The anthelmintic drugs show a remarkable diversity in their drug-specific adverse effects. Common adverse effects are listed in Table 48.10.

Interactions

The concurrent use of pyrantel pamoate (an over-the-counter anthelmintic) with piperazine is not recommended, and pyrantel pamoate is used cautiously in patients with liver impairment. Pyrantel pamoate has also been shown to raise blood levels of theophylline in children. Dexamethasone and the anthelmintic praziquantel may raise blood levels of mebendazole. Histamine H₂ antagonists (e.g., cimetidine, ranitidine hydrochloride) may also raise blood levels of praziquantel.

Dosages

For dosage information for selected anthelmintic drugs, refer to the table below.

TABLE 48.10 Anthelmintics: Common Adverse Effects

Body System	Adverse Effects
Praziquantel	
Central nervous	Dizziness, headache, drowsiness
Gastrointestinal	Abdominal pain, nausea
Other	Malaise
Primaquine	
Gastrointestinal	Nausea, vomiting, abdominal distress
Other	Headaches, pruritus, dark discoloration of urine, hemolytic anemia due to glucose-6-phosphate dehydrogenase deficiency
Pyrantel Pamoate	
Central nervous	Headache, dizziness, insomnia
Gastrointestinal	Abdominal pain, nausea
Other	Malaise

DRUG PROFILES

Anthelmintics are available only as oral preparations and, with the exception of pyrantel pamoate, all require a prescription. Different drugs are selected to treat infection by different helminthic species.

praziquantel

Praziquantel (Biltricide) is one of the primary anthelmintic drugs used for the treatment of various fluke infections. It is also useful against many species of tapeworm. It is contraindicated in patients with ocular worm infestation (ocular cysticercosis). It is available only for oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1 hr	1–3 hr	parent drug 0.8–1.5 hours, metabolites 4.5 hours	Variable

pyrantel pamoate

Pyrantel pamoate (Combantrin, Jaa Pyral) is a pyrimidine-derived anthelmintic drug indicated for the treatment of infection with intestinal roundworms, including ascariasis, enterobiasis, and other helminthic infections. It is available in Canada for oral use and is purchased over the counter.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1 hr	1–3 hr	Unknown	Unknown

NURSING PROCESS

ASSESSMENT

Before beginning treatment with an antimalarial drug, obtain a thorough travel and medication history, perform a head-to-toe physical assessment, and measure vital signs. Give special attention to assessment findings of any common manifestations of malaria, such as headache, nausea, and joint pain. Other symptoms include

DOSAGES Selected Anthelmintic Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications
praziquantel (Biltricide)	Trematode anthelmintic	Adults and children over 4 yr PO: approx. 25 mg/kg tid × 1 day	Fluke infections
pyrantel pamoate (Combantrin, Jaa Pyral)	Nematode anthelmintic	Adults and children over 1 yr PO: 11 mg/kg in a single dose (max dose 1 g)	Roundworm infections

PO, oral.

chills and rigour, followed by a fever of up to 40°C, frequently leading to extreme fatigue and prolonged sleep. Baseline visual acuity tests may be needed given the contraindications of visual field problems and optic neuritis with chloroquine and quinine sulphate. Perform a skin assessment with the use of these drugs as well because of the contraindications affecting individuals with psoriasis. Other drugs, such as mefloquine hydrochloride and primaquine phosphate, require assessment of baseline hearing (with primaquine hydrochloride) and assessment for G6PD deficiency due to possible drug-induced hemolytic anemia. Common drug interactions to assess for are listed in [Table 48.2](#).

Antiprotozoal drugs and their contraindications, cautions, and drug interactions have been previously discussed. Assess baseline kidney and liver function as well as overall health status. Prior to the use of atovaquone, determine baseline blood counts owing to the risk of drug-induced anemia, neutropenia, and leukopenia. Assess serum potassium, sodium, and glucose levels as ordered. Metronidazole requires assessment for allergy to any of the nitroimidazole derivatives as well as to parabens (for the topical dosage forms). Obtain appropriate specimens for analysis before treatment. Prior to use of metronidazole, assess blood counts, any central nervous system disorders or abnormalities, and bladder function. Pentamidine isethionate is associated with serious cardiac, hematological, skin, kidney, GI, and respiratory adverse effects; therefore, documentation of a thorough assessment of each of these systems is crucial to patient safety.

Prior to the administration of any of the anthelmintic drugs, obtain a thorough travel history and a history of foods eaten, especially meat and fish, and their means of preparation. Also assess other individuals in the patient's household for helminth infection. Obtaining stool specimens is indicated. Assess the patient's energy level, ability to perform activities of daily living, weight, and appetite, and document these findings. Assess for contraindications, such as liver disease and drug allergy, and any cautions. Assess for drug interactions, including with theophylline, antiepileptic drