. There are also five organic bases that are major structural components of these nucleic acids. DNA consists of long chains of deoxyribose sugar molecules, phosphate groups, and purine (adenine or guanine) and pyrimidine (cytosine or thymine) bases. RNA consists of long chains of ribose sugar molecules linked to phosphate groups, together with purine (adenine or guanine) and pyrimidine (cytosine or uracil) bases. A **nucleoside** is a single unit, consisting of a base and its attached sugar molecule. Nucleosides have names similar to their bases, with minor spelling modifications (e.g., adenosine, guanosine, cytidine, thymidine). A **nucleotide** is a nucleoside plus its attached phosphate molecule. Most antiviral drugs are synthetic purine or pyrimidine nucleoside or nucleotide analogues. Some pharmacology texts categorize the antiviral drugs based on their nucleoside–nucleotide activity. However, for ease of learning, this book divides antiviral drugs into those that treat HIV infections and those that treat non-HIV viral infections. **Antiretroviral drugs** are indicated specifically for the treatment of infections caused by HIV, the virus that causes AIDS. The effectiveness of antiviral drugs varies widely among patients and even over time in the same patient.

HERPES SIMPLEX VIRUS AND VARICELLA-ZOSTER VIRUS INFECTIONS

The family of viruses known as Herpesviridae includes those viruses that cause all kinds of herpes infections. There are several specific types of such viruses. Herpes simplex virus type 1 (HSV-1) causes mucocutaneous herpes, usually in the form of perioral blisters (“fever blisters” or “cold sores”). Herpes simplex virus type 2 (HSV-2) causes genital herpes. Human herpesvirus 3 (HHV-3) causes both chicken pox and shingles. This virus is more commonly known as *herpes-zoster virus* or *varicella-zoster virus* (VZV). Human herpes virus 4 (HHV-4), more frequently known as Epstein–Barr virus (EBV), is associated with illnesses such as infectious mononucleosis (“mono”) and chronic fatigue syndrome. Human herpesvirus 5 (HHV-5) is more commonly known as *cytomegalovirus* (CMV) and is the cause of CMV retinitis (a serious viral infection of the eye) and CMV disease, which is most commonly seen in immunocompromised patients. Human herpesviruses 6 and 7 are not clinically significant, and infection with these viruses may be more likely to occur in immunocompromised patients. Human herpesvirus 8, also known as *Kaposi’s sarcoma herpesvirus*, is an oncogenic virus believed to cause Kaposi’s sarcoma, an AIDS-associated cancer. All of these viruses occur, often asymptotically, in varying percentages of the population. Types 3 through 7 normally do not cause diseases that require medication, except in the case of immunocompromised patients. However, HSV-1 and HSV-2 and VZV (HHV-3) commonly cause illnesses that are now routinely treated with prescription medications.

Herpes Simplex Viruses

Although there can be anatomical overlap between the two types of herpes simplex virus, HSV-1 is most commonly associated with perioral blisters and is therefore often thought of as *oral herpes*. In contrast, HSV-2 is most commonly associated with blisters on both male and female genitalia and is therefore commonly referred to as *genital herpes*. Although they usually do not cause serious or life-threatening illness, both infections are annoying and highly transmissible through close physical contact (e.g., kissing, sexual intercourse). Outbreaks of painful skin lesions occur intermittently, with periods of latency (no sores or other symptoms) occurring between acute outbreaks. Although antiviral medications are not always required and are *not* curative, they can speed up the process of remission and reduce the duration of painful symptoms. This is particularly true if the medications are started early in an outbreak. Patients may be prescribed an ongoing lower dose of antiviral drug for prophylaxis of outbreaks. HSV infections can become serious, even life-threatening, when the patient is immunocompromised or a newborn infant. Neonatal herpes is often a life-threatening infection, and babies with this disease are often treated with intravenous (IV) antiviral drugs in neonatal critical care units. However, treatments may fail, causing infant death or permanent disability. Therefore, the best strategy is to prevent transmission to the newborn infant. For this reason, obstetricians will usually recommend delivery by Caesarean section for any mother with active genital herpes lesions.

Varicella-Zoster Virus

VZV is a type of herpesvirus (HHV-3) that most commonly causes chicken pox (varicella) in childhood, remains dormant for many years, and can then re-emerge in later adulthood as painful herpes-zoster lesions, known as *shingles*.

Chicken pox is usually an uncomfortable but self-limiting disease of childhood. However, it is highly contagious and easily spreads by either direct contact with weeping lesions or via droplet inhalation. It can also lead to significant scarring. The serious condition *Reye’s syndrome* (causing fatty liver damage with encephalopathy) may also complicate varicella, as can other viral infections such as influenza. Herpes zoster is caused by the reactivation of VZV from its dormant state, often decades after a case of childhood chicken pox. It is also referred to simply as *zoster*. Nearly one in three Canadians will develop shingles in their lifetime ([Public Health Agency of Canada, 2020](#)). Its most common manifestation is in the form of skin lesions that follow nerve tracts, known as *dermatomes*, along the skin surface. The most common site of these lesions is around the side of the trunk, although they can appear in other areas (e.g., along the trigeminal nerve dermatomes of the face). Zoster lesions are often extremely painful, and some patients require opioids for pain control and often anti-inflammatory drugs as well. In addition, postherpetic neuralgias (long-term nerve pain) remain following shingles outbreaks in as many as 50% of older adults. Early administration of antiviral drugs such as acyclovir may speed recovery, but this effect is usually not dramatic. Usually, the best results are seen when the antiviral drug is started within 72 hours of symptom onset; however, antivirals do not provide a cure.

Active childhood varicella (chicken pox) infections are usually self-limiting and are not normally treated with antiviral drugs, except in high-risk (e.g., immunocompromised) children. A univalent varicella virus vaccine is now routinely recommended for healthy children between 12 and 18 months of age who have not had chicken pox. A new combined multivalent vaccine (measles–mumps–rubella–varicella [MMRV]) is also available for healthy children aged 12 months to 12 years of age. Two vaccines, Shingrix and Zostavax®, are available for prevention of herpes shingles in patients 50 years of age or older (see Chapter 51).

In a small percentage of shingles cases, skin lesions may progress beyond the usual dermatome regions, and the virus can cause solid organ infections such as pneumonitis, hepatitis, encephalitis, and optic neuritis (infection of the optic nerve). Such infections are uncommon, with older adults and immunocompromised patients being most vulnerable. Rarely, these serious infections can be caused by first-time exposure to varicella (chicken pox). In general, these more serious infections require IV antiviral drugs, especially in high-risk patients. IV acyclovir is the most commonly used drug, and it may prevent fatalities or disability. Less serious infections are usually treated orally with acyclovir, valacyclovir, or famciclovir. Topical dosage forms of some of these drugs are also available and are discussed further in Chapter 56. Although VZV reactivation is comparable in pathology to that of HSV (i.e., oral or genital herpes lesions), VZV reactivation occurs much less regularly than HSV because of a lack of reactivation genes. Secondary bacterial infections (e.g., group A *Streptococcus* skin infection) are common with

TABLE 45.1 Examples of Antiviral Drugs (Non-HIV)

Drug	Indications
Drugs to Treat Herpesviruses	
acyclovir, famciclovir, valacyclovir hydrochloride	Herpes simplex types 1 and 2, herpes zoster, chicken pox
Trifluridine	Herpes simplex keratitis
Drugs to Treat Influenza Viruses	
amantadine hydrochloride	Influenza A
zanamivir, oseltamivir phosphate	Influenza A and B
Miscellaneous Antivirals	
ribavirin, palivizumab	Respiratory syncytial virus (RSV) infection
ganciclovir, valganciclovir, cidofovir, foscarnet sodium (available through Special Access Programme, Health Canada)	Cytomegalovirus (CMV) infection, acyclovir-resistant herpes simplex infections

VZV exacerbations, so antibiotics may also be needed. This is especially true in cases of ophthalmic involvement.

ANTIVIRALS (NON-HIV)

The drugs discussed in this section include those used to treat non-HIV viral infections such as those caused by influenza viruses, HSV, VZV, and CMV. There are also antiviral drugs used for hepatitis A, B, and C viruses (HAV, HBV, and HCV). Hepatitis treatment is discussed in further detail in Chapter 54 because it involves some additional unique drug therapy.

Mechanism of Action and Drug Effects

Most of the current antiviral drugs work by blocking the activity of a polymerase enzyme that normally stimulates the synthesis of new viral genomes. The result is impaired viral replication, which results in viral concentrations low enough to allow elimination of the virus by the patient's immune system. If this does not occur, the virus may either enter a dormant state or remain at a low level of replication with continuous drug therapy.

Indications

The antivirals discussed in this section are listed in [Table 45.1](#).

Contraindications

Most of the antiviral drugs used to treat non-HIV viral infections are surprisingly well tolerated. The only usual contraindication for most of these drugs is known severe drug allergy. However, a small number of contraindications are listed for a few of the antiviral drugs. Amantadine is contraindicated in lactating women, children younger than 12 months of age, and patients with an eczematous rash. Famciclovir is contraindicated in cases of allergy to it. Cidofovir has a strong propensity for renal toxicity, and it is contraindicated in patients who already have severely compromised renal function as well as those receiving concurrent drug therapy with other highly nephrotoxic drugs. It is also contraindicated in cases of allergy to probenecid because probenecid is recommended as concurrent drug therapy with cidofovir to help alleviate its nephrotoxicity. Ribavirin has additional specific contraindications besides drug allergy. Because of the drug's

teratogenic potential, it is contraindicated in pregnant women as well as their male sexual partners. The aerosol form must not be used by pregnant women or by women who may become pregnant during exposure to the drug. This includes health care providers administering the drug in aerosol form because of the potential for second-hand inhalation by the health care provider.

Adverse Effects

The adverse effects of the antiviral drugs are as different as the drugs themselves. Each has its own specific adverse effect profile. Because viruses reproduce in human cells, selective killing is difficult, and consequently many healthy human cells, in addition to virally infected cells, may be killed in the process, resulting in more serious toxicities for these drugs. However, this effect is usually not as pronounced as in cancer chemotherapy, which often kills many more healthy cells. The more serious adverse effects are listed by drug in [Table 45.2](#).

Interactions

Significant drug interactions that occur with the antiviral drugs arise most often when they are administered via systemic routes, such as intravenously and orally. Many of these drugs are also applied topically to the eye or body, however, and the incidence of drug interactions associated with these routes of administration is much lower. Selected common drug interactions for both antiviral and antiretroviral drugs are listed in [Table 45.3](#).

Dosages

For dosage information on some of the commonly used nonretroviral antiviral drugs, refer to the table on p. 739.

DRUG PROFILES

amantadine hydrochloride

Amantadine hydrochloride (Dom-Amantidine®), one of the earliest antiviral drugs, has a narrow antiviral spectrum in that it is active only against influenza A viruses. It has been used both prophylactically and therapeutically. However, the most recent guidelines of the Association of Medical

TABLE 45.2 Selected Antiviral Drugs: Adverse Effects

Antiviral Drug	Adverse Effects
abacavir	High risk for sensitivity reaction in patients who carry HLA-B*5701 allele
acyclovir	Nausea, vomiting, diarrhea, headache, burning when topically applied
amantadine hydrochloride	Insomnia, nervousness, lightheadedness, anorexia, nausea, anticholinergic effects, orthostatic hypotension, blurred vision
didanosine	Pancreatitis, peripheral neuropathies, seizures
foscarnet sodium (available through Special Access Programme, Health Canada)	Headache, seizures, electrolyte disturbances, acute kidney injury, bone marrow suppression, nausea, vomiting, diarrhea
ganciclovir	Bone marrow toxicity, nausea, vomiting, headache, seizures
indinavir sulphate	Nausea; abdominal, back, or flank pain; headache; diarrhea; vomiting; weakness; taste changes; acid regurgitation; nephrolithiasis
nevirapine	Rash, fever, nausea, headache, elevation in liver enzyme levels
ribavirin	Rash, conjunctivitis, anemia, mild bronchospasm
trifluridine	Ophthalmic effects: burning, swelling, stinging, photophobia, pain
zidovudine	Bone marrow suppression, nausea, headache

TABLE 45.3 Selected Antiviral Drugs: Interactions

Drug	Interacting Drugs	Interaction
Non-HIV Drugs		
acyclovir	Interferon	Additive antiviral effects
	Probenecid	Increased acyclovir levels due to decreasing renal clearance
	Zidovudine	Increased risk for neurotoxicity
amantadine hydrochloride	Anticholinergic drugs	Increased adverse anticholinergic effects
	CNS stimulants	Additive CNS stimulant effects
ganciclovir	Foscarnet	Additive or synergistic effect against CMV and HSV-2
	Imipenem	Increased risk for seizures
	Zidovudine	Increased risk for hematological toxicity (i.e., bone marrow suppression)
ribavirin	Nucleoside reverse transcriptase inhibitors	Increased risk for hepatotoxicity and lactic acidosis
HIV Drugs		
indinavir sulphate	Drugs metabolized by the CYP3A4 hepatic microsomal enzyme system (azole antifungals, clarithromycin, doxycycline, erythromycin, isoniazid, protease inhibitors, quinidine sulphate, statins, and verapamil hydrochloride)	Competition for metabolism resulting in elevated blood levels and potential toxicity
	rifabutin and ketoconazole	Increased plasma concentrations of rifabutin and ketoconazole
	Rifampin	Increased metabolism of indinavir sulphate
nevirapine	Drugs metabolized by the CYP3A4 hepatic microsomal enzyme system (see indinavir sulphate)	Increased metabolism of these drugs
	Oral contraceptives	Decreased plasma concentrations of oral contraceptives
	Protease inhibitors	Decreased plasma concentrations of protease inhibitors
	rifampin and rifabutin	Decreased nevirapine serum concentration
tenofovir disoproxil fumarate	acyclovir, ganciclovir, valacyclovir	May increase serum concentrations of tenofovir disoproxil fumarate
	Protease inhibitors	Increased serum concentrations of tenofovir disoproxil fumarate
maraviroc	CYP3A4 inhibitors (see indinavir sulphate)	May increase maraviroc toxicity
	CYP3A4 inducers (phenytoin, carbamazepine, rifampin)	May decrease effects of maraviroc
	St. John's wort	May decrease effects of maraviroc
raltegravir	atazanavir sulphate (with or without ritonavir)	May increase effects of raltegravir
	rifampin	May decrease effects of raltegravir
zidovudine	acyclovir	Increased neurotoxicity
	interferon beta	Increased serum levels of zidovudine
	Cytotoxic drugs	Increased risk for hematologic toxicity
	didanosine	Additive or synergistic effect against HIV
	ganciclovir and ribavirin	Antagonized antiviral action of zidovudine

CMV, cytomegalovirus; CNS, central nervous system; CYP3A4, cytochrome P450 enzyme 3A4; HIV, human immunodeficiency virus; HSV-2, herpes simplex virus, type 2.

Microbiology and Infectious Disease (AMMI) Canada do not recommend the use of amantadine to prevent or treat influenza. The recommendations on the use of amantadine change yearly, based on the type of influenza that is prevalent. The reader is referred to the AMMI for the latest recommendations. Currently, only immediate release tablet is available in Canada.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Within 48 hr	1–4 hr	17 hr	12–24 hr

acyclovir

Acyclovir (Zovirax) is a synthetic nucleoside analogue that is used mainly to suppress the replication of HSV-1, HSV-2, and VZV. Acyclovir is considered the drug of choice for the treatment of both initial and recurrent episodes of these viral infections.

Acyclovir is available in oral, topical, and injectable formulations. Its topical use is discussed in Chapter 56. Other similar antiviral drugs include valacyclovir hydrochloride and famciclovir. However, these latter two drugs are currently available only for oral use and are indicated for the treatment of less serious infections. Note the slight inconsistencies in the spelling of these drug names. Valacyclovir is a prodrug that is metabolized to acyclovir in the body. It has the advantage of greater oral bioavailability and less frequent dosing (three times daily versus five times daily for acyclovir). It may also provide more effective relief of pain from zoster lesions.

PHARMACOKINETICS (Acyclovir)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1.5–2 hr	1.5–2 hr	2–3 hr	10–15 hr
IV	Variable	1 hr	3 hr	8 hr

ganciclovir hydrochloride

Like acyclovir, ganciclovir hydrochloride (Cytovene®, Valcyte®) is a synthetic nucleoside analogue of guanosine, but with a much different spectrum of antiviral activity. It is indicated for the treatment of infections caused by CMV. CMV is carried by up to 50% of the adult population and normally causes no harm. However, in immunocompromised patients (including premature infants), it can cause life-threatening or disabling opportunistic infections. Valganciclovir hydrochloride (Valcyte), foscarnet (Foscavir®), and cidofovir (Vistide®) are three other antiviral drugs that are used in the treatment of CMV infection. Of these three antiviral drugs, ganciclovir is the one most often used for this purpose. A common site of CMV infections in the immunocompromised patient is the eye, and it can result in CMV retinitis, a devastating viral infection that can lead to blindness. Ganciclovir

is most commonly administered intravenously or orally. It is also administered to prevent CMV disease (generalized infection) in high-risk patients, such as those receiving organ transplants.

The dose-limiting toxicity of ganciclovir treatment is bone marrow suppression, whereas that of foscarnet and cidofovir is kidney toxicity. These toxicities must be kept in mind when deciding which drug is more appropriate in a particular patient. For example, a heart transplant recipient who contracts CMV retinitis is immunocompromised because of immunosuppressant drug therapy and is presumably taking cyclosporine, a nephrotoxic drug. Therefore, using foscarnet in this patient may be more dangerous than using ganciclovir. On the other hand, a patient who contracts a CMV infection and is immunocompromised because of a bone marrow transplant might be better treated using foscarnet.

Valganciclovir, a prodrug of ganciclovir formulated for oral use, is metabolized to ganciclovir in the body. As in the case described previously for valacyclovir hydrochloride and acyclovir, the prodrug provides greater oral bioavailability and allows less frequent daily dosing. Cidofovir and foscarnet are available only in injectable form.

PHARMACOKINETICS (Ganciclovir)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Unknown	24 hr	4.8 hr	Variable

oseltamivir phosphate and zanamivir

Oseltamivir phosphate (Tamiflu®) and zanamivir (Relenza®) belong to one of the newest classes of antiviral drugs known as *neuraminidase inhibitors*. Both drugs are active against influenza virus types A and B. They are indicated for the treatment of uncomplicated acute illness caused by influenza infection in adults. They have been shown to reduce the duration of influenza infection by several days. The neuraminidase enzyme enables budding virions to escape from infected cells and spread throughout the body. Neuraminidase inhibitors are designed to stop this process in the body, speeding recovery from infection.

The most commonly reported adverse events with oseltamivir are nausea and vomiting; those with zanamivir are diarrhea, nausea, and sinusitis. Oseltamivir is available only for oral use. The drug is indicated for both prophylaxis and treatment of influenza infection. Zanamivir is available in blister packets of 5 mg of dry powder for inhalation. It is currently indicated only for treatment of active influenza illness. Treatment with oseltamivir and zanamivir needs to begin within 2 days of symptom onset.

ribavirin

Ribavirin (Virazole®) is a synthetic nucleoside analogue of guanosine, as are many of the other antiviral drugs, but it has a spectrum of antiviral activity that is broader than that of other currently available antiviral drugs. Ribavirin interferes with both RNA and DNA synthesis and as a result inhibits both protein synthesis and viral replication overall.

The inhalational form (Virazole) is used primarily in the treatment of hospitalized infants with severe lower respiratory tract infections caused by respiratory syncytial virus (RSV). This drug was first available only in inhalational form. More recently, oral dosage forms have become available for use in the treatment of hepatitis C; these are discussed in Chapter 54.

HIV INFECTION AND AIDS

The retrovirus family got its name upon discovery of a unique feature of its replication process. Retroviruses are all RNA viruses and are unique in their use of the enzyme **reverse transcriptase** during their replication process. This enzyme promotes the synthesis of complementary (mirror image) DNA molecules from the viral RNA genome. A second enzyme, integrase, promotes the integration of this viral DNA into the host cell DNA. This hybrid DNA complex is known as a *provirus*. It produces new viral RNA genomes and proteins, which in turn combine to make mature HIV virions

Dosages Antiviral Drugs (Non-HIV)

Drug	Usual Dosage Range	Indications
acyclovir (Zovirax)	<i>Children:</i> HSV encephalitis: 10–15 mg/kg/dose q 8hr for 14–21 days <i>Adult (immunocompetent):</i> HSV-1 200–400mg PO 5x/day for 5 days HSV-2 200mg PO 5x/day OR 400mg TID Shingles: 800mg PO 5x/day for 7–10 days	HSV-1 (mucocutaneous herpes) as an outpatient, HSV-2 (genital herpes) as an outpatient, shingles (as outpatient) and HSV encephalitis (children-inpatient)
ganciclovir hydrochloride (Cytovene, Valcyte)	<i>Adults</i> IV: 5 mg/kg q12h × 2–3 wk PO: 900 mg once daily–bid with food	CMV retinitis; CMV prevention
oseltamivir phosphate (Tamiflu)	<i>Children 1–12 yr</i> PO: 30–75 mg bid <i>Adolescents 13 yr or over 40 kg/Adults</i> PO: 75 mg bid × 5 days Prophylaxis dosing for patients with sick contacts: 75 mg daily for 1 week if immunized and 2 weeks if flu vaccine was not received	Influenza A or B
ribavirin (Virazole)	<i>Children</i> Aerosol: 6 g reconstituted to 20 mg/mL via continuous aerosol × 12–18 hr/day × 3–7 days	Severe RSV infection in hospitalized infants and toddlers
zanamivir (Relenza)	<i>Children 7 yr and older/Adults</i> Inhalation*: 10 mg (2 × 5-mg powder doses) bid; first day's doses must be at least 2 hr apart and q12h thereafter × 5 days (may be continued longer if severe) Prophylaxis dosing: 2 inhalations (10 mg) daily for 10–28 days	Influenza A or B
Valacyclovir	<i>Children:</i> 20 mg/kg/dose (max 1 g) tid	1g tid x 5–7 days

*Use bronchodilator inhaler first, if applicable.

HIV, human immunodeficiency virus; HSV-1, HSV-2, herpes simplex virus types 1 and 2; IV, intravenous; PO, oral; RSV, respiratory syncytial virus.

that infect other host cells. Another important enzyme is **protease**, which serves to chemically separate the new viral RNA from viral protein molecules. These components are initially synthesized into one large macromolecular strand, and the protease enzyme carefully breaks up this strand into its key components. [Figure 45.2](#) illustrates the major structural features of the HIV virion, and [Figure 45.3](#) illustrates the steps in its replication process.

Reverse transcriptase is not normally found in host cells; both reverse transcriptase and integrase are carried by the virus. “Reversal” of the usual replication processes led to the name *reverse transcriptase* for this enzyme and also to the name *retrovirus* for this family of viruses. Furthermore, the fact that retroviruses synthesize DNA from viral RNA molecules is also a reversal of the norm because in most other organisms, RNA molecules are synthesized from DNA molecules as part of the reproductive process. Reverse transcriptase has a high rate of errors when stringing together the purine and pyrimidine bases during transcription of the viral RNA genome into a DNA molecule in the replication process. This high rate of errors allows for more frequent genetic mutations among HIV virions and often results in viral strains that are resistant to both medication and the patient’s immune system. Such mutations also hamper the development of an effective vaccine against the virus. Drugs used to treat HIV are called *antiretrovirals*.

The most common routes of transmission of HIV are sexual activity, IV drug use, and perinatal transfer from mother

to child. Sexual intercourse, primarily receptive anal and vaginal intercourse, is the most common means of infection. Probability of transmission risk increases after seroconversion and if the partner is in the advanced disease stage (has a high viral load). According to the most recent data ([World Health Organization, 2019](#)), 37.9 million people worldwide are infected with HIV. Transmission has been most common in homosexual or bisexual men, followed by high-risk heterosexual intercourse and IV drug use. Of the 63 110 Canadians living with HIV, 51.9% are bisexual and other men who have sex with men; 17.4% of people who used injection drugs;

Fig. 45.2 HIV. Within the core capsid, the diploid, single-stranded, positive-sense RNA is complexed to nucleoprotein. *gp*, glycoprotein. From Newman, W. A. (2012). *Dorland's illustrated medical dictionary* (32nd ed.). Philadelphia: Saunders.

Fig. 45.3 Life cycle of the HIV virus. The extracellular envelope protein gp120 binds to CD4 on the surface of T lymphocytes or mononuclear phagocytes, while the transmembrane protein glycoprotein gp41 mediates the fusion of the viral envelope with the cell membrane. *gp*, glycoprotein; *mRNA*, messenger RNA. From Newman, W. A. (2012). *Dorland's illustrated medical dictionary* (32nd ed.). Philadelphia: Saunders.

32.6% are attributed to heterosexual sex; 23% are women; and 9.6% are within the Indigenous population (Canadian AIDS Treatment Information Exchange [CATIE], 2018). Although HIV can be isolated from almost any bodily fluid, including tears, sweat, saliva, and urine, its concentrations in these fluids are much lower than those in blood and genital secretions. In approximately 6% of cases, specific risk factors cannot be determined. The risk of transmission to health care providers from percutaneous (needle-stick) injuries is currently calculated at approximately 0.3%. Performing hand hygiene and maintaining standard precautions/routine practices to avoid contact with all body fluids during patient care dramatically reduce the risk of caregiver infection (see Box 10.1).

The rate of new infections is rising more rapidly in minority populations than in other groups, especially among Black and Indigenous people. Indigenous populations have an incidence rate 2.7 times higher than that for other populations (CATIE, 2018). Patients in developing countries often lack access to adequate drug therapy. Untreated HIV-infected pregnant women transmit the virus to their infants in 15 to 30% of pregnancies. This can occur transplacentally—causing infection in utero—or during birth. When the first antiretroviral drugs were developed in the 1980s, it was feared that they would be too toxic and teratogenic if given to pregnant women. However, prophylactic antiretroviral treatment of infected mothers has been shown to reduce infant infection by at least two thirds and is not normally harmful to either mother or infant. Medication may also be given prophylactically to the newborn infant, typically for the first 6 weeks of life. Infants and children with established HIV infection must usually continue taking medication drugs indefinitely. Breast milk can transmit the virus to the infant in 10 to 20% of cases, and breastfeeding is contraindicated in developed countries. In developing countries, however, breastfeeding may be the only available source of nutrition for the infant.

People living with HIV who seek out regular health care, are currently receiving treatment, and have an ongoing undetectable viral load when samples are obtained do not transmit HIV to their partners (Lee, 2019). In 2016, a statement was released through the Prevention Access Campaign, indicating undetectable = untransmissible (U=U).

HIV infection that is untreated or treatment resistant eventually leads to immune system failure, with death occurring secondary to opportunistic infections. AIDS often progresses over a period of several years. Various health organizations, including the BC Centre for Disease Control and the World Health Organization (WHO), have published classification systems describing the various stages of this infection. The WHO system for adults sorts patients into one of four hierarchical clinical stages, ranging from stage 1 (asymptomatic) to stage 4 (AIDS).

Patients in stage 1 are asymptomatic or have persistent generalized lymphadenopathy (lymphadenopathy of at least two sites outside the inguinal for longer than 6 months). Stage 2 (mildly symptomatic stage) involves continued

Fig. 45.4 Timeline for the spectrum of untreated HIV infection. The timeline represents the course of untreated illness from the time of infection to clinical manifestations of disease. From Lewis, S. L., Dirksen, S. R., Heitkemper, M. M., et al. (2014). *Medical-surgical nursing: Assessment and management of clinical problems* (9th ed.). Philadelphia: Elsevier.

lymphadenopathy along with other symptoms, including fever, rash, night sweats, unexplained weight loss of less than 10% of total body weight, and recurrent respiratory infections (such as sinusitis, bronchitis, otitis media, and pharyngitis), as well as a range of dermatological conditions. Stage 3 (moderately symptomatic stage) involves disease progression with the appearance of additional clinical manifestations, such as weight loss of greater than 10% of total body weight, prolonged (more than 1 month) unexplained diarrhea, and the development of opportunistic infections. Stage 4 (the severely symptomatic stage) includes AIDS-defining illnesses such as *Mycobacterium avium* complex infection and *Pneumocystis jirovecii* pneumonia.

Figure 45.4 illustrates events that roughly correlate with these four stages of HIV infection. This figure shows the hypothetical natural course of the disease through the stages in patients *without* treatment. Patients who are effectively treated with drug therapy usually do not progress through all of these stages, or at least such progression is slowed considerably (by years). In fact, treatment advances in antiretroviral drug therapy mean that HIV is now a chronic, manageable disease. Antiretroviral therapy–driven viral suppression has shown to reduce the incidence of HIV transmission by 96% at the individual and population levels (Montaner, Guillemi, & Harris, 2018). *Antiretroviral therapy* (ART) refers to a combination of at least three antiretroviral drugs that provide maximal suppression of HIV and stop the progression of AIDS. ART is normally started immediately upon confirmation of HIV infection. Opportunistic infections are treated with infection-specific antimicrobial drugs (see corresponding chapters) as they arise. Prophylactic treatment for opportunistic infections is also common and is most frequently given when a patient's CD4⁺ count falls below 200 cells/mm³. Opportunistic malignancies, such as Kaposi's sarcoma and lymphomas, are

also treated with specific antineoplastic medications, which are discussed in Chapters 52 and 53, as well as with radiation and surgery, as indicated.

Research attempts to develop an effective anti-HIV vaccine are also underway throughout the world. Human clinical trials have been conducted since 1990, primarily in research volunteers who are not infected with HIV. However, vaccines are also being studied in patients who are HIV positive. Despite encouraging data regarding potential benefits, the design of an effective HIV vaccine continues to remain elusive.

DRUGS USED TO TREAT HIV INFECTION

Much has happened in medical science since HIV was first identified in the early 1980s. The increasing urgency and public awareness of the AIDS pandemic have stimulated much research in the fields of immunology and pharmacology. This wealth of research has resulted in the development of several increasingly effective antiretroviral drugs, as well as of antiviral drugs in general. Although new drug combinations have prolonged lives, these medications often carry significant toxicities. There are currently five classes of antiretroviral drugs: the reverse transcriptase inhibitors, the protease inhibitors, the fusion inhibitors, and the newest classes—the entry inhibitor–CCR5 co-receptor antagonists and the HIV integrase strand transfer inhibitors. There are currently two subclasses of reverse transcriptase inhibitors: nucleoside reverse transcriptase inhibitors (NRTIs) and the non-nucleoside reverse transcriptase inhibitors (NNRTIs). Drugs from many of these drug classes are combined together into a single drug dosage form for ease of use. Table 45.4 lists these drugs and their respective classes. In 2014, Health Canada approved Truvada® for the prevention of HIV in high-risk patients. HIV drug therapy is rapidly changing. The reader is referred to various websites, including the Canadian AIDS Treatment Information Exchange (CATIE; <https://catie.ca>), for updated information.

Mechanism of Action and Drug Effects

Although HIV/AIDS is a complex illness, the mechanisms of action of the drug classes are straightforward and distinct. The name of each drug class provides a reminder of its role in suppressing the viral replication process. For example, reverse transcriptase inhibitors act by blocking activity of the enzyme reverse transcriptase. Reverse transcriptase promotes the synthesis of new viral DNA molecules from the RNA genome. The protease inhibitors act by inhibiting the protease retroviral enzyme. This enzyme promotes the breakup of chains of protein molecules at designated points, a process necessary for viral replication. There is also one combination protease inhibitor that includes both lopinavir and ritonavir (Kaletra®). Both medications are protease inhibitors. The ritonavir component also serves to inhibit cytochrome P450–mediated enzymatic metabolism of the lopinavir component. There is

TABLE 45.4 Examples of Antiretrovirals Used to Treat HIV

Generic Name	Trade Name
Nucleoside Reverse Transcriptase Inhibitors (NRTI)	
abacavir sulphate	Ziagen®
abacavir sulphate/lamivudine	Kivexa®
didanosine (enteric coated)	Videx EC®
emtricitabine	Emtriva®
lamivudine	3 TC®, Heptovir®
stavudine	Zerit®
tenofovir disoproxil fumarate	Viread®
tenofovir disoproxil fumarate/emtricitabine	Truvada®
zidovudine	Retrovir®
Non-Nucleoside Reverse Transcriptase Inhibitors (NNRTI)	
delavirdine mesylate	Rescriptor®
efavirenz	Sustiva®
etravirine	Intelence®
nevirapine	Viramune®, Viramune XR®
Protease Inhibitors (PI)	
atazanavir sulphate	Reyataz®
darunavir ethanolate	Prezista®
fosamprenavir calcium	Telzir®
indinavir sulphate	Crixivan®
nelfinavir mesylate	Viracept®
ritonavir	Norvir®, Norvir Sec®
saquinavir mesylate	Invirase®
tipranavir	Aptivus®
Fusion Inhibitor (FI)	
enfuvirtide	Fuzeon®
Entry Inhibitor–CCR5 Co-receptor Antagonist (Also Known as CCR5 Antagonist)	
maraviroc	Celsentri®
HIV Integrase Strand Transfer Inhibitor (Also Known as Integrase Inhibitor) (INSTI)	
raltegravir potassium	Isentress®
Multiclass Combination Products	
efavirenz/emtricitabine/tenofovir fumarate	Atripla®
abacavir/dolutegravir/lamivudine	Triumeq®
abacavir/lamivudine/zidovudine	Trizivir®
emtricitabine/rilpivirine	Complera®
hydrochloride/tenofovir disoproxil fumarate

lopinavir/ritonavir	Kaletra®

CCR5, chemokine receptor 5; HIV, human immunodeficiency virus.

currently one fusion inhibitor, enfuvirtide. This compound works by inhibiting viral fusion. This is the process by which an HIV virion attaches to (fuses with) the membrane of a host

TABLE 45.5 Recommendation for Post-Occupational HIV Exposure Prophylaxis

There is a starter kit given for the first 5 days:

Tenofovir DF: one tablet (300 mg) once a day

- Lamivudine: one tablet (150 mg) twice a day

- Raltegravir: one tablet (400 mg) twice a day

Then for the remaining 23 days:

Tenofovir DF/emtricitabine (300/200) once daily plus raltegravir (400mg) twice daily

Reference: British Columbia Centre for Excellence in HIV/AIDS. (2020). Guidance for the use of post-exposure prophylaxis (PEP) for the prevention of HIV in British Columbia. Retrieved from http://cfenet.ubc.ca/sites/default/files/uploads/publications/centredocs/guidance_for_the_use_of_pep-31march2020.pdf

cell (T lymphocyte) before infecting it, in preparation for viral replication. The entry inhibitor–CCR5 co-receptor antagonists, or CCR5 antagonists, work by selectively and reversibly binding to the type 5 chemokine co-receptors located on the CD4 cells that are used by the HIV virion to gain entry to the cells. The integrase strand transfer inhibitors, also referred to as *integrase inhibitors*, work by inhibiting the catalytic activity of the enzyme integrase, thus preventing integration of the proviral gene into human DNA.

Single-drug therapy was most common in the early years of the HIV pandemic, partly because of a lack of treatment options. However, both the development of multiple antiretroviral drugs and the emergence of resistant viral strains have given rise to combination drug therapy as the current standard of care for ART and is the most effective treatment to date. ART usually includes at least three medications. The most commonly recommended drug combinations include two or three NRTIs; two NRTIs plus one or two protease inhibitors; or one NRTI plus one NNRTI, with one or two protease inhibitors. Despite the effectiveness of ART, health care providers may still need to alter a patient's drug regimen in cases of major drug intolerance (see Adverse Effects) or drug resistance. A patient's HIV strain can still evolve and mutate over time, which allows it to become resistant to any drug therapy, especially when that therapy is used for a prolonged period of time. Evidence of drug resistance includes a falling CD4+ count and increased viral load in a patient in whom a given drug regimen previously kept those symptoms under control.

All antiretroviral drugs have similar therapeutic effects in that they reduce the viral load. A viral load of less than 50 copies/mL is considered an undetectable viral load and is a primary goal of ART. HIV-infected patients need to be followed by health care providers with extensive training and specialization in drug therapy for infectious diseases. These health care providers must often make careful choices and changes in drug therapy over time, based on a patient's clinical response and the severity of any drug-related toxicities. When effective, treatment leads to a significant reduction in mortality and incidence

of opportunistic infections, improves patients' physical performance, and significantly increases T-cell counts.

Indications

The only usual indication for all of the current antiretroviral drugs is active HIV infection. Prophylactic therapy is also administered as per agency protocol to individuals such as health care providers (e.g., via needle-stick injuries in hospitals) and high-risk infants with a known potential exposure to HIV (Table 45.5).

Contraindications

Because of the potentially fatal outcome of HIV infection, the only usual contraindication to a medication is known severe drug allergy or other intolerable toxicity. Most of the current antiretroviral drug classes have several alternative drugs to choose from if a patient is especially intolerant of a particular drug.

Adverse Effects

Common adverse effects of selected antiretroviral drugs are listed in Table 45.2. The need to modify drug therapy because of adverse effects is not uncommon. The goal is to find the regimen that will best control infection and that has as tolerable an adverse effect profile as possible. Different patients vary widely in their drug tolerance, and their drug tolerance may change over time. Thus, medication regimens often must be strategically individualized and evolve with the course of the patient's illness.

Approximately 20% of patients infected with HIV in Canada are also infected with hepatitis C virus (HCV), which tends to cause more severe disease in patients with HIV. Hepatitis C is the most important cause of chronic liver disease in Canada and is the most common reason for liver transplantation. Unfortunately, ART is strongly correlated with increased mortality from HCV-induced liver disease because the anti-HIV drugs produce strain on the liver, as these drugs are metabolized via the liver.

A major adverse effect of protease inhibitors is lipid abnormalities, including lipodystrophy, or redistribution of fat stores under the skin. This condition often results in cosmetically undesirable outcomes for the patient, such as a "hump" at the posterior base of the neck and also a skeletonized (bony) appearance of the face. In addition, dyslipidemias such as hypertriglyceridemia can occur, and insulin resistance and type 2 diabetes can result. It is reported that in these cases, switching a patient from a protease inhibitor to an NNRTI may help to reduce such symptoms without reducing antiretroviral efficacy.

The increase in long-term antiretroviral drug therapy because of prolonged disease survival has led to the emergence of another long-term adverse effect associated with these medication—bone demineralization and possible osteoporosis. When this condition occurs, it may require treatment with standard medications for osteoporosis,

such as calcium, vitamin D, and bisphosphonates (see Chapter 35).

Interactions

Common selected drug interactions involving both antiretrovirals and other antivirals are listed in [Table 45.3](#).

Dosages

Because of rapidly changing antiviral drug therapy and the complexity of dosing and the disease state, only selected dosages are listed in this book (refer to the Dosages table on p. 746). Refer to an up-to-date drug information handbook for specifics on dosing.

DRUG PROFILES

enfuvirtide

Enfuvirtide (Fuzeon) is the only medication in one of the newest classes of antiretroviral drugs called *fusion inhibitors*. It acts by suppressing the fusion process whereby a virion is attached to the outer membrane of a host T cell before entry into the cell and subsequent viral replication. This mechanism of action serves as yet another example of how antiretroviral drugs are strategically designed to interfere with specific steps of the viral replication process. The use of combinations of drugs that work by different mechanisms improves a patient's chances for continued survival by reducing the likelihood of viral resistance to the drug therapy regimen. Enfuvirtide is indicated for treatment of HIV infection in combination with other antiretroviral drugs. This drug is not used as a first-line agent but prescribed for patients in treatment who continue to have HIV replication despite ongoing ART. Adults and children have shown comparable tolerance of the drug in clinical trials thus far. Use of this drug in combination with other standard antiretroviral drugs has been associated with markedly reduced viral loads compared with drug regimens that did not include this drug. The drug is currently available only in injectable form.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Subcut	Unknown	4–8 hr	4 hr	Unknown

indinavir sulphate

Indinavir sulphate (Crixivan) belongs to the protease inhibitor class of antiretroviral drugs. Others in this class include ritonavir (Norvir, Norvir Sec), saquinavir mesylate (Invirase), nelfinavir mesylate (Viracept), atazanavir sulphate (Reyataz), fosamprenavir calcium (Telzir), darunavir ethanolate (Prezista), tipranavir (Aptivus), and the combination product lopinavir/ritonavir (Kaletra®). Indinavir can be taken in combination with other anti-HIV therapies or alone. It is best dissolved and absorbed in an acidic gastric environment, and the presence of high-protein and high-fat foods reduces its absorption. Therefore, it is recommended that indinavir be administered in a fasting state.

Indinavir therapy produces increases in CD4+ cell counts and significant reductions in viral load. Protease inhibitors are commonly given in combination with two reverse transcriptase inhibitors to maximize efficacy and decrease the likelihood of viral drug resistance. Indinavir is relatively well tolerated in most patients. Nephrolithiasis (kidney stones) occurs in approximately 4% of patients. Patients who take indinavir are encouraged to drink at least 1.5 L of liquids every day to maintain hydration and help avoid nephrolithiasis. Indinavir and all other protease inhibitors are available only for oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	2 wk to therapeutic effect	0.5–1 hr	1.5–2.5 hr	6 mo

maraviroc

Maraviroc (Celesentri) is the only drug available in a new class of antiretrovirals called *CCR5 antagonists*. Maraviroc works by selectively and reversibly binding to the chemokine co-receptors located on the CD4 cells. It is used in treatment-experienced patients with evidence of viral replication and HIV-1 strains that are resistant to multiple antiretroviral therapies. It is used in combination with other antiretroviral drugs. Hepatotoxicity with allergic-type features has been reported. Drug interactions of significance include interactions with cytochrome P450 3A4 (CYP3A4) inhibitors (azole antifungals, clarithromycin, doxycycline, erythromycin, isoniazid, nefazodone, protease inhibitors, quinidine sulphate, and verapamil hydrochloride), which may increase maraviroc toxicity. CYP3A4 inducers, including phenytoin, carbamazepine, nafcillin, and rifampin, may decrease maraviroc's effects. Maraviroc is available only for oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Unknown	0.5–4 hr	14–18 hr	Unknown

nevirapine

Nevirapine (Viramune) is an NNRTI. This is the second class of antiviral drugs indicated for the treatment of HIV infection. Other currently available NNRTIs include delavirdine mesylate (Rescriptor), efavirenz (Sustiva), and etravirine (Intelence). These drugs are often used in combination with NRTIs.

Nevirapine is well tolerated compared with other therapies for HIV. The most common adverse effects associated with nevirapine therapy are rash, fever, nausea, headache, and abnormal liver function tests. Nevirapine and the other NNRTIs are available only for oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	2 hr	2–4 hr	25–30 hr	24 hr

 raltegravir potassium

Raltegravir potassium (Isentress) is one of two drugs in the new class called *integrase inhibitors*. Dolutegravir sodium (Tivicay®) is also available. Raltegravir works by inhibiting the activity of the integrase enzyme, thus preventing integration of the proviral gene into human DNA. Raltegravir is used in treatment-experienced patients with virus that shows multidrug resistance and active replication. Myopathy and rhabdomyolysis have been reported, as well as an immune reconstitution syndrome, which may result in an inflammatory response to a residual opportunistic infection. Raltegravir does not interact with CYP3A4 inducers or inhibitors (as many other AIDS drugs do).

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Unknown	3 hr	9 hr	Unknown

tenofovir disoproxil fumarate

Tenofovir disoproxil fumarate (Viread) is one of many NRTIs. Others in this class include emtricitabine (Emtriva), lamivudine (Epivir), stavudine (Zerit), and abacavir sulphate (Ziagen), as well as many combination products. Lactic acidosis and severe hepatomegaly have been reported with this drug and others in its class. Tenofovir is indicated for use against HIV infection in combination with other antiretroviral drugs. It is currently available only for oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	4–8 days for therapeutic effect	1 hr	serum (17 hr), intracellular (10–50 hr)	7 days

 zidovudine

Zidovudine (Retrovir), also known as *azidothymidine* or AZT, is a synthetic nucleoside analogue of thymidine that has had an enormous impact on the treatment and quality of life of people infected with HIV who have AIDS. It was the first and, for a long time, the only anti-HIV medication. Zidovudine, along with other antiretroviral drugs, is given to HIV-infected pregnant women and to newborns to prevent maternal transmission of the virus to the infant. The major dose-limiting adverse effect of zidovudine is bone marrow suppression, and this is often the reason a patient with HIV infection must be switched to

another anti-HIV drug such as zalcitabine or didanosine. Some patients may receive a combination of two of these drugs, in lower doses, to maximize their combined actions. This strategy may reduce the likelihood of toxicity. Zidovudine is available in both oral and injectable formulations.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	At least 6 mo for therapeutic effect	0.4–1.5 hr	0.5–3 hr	3–5 hr

OTHER VIRAL ILLNESSES

There are numerous other viral infections; however, five of recent significance are avian influenza, West Nile virus (WNV), severe acute respiratory syndrome (SARS), H1N1, and the novel coronavirus, COVID-19. As of this writing, there is more information to be discovered about COVID-19.

In 2001, the first documented cases of WNV infection occurred in Canada, 2 years after it was identified in New York City. WNV is now endemic in all provinces in Canada and in the United States. WNV is a member of the arbovirus family and is transmitted to humans by mosquitoes. It also infects animals, primarily birds, and has been detected in horses and cows. In humans, WNV infection can lead to meningitis and encephalitis. It is currently being investigated to determine whether maternal–fetal transmission can occur during pregnancy. In the United States in 2001, an epidemic occurred with more than 4 000 documented human cases, including 284 deaths. Patients who had undergone organ transplants constituted one of the key groups infected. The virus can also be transmitted through blood transfusions, including platelets, red blood cells, and fresh frozen plasma, and has been detected in breast milk. There is new evidence that health care providers may develop WNV via needle sticks or cuts.

In June 2003, Health Canada began screening blood donations for WNV using a test developed by Canadian Blood Services. There are currently no specific antiviral medications or vaccines available for prevention or treatment of human WNV infection. Prevention focuses on reducing mosquito reproduction by eliminating unneeded pools of water near residential environments.

November 2002 marked the emergence of a new, serious viral infectious disease known as SARS. A large outbreak later occurred in Singapore in March 2003. This outbreak was eventually traced to a traveller returning from Hong Kong. Cases later appeared in Europe and North America. SARS can range from a mild to a life-threatening respiratory illness. The disease usually resolves on its own within 3 to 4 weeks. However, 10 to 20% of patients required mechanical ventilation and critical care support, and the overall fatality rate was 3%. Although standard antiviral drugs, including

Dosages Antiretroviral Drugs

Drug	Pharmacological Class	Usual Dosage Range
enfuvirtide (Fuzeon)	HIV-1 fusion inhibitor	<i>Children 6–16 yr</i> Subcut: 2 mg/kg bid (max 90 mg/dose) <i>Adults</i> Subcut: 90 mg bid
indinavir sulphate (Crixivan)	Protease inhibitor	<i>Adults</i> PO: 800 mg q8h boosted with ritonavir (100–200 mg bid)
maraviroc (Celsentri)	CCR5 antagonist	<i>Adults older than 18 yr</i> PO: 300 mg bid
nevirapine (Viramune)	Non-nucleoside reverse transcriptase inhibitor	<i>Adults</i> PO: 200 mg daily × 14 days, then bid
raltegravir potassium (Isentress)	Integrase strand transfer inhibitor	<i>Children 2 to younger than 12 yr</i> PO (chewable tab): 50–300 mg bid <i>Adults & children older than 12 yr</i> PO: 400 mg bid; once suppressed, may switch to 1200mg once daily
tenofovir disoproxil fumarate (Viread)	Nucleotide reverse transcriptase inhibitor	<i>Adults & adolescents 12 yr and older</i> PO: 300 mg once daily
zidovudine (Retrovir, AZT)	Nucleotide reverse transcriptase inhibitor	<i>Children 3 mo to 12 yr</i> IV: 120 mg/m ² q6h (max 160 mg/dose) <i>Children 4 kg and above</i> PO: 18–24 mg/kg/day, divided bid–tid <i>Adults and adolescents 30 kg and above</i> PO: 600 mg/day divided bid–tid IV: 1–2 mg/kg q4h <i>Pregnant women</i> PO: 100 mg 5×/day until start of labour, then give IV bolus dose of 2 mg/kg over 1 hr, followed by an IV infusion of 1 mg/kg/hr until the umbilical cord is clamped <i>Newborn</i> PO (oral solution): 2 mg/kg q6h starting within 12 hr of birth until 6 wk

IV, intravenous; PO, oral.

oseltamivir, have been used to treat SARS, no specific drug therapy has proved to be definitively helpful. The cause of SARS was determined to be a coronavirus, which was named the SARS *coronavirus*. Coronaviruses commonly cause mild to moderate upper respiratory tract illnesses in humans, including the common cold.

Avian influenza, or “bird flu,” is an influenza virus infection that has been shown to infect birds in Europe as well as birds and humans in Asia. This disease is caused by an influenza A virus known as *avian influenza A, subtype H5N1*. The virus is carried in the intestines of many wild birds worldwide, often without causing any serious illness. However, more serious infections can be fatal and can spread rapidly among an entire flock of birds. Usually, these viruses do not infect humans. However, since 1997, there have been cases of human infection, mostly following contact with infected birds or their secretions or excrement (e.g., among poultry workers). The majority of these cases have occurred in Europe and Asia. Human-to-human transmission has been especially rare.

Symptoms have ranged from typical flulike symptoms such as fever, cough, sore throat, and muscle aches to eye infections and acute respiratory illness, even with life-threatening complications. This virus is resistant to amantadine, although it is believed (but remains to be confirmed) that zanamivir and oseltamivir would offer some therapeutic benefit for this condition.

Many health experts fear a flu pandemic caused by this virus if it mutates to a more easily transmissible form. This occurs frequently with influenza viruses in general, which is why a new seasonal flu vaccine must be developed each year. Although no one can predict if and when such a pandemic might occur with this virus, the WHO and other health agencies, including the BC Centre for Disease Control and the Public Health Agency of Canada, are continuously monitoring activity patterns as well as the virus's resistance to other antiviral drugs. Some countries have implemented a ban on the import of birds from countries where avian influenza has been shown to be prevalent.

In 2009, the WHO signaled that a pandemic was underway with the new influenza virus H1N1 (originally called *swine flu*). The H1N1 virus spreads person to person, much the same way the regular seasonal influenza virus spreads. Symptoms include fever, cough, sore throat, body aches, chills, and fatigue. Severe illness and death have occurred with H1N1. A vaccine was developed and made available in October 2009. Antiviral medications such as oseltamivir or zanamivir are recommended for all patients with suspected or confirmed influenza requiring hospitalization. Prophylactic treatment is considered for patients at high risk for complications. Other strains of the influenza virus, besides H1N1, have emerged in recent years.

A recent significant viral outbreak is Ebola virus hemorrhagic disease, occurring in West Africa. Ebola was discovered in 1976, and several outbreaks have occurred in African countries since then. The most widespread epidemic of Ebola virus disease began in 2013 in Guinea and persisted for over 2 years. The WHO declared the epidemic over in 2016. Ebola is characterized by flulike symptoms that progress to bleeding, organ failure, and death. It is spread via direct contact with blood or body fluids of an infected animal or human. There have never been any cases of Ebola in Canada, and Canada Border Services Agency assesses everyone arriving in Canada for signs of illness. All individuals from Sierra Leone, Guinea, and Liberia are screened and assessed. Canada was instrumental in developing a vaccine called rVSV-ZEBOV (see Chapter 51) at the Public Health Agency of Canada's National Microbiology Laboratory in Winnipeg.

The WHO declared a pandemic for a novel coronavirus, COVID-19, in March, 2020. More information will follow in subsequent writings of this textbook as evidence-based data become available.

❖ NURSING PROCESS

◆ ASSESSMENT

Before administering an antiviral drug, perform a thorough head-to-toe physical assessment and take a medical and medication history. Document any known allergies. Assess the patient's nutritional status and baseline vital signs because of the profound effects of viral illnesses on physiological status, particularly if the patient is immunocompromised. Assess for any contraindications, cautions, and drug interactions.

When assessing the use of non-HIV antivirals, inquire about the patient's allergy to medications. Ask for a list of any prescription and over-the-counter (OTC) drugs as well as natural health products the patient is taking. Before initiation of therapy, assess energy levels, any weight loss, vital signs, and the characteristics of any visible lesions. Document the findings for baseline comparison. It is also important to assess age because safety and efficacy of amantadine in neonates and infants less than 12 months of age have not been proven. Cidofovir requires assessment of renal function and is contraindicated in those with kidney compromise or with use of other nephrotoxic drugs. Ribavirin is contraindicated

in pregnant women and in their male sexual partners because of its teratogenic properties; it must also not be handled by health care providers who are or might be pregnant. With ribavirin, analysis of respiratory secretions via sputum specimen will most likely be ordered for diagnostic purposes prior to initiation of drug therapy. With respiratory illness, also assess and document breath sounds, respiratory rate and patterns, cough, sputum production, and vital signs, including temperature. With foscarnet and cidofovir, assess kidney function because of the potential for renal toxicity.

Before giving acyclovir, assess vital signs and take a thorough medication history. Assess pain levels associated with the zoster lesions prior to giving the medication because relief of pain is expected with use of the drug. See Chapter 56 for more information on the topical form of acyclovir. Famciclovir also requires assessment of allergies. Oseltamivir and zanamivir, useful against influenza virus types A and B, must be given as ordered within 2 days of the onset of flu symptoms. Ganciclovir is associated with a dose-limiting toxicity of bone marrow suppression; therefore, assess blood counts prior to and during use.

With the use of HIV antivirals, or antiretrovirals, closely assess allergies, cautions, contraindications, and drug interactions. Because of the severity of HIV infections and potential for a fatal outcome, the main contraindication includes severe drug allergy and other toxicities. Use of protease inhibitors requires assessment of the patient's medical history, vital signs, baseline weight, allergies, medication history, and results of baseline laboratory tests, such as complete blood count (CBC) and kidney and liver function studies. These laboratory tests are generally ordered during the different phases of treatment; document the results appropriately. A major adverse effect of the protease inhibitors is lipid abnormalities, with redistribution of fat stores under the skin leading to undesirable cosmetic outcomes for the patient. Assess emotional status and support systems due to the impact of this adverse effect on body image. Bone demineralization is yet another adverse effect with long-term use, so assessment of calcium and vitamin D levels is crucial to patient safety before, during, and after therapy.

The antiretroviral drug maraviroc requires assessment of allergies and liver function as well as review of the list of medications the patient is taking because of many interacting drugs. Raltegravir is associated with myopathies and breakdown of muscle cells; thus, baseline notation of skeletal muscle functioning and pain level is crucial to patient safety. Perform a baseline measurement, and frequently monitor vital signs, including temperature, owing to the possibility of opportunistic infections. The health care provider may also order CBCs and other laboratory studies before, during, and after therapy. Avoid use of tenofovir in patients with liver disorders. Bone marrow suppression is a dose-limiting adverse effect of zidovudine, so review blood cell counts and results of clotting studies before and during therapy.

With any of the drugs presented in this chapter, especially those used for the management of HIV infection, assessment of the patient's knowledge about the illness and the need for

long-term and often lifelong therapy is crucial. In addition, assess the patient's educational level and reading level and the way in which the patient learns best. Familiarity with community resources is important in implementing patient education effectively. Be sure to assess mental health status and emotional state because of the psychological impact and stigma associated with this chronic illness. Referrals to social work, counselling, and support groups may be appropriate. Values systems, social patterns, hobbies, support systems, and spiritual beliefs should also be acknowledged and documented. Perform an assessment of financial status and resources as well. Many patients may need to be referred to social services because of lack of health care coverage and because many of these drugs need to be taken lifelong. For patients with chronic illnesses, the synthesis of this information will help ensure the development of a collaborative plan of care that is complete and holistic.

◆ NURSING DIAGNOSES

- Reduced activity intolerance as a result of weakness secondary to decreased energy from pathology of viral infections
- Ineffective knowledge as a result of lack of information about and experience with long-term medication therapy and lack of information about the viral infection, its transmission, and its treatment
- Risk for injury related to the immunosuppressive effects of viral disease processes and their treatment

◆ PLANNING

◆ Goals

- Patient will experience improved energy and activity level while receiving therapy.
- Patient will demonstrate improved knowledge base about the disease process and the need for potential lifelong therapy.
- Patient will remain free from injury while taking medication for viral disease.

◆ Expected Patient Outcomes

- Patient experiences increased periods of comfort, with greater participation in care and activities of daily living, as a result of successful treatment of viral infection.
 - Patient's energy levels improve to a level greater than what was experienced before antiviral therapy.
- Patient states the rationale for the treatment regimen and the possibility of lifelong therapy with HIV illnesses.
 - Patient understands the need for taking the medication exactly as prescribed.
 - Patient identifies possible adverse effects associated with the HIV antiviral drugs, such as GI upset.
 - Patient identifies financial resources to pay for lifelong medication therapy.
- Patient states the physical impact of a viral infection on the patient's overall state of health (e.g., compromised immune

system) and the effect of appropriate therapy with either non-HIV antivirals or HIV antivirals (antiretrovirals).

- Patient takes appropriate precautions during antiviral therapy, such as avoiding others who are ill and staying away from crowds.

◆ IMPLEMENTATION

Nursing interventions pertinent to patients receiving non-HIV antivirals include use of the appropriate technique when applying or administering ointments, aerosol powders, and IV or oral forms of medication. Wearing gloves and performing thorough hand hygiene before and after the administration of medication are necessary to prevent contamination of the site and spread of infection. It is important to both your safety and the safety of the patient to always begin by performing hand hygiene and maintain standard precautions/routine practices (see Box 10.1). The use of non-HIV antivirals or antiretrovirals may lead to superimposed infection or superinfections, so constantly monitor for such infections and implement measures for their prevention (see Chapters 52 and 53). Instruct the patient to take oral antivirals with meals to help minimize GI upset. Also advise the patient to store capsules at room temperature and not to crush or break the capsules. Acyclovir is available in various dosage forms, and there are slight inconsistencies in the spelling of the drug names, so be sure to double-check the specific drug and dosage form ordered. Topical dosage forms (e.g., acyclovir) should be applied using a finger cot or gloves to prevent autoinoculation. Avoid eye contact with the drug. IV acyclovir is stable for 12 hours at room temperature and will often precipitate when refrigerated. Dilute IV infusions as recommended (e.g., with 5% dextrose in water or normal saline) and infuse with caution. Infusion over longer than 1 hour is suggested to avoid the kidney tubule damage seen with more rapid infusions. Be sure to refer to the manufacturer's guidelines for administration. Encourage adequate hydration during the infusion and for several hours afterward to prevent drug-related crystalluria. Carefully monitor the IV site. Document and report to the health care provider any redness, heat, pain, swelling, or red streaks that may indicate possible phlebitis. Document the characteristics of any lesions. Implement appropriate isolation for individuals with chicken pox or herpes zoster, and give analgesics for comfort, as ordered. Some of the more common adverse effects of acyclovir include nausea, diarrhea, and headache; comfort measures may need to be implemented.

Amantadine and other antivirals need to be taken for the entire course of therapy, and if a dose is missed, instruct the patient to take the dose as soon as it is remembered or to contact the health care provider for further instructions. If dry mouth occurs due to anticholinergic effects, sucking on sugarless candy or chewing gum might be helpful. Encourage daily mouth care, including the use of dental floss, and regular preventive care dental visits. Saliva substitutes may be needed; inform the patient that if dry mouth continues for longer than 2 weeks,

the patient should contact the health care provider for further management.

Orthostatic hypotension may occur, so it is important to monitor vital signs with postural blood pressures during therapy. If ganciclovir sodium is given intravenously, dilute it with 5% dextrose in water or normal saline to a concentration and in a time frame indicated by the drug monograph. Be sure to follow the manufacturer's guidelines for administration. Administration into large veins is recommended, to provide the dilution needed to minimize the risk for vein irritation. When handling the solution of ganciclovir sodium, avoid exposure of eyes, mucous membranes, and skin to the drug, and use latex gloves and safety glasses for handling and preparation. If the drug comes in contact with the eyes, flush with plain water. If it comes in contact with mucous membranes or skin, thoroughly wash and rinse the affected areas with soap and water. Laboratory values including blood counts will most likely be monitored during therapy due to possible bone marrow toxicity. Ribavirin may be given by oral inhalation, but the drug is not to be administered to pregnant women or handled by health care providers who are (or may be) pregnant. Continually monitor for possible altered breath sounds, as wheezing may occur due to mild bronchospasm. Some antivirals are spelled similarly or sound alike; when these drugs are given, always check the order closely against the drug being administered. For example, acyclovir may be mistaken for valacyclovir hydrochloride or famciclovir. When the patient is taking oseltamivir and other non-HIV antivirals for influenza, it is important to remember that this medication must be prescribed and is most effective if started within 2 days of the onset of flu symptoms.

Aerosol generators are available from the drug manufacturer. Discard reservoir solutions if levels are low or empty, and change every 24 hours. For patients taking ribavirin and similar drugs for treatment of RSV via a small particle aerosol generator (SPAG) device, provide clear and precise instructions on how to properly mix and administer the drug. Be sure to reconstitute the drug (e.g., ribavirin powder) as instructed by the manufacturer's guidelines. Discard old solutions left in the equipment before adding fresh medication. Drugs administered using SPAG equipment are usually administered 12 to 18 hours daily for up to 7 days, beginning within 3 days of the onset of symptoms. There is much controversy about use of this drug in patients on ventilators, and it is to be administered only by health care providers who are specially trained in the use of the drug. Frequently empty any "rainout" in the tubing of the ventilator and continually monitor breath sounds in patients receiving inhaled forms of this drug, whether they are receiving artificial ventilation or not. Zanamivir is administered by inhalation using a Diskhaler® device. Be sure that the patient exhales completely first; then, while holding the mouthpiece between the teeth with lips snug around it and tongue down and out of the way, the patient needs to inhale deeply through the mouth and then hold the breath as long as possible prior to exhaling. Zanamivir should not be prescribed to patients with underlying respiratory disease, such as asthma or chronic

obstructive pulmonary disease, as it has been found to cause exacerbations. Encourage rinsing of the mouth with water to prevent irritation and dryness, and instruct the patient never to exhale into the Diskhaler.

HIV antivirals, or antiretrovirals, include numerous drugs. There are special administration and handling guidelines for some of the dosage forms of these drugs. With zidovudine, monitor for the adverse effects of bone marrow suppression by checking the CBC. If the patient experiences signs and symptoms of an opportunistic infection (e.g., respiratory signs and symptoms, fever, changes in oral mucosa), contact the health care provider immediately. The patient may experience headaches; therefore, provide the appropriate form of analgesia, as ordered. See Table 45.2 for a listing of more adverse effects associated with the various antiviral drugs.

With the film-coated oral dosage forms, advise the patient not to alter the drugs in any way. Patients may improve the taste of ritonavir by mixing it with chocolate milk or a nutritional beverage within 1 hour of its dosing. Emphasize to the patient and the patient's family that ritonavir's dosage form needs to be protected from light. Absorption of oral dosages of zidovudine is not impeded by taking the drug with food or milk, but instruct the patient to remain upright or with the head of the bed elevated while administering the medication and for up to 30 minutes afterward to prevent esophageal ulceration. Give IV doses only if the solution is clear and does not contain any particulate matter. Be sure to use the appropriate dosage, diluents, and infusion time. Because these drugs often come in oral dosage forms, it is usually recommended that they be given with food. Generally, administer zidovudine and other antiretrovirals at evenly spaced intervals around the clock, as ordered, to ensure steady-state levels. With all oral and parenteral dosage forms of antiretrovirals, observe the patient for nausea and vomiting as well as any changes in weight, anorexia, or changes in bowel activities and patterns. Maraviroc and tenofovir are available for oral dosing and are to be given as prescribed.

Throughout therapy, always remember that the goal of treatment is to find the regimen that provides the best control of the individual patient's infection with the most tolerable adverse effects possible. Because patients vary greatly in their drug tolerance, carefully individualize medication regimens. Other nursing interventions associated with these drugs include the following:

1. Continually monitor for adverse effects throughout therapy, with a focus on the various organ systems, such as the GI, neurological, renal, and hepatic systems.
2. With oral forms of indinavir and nevirapine, encourage at least 6 to 8 glasses of water (unless contraindicated) daily to maintain adequate hydration and help prevent nephrolithiasis.
3. Nevirapine, zidovudine, and similar drugs may be associated with a rash; however, if the rash is accompanied by blistering, fever, malaise, myalgias, oral lesions, swelling or edema, or conjunctivitis, contact the health care provider immediately.

4. If drug therapy results in worsening of signs and symptoms, notify the health care provider immediately, who may discontinue the drug.
5. Continually monitor laboratory testing (e.g., CBC, kidney and liver function tests, and HIV RNA levels) and report any abnormalities to the health care provider. See the Patient Teaching Tips for more information.

◆ EVALUATION

The therapeutic effects of non-HIV antivirals and HIV antivirals (or antiretrovirals) include elimination of the virus or a decrease in the symptoms of the viral infections. There may be a delayed progression of HIV infection and AIDS as well as a decrease in flulike symptoms and the frequency of herpetic flare-ups and other lesion breakouts. With successful therapy, herpetic lesions will crust over, and the frequency of recurrence will decrease. In addition, constantly evaluate for the occurrence of adverse effects and toxicity associated with specific antiviral and antiretroviral drugs. These specific adverse effects are listed in [Table 45.2](#). Continually re-evaluate the collaborative plan of care to ensure that the goals and outcome criteria have

CASE STUDY

Antiviral Therapy

One of your patients, Suria, a 33-year-old biology professor, has just started therapy with tenofovir/emtricitabine and dolutegravir. She has many questions about this medication therapy, and you are meeting with her to review her questions.

1. She asks you why there are three drugs in this particular therapy. What is your explanation?

2. You are developing a patient teaching guide for Suria, emphasizing any specific cautions and symptoms to report to the health care provider. What instructions will you include?

3. At what level of platelets and white blood cells would there probably be a change or discontinuation of this drug?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

been met. Remain constantly attentive in reviewing reports from the BC Centre for Disease Control, Health Canada, other provincial and territorial health care agencies, and public health care agencies on new strains of viruses and flu syndromes (see earlier discussion).

PATIENT TEACHING TIPS

- Alert the patient to the adverse effect of dizziness while taking antiviral drugs, and instruct the patient to use caution while driving or participating in activities requiring alertness. Advise the patient to take all medications exactly as prescribed and for the full course of therapy.
- Patients should consult the health care provider before taking any other prescribed or OTC drugs or natural health products.
- Inform the patient of all possible drug interactions, including with OTC medications and natural health products.
- Advise patients who are immunocompromised to avoid crowds and persons with infections.
- Advocate for standard precautions/routine practices and safer sex practices for all patients, but especially those with sexually transmitted viral infections, such as patients who are HIV positive. Condom use is a necessity in the prevention of these viral infections and other sexually transmitted infections. The presence of genital herpes requires sexual abstinence.
- It is generally recommended that female patients with genital herpes undergo a Papanicolaou (Pap) smear test every 6 months or as ordered by the health care provider to monitor the virus and effectiveness of treatment.
- Instruct the patient to report the following adverse reactions to the health care provider: decreased urinary output, seizure activity, syncope, jaundice, wheezing, abnormal sensations in the hands and feet, vomiting, or diarrhea.
- Provide the patient with adequate demonstrations, teaching aids, and instructions for special application procedures (e.g., instillation of ophthalmic drops, use of finger cots or gloves when applying medication to lesions, use of respiratory inhalation forms). Explain that gloves or finger cots are needed for medication application and cleansing to prevent the spread of lesions.
- Educate the patient that adherence to their medications is crucial to suppress viral replication and prevent opportunistic infections from occurring.
- Encourage fluids up to 3 000 mL/24 hr unless contraindicated.
- Educate the patient about the fact that antiviral drugs suppress but do not cure the viral infection.
- Instruct the patient to start valacyclovir or other antivirals as prescribed but at the first sign of a recurrent episode of genital herpes or herpes zoster. In addition, explain that early treatment within 24 to 48 hours is needed to achieve full therapeutic results.
- Instruct the patient to report to the health care provider immediately any difficulty breathing; drastic changes in blood pressure; bleeding; new symptoms; worsening of infection, fever, or chills; or other unusual problems.
- Emphasize the importance of follow-up appointments.

KEY POINTS

- Viruses are difficult to kill and to treat because they live inside human cells. Most antiviral drugs act by inhibiting replication of the virus. In this chapter, antiviral drugs are categorized as either non-HIV antivirals or HIV antivirals (antiretrovirals).
- Non-HIV antivirals include amantadine, acyclovir, ganciclovir, oseltamivir, and ribavirin. HIV antivirals include enfuvirtide, indinavir, maraviroc, nevirapine, raltegravir, tenofovir, and zidovudine.
- Administer antiretroviral drugs only after reading and understanding the orders from the health care provider

and after performing a thorough nursing assessment that includes a review of the patient's nutritional status, weight, baseline vital signs, and kidney and liver functioning, as well as an assessment of heart sounds, neurological status, and GI functioning.

- Comfort measures and supportive nursing care are to accompany drug therapy. Patients need to drink plenty of fluids and to space medications around the clock, as ordered, to maintain steady blood levels of the drug.

EXAMINATION REVIEW QUESTIONS

1. The nurse is caring for a client prescribed zidovudine. Which of the following adverse events would the nurse monitor?
 - a. Retinitis
 - b. Deep vein thrombosis
 - c. Kaposi's sarcoma
 - d. Bone marrow suppression
2. After giving an injection to a patient with HIV infection, the nurse accidentally receives a needle stick from a needle disposal box that was too full. Which of the following drugs might be included in recommendations for treating an occupational HIV exposure?
 - a. Didanosine and emtricitabine
 - b. Lamivudine and enfuvirtide
 - c. Tenofovir, lamivudine, and raltegravir
 - d. Acyclovir
3. The nurse is teaching a patient who has been prescribed acyclovir for genital herpes. Which of the following statements by the nurse to the patient would be most accurate?
 - a. "This drug will help the lesions dry and crust over."
 - b. "Acyclovir will eradicate the herpes virus."
 - c. "This drug will prevent the spread of this virus to others."
 - d. "Be sure to give this drug to your partner, too."
4. A patient who has been newly diagnosed with HIV has many questions about the effectiveness of drug therapy. After a teaching session, which statement by the patient reflects a need for more education?
 - a. "I will be monitored for adverse effects and improvements while I'm taking this medicine."
 - b. "These drugs do not eliminate the HIV, but hopefully the amount of virus in my body will be reduced."
 - c. "There is no cure for HIV."
 - d. "These drugs will eventually eliminate the virus in my body."
5. After surgery for organ transplantation, a patient is receiving ganciclovir sodium, even though he does not have a viral infection. Which statement best explains the rationale for this medication therapy?
 - a. Ganciclovir sodium is used to prevent potential exposure to the HIV virus.
 - b. This medication is given prophylactically to prevent influenza A infection.
 - c. Ganciclovir sodium is given to prevent CMV infection.
 - d. The drug works synergistically with antibiotics to prevent superinfections.
6. The nurse is reviewing the use of multidrug therapy for HIV with a patient. Which statements are correct regarding the reason for using multiple drugs to treat HIV? (Select all that apply.)
 - a. The combination of drugs has fewer associated toxicities.
 - b. The use of multiple drugs is more effective against resistant strains of HIV.
 - c. Effective treatment results in reduced T-cell counts.
 - d. The goal of this treatment is to reduce the viral load.
 - e. This type of therapy reduces the incidence of opportunistic infections.
7. The order for an 11-year-old child who has chicken pox reads: "Give acyclovir (Zovirax) 20 mg/kg PO daily $\times$ 5 days. The child weighs 45 kg. How much is each dose? Is this dose safe for this child?"

CRITICAL THINKING ACTIVITIES

1. A 19-year-old male college student was diagnosed with HIV approximately 7 months ago, and he has been going through several treatment regimens. The infectious disease specialist is planning this treatment regimen again and will soon start treatment with didanosine. The student has experienced some bone marrow depression off and on during the last few months. He asks the nurse, "Why is the doctor changing to didanosine therapy? What adverse effects does this new medicine have?" What are the nurse's best answers to his questions?
2. A young adult female patient underwent bone marrow transplantation, and less than 1 year later she contracted a cytomegalovirus (CMV) infection. She is concerned about the medications and asks, "Are these antiviral drugs going to be a problem? What if I get pregnant?" What is the nurse's priority when responding to her questions? Explain your answer.

3. A college student has had symptoms of the flu since Friday, but she does not go to the student health office until the following Tuesday. She tells the nurse that she is “miserable” and that she heard about Tamiflu on the Internet. She wants

to take it to “keep the flu from getting worse.” What is the nurse’s priority action at this time?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Antitubercular Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Identify the various first-line and second-line drugs indicated for the treatment of tuberculosis.
2. Discuss the mechanisms of action, dosages, adverse effects, routes of administration, special dosing considerations, cautions, contraindications, and drug interactions of the antitubercular drugs.
3. Develop a collaborative plan of care that includes all phases of the nursing process for patients receiving antitubercular drugs.
4. Develop a comprehensive teaching guide for patients and families impacted by a diagnosis of tuberculosis or treatment with antitubercular drugs.

KEY TERMS

Aerobic Requiring oxygen for the maintenance of life. (p. 754)

Antitubercular drugs Drugs used to treat infections caused by *Mycobacterium* bacterial species. (p. 754)

Bacillus A rod-shaped bacterium. (p. 754)

Granulomas Small nodular aggregations of inflammatory cells (e.g., macrophages, lymphocytes); usually characterized by clearly delimited boundaries, as found in tuberculosis. (p. 753)

Interferon gamma release assays (IGRAs) Surrogate markers of *Mycobacterium tuberculosis* infection; indicate a cellular immune response to *M. tuberculosis*. (p. 754)

Isoniazid The primary and most commonly prescribed antitubercular drug. (p. 755)

Multidrug-resistant tuberculosis (MDR-TB) Tuberculosis that demonstrates resistance to two or more drugs. (p. 764)

Slow acetylator An individual with a genetic defect that causes a deficiency in the enzyme needed to metabolize isoniazid, the most widely used tuberculosis drug. (p. 758)

Tubercle bacilli Another common name for rod-shaped tuberculosis bacteria; essentially synonymous with *Mycobacterium tuberculosis*. These are small, round, grey translucent granulomatous lesions, usually with a caseated (cheesy) consistency in their interior. (See *granulomas*.) (p. 754)

Tuberculosis (TB) Any infectious disease caused by species of *Mycobacterium*, usually *Mycobacterium tuberculosis* (adjectives: *tuberculous*, *tubercular*). (p. 753)

DRUG PROFILES

ethambutol (ethambutol hydrochloride)*, p. 757

isoniazid, p. 757

pyrazinamide, p. 758

rifabutin, p. 758

rifampin, p. 758

streptomycin (streptomycin sulphate)*, p. 758

Key drug

* Full generic name is given in parentheses. For the purposes of this text, the more common, shortened name is used.

TUBERCULOSIS

Tuberculosis (TB) is the medical diagnosis of any infectious disease caused by a bacterial species known as *Mycobacterium*. TB

is most commonly characterized by **granulomas** in the lungs. They are nodular accumulations of inflammatory cells (e.g., macrophages, lymphocytes) that are delimited (“walled off” with clear boundaries) and have a centre that has a cheesy, or caseated, consistency. (*Casein* is the name of a protein that is prevalent in cheese and milk.) Although there are two mycobacterial species that can cause TB, *Mycobacterium tuberculosis* (*MTB*) and *M. bovis*, infections caused by *M. tuberculosis* are the most common. There are also several other mycobacterial species, including *M. leprae*, which causes leprosy, and *M. avium-intracellulare* complex, which causes a disease that is similar to TB but often has gastrointestinal (GI) symptoms. Both of these latter diseases have varying susceptibility to different drugs used for TB. Infections with these bacteria are much less of a public health problem and hence are not the focus of this chapter.

MTB is an aerobic bacillus, which means that it is a long and slender, rod-shaped microorganism (**bacillus**) that requires a large supply of oxygen for it to grow and flourish (**aerobic**). This bacterium's need for a highly oxygenated body site explains why *Mycobacterium* infections most commonly affect the lungs. Early manifestations are often nonspecific and include a productive cough that lasts longer than 2 weeks and may contain blood, as well as weight loss, chest pain, weakness and fatigue, loss of appetite, fever, night sweating, and chills. Other common sites of infection are the growing ends of bones and the brain (cerebral cortex). Less common sites of infection include the kidney, liver, and genitourinary tract, as well as virtually every other tissue and organ in the body.

These **tubercle bacilli** (a common synonym for MTB) are transmitted from one of three sources: humans, cows (bovine; hence the species name *M. bovis*), or birds (avian), although bovine and avian transmission is much less common than human transmission. Tubercle bacilli are conveyed in droplets expelled by infected people or animals during coughing or sneezing and are then inhaled by the new host. After these infectious droplets are inhaled, the infection spreads to the susceptible organ sites by means of the blood and lymphatic system. MTB is a slow-growing organism, which makes it more difficult to treat than most other bacterial infections. Many of the antibiotics used to treat TB work by inhibiting growth (bacteriostatic) rather than by directly killing the organism. The reason microorganisms that grow slowly are more difficult to kill is because their cells are not as metabolically active as those of faster-growing organisms.

Most bactericidal (cell-killing) drugs work by disrupting critical cellular metabolic processes in organisms. Therefore, the most drug-susceptible organisms are those with faster (not slower) metabolic activity.

The first infectious episode is considered the primary TB infection; reinfection represents the more chronic form of the disease. However, TB does not develop in all people who are exposed to the bacteria. In some cases, the bacteria become dormant and are walled off by calcified or fibrous tissues. Patients with dormant bacteria may test positive for exposure, but are not necessarily infectious. In immunocompromised patients such as those with HIV, TB can inflict devastating and irreversible damage. The prevalence of HIV-TB co-infection is unknown. The steps for diagnosis of TB are listed in [Box 46.1](#).

Canada has one of the lowest rates of active TB cases internationally. This is attributed to intensified public health efforts aimed at preventing, diagnosing, and treating TB as well as HIV infection, including more effective antiretroviral drug therapy (see [Chapter 45](#)). The reported number of new active and retreatment TB cases in 2017 was 1 796 ([Public Agency of Canada, 2019](#)). British Columbia, Manitoba, Saskatchewan, Nunavut, and the Northwest Territories have incidence rates higher than the national rate. Nunavut reports the highest incidence rate overall. The majority of reported TB cases are in foreign-born individuals at 71.8%; however, the incidence rate among Canadian-born Indigenous people remains the highest at 21.6 per 100 000 ([Public Health Agency of Canada, 2019](#)). Indigenous individuals face many health inequities, such as a

BOX 46.1 Diagnosis of Tuberculosis

Step 1: Perform tuberculin skin test (Tubersol®) or **interferon gamma release assay** (IGRA). The tuberculin skin test is assessed for size of induration, positive predictive value, and risk of disease if the person is truly infected. IGRAs are more specific than the tuberculin skin test in populations vaccinated with Bacille Calmette–Guérin (BCG), especially if the BCG is given after infancy or multiple times.

Step 2: If skin test results are positive, then perform chest X-ray.

Step 3: If chest X-ray shows signs of TB, then perform culture of sputum* or stomach secretions.

* The acid-fast bacillus smear test is performed on sputum as a quick method of determining whether TB treatment and precautions are needed until a more definite diagnosis is made.

higher incidence of diabetes and HIV/AIDS, crowded living conditions, and limited access to health care. Of increasing concern internationally is the number of cases of **multidrug-resistant tuberculosis (MDR-TB)**, posing a serious threat to TB prevention and control efforts. However, between 2007 and 2017, reported drug resistance in Canada remained consistently below international levels ([LaFreniere, Hussain, & Vachon, 2018](#)).

TB infects one third of the world's population. It is currently second only to HIV in the diseases with the greatest number of deaths caused by a single infectious organism. According to the World Health Organization (WHO), MDR-TB is defined as TB that is resistant to both isoniazid and rifampin ([WHO, 2018](#)). Close contacts of patients with MDR-TB need to be treated as well, usually with isoniazid for 6 to 9 months. Extensively drug-resistant tuberculosis (XDR-TB) is TB that is resistant to isoniazid, rifampin, and fluoroquinolone and at least one of the three second-line drugs. XDR-TB affects 6.2% of MDR-TB cases. Patients who are diagnosed with XDR-TB can be cured but success is much less than with other forms of TB ([WHO, 2018](#)).

Several factors have contributed to this TB crisis, but one important source of the problem is the increasing number of people who are members of groups that are particularly susceptible to the infection. These groups include people experiencing homelessness, those who are undernourished or malnourished, people infected with HIV, those who misuse drugs, patients with cancer, those taking immunosuppressant drugs, residents of correctional or long-term care facilities, and those who live in crowded housing with poor sanitation. Many factors affecting members of these groups also increase the likelihood that an acquired TB infection will be drug resistant. The majority of TB cases in Canada occur in new Canadians whose TB is reactivated either soon after their arrival in Canada or when they age (possibly because of a weakened immune system associated with the stressors of immigration or aging).

ANTITUBERCULAR DRUGS

The drugs used to treat infections caused by all forms of *Mycobacterium* are called **antitubercular drugs**, and these drugs fall into two categories: primary (first-line) and secondary

BOX 46.2 First-Line and Second-Line Antitubercular Drugs

First-Line Drugs

ethambutol hydrochloride (EMB)
isoniazid (INH)
pyrazinamide (PZA)
rifampin (RMP)

Second-Line Drugs

amikacin sulphate
levofloxacin hemihydrate
moxifloxacin hydrochloride

(second-line) drugs. As these designations imply, primary drugs are those tried first, whereas secondary drugs are reserved for more complicated cases, such as infections resistant to primary drugs. Two effective drugs must be administered at all times. Therapy is given in two phases: the initial intensive and continuation. The initial intensive phase consists of drugs used in combination to achieve rapid destruction of the TB bacilli and rapid improvement in the patient's clinical condition. This phase results in reduced morbidity, mortality, and disease transmission. It lasts about 2 months, with drugs administered 5 days a week. A total of at least three effective drugs are recommended during this phase when bacillary load is high, to prevent drug resistance. All patients in Canada with active TB that is potentially drug resistant should be treated with a regimen of isoniazid, rifampin, pyrazinamide, and ethambutol for the initial 2 months. The second, or continuation, phase consists of the use of two drugs. The time frame for this phase is variable, depending on risk of relapse, the drugs given in the first phase, and drug susceptibility testing. During this phase, drugs may be given daily or intermittently. Intermittent administration is 3 days a week, and this approach is used with directly observed treatment (DOT). DOT is recommended for patients who have risk factors for nonadherence or who are members of population groups with historically high rates of treatment failure or relapse or poor rates of treatment completion. The antimycobacterial activity, efficacy, and potential adverse and toxic effects of the various drugs determine the class to which they belong. **Isoniazid** is a primary antitubercular drug and is the most widely used drug. It can be administered either as the sole drug in the prophylaxis of TB or in combination with other antitubercular drugs in the treatment of TB. The various first-line and second-line antitubercular drugs are listed in [Box 46.2](#). There are also two miscellaneous TB-related injections—one diagnostic, the other a vaccine. These are described in [Box 46.3](#).

Important considerations during drug selection are the likelihood of drug-resistant organisms and drug toxicity. The following are other key elements essential in the planning and implementation of effective therapy:

- Drug susceptibility tests are performed on the first *Mycobacterium* species that is isolated from a patient specimen (to prevent the development of MDR-TB).
- Before the results of the susceptibility tests are known, the patient is started on a four-drug regimen consisting of

BOX 46.3 Miscellaneous TB-Related Injections

Purified protein derivative (PPD): A diagnostic injection given intradermally in doses of 5 tuberculin units (0.1 mL) to detect exposure to the TB organism. It is composed of a protein precipitate derived from TB bacteria. A positive result is actually indicated by induration (not erythema) at the site of injection and is also known as the Mantoux reaction, named for a physician who described it.

Bacillus Calmette–Guérin (BCG): A vaccine injection derived from an inactivated strain of *Mycobacterium bovis*. Although it is not normally administered in Canada because the risk of TB is not as high as elsewhere, it is given in some areas such as Indigenous communities in the Northwest Territories, where TB is endemic. BCG is part of the vaccination schedule for infants in these areas and is also offered to infants in the provinces of Ontario and Saskatchewan in communities where the risk of contracting TB is high. BCG is also used in much of the world to vaccinate young children against TB. Although it does not prevent infection, evidence indicates that it reduces active TB by 60 to 80% and is even more effective at preventing more severe cases involving dissemination of infection throughout the body. This vaccine can cause false-positive results on tuberculin skin tests.

isoniazid, rifampin, pyrazinamide, and ethambutol, which together are 95% effective in combating the infection. The use of multiple medications reduces the possibility of the organism becoming drug resistant. These drugs are given for the first 2 months of treatment.

- Once drug susceptibility results are available, the regimen is adjusted accordingly. For example, if the tests reveal the disease is susceptible to all first-line drugs, then ethambutol can be stopped and pyrazinamide is then continued for the first 2 months. Then, isoniazid and rifampin are continued for the remaining 4 months. Treatment is continued for 9 months if there are risk factors for relapse, such as positive cultures or HIV co-infection.
- Patient adherence to the prescribed drug regimen needs to be monitored closely (e.g., by health units), because the incidence of both patient nonadherence and adverse effects is high.
- Despite the availability of many drugs to combat TB and the efforts mounted to detect and treat those infected with the disease, treatment has been made difficult by two previously mentioned problems: patient nonadherence with therapy and the growing incidence of drug-resistant organisms.

Mechanism of Action and Drug Effects

The mechanisms of action of the various antitubercular drugs vary depending on the drug. These drugs act on MTB by inhibiting protein synthesis, inhibiting cell wall synthesis, or by other mechanisms. The antitubercular drugs are listed in [Table 46.1](#) by their mechanism of action. The major effects of drug therapy include reduction of cough and, therefore, reduction of the infectiousness of the patient. This reduction normally occurs within 2 weeks of the initiation of drug therapy, assuming that the patient's TB strain is drug sensitive.

Indications

Antitubercular medications are indicated for the treatment of TB infections, including both pulmonary and extrapulmonary

TABLE 46.1 Antitubercular Drugs: Mechanisms of Action

Drugs	Description
Inhibit Protein Synthesis	
rifabutin, rifampin, rifapentine, streptomycin	Streptomycin works by interfering with normal protein synthesis and causing the production of faulty proteins. Rifampin acts at a different point in the protein synthesis pathway than that for streptomycin. Rifampin inhibits RNA synthesis and may also inhibit DNA synthesis. Human cells are not as sensitive as mycobacterial cells and are not affected by rifampin except at high drug concentrations.
Inhibit Cell Wall Synthesis	
isoniazid	Isoniazid acts at least partly by inhibiting the synthesis of cell wall components, but the mechanism of this drug is still not clearly understood.
Other Mechanisms	
ethambutol, isoniazid, pyrazinamide	Isoniazid is taken up by mycobacteria cells and undergoes hydrolysis to isonicotinic acid, which reacts with cofactor NAD to form a defective NAD that is no longer active as a coenzyme for certain life-sustaining reactions in the <i>Mycobacterium tuberculosis</i> organism. Ethambutol affects lipid synthesis, which results in the inhibition of mycolic acid incorporation into the cell wall and thus inhibits protein synthesis. The mechanism of action of pyrazinamide in the inhibition of TB is unknown. It can be either bacteriostatic or bactericidal, depending on the susceptibility of the particular <i>Mycobacterium</i> organism and the concentration of the drug attained at the site of infection.

NAD, nicotinamide adenine; TB, tuberculosis.

TB. Most antitubercular drug effects have not been fully tested in pregnant women. However, the combination of isoniazid and ethambutol has been used to treat pregnant women with clinically apparent TB, without teratogenic complications. Rifampin is another drug that is often safe during pregnancy; it is likely to be chosen to treat advanced TB.

Besides being used for the initial treatment of TB, antitubercular drugs have also proved effective in the management of treatment failures and relapses. Infection with species of *Mycobacterium* other than *M. tuberculosis* and atypical mycobacterial infections have also been successfully treated with these drugs. However, in general, antitubercular drugs are not as effective against other species of *Mycobacterium* as they are against MTB. Some of these other species that may be of particular concern in immunocompromised patients are *M. avium-intracellulare*, *M. flavescens*, *M. marinum*, and *M. kansasii*. Additional *Mycobacterium* infections that may respond to antitubercular drugs are those caused by *M. fortuitum*, *M. chelonae*, *M. smegmatis*, *M. xenopi*, and *M. scrofulaceum*. Treatment regimens for these non-TB mycobacterial infections often include the macrolide antibiotics clarithromycin or azithromycin (see Chapter 43), either alone or in combination with one or more antitubercular drugs.

In summary, antitubercular drugs are used primarily for the prophylaxis or treatment of TB. The effectiveness of these drugs depends on the type of infection, adequate dosing, sufficient duration of treatment, adherence to drug regimen, and the selection of an effective drug combination. The indications of the different antitubercular drugs are listed in Table 46.2.

Contraindications

Contraindications to the use of various antitubercular drugs include severe drug allergy and major kidney or liver dysfunction. However, it must be recognized that the urgency of treating a potentially fatal infection may have to be balanced

against any prevailing contraindications. In extreme cases, patients are sometimes given a drug to which they have some degree of allergy, along with supportive care that enables them to at least tolerate the medication. Examples of such supportive care include treatment with antipyretics (e.g., acetaminophen), antihistamines (e.g., diphenhydramine hydrochloride), or even corticosteroids (e.g., prednisone or methylprednisolone).

One relative contraindication to ethambutol is optic neuritis. Chronic alcohol use, especially when associated with major liver damage, may also be a contraindication with any antitubercular drug. Other contraindications for specific drugs, if any, can be found in the drug profiles listed later in the chapter.

Adverse Effects

Antitubercular drugs are fairly well tolerated. Isoniazid, one of the mainstays of treatment, is noted for causing pyridoxine deficiency and liver toxicity. For this reason, supplements of pyridoxine (vitamin B₆; see Chapter 42) are often given concurrently with isoniazid, with a common oral dose being 25 mg daily. The most problematic drugs and their associated adverse effects are listed in Table 46.3.

Interactions

The drugs that can interact with antitubercular drugs can cause significant effects. See Table 46.4 for a listing of selected interactions. Besides these drug interactions, isoniazid can cause false-positive urine readings on urine glucose tests (e.g., Clinitest®) and an increase in the serum levels of the liver function enzymes alanine aminotransferase and aspartate aminotransferase.

Dosages

For the recommended dosages of selected antitubercular drugs, refer to the table on p. 759.

TABLE 46.2 Antitubercular Drugs: Indications

Drug	Indications
amikacin sulphate	Used in combination with other antitubercular drugs in the treatment of clinical TB
ethambutol	First-line drug for treatment of TB
isoniazid	Used alone or in combination with other antitubercular drugs for treatment of pulmonary and extrapulmonary <i>M. tuberculosis</i> infection after failure of first-line drugs
pyrazinamide	Used with other antitubercular drugs in the treatment of clinical TB
rifabutin	Used to prevent or delay development of <i>M. avium-intracellulare</i> bacteremia and disseminated infections in patients with advanced HIV infection
rifampin	Used with other antitubercular drugs in the treatment of clinical TB Used in the treatment of diseases caused by mycobacteria other than <i>M. tuberculosis</i> Used for preventive therapy in patients exposed to isoniazid-resistant <i>M. tuberculosis</i> Used to eliminate meningococci from the nasopharynx of asymptomatic <i>Neisseria meningitidis</i> carriers when the risk of meningococcal meningitis is high Used for chemoprophylaxis in contacts of patients with Hib infection Used in the treatment of endocarditis caused by methicillin-resistant staphylococci, chronic staphylococcal prostatitis, and multiple-anti-infective-resistant pneumococci
streptomycin	Used in combination with other antitubercular drugs in the treatment of clinical TB and other mycobacterial diseases

Hib, *Haemophilus influenzae* type b; HIV, human immunodeficiency virus; TB, tuberculosis.

TABLE 46.3 Antitubercular Drugs: Common Adverse Effects

Drug	Adverse Effects
amikacin sulphate	Ototoxicity, nephrotoxicity
ethambutol	Retrobulbar neuritis, blindness
isoniazid	Peripheral neuropathy, hepatotoxicity, optic neuritis and visual disturbances, hyperglycemia
levofloxacin, moxifloxacin hydrochloride	Dizziness, headache, GI disturbances, visual disturbances, insomnia
pyrazinamide	Hepatotoxicity, hyperuricemia
rifabutin	GI tract disturbances, rash, neutropenia, red–orange–brown discoloration of urine, sweat, tears, sputum
rifampin	Hepatitis; hematological disorders; red–orange–brown discoloration of urine, tears, sweat, sputum
streptomycin	Ototoxicity, nephrotoxicity, blood dyscrasias

TABLE 46.4 Selected Antitubercular Drugs: Drug Interactions

Drug	Interacting Drugs	Mechanism	Results
isoniazid	Antacids	Reduce absorption	Decreased isoniazid levels
	rifampin	Has additive effects	Increased central nervous system effects and hepatotoxicity
	phenytoin, carbamazepine	Decrease metabolism	Increased phenytoin and carbamazepine effects
streptomycin	Nephrotoxic and neurotoxic drugs	Additive effects	Increased toxicity
	Oral anticoagulants	Alter intestinal flora	Increased bleeding tendencies
rifampin	β -Blockers, benzodiazepines, cyclosporine, oral anticoagulants, oral antihyperglycemics, oral contraceptives, phenytoin, quinidine sulphate, sirolimus, theophylline	Increase metabolism	Decreased therapeutic effects of these drugs

DRUG PROFILES

ethambutol hydrochloride

Ethambutol hydrochloride (Etibi®) is a first-line bacteriostatic drug used in the treatment of TB. It works by diffusing into the mycobacteria and suppressing ribonucleic acid (RNA) synthesis, which thereby inhibits protein synthesis. Ethambutol is included with isoniazid, pyrazinamide, and rifampin in many TB combination drug therapies. It may also be used to treat other mycobacterial diseases. It is contraindicated in patients with optic neuritis as it can both exacerbate and cause this condition, which can result in varying degrees of vision loss. Ethambutol is also contraindicated in children younger than 13 years of age. It is available only in oral form.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Variable	2–4 hr	3.5 hr	24 hr

isoniazid

Isoniazid (Isotamine®), abbreviated *INH*, is the mainstay in the treatment of TB and is also the most widely used antitubercular drug. It may be given as a single drug for prophylaxis or in combination with other antitubercular drugs for the treatment of active TB. It is a bactericidal drug that kills the mycobacteria

by disrupting cell-wall synthesis and essential cellular functions. Isoniazid is metabolized in the liver through a process called *acetylation*, which requires a certain enzymatic pathway to break down the drug. However, some people have a genetic deficiency of the liver enzymes needed for this to occur. Such individuals are called **slow acetylators**. When isoniazid is taken by slow acetylators, the drug accumulates because there is not enough of the enzyme to break down the isoniazid. Therefore, the dosages of isoniazid may need to be adjusted downward in these patients.

Isoniazid is used in oral form. There is also a combination oral formulation of isoniazid, pyrazinamide, and rifampin (Rifater®). Isoniazid is contraindicated in those with previous isoniazid-associated liver injury or acute liver disease.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Variable	1–2 hr	1–4 hr	24 hr

pyrazinamide

Pyrazinamide (Tebrazid®) is an antitubercular drug that can be either bacteriostatic or bactericidal, depending on its concentration at the site of infection and the particular susceptibility of the mycobacteria. It is commonly used in combination with other antitubercular drugs for the treatment of TB. Its mechanism of action is unknown, but it is believed to work by inhibiting lipid and nucleic acid synthesis in the mycobacteria. Pyrazinamide is available in oral form. It is contraindicated in patients with severe liver disease or acute gout. In Canada, it is also not normally used in pregnant patients because of a lack of teratogenicity data, although it may be considered when there is resistance to isoniazid, rifampin, or ethambutol.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Variable	2 hr	9–10 hr	24 hr

rifabutin

Rifabutin (Mycobutin®) is the second drug discovered of three currently available rifamycin antibiotics, the others being rifampin and rifapentine. Rifabutin is a derivative of rifamycin. It is commonly used to prevent infections caused by *M. avium* complex, which includes several non-TB mycobacterial species; this is also the case with rifampin. A notable adverse effect of rifabutin is that it can turn urine, feces, saliva, skin, sputum, sweat, and tears a red–orange to red–brown colour. Rifabutin is currently available only for oral use. Rifapentine can be administered once a week because its half-life is five times longer than rifampin. However, its profile of effectiveness is not favourable and it is not recommended for treatment use in Canada. It is available only through Health Canada's Special Access Programme.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Variable	2–4 hr	16–69 hr	1 to several days

rifampin

Rifampin (Rifadin®, Rofact®) is the first drug discovered of the rifamycin class of synthetic macrocyclic antibiotics, which also includes rifabutin and rifapentine. The term *macrocyclic* connotes the large and complex hydrocarbon ring structure included in all the rifamycin compounds. Rifampin is the most potent antitubercular drug available. Its use shortens the length of the drug regimen to 9 months or less (if used in combination with pyrazinamide). Rifampin has activity against many *Mycobacterium* species, as well as against *Meningococcus*, *Haemophilus influenzae* type b, and *M. leprae*. It is a broad-spectrum bactericidal drug that kills the offending organism by inhibiting protein synthesis. Rifampin is available in oral formulations and, as previously mentioned, in combination with isoniazid and pyrazinamide (Rifater®). Rifampin is contraindicated in patients with a known drug allergy to it or to any other rifamycin. The drug is a potent enzyme inducer and is associated with many drug interactions (see Table 46.4). Rifampin may cause urine, saliva, tears, and sweat to be red–orange coloured.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Variable	2–4 hr	3.5 hr	Up to 24 hr

streptomycin sulphate

Streptomycin sulphate is an aminoglycoside antibiotic. Introduced in 1944, it was the first drug that could effectively treat TB. Because of its toxicities and the pain associated with injections, it is used only as second-line therapy. Amikacin sulphate is the preferred injectable drug and is recommended by the Canadian Thoracic Society. Streptomycin is currently available only in injectable form. It is usually not given to pregnant patients because of risk of fetal harm.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IM	Variable	1–2 hr	2–3 hr	Up to 24 hr

NURSING PROCESS

ASSESSMENT

Before administering any of the antitubercular drugs, to ensure the safe and effective use of these drugs, obtain a thorough medical

DOSAGES Selected Antitubercular Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications
ethambutol hydrochloride (Etibi)	Synthetic first-line antimycobacterial antibiotic	<i>Adults and adolescents over 13 yr</i> PO: 15–20 mg/kg/day; may also be divided in 2×/wk (max 2.5 g) and 3×/wk (max 2.5 g) dosage regimens with higher doses	Active TB
 isoniazid (Isotamine)	Synthetic first-line antimycobacterial antibiotic	<i>Children 12 yr and under or less than 35 kg</i> PO: 10–15 mg/kg/day (max 300 mg) or 20–30 mg/kg 3×/wk (max 600–900 mg/dose) <i>Adults</i> PO: 5 mg/kg daily (max 300 mg) or 10 mg/kg ×/wk (max 600 mg/dose)	Active TB
pyrazinamide (Tebrazid)	Synthetic first-line antimycobacterial antibiotic	<i>Children and adults</i> PO: 20–25 mg/kg/day (max 2 g) or 30–40 mg/kg 3×/wk (max 4 g) PO: 35 mg/kg/day (max 2 g) <i>Adults</i> PO: 20–25 mg/kg/day	Active TB
rifabutin (Mycobutin)	Semisynthetic second-line antimycobacterial antibiotic	<i>Adults</i> PO: 300 mg daily or 150 mg bid	Active TB
rifampin (Rifadin, Rofact)	Semisynthetic first-line antimycobacterial antibiotic	<i>Children</i> PO: 15 mg/kg daily (max 600 mg) or 10–20 mg/kg 3×/wk (max 600 mg) <i>Adults</i> PO: 10 mg/kg (max 600 mg) daily or 10 mg/kg 3×/wk (max 600 mg)	Active TB, latent TB in patients with advanced HIV

HIV, human immunodeficiency virus; PO, oral; TB, tuberculosis.

history, medication profile, and nursing history. Perform a complete head-to-toe physical assessment. Note any specific history of diagnoses or symptoms of TB. Determine the results of the patient's last purified protein derivative (PPD), or tuberculin skin test, and the reaction at the site of the intradermal injection. Review the most recent chest X-ray results. Assess the results of liver function studies (e.g., bilirubin level, liver enzyme levels) and kidney function studies (e.g., glomerular filtration rate, blood urea nitrogen [BUN], creatinine clearance). These values provide a comparative baseline throughout therapy. As noted earlier, major liver or kidney dysfunctions are contraindications to antitubercular drug therapy.

Because some drugs may lead to peripheral neuropathies, note baseline neurological functioning prior to therapy. Assess hearing status, especially when streptomycin is to be used, because of its drug-related ototoxicity. A gross eye examination is important because of the drug-induced adverse effects of visual disturbances and optic neuritis with isoniazid and levofloxacin. Blindness may occur with the use of ethambutol.

Assessment of age is also important because the likelihood of adverse reactions and toxicity is increased in older adults due to age-related liver and kidney dysfunction. Additionally, the safety of antitubercular drugs in children 13 years of age or younger has not been established. Assess the patient's complete blood count (CBC) before administering isoniazid, streptomycin, or rifampin because of potential for drug-related hematological disorders.

Kidney studies, such as creatinine clearance and BUN, may be ordered prior to therapy with streptomycin due to the nephrotoxicity associated with its use. Prior to the use of pyrazinamide, document uric acid baseline levels because of the possibility of the drug-induced adverse effect of hyperuricemia and subsequent symptoms of gout. Analysis of sputum specimens is usually ordered as well to aid in determining the appropriate drug regimen. Contraindications, cautions, and drug interactions have been discussed previously.

◆ NURSING DIAGNOSES

- Reduced therapeutic regimen management by patient and family as a result of poor adherence to antitubercular drug therapy and lack of knowledge about long-term therapies
- Inadequate knowledge as a result of the disease process and treatment protocol
- Potential risk for injury as a result of nonadherence to the drug therapy regimen and overall poor health status

◆ PLANNING

◆ Goals

- Patient will experience improved therapeutic regimen management and adherence.

- Patient, patient's family, and others in the home environment will understand the disease process, methods of spread, and the need for the patient to remain on therapy, as prescribed.
- Patient will gain increased knowledge about antitubercular medication therapy and take medication regularly and for the length of time prescribed.
- Patient will remain free from injury related to nonadherence to antitubercular drugs.

◆ Expected Patient Outcomes

- Patient shows improvement of disease state with adherence to the drug regimen, including a decrease in cough, fever, and sputum production; return of laboratory values to normal ranges; and no spread of infection to those in the home or surrounding environments.
 - Patient reports family support and lack of spread of infection to those in the home environment during antitubercular drug therapy.
- Patient states rationale for antitubercular drug therapy as well as anticipated adverse effects.
 - Patient takes medications as ordered and regularly, acknowledging that this will promote effective therapy and prevent complications, relapses, or recurrences.
 - Patient minimizes adverse effects by taking medication as prescribed.
 - Patient reports the following to the prescriber immediately: fever, increase in cough or sputum production, hearing loss, severe numbness or tingling of extremities, or altered vision.

◆ IMPLEMENTATION

Because drug therapy is the mainstay of treatment for TB and often lasts for up to 24 months, patient education is critical, with special emphasis on adherence to the drug regimen. Provide simple, clear, and concise instructions to patients, with appropriate use of audiovisual aids and take-home information. Include in the education the fact that multiple drugs are often used to improve cure rates. Patients need to be able to state an understanding of all instructions. Because many patients affected by TB may be from other countries and cultures, it is important to have interpreter services available.

All antitubercular drugs need to be given exactly as ordered and at the same time every day. Consistent use and dosing around the clock are critical to maintaining steady blood levels and minimizing the chances of resistance to the drug therapy. Emphasize to patients the need for strict adherence to the therapeutic regimen. Additionally, emphasize that the entire prescription must be finished over the prescribed time and as ordered by a health care provider, even if the patient is feeling better.

Although many drugs are given without food for maximum absorption, antitubercular drugs may need to be taken

with food to minimize GI upset. Continuously monitor for any signs and symptoms of liver dysfunction, such as fatigue, jaundice, nausea, vomiting, dark urine, and anorexia; if any of these occur, notify the health care provider immediately. Also monitor kidney functioning (e.g., BUN, creatinine) and notify the health care provider if levels are altered. If vision changes occur (e.g., altered colour perception, changes in visual acuity), in particular with ethambutol use, these changes must be reported immediately to the health care provider. Monitor uric acid levels during therapy, and advise patients to report any symptoms of gout, such as hot, painful, or swollen joints of the big toe, knee, or ankle. In addition, the health care provider must be notified if there are signs and symptoms of peripheral neuropathy (e.g., numbness, burning, or tingling of extremities). Pyridoxine (vitamin B₆) may be beneficial for isoniazid-induced peripheral neuropathy. If the health care provider has ordered collection of sputum to test for acid-fast bacilli, it is best to obtain samples early in the morning. The most common order is for three consecutive morning specimens and a repeat specimen several weeks later. All drugs are to be taken as ordered and without any omission of doses for maximal therapeutic results.

Follow-up visits to the health care provider are important for monitoring therapeutic effects and observing for adverse effects and toxicity. If intravenous (IV) dosing of an antitubercular drug is ordered, use the appropriate diluent and infuse over the recommended time. Monitor the IV site every hour during the infusion for extravasation with possible tissue inflammation (e.g., redness, heat, swelling at the IV site). See the Patient Teaching tips for more information on antitubercular drugs.

Ethnocultural considerations associated with antitubercular drugs include those relating to patient and family education. When patients have active TB, thorough teaching of all family members is required, and some family members may need prophylactic therapy with isoniazid for 9 months. Because some ethnocultural practices include living in tight-knit communities and close living quarters, this teaching is crucial to make sure the spread of this highly communicable disease is adequately prevented. All family members of patients with active TB, and others in close contact with them, must receive the same thorough instructions about maintaining their health and adhering to their medication regimens.

Health care facilities and individual health care workers are responsible for using effective TB infection prevention and control measures. Airborne precautions should be initiated immediately for suspected or confirmed TB. Respirators certified by the US National Institute for Occupational Safety and Health (N95 or higher filter class) are to be used by health care providers who care for or transport patients with suspected or confirmed TB ([Public Health Agency of Canada & Canadian Lung Association/Canadian Thoracic Society, 2014](#)).

◆ EVALUATION

Always document a patient's response, or lack of response, to a therapeutic regimen. A therapeutic response to antitubercular therapy is reflected by a decrease in the symptoms of TB, such as cough and fever, and by weight gain. Along with improved clinical status, the results of laboratory studies (culture and sensitivity tests) and chest X-ray findings will aid in the confirmation of resolution of the infection. Goals and expected outcomes should continue to be monitored to confirm that the infection is being adequately treated and that the drug therapy is providing therapeutic relief without complications or toxicity and with minimal adverse effects. Also monitor patients for the occurrence of adverse reactions to antitubercular drugs, such as hearing loss (related to ototoxicity); nephrotoxicity; seizure activity; altered vision or blindness; extreme GI upset; fatigue; nausea; vomiting; fever; jaundice; numbness, tingling, or burning of extremities; abdominal pain; and easy bruising. Family members or others in close contact with patients with active TB should undergo further evaluation during and after the original patient's completion of therapy.

CASE STUDY

Antitubercular Drugs

Monika, a 59-year-old, runs a farm along with her husband, Richard, who has recently returned home from a trip to India. Recently, she has been experiencing weight loss, night sweats, and a chronic cough. When she is given a purified protein derivative (PPD) test, the result is positive, and a chest X-ray indicates areas of consolidation characteristic of TB. She is hospitalized, and droplet transmission precautions are initiated to prevent the spread to others.

1. What is the next step in diagnosing the disease?

The physician orders that Monika be started on a four-drug regimen consisting of isoniazid, rifampin, pyrazinamide, and ethambutol until the final results of testing are obtained.

2. What is the purpose of the multiple drugs on this order?

3. What needs to be assessed before Monika begins this medication therapy?

Two weeks later, Monika is discharged. In addition to the current drug regimen, she is given instructions to take pyridoxine (vitamin B₆).

4. Monika asks, "Can't I just take my regular multivitamin? Why do I need this one?" What is the nurse's best answer?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

PATIENT TEACHING TIPS

- During initial periods of the illness, instruct patients to make every effort to wash their hands frequently and cover their mouths when coughing or sneezing. Emphasize methods of proper disposal of secretions.
- Educate patients to take medications exactly as ordered by the health care provider, with attention to the need for long-term therapy and strict adherence to the drug regimen. Treatment may be ineffective if drugs are taken intermittently or stopped once the patient begins to feel better.
- Stress to patients the importance of follow-up appointments with the health care provider or health clinic so that the infection and therapeutic effectiveness of the drug regimen may be closely monitored.
- Instruct patients to avoid certain medications while taking antitubercular drugs, such as antacids, phenytoin, carbamazepine, β -blockers, benzodiazepines, oral anticoagulants, oral antihyperglycemic drugs, oral contraceptives, and theophylline. Inform the patient of all drug interactions prior to beginning therapy.
- Pyridoxine (vitamin B₆) may be indicated for patients taking isoniazid to prevent isoniazid-precipitated peripheral neuropathies and numbness, tingling, or burning of extremities.
- Educate patients taking isoniazid about the occurrence of the following adverse effects: numbness or tingling of extremities, abdominal pain, jaundice, and visual changes.
- Advise patients taking rifampin to immediately report to a health care provider the occurrence of any of the following adverse effects: fever, nausea, vomiting, loss of appetite, jaundice, or unusual bleeding. These may indicate the possible occurrence of the adverse effects of hepatitis or various hematological disorders.
- Encourage patients to wear sunscreen and protective clothing during drug therapy to avoid ultraviolet light exposure. Drug-related photosensitivity reactions may be prevented by avoiding exposure to the sun.
- Women taking oral contraceptives who are prescribed rifampin should know that they must switch to another form of birth control. Oral contraceptives become ineffective when given with rifampin.
- Emphasize to patients the importance of proper rest, good sleep habits, adequate nutrition, and maintenance of general health.
- Advise patients to always keep antitubercular drugs and other medications out of the reach of children.
- Recommend that patients wear medical alert jewellery and carry a list at all times of allergies, medications, and medical conditions.
- Instruct patients to contact a health care provider immediately if they experience or observe any increase in fatigue, cough, or sputum production; bloody sputum; chest pain; unusual bleeding; or yellowing of the skin or eyes.
- Patients taking rifampin or rifabutin may experience red-orange-brown discoloration of the skin, sweat, tears, urine, feces, sputum, saliva, and tongue as an adverse effect of the drug. The discoloration reverses with discontinuation of the drug; however, contact lenses may be permanently stained.

KEY POINTS

- All antitubercular drugs are to be taken exactly as prescribed. Emphasize the importance of adherence to the therapeutic regimen and long-term dosing combined with healthy living practices.
- Therapeutic effects of antitubercular drugs include resolution of pulmonary and extrapulmonary MTB infections.
- Vitamin B₆ is needed to combat peripheral neuropathy associated with isoniazid.
- Counsel women taking oral contraceptive therapy who are prescribed rifampin about the need to use other forms of birth control.
- Educate patients about the importance of strict adherence to the drug regimen for improvement or cure of the condition. Provide instructions and education in various formats, including information about drug interactions and the need to avoid alcohol while taking any of the antitubercular medications.

EXAMINATION REVIEW QUESTIONS

- The nurse is teaching a patient who is starting antitubercular therapy with rifampin. Which of the following would be an expected adverse effect?
 - Headache and neck pain
 - Gynecomastia
 - Red–brown urine
 - Numbness or tingling of extremities
- During antitubercular therapy with isoniazid, the patient receives another prescription for pyridoxine hydrochloride. Which statement by the nurse best explains the rationale for this second medication?
 - “This vitamin will help to improve your energy levels.”
 - “This vitamin helps to prevent neurological adverse effects.”
 - “This vitamin works to protect your heart from toxic effects.”
 - “This vitamin helps to reduce GI adverse effects.”
- The nurse is counselling a woman who is beginning antitubercular therapy with rifampin, who also takes an oral contraceptive. Which statement by the nurse is most accurate regarding potential drug interactions?
 - “You will need to switch to another form of birth control while you are taking rifampin.”
 - “Your birth control pills will remain effective while you are taking rifampin.”
 - “You will need to take a stronger dose of birth control pills while you are on rifampin.”
 - “You will need to abstain from sexual intercourse while on rifampin to avoid pregnancy.”
- The nurse is providing education to a patient who has been newly diagnosed with TB. Which of the following data should the nurse provide to the patient about the period for being contagious?
 - During all phases of the illness
 - Any time up to 18 months after therapy
 - During the postictal phase of TB
 - During the initial period of the illness until two consecutive culture specimens are negative
- While monitoring a patient taking antitubercular drugs, the nurse understands that a therapeutic response to medication would be indicated by which improvement in the patient’s condition?
 - The patient states that she is feeling much better.
 - The patient’s laboratory test results show a lower white blood cell count.
 - The patient reports a decrease in cough and night sweats.
 - There is a decrease in symptoms, along with improved chest X-ray and sputum culture results.
- The nurse is monitoring for liver toxicity in a patient who has been receiving long-term isoniazid therapy. Manifestations of liver toxicity include which of the following? (Select all that apply.)
 - Orange discoloration of sweat and tears
 - Darkened urine
 - Dizziness
 - Fatigue
 - Visual disturbances
 - Jaundice
- The order for isoniazid reads: “Give 5 mg/kg PO daily.” The patient weighs 125 kg. What is the amount per dose? Is this a safe dose?

CRITICAL THINKING ACTIVITIES

- The nurse is reviewing medication therapy with a patient who has been newly diagnosed with TB. The patient asks, “How will the doctors know when I’m better? Will I have this disease forever?” What are the priorities when answering the patient’s questions?
 - A 28-year-old health care worker has been diagnosed with active TB. She will be taking rifampin and is reviewing her current list of medications with the office nurse and asks, “I use birth control because we really don’t want children right now. Can I still use ‘the pill’?” What is the priority when answering her questions?
 - Peter, a 48-year-old businessman, has been taking rifampin as part of therapy for TB. He has been told that his bodily secretions will turn a red–orange–brown colour, and he asks, “What about my contact lenses? I can still wear them, right?” What is the nurse’s best answer?
- For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Antifungal Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Identify the various antifungal drugs.
2. Describe the mechanisms of action, indications, contraindications, routes of administration, adverse and
3. Develop a collaborative plan of care that includes all phases of the nursing process for patients receiving antifungal drugs.

KEY TERMS

Antimetabolite A drug that either is a receptor antagonist or resembles a normal human metabolite and interferes with its function in the body, usually by competing for the metabolite's usual receptors or enzymes. (p. 765)

Dermatophytes Several fungi that are often found in soil and infect the skin, nails, or hair of humans. (p. 764)

Ergosterol The main sterol in fungal membranes (See *sterols*, below). (p. 766)

Fungi A large, diverse group of eukaryotic microorganisms that require an external carbon source and that form a plant

structure known as a *thallus*. Fungi consist of yeasts and moulds. (p. 764)

Moulds Multicellular fungi characterized by long, branching filaments called *hyphae*, which entwine to form a complex branched structure known as a *mycelium*. (p. 764)

Mycosis Generally, any fungal infection. (p. 764)

Pathological fungi Fungi that cause mycoses. (p. 764)

Sterols Substances in the cell membranes of fungi to which polyene antifungal drugs bind. (p. 765)

Yeasts Single-celled fungi that reproduce by budding. (p. 764)

DRUG PROFILES

amphotericin B, p. 767

caspofungin (caspofungin acetate)*, p. 768

fluconazole, p. 768

nystatin, p. 768

terbinafine (terbinafine hydrochloride)*, p. 768

voriconazole, p. 768

Key drug

* Full generic name is given in parentheses. For the purposes of this text, the more common, shortened name is used.

FUNGAL INFECTIONS

Fungi comprise a large and diverse group of microorganisms that includes all yeasts and moulds. **Yeasts** are single-celled fungi that reproduce by *budding* (in which a daughter cell forms by pouching out of and breaking off from a mother cell). These organisms have common practical uses in baking breads and preparing alcoholic beverages. **Moulds** are multicellular and are characterized by long, branching filaments. Some fungi are part of the normal flora of the skin, mouth, intestines, and vagina.

An infection caused by a fungus is called a **mycosis**. A variety of fungi can cause clinically significant infections or *mycoses*. These are called **pathological fungi**, and the infections they cause range in severity from infections with annoying

symptoms (e.g., athlete's foot) to systemic mycoses that can become life-threatening. These infections are acquired by various routes—fungi can be ingested orally; they can grow on or in the skin, hair, or nails; and, if the fungal spores are airborne, they can be inhaled. There are four general types of mycotic infections: *systemic*, *cutaneous*, *subcutaneous*, and *superficial*. The latter three are infections of various layers of the *integumentary* system (skin, hair, and nails). Fungi that cause integumentary infections are known as **dermatophytes**, and such infections are known as *dermatomycoses*. The most severe systemic fungal infections generally affect people whose host immune defences are compromised. Commonly, these are patients who have received organ transplants and are taking immunosuppressive drug therapy, cancer patients who are immunocompromised as the result of chemotherapy, patients with autoimmune diseases receiving immunosuppressants, and patients with AIDS. In addition, the use of antibiotics, antineoplastics, or immunosuppressants such as corticosteroids may result in colonization by *Candida albicans*, followed by the development of a systemic infection. When the infection affects the mouth, it is referred to as *oral candidiasis*, or *thrush*. Thrush is common in newborns and patients who are immunocompromised. Vaginal candidiasis, commonly called a *yeast infection*, often affects women who are pregnant, have diabetes, are taking antibiotics, or are taking oral contraceptives. Most yeast infections are not contagious; however, *C. albicans* can be transmitted from mother to child

TABLE 47.1 Mycotic Infections

Mycosis	Fungus	Endemic Location	Reservoir	Transmission	Primary Tissue Affected
Systemic Infection					
Aspergillosis	<i>Aspergillus</i> spp.	Universal	Soil	Inhalation	Lungs
Blastomycosis	<i>Blastomyces dermatitidis</i>	North America	Soil, animal droppings	Inhalation	Lungs
Candidiasis	<i>Candida albicans</i> , <i>glabrata</i> , <i>krusei</i> , <i>tropicalis</i> , <i>parapsilosis</i>	Universal	Humans	Direct contact, overgrowth in response to treatment with antibiotic to which it is nonsusceptible	Blood, lungs
Coccidioidomycosis	<i>Coccidioides immitis</i>	Great Lakes, Canada	Soil, dust	Inhalation	Lungs
Cryptococcosis	<i>Cryptococcus neoformans</i>	Universal	Soil, birds, and chicken	Inhalation	Lungs, meninges of brain
Histoplasmosis	<i>Histoplasma capsulatum</i>	Universal	Soil, birds, and chickens	Inhalation	Lungs
Cutaneous Infection					
Candidiasis	<i>Candida albicans</i>	Universal	Humans	Direct contact, overgrowth in response to treatment with antibiotic to which it is susceptible	Mucous membrane, skin disseminated (may be systemic)
Dermatophytosis, tinea	<i>Epidermophyton</i> spp., <i>Microsporum</i> spp., <i>Trichophyton</i> spp.	Universal	Humans	Direct and indirect contact with infected persons	Scalp, skin (e.g., groin, feet)
Tinea versicolor	<i>Malassezia furfur</i>	Universal	Humans	Unknown*	Skin

Spp, species.

**Malassezia* spp. are a usual part of the normal human flora and appear to cause infection only in select individuals.

during childbirth and occasionally during sexual intercourse. The characteristics of some of the systemic and cutaneous mycotic infections are summarized in Table 47.1.

ANTIFUNGAL DRUGS

Drugs used to treat fungal infections are called *antifungal drugs*. Systemic mycotic infections and some cutaneous or subcutaneous mycoses are treated with oral or parenteral drugs. Antifungals comprise a fairly small group of drugs. There are few such drugs because the fungi that cause these infections have proved to be difficult to kill, and research into new and improved drugs has occurred at a slow pace. One difficulty is that often the chemical concentrations required for experimental drugs to be effective cannot be tolerated by humans. The drugs that have proved successful in the treatment of systemic mycoses as well as severe dermatomycoses include amphotericin B, caspofungin, clotrimazole, fluconazole, itraconazole, ketoconazole, micafungin sodium, miconazole, nystatin, posaconazole, anidulafungin, ravuconazole (in clinical III trials), terbinafine, and voriconazole. These drugs are the focus of this chapter.

Topical antifungal drugs are the most commonly used drugs in this class and are often administered without a prescription for the treatment of dermatomycoses as well as oral and vaginal mycoses. Although topical drug therapy is usually sufficient for these conditions, systemic oral medications are sometimes used, especially for more severe or recurrent cases. Antifungal drugs available for topical use are discussed further in Chapter 56. One antifungal drug, griseofulvin, is individually listed and is not specifically classified according to its chemical structures. The remaining drugs currently include four specific chemical classes: *polyenes* (amphotericin B and nystatin), *imidazoles* (ketoconazole), *triazoles*

(fluconazole, itraconazole, voriconazole, and posaconazole), and the *echinocandins* (caspofungin, micafungin sodium, and anidulafungin). The imidazoles and triazoles are sometimes referred to by the more general term *azole antifungals*. Also included in some of these classes are drugs for topical use.

Mechanism of Action and Drug Effects

The mechanisms of action of the various antifungal drugs differ between drug subclasses. Flucytosine, also known as *5-fluorocytosine* (5-FC), available through the Special Access Programme, Health Canada, acts in much the same way as antiviral drugs. It is an **antimetabolite**, which is a drug that disrupts critical cellular metabolic pathways of the fungal cell. Once inside a susceptible fungal cell, the drug is deaminated by the enzyme cytosine deaminase to 5-fluorouracil (5-FU). Because human cells do not have this enzyme, they are not harmed by this antimetabolite. Once the 5-FU is generated inside the fungal cell, it interferes with fungal deoxyribonucleic acid (DNA) synthesis, which results in the inhibition of cell growth and reproduction and in cell death. 5-FU is also available as an antineoplastic (anticancer) drug and is discussed in more detail in Chapter 52.

Griseofulvin, like flucytosine, is one of the older types of antifungal drugs. It works by preventing susceptible fungi from reproducing. It enters the fungal cell through an energy-dependent transport system and inhibits fungal mitosis (cell division) by binding to key structures known as *microtubules*. It has also been proposed that griseofulvin causes the production of defective DNA, which is then unable to replicate. Although griseofulvin and flucytosine are still currently available in the Canadian market, their clinical use has largely been supplanted by the newer antifungal drug classes.

The polyenes (amphotericin B and nystatin) act by binding to **sterols** in the cell membranes of fungi. The main sterol in fungal

membranes is **ergosterol**. Human cell membranes have cholesterol instead of ergosterol. Because polyene antifungals have a strong chemical affinity for ergosterol instead of cholesterol, they do not bind to human cell membranes and therefore do not kill human cells. Once the polyene drug molecule binds to the ergosterol, a channel forms in the fungal cell membrane that allows potassium and magnesium ions to leak out of the fungal cell. This loss of ions causes fungal cellular metabolism to be altered, which leads to the death of the cell. Imidazoles and triazoles (ketoconazole, fluconazole, itraconazole, voriconazole, and posaconazole) act as either fungistatic or fungicidal drugs, depending on their concentration in the fungus. They are most effective in combatting rapidly growing fungi and work by inhibiting fungal cell cytochrome P450 enzymes. These enzymes are needed to produce ergosterol. The allylamine terbinafine is believed to act by a similar mechanism. When the production of ergosterol is inhibited, other sterols called *methylsterols* are produced instead, which results in a defect similar to that caused by the polyene antifungals, namely a leaky cell membrane that allows needed electrolytes to escape. The fungal cells die because they cannot carry on cellular metabolism. They are referred to as “hole-punchers” because of this mechanism of action.

The echinocandins (caspofungin, anidulafungin sodium, and micafungin) act by preventing the synthesis of *glucans*, essential components of fungal cell walls that are not present in mammalian cells. This also contributes to fungal cell death. Some of the fungi that are susceptible to these drugs are the pathogens involved in the mycoses listed in [Table 47.1](#).

Indications

Indications for the use of the various antifungal drugs are specific to the drugs. The adverse effects of the newer antifungals are fewer and less serious than those of the older drugs. However, the drug of choice for the treatment of many severe systemic fungal infections remains one of the oldest antifungals, amphotericin B, which does have major adverse effects. Amphotericin B is effective against a wide range of fungi and is used to treat aspergillosis, blastomycosis, candidiasis, coccidioidomycosis, cryptococcosis, fungal endocarditis, histoplasmosis, zygomycosis, fungal septicemia, and many other systemic fungal infections. The activity of nystatin is similar to that of amphotericin B, but its usefulness is limited because of its toxic effects when given in the doses required to accomplish the same antifungal actions as amphotericin B. It is also not available in a parenteral form. Nystatin is most commonly used to treat oropharyngeal candidiasis, or thrush and candidal diaper dermatitis.

Fluconazole and itraconazole are synthetic azole antifungals. Fluconazole can pass into the cerebrospinal fluid (CSF) and inhibit the growth of cryptococcal fungi. This makes it effective in the treatment of cryptococcal meningitis. Both fluconazole and itraconazole are active against oropharyngeal and esophageal *Candida* infections. Itraconazole has poor CSF penetration but can be widely distributed throughout other areas of the body. It is indicated for the treatment of fungal infections in immunocompromised and nonimmunocompromised patients with disseminated candidiasis, histoplasmosis, blastomycosis, and aspergillosis. Ketoconazole inhibits many dermatophytes and fungi that cause systemic mycoses, but it is not active against *Aspergillus* organisms or *Phycomycetes* (common moulds) such as *Mucor* species (spp.). Fortunately, the newest triazole

antifungal drug, voriconazole, does have activity against some of these more tenacious fungi, including *Aspergillus* spp. causing invasive infection, *Scedosporium* spp., and *Fusarium* spp.

Of the azole antifungals, fluconazole is the most effective for combating serious infections with *Candida*, *Cryptococcus*, *Blastomyces*, and *Histoplasma* organisms. Fluconazole is also used as prophylaxis to decrease the incidence of candidiasis in patients undergoing bone marrow transplantation who also receive cytotoxic chemotherapy or radiation therapy and all solid organ transplant patients for six months post-transplant.

Griseofulvin inhibits dermatophytes of *Microsporum*, *Trichophyton*, and *Epidermophyton* spp. It has no effect on filamentous fungi such as *Aspergillus*, yeasts such as *Candida* spp., or dimorphic species such as *Histoplasma*. Terbinafine is a synthetic allylamine derivative used in an oral form for treatment of *onychomycoses*, fungal infections of the fingernails or toenails. The imidazole itraconazole is also sometimes used for this purpose. Topical forms of terbinafine are also used for various skin infections (see [Chapter 56](#)). The duration and frequency of topical treatment varies with the indication and is dependent on the severity of the infection.

Contraindications

Drug allergy, liver failure, kidney failure, and porphyria (for griseofulvin) are the most common contraindications for antifungal drugs. Itraconazole should not be used to treat onychomycoses in patients with severe heart problems. Prior treatment with itraconazole may reduce or inhibit the activity of polyenes such as amphotericin B. Voriconazole can cause fetal harm in pregnant women.

Adverse Effects

The major adverse effects caused by antifungal drugs are encountered most commonly in conjunction with amphotericin B treatment. Drug interactions and hepatotoxicity are the primary concerns in patients receiving other antifungal drugs, but the intravenous (IV) administration of amphotericin B is associated with a multitude of adverse effects. The most common and problematic of the adverse effects of the various antifungal drugs are listed in [Table 47.2](#). With amphotericin B treatment in particular, health care providers commonly order various premedications (including antiemetics, antihistamines, antipyretics, and corticosteroids) to prevent or minimize infusion-related reactions. The likelihood of such reactions can also be reduced by using longer-than-average drug infusion times (i.e., 2 to 6 hours) and initiating a pre-infusion administration of 500-1000mL of normal saline to reduce the risk of nephrotoxicity with the use of this particular drug.

Interactions

There are many important drug interactions associated with antifungal drugs, some of which can be life-threatening. A common underlying source of the problem is that many of the antifungal drugs, as well as other drugs, are metabolized by the cytochrome P450 enzyme system. The result of the coadministration of two drugs that are both broken down by this system is that they compete for a limited number of enzymes, and one of the drugs ends up accumulating in the body. Key drug interactions for the systemic antifungal drugs are summarized in [Table 47.3](#).

TABLE 47.2 Selected Antifungal Drugs: Common Adverse Effects and Cautions

Body System	Adverse Effects	Caution
Amphotericin B (Systemic)		
Cardiovascular	Cardiac dysrhythmias	Recheck dosage and type of amphotericin B being administered
Central nervous	Neurotoxicity, tinnitus, visual disturbances, paresthesias, convulsions	
Kidneys	Kidney toxicity, potassium loss, hypomagnesemia	
Pulmonary	Pulmonary infiltrates	
Other (infusion related)	Fever, chills, headache, malaise, nausea, hypotension (occasionally), gastrointestinal upset, anemia	
Caspofungin (Systemic)		
Central nervous	Fever, chills, headache	Adjust dose for patients with liver dysfunction
Cardiovascular	Hypotension, peripheral edema, tachycardia	
Gastrointestinal	Nausea, vomiting, diarrhea, hepatotoxicity	
Hematological	Decreased hemoglobin and hematocrit, leukopenia, anemia	
Integumentary	Rash, facial edema, itching	
Voriconazole (Systemic)		
Central nervous	Hallucinations	
Gastrointestinal	Nausea, vomiting	
Hepatic	Increased liver enzyme levels	
Integumentary	Rash	
Other	Photophobia, hypokalemia	
Fluconazole (Systemic)		
Gastrointestinal	Nausea, vomiting, diarrhea, stomach pain	Use with caution in patients with kidney or liver dysfunction
Other	Increased liver enzymes, dizziness	
Nystatin (Topical)		
Gastrointestinal	Nausea, vomiting, anorexia, diarrhea, cramps	Local irritation may occur
Integumentary	Rash, urticaria	
Terbinafine (Systemic, Topical)		
Central nervous	Headache, dizziness	Rarely causes irritation
Gastrointestinal	Nausea, vomiting, diarrhea	
Integumentary	Rash, pruritus	
Other	Alopecia, fatigue	

TABLE 47.3 Antifungal Drugs: Drug Interactions

Drug	Possible Effects
Amphotericin B	
Digitalis glycosides	Amphotericin B–induced hypokalemia may increase the potential for digitalis toxicity
Nephrotoxic drug	Additive nephrotoxicity
Thiazide diuretics	Severe hypokalemia or decreased adrenal cortex response to corticotropin
Fluconazole, Itraconazole	
cyclosporine, phenytoin, sirolimus	Increased plasma concentrations of both drugs
Oral anticoagulants	Increased effects of anticoagulants
Oral antihyperglycemics	Reduced metabolism of antihyperglycemic drugs
Statins	Reduced metabolism of statins, increased toxicity
Voriconazole	
quinidine sulphate	Prolongation of QT interval on electrocardiogram

Dosages

For the dosage information on selected antifungal drugs, refer to the table on p. 769.

DRUG PROFILES

amphotericin B

Amphotericin B (Fungizone®) remains one of the drugs of choice for the treatment of severe systemic mycoses. The main drawback of amphotericin B therapy is that the drug causes many adverse effects. Almost all patients given the drug intravenously experience infusion syndrome often referred to as the “shake and bake” syndrome including fever, chills, hypotension, tachycardia, malaise, muscle and joint pain, anorexia, nausea and vomiting, and headache. For this reason, pretreatment with antipyretics, antihistamines, antiemetics, and corticosteroids is common to decrease the severity of the infusion-related reaction.

Lipid formulations of amphotericin B were developed in an attempt to decrease the incidence of adverse effects and increase its efficacy;

however, lipid formulations may not achieve optimal concentrations within tissues owing to the lower volume of distribution. There are currently three lipid preparations of amphotericin B: amphotericin B lipid complex (Abelcet®), amphotericin B cholesteryl complex (Fungizone), and liposomal amphotericin B (AmBisome®).

Amphotericin B is contraindicated in patients who have a known hypersensitivity to it and in those with severe bone marrow suppression or kidney impairment. However, patients who have life-threatening fungal infections may still be treated with this drug if cultures indicate that no other drug will kill the infection. The drug is available only in injectable form. Often a 1-mg test dose is given over 20 to 30 minutes to see if the patient will tolerate the drug. It has been used as a local irrigant (in the bladder) for the treatment of candidal cystitis and has been used intrapleurally and intraperitoneally for the treatment of fungal infections in these body cavities.

PHARMACOKINETICS (conventional Amphotericin B)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Variable	1 hr	1–15 days	Variable

caspofungin acetate

Caspofungin acetate (Cancidas®) was the first echinocandin antifungal drug, approved in 2003. It is used for treatment of severe *Aspergillus* infection (invasive aspergillosis) in patients who are intolerant of or have infections refractory to other drugs. Caspofungin doses need to be reduced in patients with impaired liver function. This drug is available only in injectable form. Two additional echinocandins, micafungin sodium (Mycamine®) and anidulafungin (Eraxis®), have since been approved.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	Unknown	1 hr	9–50 hr	Unknown

fluconazole

Fluconazole (Diflucan®) has proved to be a significant improvement in the area of antifungal treatment. It has a much better adverse effect profile than that of amphotericin B, and it also has excellent coverage against many fungi. In fact, it is often preferred to amphotericin B because of these qualities. Since oral fluconazole has excellent bioavailability—which means that almost the entire dose administered is absorbed into the circulation—the daily dose for oral tablets, suspension, and IV administration is the same. Administration of a loading dose on the first day of treatment, consisting of twice the usual daily dose, results in plasma concentrations that are close to a steady state by the second day. Fluconazole is available as over-the-counter medication.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1 hr	1–2 hr	22–30 hr	Variable

nystatin

Nystatin is a polyene antifungal drug that is often applied topically for the treatment of candidal diaper rash, taken orally as prophylaxis against candidal infections during periods of neutropenia in patients receiving immunosuppressive therapy, and used for the treatment of oral and vaginal candidiasis. It is not available in a parenteral form but is available as an oral suspension, topical cream, vaginal cream, and vaginal suppository. It is also available with metronidazole (Flagyl®) in a vaginal ovule or topical cream (Flagystatin®) for the treatment of mixed *Trichomonas vaginalis* and *C. albicans* infections. Nystatin ointments and creams are available over the counter.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	24–72 hr	Unknown	Unknown	Unknown

terbinafine hydrochloride

Terbinafine hydrochloride (Lamisil®) is classified as an allylamine antifungal drug and is currently the only drug in its class. It is available as a topical cream and spray for treating superficial dermatological infections, including *tinea pedis* (athlete's foot), *tinea cruris* (jock itch), and *tinea corporis* (ringworm). A tablet form is also available for systemic use and is used primarily to treat onychomycoses of the fingernails or toenails.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Unknown	1–2 hr	~36 hr	Unknown

voriconazole

Voriconazole (Vfend®) is used for treating severe fungal infections caused by *Aspergillus* spp. (invasive aspergillosis). It is also used for the treatment of systemic *Candida* infections of the skin, abdomen, kidney, bladder wall, and wounds. Therapy must be initiated with the specified loading dose regimen of either IV or oral voriconazole to achieve adequate plasma concentrations on the first day of therapy. Voriconazole is contraindicated in patients with a known drug allergy to it and in patients taking certain other drugs metabolized by the cytochrome P450 enzyme CYP3A4 (e.g., quinidine sulphate) because of the risk for induction of serious cardiac dysrhythmias. It is also the only antifungal drug contraindicated in pregnancy. The drug is available in oral and injectable forms.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Unknown	1–2 hr	Variable	Unknown

DOSAGES Selected Antifungal Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications
amphotericin B (Fungizone)	Polyene antifungal	<i>Adults and children</i> IV: initial daily dose, 0.25 mg/kg; titrate up to 1–1.5 mg/kg/day	Broad spectrum of systemic fungal infections
amphotericin B lipid complex (ABLC); doses vary with product as follows: Abelcet AmBisome Amphotec	Polyene antifungal	<i>Adults and children</i> IV: 5 mg/kg once daily, infused at 2.5 mg/kg/hr IV: 3–6 mg/kg/day, infused over 1–2 hr IV: 3–4 mg/kg/day, infused at 1 mg/kg/hr	Systemic fungal infections
caspofungin (Cancidas)	Echinocandin antifungal	<i>Children</i> 70 mg/m ² (BSA) on day 1 then 50 mg/m ² daily <i>Adults</i> IV: 70 mg loading dose on day 1, followed by 50 mg/day thereafter; infuse doses over 1 hr	Invasive aspergillosis in patients who do not tolerate or respond to other drugs
fluconazole (Diflucan)	Synthetic triazole antifungal	<i>Children</i> IV/PO: 6–12 mg/kg/day 10–12 wk after negative CSF cultures <i>Adults</i> IV/PO: 200–400 mg daily × minimum of 10 wk after negative CSF culture results <i>Children</i> IV/PO: 3–12 mg/kg/dose daily-bid (depending on indication and severity of infection) <i>Adults</i> IV/PO: 100–400 mg/day × 2–5 wk (dose and duration depend on severity of infection)	Cryptococcal meningitis Oropharyngeal and esophageal candidiasis, systemic candidiasis
Nystatin	Polyene antifungal	<i>Infants</i> PO: 100 000 units oral suspension painted into recesses of the mouth <i>Adults and children</i> PO: 400 000–600 000 units oral suspension (for children, dropped on tongue, swished, and swallowed) in oral cavity qid <i>Adults</i> PO (tab): 500 000–1 000 000 units tid Topical (cream, lotion, or powder): apply bid Vaginal: insert one vaginal tablet or applicator of cream once to twice daily × 2 wk	Oral candidiasis, intestinal moniliasis Intestinal candidiasis Topical candidiasis Vaginal candidiasis
terbinafine hydrochloride (Lamisil)	Synthetic allylamine antifungal	<i>Adults</i> PO: 250 mg/day × 6 wk (fingernail); 12 wk (toenail) Topical cream or solution: apply bid to affected area × 1–2 wk	Onychomycosis (fungal infection of finger- or toenails) Athlete's foot (tinea pedis), jock itch (tinea cruris), ringworm (tinea corporis)
voriconazole (Vfend)	Synthetic triazole antifungal	<i>Adults 40 kg and over</i> PO: loading dose of 400 mg × 2 doses q12h, then 200 mg bid maintenance <i>Adults less than 40 kg</i> PO: loading dose of 200 mg × 2 doses q12h, then 100 mg bid maintenance IV: loading dose of 6 mg/kg/mL × 2 doses q12h, then 3–4 mg/kg bid	Invasive aspergillosis; candidemia and other invasive candidiasis

CSF, cerebrospinal fluid; IV, intravenous; PO, oral.

❖ NURSING PROCESS

◆ ASSESSMENT

Although topical dosage methods are discussed in detail in [Chapter 56](#), it is important to discuss here all antifungal dosage forms and related nursing processes. Before initiation of therapy with antifungals, assess and document vital signs, weight, complete blood count (CBC) with differential, liver and kidney function tests, and culture and sensitivity test results.

Before administering amphotericin B (or any other antifungal drug), identify any contraindications, cautions, and drug interactions (see [Tables 47.2 and 47.3](#)). Baseline kidney function studies are generally ordered as well as liver function tests, owing to adverse effects of nephrotoxicity and hepatotoxicity. Avoid any concurrent administration of nephrotoxic drugs if at all possible. There is a risk for severe adverse reactions (e.g., cardiac dysrhythmias, headache, chills, malaise, nausea, hypotension, anemia, gastrointestinal [GI] upset) with IV amphotericin B administration. Perform an assessment of any special premedication orders for the use of antiemetics, antihistamines, antipyretics, and anti-inflammatory drugs prior to giving amphotericin B. Bone marrow suppression is another contraindication to the use of amphotericin B.

Caspofungin requires careful assessment of blood pressure, pulse rate, liver function, red blood cell (RBC) counts, and white blood cell counts because of potential drug-induced adverse effects of hypotension, tachycardia, and hepatotoxicity. Fluconazole requires close assessment of pre-existing GI problems and kidney and liver functioning because of drug-induced adverse effects on these systems. See [Tables 47.2 and 47.3](#) for more information about specific adverse effects and drug interactions for all antifungals.

◆ NURSING DIAGNOSES

- Risk of acute pain as a result of symptoms of the infectious process
- Inadequate knowledge as a result of a lack of information about and experience with antifungal drug therapy
- Potential risk for injury related to adverse effects of the medication regimen

◆ PLANNING

◆ Goals

- Patient will have minimal to no pain after therapy has been initiated.
- Patient will gain increased knowledge about the antifungal drug, its use, and its adverse effects.
- Patient will experience minimal to no injury to self as related to the adverse effects of antifungal therapy.

◆ Expected Patient Outcomes

- Patient is free of pain associated with the fungal infection once therapy is initiated.
 - Patient's fever and discomfort associated with the infection decrease with therapy.

- Patient experiences improved health status, energy, and well-being.
- Patient demonstrates adequate knowledge about medication regimen by following directions about when and how to take the antifungal drug.
- Patient experiences minimal to no adverse effects of drug therapy and reports to the health care provider any nausea, vomiting, or GI upset that becomes unmanageable.
- Patient remains adherent to the medication regimen, not skipping doses while experiencing relief from the infection, and experiences a return to normal vital signs and negative findings on culture and sensitivity tests after the full course of therapy.
- Patient experiences improved appetite, energy level, physical strength, and stamina after taking antifungal drugs for the prescribed period.
- Patient experiences minimal to no injury to self and is able to manage adverse effects or contacts the health care provider if they become problematic.
 - Patient takes medication as prescribed.
 - Patient returns to the health care provider regularly as recommended for monitoring of the infection and of drug therapy with various blood tests (e.g., CBC with differential, RBC count, hemoglobin level, hematocrit, kidney and liver function tests).

◆ IMPLEMENTATION

The nursing interventions appropriate for patients receiving antifungal drugs vary depending on the particular drug. With IV amphotericin B, do not administer solutions that are cloudy or have precipitates. Use of an IV infusion pump is recommended. Once the IV infusion has begun, monitor vital signs every 15 minutes, or as needed, to assess for adverse reactions, such as cardiac dysrhythmias, visual disturbances, paresthesias (numbness or tingling of the hands or feet), respiratory difficulty, pain, fever, chills, and nausea (see [Table 47.2](#) for a list of adverse effects). If a severe reaction occurs (e.g., exacerbation of adverse effects or a decline in vital signs), discontinue the infusion while continuing to closely monitor the patient, and contact the health care provider immediately. Monitor the IV site for signs of phlebitis (e.g., heat, pain, and redness over the vein). Continuously monitor all laboratory values during therapy (see earlier discussion). During long-term or at-home therapy, document weight frequently, as indicated. A gain of 1 kg or more in a 24-hour period or 2.3 kg or more in 1 week may indicate possible medication-induced kidney damage and the need for prompt medical attention. Follow manufacturer guidelines and the health care provider's orders for specific solutions and rates of IV administration. See the Patient Teaching Tips for further information.

Use only clear solutions of caspofungin, and dilute doses with the recommended amounts of normal saline. Liver toxicity may occur, so monitor liver function tests during therapy as ordered. In addition, monitor the patient for the occurrence of tachycardia, hypotension, fever, chills, or headaches. Hemoglobin and hematocrit levels must also be monitored frequently because of the possibility of drug-induced anemias. Fluconazole may be given either orally or

intravenously, with IV dosage forms used if there is a specific indication or if the oral dosage forms are poorly tolerated. Administer IV dosage forms only if the solution is clear, and do not add other medications. If itching or a rash occurs, stop the infusion, take vital signs, and contact the health care provider. Nystatin is given orally as a suspension. For treatment of infections of the oral cavity, the nystatin should be dropped directly on the tongue using the calibrated dropper and held in the mouth for as long as possible and then swallowed. Instruct the patient to swish the medication solution thoroughly in the mouth for as long as possible before swallowing. For treatment of intestinal infections, nystatin may be dropped directly on the tongue by means of the calibrated dropper, or may be mixed with milk or lukewarm formula, honey, jelly, or peanut butter. Terbinafine may be given orally or topically. Local skin reactions that need to be reported include blistering, itching, oozing, redness, and swelling. Oral dosing of voriconazole is given 1 hour before or 1 hour after a meal. IV doses may be diluted with 5% dextrose in water or normal saline, with the accurate dose infused over the recommended time. Monitor visual acuity when this drug is given (especially if ordered for longer than 28 days); any visual changes should be reported to the health care provider.

EVALUATION

The therapeutic effects of antifungals include improvement and eventual resolution of the signs and symptoms of fungal infection, if the patient has remained totally adherent to the therapy regimen. Increase in energy levels and improvement in overall

sense of well-being, accompanied by a normal temperature and other vital sign values, also indicate a therapeutic response. Specific adverse effects for which to monitor in patients receiving antifungals are listed in Table 47.2. Evaluate goals and expected outcomes in the context of the collaborative plan of care.

CASE STUDY

Amphotericin B

Albert, a 63-year-old retired delivery driver, has been hospitalized for pneumonia. Since his admission, he has been diagnosed with a severe systemic fungal infection, and an amphotericin B infusion will be started. Before beginning this medication, the nurse assesses the results of his kidney and liver function laboratory studies, as well as his CBC. The patency

of the IV line is verified, and the nurse gives Albert a dose of oral acetaminophen (Tylenol®) as well as an antihistamine before starting the infusion.

1. What is the purpose of the acetaminophen and antihistamine?
2. The nurse stays with Albert for the first 15 minutes of the infusion and monitors his vital signs. Explain the rationale for these nursing actions.
3. One hour after the infusion is completed, Albert calls the nurse and says that he feels as if he may vomit, and he has chills, yet feels hot at the same time. What does the nurse need to do next?
4. Albert continues to feel “terrible” the rest of the night, and the next morning his health care provider changes the order to liposomal amphotericin B (AmBisome). Why did the health care provider continue an antifungal medication? What is the rationale behind this order change?

For answers see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

PATIENT TEACHING TIPS

- Instruct female patients taking antifungal medications for the treatment of vaginal infections to abstain from sexual intercourse (infection can be spread to the patient's partner via vaginal intercourse) until the treatment is completed and the infection is resolved, and advise patients to continue to take the medication even if actively menstruating. Tell patients to notify a health care provider if symptoms persist after treatment is completed.
- Some patients receiving amphotericin B may need long-term treatment (i.e., over weeks or months). If so, advise patients that possible adverse effects include tinnitus, blurred vision, burning and itching at the infusion site, headache, rash, fever, chills, hypokalemia, GI upset, and various anemias.
- Instruct patients taking caspofungin to immediately report to a health care provider any problems with shortness of breath, itching, facial swelling, or a rash.
- Encourage patients taking antifungals to practice good hand hygiene.
- Instruct patients regarding the proper dosing instructions for nystatin (e.g., for oral solutions, swish and swallow). If vaginal troches (small lozenges that dissolve in the vagina) are prescribed, use the appropriate applicator with a gloved hand and insert high into the vagina, and follow this with thorough hand hygiene (see Chapter 10).
- Yeast infections are common during pregnancy. Topical antifungals can be used for up to 7 days and are considered safe during pregnancy. Educate patients about the importance of using over-the-counter medications only when an infection is present; using these medications when there is no infection may contribute to the development of drug-resistant strains. Educate patients about the classic manifestations of a yeast infection (e.g., itching, burning, white discharge) and possible other sites of yeast infections (e.g., cutaneous candida, perineum, under breast and abdominal skin folds).
- Encourage patients to keep affected body areas clean and dry and to wear light and cool cotton underclothing, in the case of a vaginal infection. Avoid contact of the topical dosage form with the eyes, mouth, nose, or other mucous membranes.
- Voriconazole is to be taken 1 hour before or 1 hour after meals. Warn patients about the adverse effect of photophobia with the use of this drug.

KEY POINTS

- Fungi are a large and diverse group of microorganisms and consist of yeast and moulds. Yeasts are single-celled fungi that may be harmful (e.g., causing infections) or helpful (e.g., aiding in baking or brewing beer). Moulds are multicellular and are characterized by long, branching filaments called *hyphae*.
- Candidiasis is an opportunistic fungal infection caused by *Candida albicans* and occurs in patients taking broad-spectrum antibiotics, antineoplastics, or immunosuppressants, as well as in persons who are immunocompromised. When candidiasis occurs in the mouth, it is commonly termed *oral candidiasis* or *thrush*. Oral candidiasis is more commonly seen in newborns and individuals who are immunocompromised, such as those with HIV/AIDS, than in the general population.
- Vaginal candidiasis is a yeast infection occurring primarily in women who have diabetes, are taking oral contraceptives, or are pregnant.
- Antifungals may be administered either systemically or topically. Some of the most common systemic antifungal drugs are amphotericin B and fluconazole; nystatin is an example of a topical antifungal.
- Before administering antifungals, thoroughly assess for allergies and determine what other drugs the patient is taking, including prescription drugs, over-the-counter drugs, and natural health products.
- Amphotericin B must be properly diluted according to manufacturer guidelines and administered using an IV infusion pump. Tissue extravasation of fluconazole at the IV infusion site leads to tissue necrosis; therefore, check the site hourly and document the assessment.

EXAMINATION REVIEW QUESTIONS

1. The nurse is assessing a patient who is about to receive antifungal drug therapy. Which problem would be most concerning for the nurse?
 - a. Endocrine disease
 - b. Liver disease
 - c. Heart disease
 - d. Pulmonary disease
2. While monitoring a patient who is receiving IV amphotericin B, which of the following would the nurse watch for as a potential expected adverse effect(s)?
 - a. Hypertension
 - b. Bradycardia
 - c. Fever and chills
 - d. Diarrhea and stomach cramps
3. The nurse is caring for a patient who has been prescribed antifungal drug therapy. Which of the following factors contributes to the drug interactions with antifungal therapy?
 - a. History of cardiac disease
 - b. History of gallbladder surgery
 - c. Ethnic background
 - d. Cytochrome P450 enzyme system
4. A patient is receiving an infusion of amphotericin B. Which of the following administration techniques may be used to minimize infusion-related adverse effects?
 - a. Encouraging fluids during the infusion
 - b. Infusing the medication quickly
 - c. Infusing the medication over an extended period of time
 - d. Stopping the infusion for 2 hours after half of the bag has infused and then resuming 1 hour later
5. The nurse is teaching a client about taking nystatin orally for oral candidiasis. Which of the following instructions is most appropriate?
 - a. "Rinse for 5 minutes after meals and then spit out."
 - b. "Rinse for 2 minutes after meals and then swallow."
 - c. "Dissolve the medication in a glass of juice and then swallow."
 - d. "The drug should be swallowed and followed by a glass of water."
6. The nurse is monitoring a patient who has been prescribed capsogun. Which of the following serious adverse effects would give the nurse most concern? (Select all that apply.)
 - a. Blood dyscrasias
 - b. Hypotension
 - c. Pulmonary infiltrates
 - d. Tinnitus
 - e. Hepatotoxicity
7. The order reads, "Give nystatin suspension, 500 000 units by mouth (swish and swallow) 4 times a day for 1 week." The medication is available in a suspension of 100 000 units per mL. How many millilitres will the nurse give per dose?
8. The nurse notes in a patient's medication history that the patient is taking terbinafine (Lamisil). Based on this finding, the nurse interprets that the patient has which disorder?
 - a. Vaginal candidiasis
 - b. Cryptococcal meningitis
 - c. Invasive aspergillosis
 - d. Fungal infection of toenails or fingernails

CRITICAL THINKING ACTIVITIES

1. The nurse is reviewing newly written orders for a patient who has a vaginal yeast infection. One order reads, “Fluconazole, 150 mg, one tablet by mouth now for vaginal yeast infection.” The unit secretary sees the order and asks, “Is that a mistake? How can one pill help that problem?” What is the nurse’s best answer to this question?
 2. A patient has severe respiratory aspergillosis and has not responded to antifungal therapy after 4 days. There is a new order for caspofungin (Cancidas). What is the most important assessment action by the nurse before administering this drug?
 3. When the nurse is administering medications, the patient takes the oral nystatin suspension and says, “I know how to take this.” He then swallows the liquid medication all at once. What is the nurse’s priority action at this time?
- For answers see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Antimalarial, Antiprotozoal, and Anthelmintic Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Briefly discuss the infectious process associated with malaria, other protozoal infections, and helminthic infection processes.
2. Compare the signs and symptoms of malarial, other protozoal, and helminthic infection processes.
3. Identify the more commonly used antimalarial, antiprotozoal, and anthelmintic drugs.
4. Discuss the mechanisms of action, indications, cautions, contraindications, adverse effects, dosages, drug interactions, and routes of administration of the antimalarial, antiprotozoal, and anthelmintic drugs.
5. Develop a collaborative plan of care that includes all phases of the nursing process for patients receiving antimalarial, antiprotozoal, or anthelmintic drugs.

KEY TERMS

Anthelmintic A category of drugs that destroy or prevent the development of parasitic worm (helminthic) infections. Also called *antihelminthic* or *vermicidal*. (Note that the terms for the drug categories are spelled with only one *h*, which appears in the second syllable of the term, whereas the term for worm infection (*helminthic*) is spelled with two *h*'s, appearing in both the first and third syllables of the term.) (p. 781)

Antimalarial drugs Drugs that destroy or prevent the development of the malaria parasite (*Plasmodium* sp.) in humans. Antimalarial drugs are a subset of the broader category of antiprotozoal drugs. (p. 776)

Antiprotozoal A type of drug that destroys or prevents the development of protozoa in humans. (p. 780)

Helminthic infections Parasitic worm infections. (p. 783)

Malaria A widespread protozoal infectious disease caused by four species of the genus *Plasmodium*. (p. 774)

Parasite Any organism that feeds on another living organism (known as a *host*) in a way that results in harm to the host organism. (p. 775)

Parasitic protozoa Harmful protozoa that live on or in human beings or animals and cause disease. (Also called *parasitic protozoans*.) (p. 774)

Protozoa Single-celled organisms that are the smallest and simplest members of the animal kingdom. (p. 774)

DRUG PROFILES

atovaquone, p. 781

chloroquine diphosphate and hydroxychloroquine (hydroxychloroquine sulphate)*, p. 777

mefloquine hydrochloride, p. 778

metronidazole, p. 781

pentamidine isetionate, p. 782

praziquantel, p. 784

primaquine phosphate, p. 778

pyrantel pamoate, p. 784

Key drug

* Full generic name is given in parentheses. For the purposes of this text, the more common, shortened name is used.

termed **parasitic protozoa**. Billions of people worldwide are infected with these organisms, and as a result, these infections are considered a serious health problem. Some of the more common protozoal infections are malaria, leishmaniasis, trypanosomiasis, amoebiasis, giardiasis, and trichomoniasis. They are relatively uncommon in Canada but are becoming increasingly prevalent in immunocompromised individuals, including those with AIDS. Protozoal diseases are particularly prevalent among people living in tropical climates because it is easier for protozoa to survive and be transmitted in environments that are warm and humid year-round. Although the population of Canada is relatively free from many of these protozoal infections, international travel and the immigration of people from other countries where such infections are endemic are providing opportunities for increased exposure of Canadians to protozoal infections.

OVERVIEW

There are more than 28 000 known types of **protozoa**, which are single-celled organisms. Those that live on or in humans are

MALARIA

The most significant protozoal disease in terms of morbidity and mortality is **malaria**. Worldwide, it is estimated that 350

to 500 million people are infected, with an annual death rate of 1 to 2 million people. In Africa alone, malaria accounts for more than 1 million infant deaths per year. The geographic areas with the highest prevalence of malaria are sub-Saharan Africa, Southeast Asia, and Latin America. Approximately 400 to 500 cases of malaria are reported to [Health Canada \(2016\)](#) annually, and these are seen mostly in people who have travelled to malaria-endemic countries. Malaria is caused by a particular genus of protozoa called *Plasmodium*, and there are four species of organisms in this genus, each with its own characteristics and its own ability to resist being killed by antimalarial drugs. These four species are *Plasmodium vivax*, *Plasmodium falciparum*, *Plasmodium malariae*, and *Plasmodium ovale*. Although *P. vivax* is the most widespread of the four species, *P. falciparum* is almost as widespread, causes significant morbidity and mortality, and is more drug resistant. The two remaining species are much less common and more geographically limited in their occurrence, but they can still cause serious malarial infections.

Most commonly, malaria is transmitted by the bite of an infected female *Anopheles* mosquito. This type of mosquito is endemic to many tropical regions of the world. Malaria can also be transmitted via blood transfusions, congenitally from mother to infant via an infected placenta, or through the use of contaminated needles. Despite the combined efforts of many countries to eradicate malaria, it remains one of the most devastating infectious diseases in the world. As is also the case with tuberculosis (see [Chapter 46](#)) and AIDS (see [Chapter 45](#)), many lives are lost to malaria, and the cost of treating and preventing the disease imposes a tremendous economic burden on the often poor countries where the disease is prevalent.

The *Plasmodium* life cycle is quite complex and involves many stages. The organism has two interdependent life cycles: the *sexual cycle*, which takes place inside the mosquito, and the *asexual cycle*, which occurs in the human host ([Figure 48.1](#)). In addition, the asexual cycle of the [parasite](#) consists of a phase outside the

erythrocyte (primarily in liver tissues) called the *exoerythrocytic phase* (or the *liver phase*) and a phase inside the erythrocyte called the *erythrocytic phase* (or the *blood phase*). The malarial parasite undergoes many changes during these two phases ([Figure 48.2](#)).

Malaria signs and symptoms are often described in terms of the classic malaria paroxysm. A *paroxysm* is a sudden recurrence or intensification of symptoms. Symptoms include chills and rigour (violent shivering), followed by fever of up to 40°C and diaphoresis, often leading to extreme fatigue and prolonged sleep. This syndrome often repeats itself periodically in 48- to 72-hour cycles. Other common symptoms include headache, nausea, and joint pain.

ANTIMALARIAL DRUGS

Treatment for malaria is not initiated until the diagnosis has been confirmed by examination of a patient's blood under microscope using a "blood smear" ([Public Health Agency of Canada, 2017](#); [World Health Organization, 2019](#)). If malaria parasites are detected using a stain, diagnosis is confirmed. Once confirmed, appropriate antimalarial treatment must be initiated immediately. Treatment is guided by three main factors: the infecting *Plasmodium* species, the clinical status of the patient, and the drug susceptibility of the infecting parasites as determined by the geographic area where the infection was acquired. Because resistance patterns are constantly changing, depending on geographic location, the reader is referred to the website of the US Centers for Disease Control and Prevention (CDC) for the most up-to-date information.

People travelling to different parts of the world may require antimalarial prophylaxis, and they need to check with their health care provider or a travel clinic for specific drug therapy. The Public Health Agency of Canada's website provides a summary of information, including doses, for the antimalarial drugs routinely used in Canada. The Committee to Advise on Tropical Medicine and Travel (CATMAT), composed of experts, provides travel health-related advice for travellers

Fig. 48.1 An infected anopheles mosquito carries parasites to humans, causing malaria. These parasites mature in the liver before entering the bloodstream and rupturing red blood cells. A pregnant woman infected with malaria may transmit the disease to her unborn fetus.

and health care providers. CATMAT provides recommendations for the prevention and treatment of infectious diseases, strategies to disseminate this information, and priorities for research.

Antimalarial drugs administered to humans cannot affect the parasite during its sexual cycle when it resides in the mosquito. Instead, these drugs act against the parasite during its asexual cycle, which takes place within the human body. Often, antimalarial drugs are given in various combinations to achieve an additive or synergistic antimalarial effect. One example is the combination of the two antiprotozoal drugs atovaquone and proguanil hydrochloride (Malarone®). Malaria management is changing as the prevalence of drug-resistant malaria increases. For example, in Canada, doxycycline may be used to treat cases of drug-resistant malaria (see [Public Health Agency of Canada, 2020](#)).

Mechanism of Action and Drug Effects

The mechanisms of action of the various antimalarial drugs differ depending on the chemical family of drugs to which they belong. The *4-aminoquinoline derivatives* (chloroquine diphosphate and hydroxychloroquine sulphate) act by inhibiting deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) polymerase, enzymes essential to DNA and RNA synthesis by the parasite cells. Parasite protein synthesis is also disrupted, because protein synthesis is dependent on functioning nucleic acids (DNA and RNA). These drugs also raise the pH within the parasite, which interferes with the parasite's ability to metabolize and use erythrocyte hemoglobin; this is one reason these drugs are inadequate during the exoerythrocytic (liver) phase of infection. All of these actions contribute to the destruction of the parasite. Quinine sulphate, quinidine sulphate, and mefloquine are thought to be similar to the 4-aminoquinoline

derivatives in their actions, in that all are believed to raise the pH within the parasite.

The *diaminopyrimidines* (trimethoprim [see [Chapter 43](#)]) act by inhibiting dihydrofolate reductase, an enzyme that is needed for the production of certain vital substances in malarial parasites. Specifically, inhibiting this enzyme blocks the synthesis of tetrahydrofolate, which is a precursor of purines and pyrimidines (nucleic acid components) and certain amino acids (protein components) that are essential for the growth and survival of plasmodia parasites. This drug is effective only during the erythrocytic phase. Trimethoprim is often used with a sulfonamide (sulfadoxine or dapson) because of the resulting synergistic effects exerted by such drug combinations. Tetracyclines such as doxycycline (see [Chapter 43](#)) and lincomycins such as clindamycin hydrochloride (see [Chapter 44](#)) may also be used in combination with some of the other antimalarial drugs because of the synergistic effects resulting from these drug combinations.

Primaquine phosphate, an *8-aminoquinoline* that is structurally similar to the 4-aminoquinolines, has the ability to bind to and alter parasitic DNA. It is one of the few drugs effective in the exoerythrocytic phase. Atovaquone/proguanil also works by interfering with nucleic acid synthesis.

The drug effects of the antimalarial drugs are mostly limited to their ability to kill parasitic organisms, most of which are *Plasmodium* species (spp.). However, some of these drugs have other drug effects and therapeutic uses. Hydroxychloroquine also has anti-inflammatory effects and is sometimes used in the treatment of rheumatoid arthritis and systemic lupus erythematosus. Quinine sulphate and quinidine sulphate can decrease the excitability of both heart and skeletal muscles. Quinidine sulphate is currently used to treat certain types of cardiac dysrhythmias (see [Chapter 26](#)).

Fig. 48.2 Life cycle of the malarial parasite. (From Van Meter, K., & Hubert, R. (2010). *Microbiology for the healthcare professional*. St. Louis, MO: Mosby.)

Indications

Antimalarial drugs are used to kill *Plasmodium* organisms, the parasites that cause malaria. The various antimalarial drugs act during different phases of the parasite's growth inside the human host. The antimalarials that exert the greatest effect on all four *Plasmodium* organisms during the erythrocytic or blood phase are chloroquine phosphate and hydroxychloroquine sulphate. Other drugs known to work during the blood phase are quinine sulphate, quinidine sulphate, and mefloquine hydrochloride. Because these drugs are inadequate during the exoerythrocytic phase, they cannot prevent infection. Health Canada, however, recommends the use of mefloquine hydrochloride for prevention and not as routine treatment for malaria because of the drug's adverse effect profile. The most effective antimalarial drug for eradicating the parasite during the exoerythrocytic phase is primaquine phosphate, which actually works during both asexual phases. Primaquine phosphate is indicated specifically for infection with *P. vivax*. Chloroquine and hydroxychloroquine (4-aminoquinolines) are the drugs of choice for the treatment of susceptible strains of malarial parasites. They are highly toxic to all *Plasmodium* spp., except resistant strains of *P. falciparum*.

Quinine sulphate is indicated for infection with chloroquine diphosphate-resistant *P. falciparum*, which can cause a type of malaria that affects the brain. Quinine sulphate can be used alone but is more commonly given in combination with a second drug such as a tetracycline (e.g., doxycycline hyclate). Other antimalarial drugs are generally preferred for the treatment of active disease. Mefloquine hydrochloride is a newer antimalarial drug that may be used for both prophylaxis and treatment of malaria caused by *P. falciparum* or *P. vivax*. The drug combination atovaquone/proguanil (Malarone) is also used for the prevention and treatment of *P. falciparum* infection.

Contraindications

Contraindications to various antimalarial drugs include drug allergy, tinnitus, and pregnancy (for quinine sulphate, and doxycycline hyclate). Severe kidney, liver, or hematological dysfunction may also be a contraindication to the use of antimalarial drugs. Other drug-specific contraindications are noted in the drug profiles below.

Adverse Effects

Antimalarial drugs cause diverse adverse effects, and these are listed for each drug in Table 48.1.

Interactions

Some common drug interactions associated with antimalarial drugs are listed in Table 48.2.

Dosages

For the recommended dosages for selected antimalarial drugs, refer to the table on p. 778.

DRUG PROFILES

chloroquine diphosphate and hydroxychloroquine sulphate

Chloroquine diphosphate is a synthetic antimalarial drug that is chemically classified as a 4-aminoquinoline derivative.

TABLE 48.1 Antimalarial Drugs: Common Adverse Effects

Body System	Adverse Effects
Chloroquine Diphosphate and Hydroxychloroquine Sulphate	
Gastrointestinal	Diarrhea, anorexia, nausea, vomiting
Central nervous	Dizziness, headache, seizure, personality changes
Other	Alopecia, rash, pruritis
Mefloquine Hydrochloride	
Central nervous	Headache, fatigue, tinnitus
Gastrointestinal	Stomach pain, anorexia, nausea, vomiting
Other	Fever, chills, rash, myalgia
Primaquine Phosphate	
Gastrointestinal	Nausea, vomiting, abdominal distress
Other	Headaches, pruritus, dark discoloration of urine, hemolytic anemia due to G6PD deficiency
Quinine Sulphate	
Central nervous	Visual disturbances, dizziness, headaches, tinnitus
Gastrointestinal	Diarrhea, nausea, vomiting, abdominal pain
Other	Rash, pruritus, hives, photosensitivity respiratory difficulties

G6PD, glucose-6-phosphate dehydrogenase.

TABLE 48.2 Antimalarial Drugs: Drug Interactions

Drug	Mechanism	Result
Chloroquine Diphosphate		
divalproex sodium, valproic acid, anthelmintics, β -blockers, digoxin	Decreased serum levels of target drug	Treatment failures of target drugs
Mefloquine Hydrochloride		
β -Blockers, calcium channel blockers, quinidine sulphate, quinine sulphate	Unknown	Increased risk of dysrhythmia, cardiac arrest, seizures
Primaquine Phosphate		
Other hemolytic drugs	Unknown	Increased potential for myelotoxic effects (monitor for muscle weakness)

It is also indicated for the treatment of other parasitic infections, such as amoebiasis. Hydroxychloroquine sulphate (Plaquenil®) is another synthetic 4-aminoquinoline derivative that differs from chloroquine diphosphate by only one hydroxyl group ($^{\circ}\text{OH}$). Its efficacy in treating malaria is comparable to that of quinine sulphate. Both medications also possess anti-inflammatory actions and have been used to treat rheumatoid arthritis and systemic lupus erythematosus since the 1950s. However, only hydroxychloroquine sulphate is now used for these indications.

Contraindications to the use of 4-aminoquinoline derivatives include visual field changes, optic neuritis, and psoriasis, but their use may still be warranted, based on sound clinical judgement.

Chloroquine diphosphate and hydroxychloroquine sulphate are available only for oral use. The use of these drugs during pregnancy may outweigh the potential harm, but it is recommended that they be used in pregnant women only in truly urgent situations. These drugs are also distributed into breast milk.

PHARMACOKINETICS (CHLOROQUINE DIPHOSPHATE)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	8–10 hr	1–2 hr	3–5 days	Variable

PHARMACOKINETICS (HYDROXYCHLOROQUINE SULPHATE)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	4 hr	2–3 hr	40 days	Variable

mefloquine hydrochloride

Mefloquine hydrochloride is an analogue of quinine sulphate that is indicated for the management of mild-to-moderate acute malaria and for the prevention and treatment of malaria caused by chloroquine-resistant organisms. It is also used to treat multidrug-resistant strains of *P. falciparum*, which, as already noted, is a species of *Plasmodium* that is difficult to kill. The drug is commonly used prophylactically by travellers to prevent malarial infection while visiting malaria-endemic areas. The tetracycline antibiotic doxycycline hyclate (see Chapter 43) is also commonly used for this purpose. Mefloquine hydrochloride should not be used by

patients with active depression or a history of mental health disturbances (e.g., depression, generalized anxiety disorder, psychosis, schizophrenia, other major mental health disorders) or a history of convulsions, as the drug may precipitate these conditions. Mefloquine hydrochloride is available only for oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Less than 24 hr	6–24 hr	21–22 days	Variable

primaquine phosphate

Primaquine phosphate is similar in chemical structure and anti-malarial activity to the 4-aminoquinolines, but it is classified as an 8-aminoquinoline. It is one of the few antimalarial drugs that can destroy malarial parasites in their exoerythrocytic phase. Primaquine phosphate is indicated for curative therapy in acute cases of *P. vivax*, *P. ovale*, and, to a lesser degree, *P. falciparum* infection.

Primaquine phosphate is contraindicated in patients with known allergy or any disease states that may cause granulocytopenia, such as rheumatoid arthritis or systemic lupus erythematosus. Primaquine phosphate must be used with caution in patients with methemoglobinemia, porphyria, methemoglobin reductase deficiency, and glucose-6-phosphate dehydrogenase (G6PD) deficiency (see Chapter 2). It is available only for oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	2 hr	1–3 hr	7 hr	24 hr

DOSAGES Selected Antimalarial Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications
atovaquone/ proguanil hydrochloride* (Malarone)	Antimalarial	<i>Children</i>	Malaria prophylaxis of <i>P. falciparum</i>
		PO: Dosage varies depending on weight; 1–3 tab/day	
		For all weights: start 1–2 days before entering endemic area and continue × 7 days after leaving endemic area†	
		<i>Adults over 40 kg</i>	Malaria treatment of <i>P. falciparum</i>
		PO: 1 tab/day; begin 1–2 days before entering endemic area and continue during exposure and × 7 days after leaving endemic area†	
		<i>Children</i>	
		PO: Dosage varies depending on weight; 1–tab/day × 3 days	
		<i>Adults over 40 kg</i>	
		PO: 4 tabs daily × 3 days	

DOSAGES Selected Antimalarial Drugs—Cont'd

Drug	Pharmacological Class	Usual Dosage Range	Indications
chloroquine diphosphate (tablet: 155 mg chloroquine base (250 mg chloroquine diphosphate))	Synthetic antimalarial and antiamoebic	<i>Children</i> PO: 5 mg base/kg weekly; max 310 mg base weekly; begin 1 wk before entering endemic area and continue during exposure and × 4 wk after leaving endemic area <i>Adults</i> PO: 500 mg weekly, taken on exactly the same day every week, 2 wk before entering endemic area and × 4 wk after leaving endemic area	Malaria prophylaxis
		<i>Children</i> PO: 25 mg base/kg over 3 days; 10 mg base/kg on days 1 and 2 (do not exceed 620 mg base); 5 mg base/kg on day 3 <i>Adults</i> PO: 1 000 mg followed by 500 mg after 6–8 hr; followed by 500 mg on each of 2 consecutive days; 3-day total dose of 2.5 g	Malaria treatment
hydroxychloroquine sulphate (Plaquenil) Tablet: 155 mg base	Synthetic antimalarial	<i>Children 6 yr and older</i> PO: 5 mg base/kg (do not exceed adult dose) once weekly; on exactly the same day of each week beginning 2 wk before entering endemic area, continue during exposure and × 8 wk after leaving endemic area <i>Adults</i> PO: 400 mg on exactly the same day of each week beginning 2 wk before entering endemic area; continue during exposure and × 8 wk after leaving endemic area	Malaria prophylaxis
		<i>Children 6 yr and older</i> PO: Total dose of 25 mg base/kg over 3 days: 10 mg base/kg (not to exceed 620 mg base) on day 1, 5 mg base/kg 4 hr after first dose; 5 mg base/kg 18 hr after the second dose; 5 mg base/kg 24 hr after the third dose <i>Adults</i> PO: Loading dose of 800 mg, followed by 400 mg in 6–8 hr; followed by 400 mg on each of the next 2 days for a total of 2 g of hydroxychloroquine sulphate or 1.55 g base; or single dose of 800 mg	Malaria treatment Treatment of acute malaria attack
mefloquine hydrochloride (Lariam®)	Synthetic antimalarial	<i>Children</i> PO: Weekly dosing varies depending on weight <i>Adults and children over 45 kg</i> PO: 250 mg weekly; begin 1 wk before entering endemic area and continue × 4 wk after leaving endemic area	Malaria prophylaxis
primaquine phosphate	Synthetic antimalarial	<i>Children</i> 0.5 mg base/kg/day; begin 1 day before entering endemic area and continue for 7 days after leaving endemic area <i>Adults</i> PO: 30 mg base daily; begin 1 day before entering endemic area and continue during exposure and for 7 days after leaving endemic area	Malaria prophylaxis

PO, oral.

*Each tablet of Malarone contains atovaquone 250 mg and proguanil hydrochloride 100 mg. Each Malarone pediatric tablet contains atovaquone 62.5 mg and proguanil hydrochloride 25 mg.

[†]In addition to endemic areas, prophylaxis should be given for travel to any nonendemic area where prophylaxis for malaria is recommended by international travel health authorities.

TABLE 48.3 Types of Protozoal Infections

Protozoal Infection	Description	Antiprotozoal Drug
Amoebiasis	Caused by the protozoal parasite <i>Entamoeba histolytica</i> ; infection mainly resides in the large intestine but can also migrate to other parts of the body, such as the liver; usually transmitted in contaminated food or water	metronidazole, paromomycin sulphate
Giardiasis	Caused by <i>Giardia lamblia</i> ; the most common intestinal protozoal infection, usually residing in the intestinal mucosa (most commonly the duodenum); may cause diarrhea, bloating, and foul-smelling stools; transmitted in contaminated food or water or by contact with stool from infected persons; in Canada, referred to as “beaver fever”	metronidazole, paromomycin sulphate
Pneumocystosis	Pneumonias caused by <i>Pneumocystis jirovecii</i> occur almost exclusively in immunocompromised people; always fatal if left untreated	atovaquone, dapsone, primaquine phosphate, pentamidine isethionate, sulfamethoxazole/trimethoprim, trimetrexate
Toxoplasmosis	Caused by <i>Toxoplasma gondii</i> ; can produce systemic infection in both immunocompetent and immunocompromised hosts; domesticated animals, usually cats, serve as the intermediate host for parasites, passing infective oocysts in their feces	Sulfonamides with pyrimethamine, clindamycin hydrochloride, metronidazole
Trichomoniasis	Sexually transmitted infection caused by <i>Trichomonas vaginalis</i>	metronidazole

OTHER PROTOZOAL INFECTIONS

There are several other common protozoal infections. These include amoebiasis (caused by *Entamoeba histolytica*), giardiasis (caused by *Giardia lamblia*), toxoplasmosis (caused by *Toxoplasma gondii*), amoebic dysentery or intestinal amoebiasis, and trichomoniasis (caused by *Trichomonas vaginalis*). These diseases are most prevalent in tropical regions. Pneumocystosis, which is caused by *Pneumocystis jirovecii* (formerly known as *Pneumocystis carinii*), used to be classified as a protozoal infection but is now classified as fungal infection. It is a common infection that complicates HIV and AIDS. Pneumocystosis is discussed in this chapter and not in the antifungal chapter (see Chapter 47) because it is treated with drugs discussed in this chapter.

These protozoal infections can be transmitted in a number of ways: from person to person (e.g., via sexual contact), through the ingestion of contaminated water or food, through direct contact with the parasite, or by the bite of an insect vector (mosquito or tick). Parasitic infections can be systemic and occur throughout the body, or they can be localized to a specific region. For example, amoebiasis most commonly affects the gastrointestinal (GI) tract (e.g., amoebic dysentery), whereas pneumocystosis is predominantly a pulmonary infection.

The more common protozoal infections are described briefly in Table 48.3, along with the antiprotozoal drugs commonly used in their treatment. Only selected drugs are discussed here. Patients whose immune systems are compromised have an increased potential for acquiring a protozoal infection; often, such infections are fatal in these patients.

NONMALARIAL ANTIPROTOZOAL DRUGS

Several drugs used to treat malaria are also used to treat nonmalarial protozoal infections, including chloroquine, primaquine, and atovaquone. Other antiprotozoal drugs normally used against nonmalarial parasites include metronidazole, paromomycin sulphate, and pentamidine isethionate.

TABLE 48.4 Antiprotozoal Drugs: Mechanisms of Action

Antiprotozoal Drug	Mechanism of Action
atovaquone	Atovaquone selectively inhibits mitochondrial electron transport, reducing synthesis of adenosine triphosphate (required for cellular energy); also inhibits nucleic acid synthesis
metronidazole	Interferes with DNA, resulting in inhibition of protein synthesis and cell death in susceptible organisms
pentamidine isethionate	Inhibits production of much-needed substances such as DNA and RNA. Can bind to and aggregate ribosomes; it is directly lethal to <i>Pneumocystis jirovecii</i> (now classified as a fungus) through inhibiting glucose metabolism, protein and RNA synthesis, and intracellular amino acid transport

DNA, deoxyribonucleic acid; RNA, ribonucleic acid.

Mechanism of Action and Drug Effects

Antiprotozoal drugs work by several different mechanisms. The most commonly used antiprotozoal drugs, together with brief descriptions of their mechanisms of action, are given in Table 48.4. Chloroquine was discussed earlier in this chapter in the section on malaria. The drug effects of antiprotozoal drugs are limited primarily to their ability to kill various forms of protozoal parasites.

Indications

Antiprotozoal drugs are used to treat various protozoal infections, ranging from intestinal amoebiasis to pneumocystosis. Indications for selected drugs are summarized in Table 48.5. Atovaquone and pentamidine isethionate are used for the treatment of *P. jirovecii* infection. Metronidazole (effective for tissue amebicides in the bowel, liver, and extraintestinal tissues) and paromomycin sulphate (a luminal drug that acts on the bowel lumen to eradicate infection) are used to treat intestinal amoebiasis, the usual causative organism being *Entamoeba histolytica*. Metronidazole is also effective against several forms of bacteria,

TABLE 48.5 Indications for Selected Antiprotozoal Drugs

Antiprotozoal Drug	Drug Effects
atovaquone	Indicated for treatment of acute mild to moderately severe <i>Pneumocystis jirovecii</i> (classified as a fungus) pneumonia in patients who cannot tolerate trimoxazole/sulfamethoxazole
metronidazole	Indicated for treatment of bacterial (including anaerobic), protozoal, and helminthic infections
pentamidine isethionate	Indicated for prevention and treatment of <i>P. jirovecii</i> pneumonia

including anaerobic bacteria (see [Chapter 44](#)), as well as against protozoa and helminths (parasitic worms). Worm infection (helminthiasis) is discussed later in the chapter.

Contraindications

Contraindications to the use of antiprotozoal drugs include known drug allergy. Additional contraindications may include serious kidney or liver dysfunction or other illnesses, with the seriousness of the infection weighed against the patient's overall condition.

Adverse Effects

The adverse effects of antiprotozoal drugs vary depending on the drug and are listed in [Table 48.6](#).

Interactions

The common drug and laboratory test interactions associated with the use of antiprotozoal drugs are listed in [Table 48.7](#).

Dosages

For dosage information on selected antiprotozoal drugs, refer to the table on p. 782.

DRUG PROFILES

Antiprotozoal drugs are used for a number of infectious diseases, including infections with *Pneumocystis jirovecii* and *Trichomonas vaginalis*, amoebic dysentery (*Entamoeba histolytica*), toxoplasmosis, and giardiasis, among many others. All require a prescription and are available in either oral or injectable forms.

atovaquone

Atovaquone (Mepcon) is a synthetic antiprotozoal drug indicated for the treatment of mild to moderate *P. jirovecii* pneumonia in patients who cannot tolerate sulfamethoxazole/trimethoprim ([Chapter 43](#)). It is available only for oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	8–24 hr	24–96 hr	2–3 days	Unknown

TABLE 48.6 Selected Antiprotozoal Drugs: Adverse Effects

Body System	Adverse Effects
Atovaquone	
Hematological	Anemia, neutropenia, leukopenia
Integumentary	Pruritus, urticaria, rash
Gastrointestinal	Anorexia, elevated liver enzymes, gastritis, nausea, vomiting, diarrhea, constipation
Central nervous	Headache
Metabolic	Hyperkalemia, hypoglycemia, hyponatremia
Other	Cough
Metronidazole	
Central nervous	Headache, dizziness, confusion, fatigue, peripheral neuropathy, weakness
Eyes, ears, nose, and throat	Blurred vision, sore throat, dry mouth, metallic taste, glossitis
Gastrointestinal	Nausea, vomiting, diarrhea, constipation
Genitourinary	Dysuria, cystitis
Hematological	Neutropenia
Integumentary	Rash, pruritus, urticarial
Paromomycin Sulphate	
Gastrointestinal	Stomach cramps, nausea, vomiting, diarrhea
Central nervous	Hearing loss, dizziness, tinnitus
Pentamide Isetionate	
Cardiovascular	Hypotension, chest pain, dysrhythmias
Hematological	Leukopenia, thrombocytopenia, neutropenia
Integumentary	Pain at injection site, pruritus, urticaria, rash
Genitourinary	Nephrotoxicity
Gastrointestinal	Increased liver enzyme levels, pancreatitis, metallic taste, nausea, vomiting, diarrhea
Respiratory	Cough, wheezing, dyspnea, pharyngitis
Metabolic	Hypoglycemia followed by hyperglycemia
Other	Fatigue, chills, night sweats

metronidazole

Metronidazole (Flagyl) is an antiprotozoal drug that also has fairly broad antibacterial activity as well as **anthelmintic** activity. The therapeutic uses of metronidazole are many and range from the treatment of trichomoniasis, amoebiasis, and giardiasis to the treatment of anaerobic bacterial infections and antibiotic-induced pseudomembranous colitis (see [Chapters 43 and 44](#)).

Metronidazole is believed to directly kill protozoa by causing free-radical reactions that damage their DNA and other vital biomolecules. Tinidazole is a newer, similar drug, available as Fasigyn® through Health Canada's Special Access Programme.

Metronidazole is contraindicated during the first trimester of pregnancy. Patients should avoid the use of alcohol (including drugs containing alcohol) while taking metronidazole because of the possibility of a disulfiram-like reaction (Antabuse® effect; e.g., flushing, vomiting, tachycardia). This reaction may occur due to the inhibition of the oxidation of acetaldehyde, the primary metabolite of alcohol.

TABLE 48.7 Antiprotozoal Drugs: Drug and Laboratory Test Interactions

Antiprotozoal Drug	Mechanism	Result
atovaquone	Compete for binding on protein, resulting in free, active atovaquone	Highly protein-bound drugs (e.g., warfarin sodium, phenytoin): may increase atovaquone drug concentrations and risk of adverse reactions
metronidazole	Decreased absorption of vitamin K from the intestines due to elimination of the bacteria needed to absorb vitamin K, increased plasma acetaldehyde concentration after ingestion of alcohol	Alcohol: causes a disulfiram-like reaction; action of warfarin sodium may be increased (increased bleeding risk)
pentamidine isethionate	Additive nephrotoxic effects	Use with an aminoglycoside, amphotericin B, colistimethate sodium, cisplatin, or vancomycin hydrochloride may result in nephrotoxicity

Metronidazole is available in oral and parenteral form as well as in topical preparations.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1 hr	1–2 hr	8 hr	Variable

pentamidine isethionate

Pentamidine isethionate is an antiprotozoal drug used mainly for the management of the fungal infection *P. jirovecii* pneumonia. It acts by inhibiting protein and nucleic acid synthesis. It is used for the treatment of active pneumocystosis and for prophylaxis of *P. jirovecii* pneumonia in patients with a high potential for initial or recurrent *Pneumocystis* infection, such as patients with HIV infection and AIDS.

The only contraindication to pentamidine isethionate is known hypersensitivity to the drug. The drug needs to be used with caution in patients with blood dyscrasias, liver or kidney disease, diabetes mellitus, heart disease, hypocalcemia, or hypertension. Pentamidine isethionate is available solely for parenteral use. Intramuscular injections of this drug have been associated with pain, tenderness, redness, and induration at the site and should be used only when intravenous (IV) infusion is not feasible in patients with sufficient muscle mass.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	0.5–1 hr	40 min	5–8 wk	Variable

DOSAGES Selected Antiprotozoal Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications
atovaquone* (Mepron®)	Synthetic antipneumocystis drug	<i>Adults</i> PO: 750 mg bid with meals × 21 days	Treatment of active PJP (now classified as a fungus)
metronidazole (Flagyl®)	Amoebicide, antibacterial, trichomonicide	<i>Children</i> PO: 35–50 mg/kg tid × 5–7 days <i>Adults</i> PO: 500–750 mg tid 3 × 5–10 days <i>Children</i> PO: 25–35 mg/kg/day divided bid × 5–7 days <i>Adults</i> PO: 250 mg bid × 5–7 days <i>Adults: 1-day treatment</i> PO: 2 g × 1 dose after a meal <i>Adults: 10-day treatment</i> PO: 250 mg tid × 10 days	Amoebiasis, including amoebic liver abscess Trichomoniasis
pentamidine isethionate	Synthetic antipneumocystis drug	<i>Adults and children:</i> IV/IM: 4 mg/kg/day by slow infusion × 14 days	Treatment of active PJP (now classified as a fungus)

IV, intravenous; IM, intramuscular; PJP, *Pneumocystis jirovecii* pneumonia; PO, oral.

*A combination product containing atovaquone and proguanil is also used against malaria.

HELMINTHIC INFECTIONS

Parasitic **helminthic infections** (worm infections) are a worldwide problem. It has been estimated that one third of the world's population is infected with these parasites, but persons living in developing countries where sanitary conditions are often poor are by far the most common victims. The incidence of worm infection in developed countries where sewage treatment is adequate is much lower, and usually only a few select helminthic diseases cause problems. The most prevalent helminthic infection in Canada is enterobiasis, caused by one genus of roundworm (also called pinworm), *Enterobius*.

Helminths that are parasitic in humans are classified in the following categories:

- Platyhelminthes (flatworms)
- Cestodes (tapeworms)
- Trematodes (flukes)
- Nematodes (roundworms)

TABLE 48.8 Helminthic Infections

Infection	Organism and Other Facts
Nematodes (Intestinal and Tissue Roundworms)	
Ascariasis	Caused by <i>Ascaris lumbricoides</i> (giant roundworm); worm resides in small intestine; treated with pyrantel pamoate or mebendazole
Enterobiasis	Caused by <i>Enterobius vermicularis</i> (pinworm); worm resides in large intestine; treated with pyrantel pamoate or mebendazole
Plathelminthes (Intestinal Tapeworms or Flatworms)	
Diphyllobothriasis	Caused by <i>Diphyllobothrium latum</i> (fishworm); acquired from fish; treated with paromomycin sulphate or praziquantel
Hymenolepiasis	Caused by <i>Hymenolepis nana</i> (dwarf tapeworm); treated with paromomycin sulphate or praziquantel
Taeniasis	Caused by <i>Taenia saginata</i> (beef tapeworm); acquired from beef; treated with paromomycin sulphate or praziquantel Caused by <i>Taenia solium</i> (pork tapeworm); acquired from pork; treated with paromomycin sulphate or praziquantel

The characteristics of a few of the most common of the many helminthic infections are summarized in [Table 48.8](#). These usually first infect the intestines of their host and reside there, but they can sometimes also migrate to other tissues.

ANTHELMINTIC DRUGS

Unlike protozoa, which are the single-celled members of the animal kingdom, helminths are larger and have complex multicellular structures. Anthelmintic (also spelled *antihel-mintic*) drugs work to destroy these organisms by disrupting their structures. The currently available anthelmintic drugs are specific to the worms they can kill. For this reason, the causative worm in an infected host must be accurately identified before treatment is started. This can usually be done by analyzing samples of feces, urine, blood, sputum, or tissue from the infected host for the presence of ova or larvae of the particular parasite. Three anthelmintics are commercially available in Canada: mebendazole (Vermox®), praziquantel (Biltricide®), and pyrantel pamoate (Combantrin®, Jaa Pyral®).

Other drugs, such as niclosamide and piperazine, may be available either in other countries or by special request to Health Canada. Anthelmintics are specific in their actions. Mebendazole can be used to treat both tapeworms and roundworms. Praziquantel can kill flukes (trematodes). Pyrantel pamoate is effective against giant roundworms and pinworms.

Mechanism of Action and Drug Effects

The mechanisms of action of the various anthelmintics vary greatly from drug to drug, although there are some similarities among the drugs used to kill similar types of worms. The anthelmintic drugs and their respective mechanisms of action are listed in [Table 48.9](#). The drug effects of anthelmintic drugs are limited to their ability to kill various forms of worms and flukes.

Indications

Anthelmintic drugs are used to treat roundworm, tapeworm, and fluke infections. Specific drugs are used to treat specific helminthic infections.

TABLE 48.9 Anthelmintics: Mechanisms of Action

Drug	Mechanism of Action	Indication
mebendazole	Selectively and irreversibly inhibits the uptake of glucose and other nutrients, which results in depletion of endogenous glycogen stores, eventual autolysis of the parasitic worm, and its death	Treatment of single or mixed helminthic infestations
praziquantel	Increases permeability of the cell membrane of susceptible worms to calcium, which results in the influx of calcium; this causes the worms to be dislodged from their usual site of residence in the mesenteric veins to the liver, where they are killed by host tissue reactions	Schistosomiasis, opisthorchiasis (liver fluke infection), clonorchiasis (infection with clonorchis or Chinese or Oriental liver fluke), diphyllobothriasis (fish worm infection), hymenolepiasis (dwarf tapeworm infection), neurocysticercosis
pyrantel pamoate	Blocks acetylcholine at the neuromuscular junction, which results in paralysis of the worm; the paralyzed worm is expelled from the gastrointestinal tract by normal peristalsis	Ascariasis, enterobiasis, other helminthic infections

Contraindications

The only usual contraindication to a specific anthelmintic drug product is known drug allergy. Pyrantel pamoate is contraindicated in patients with liver disease. Praziquantel is also contraindicated in patients with ocular cysticercosis (tapeworm infection of the eye).

Adverse Effects
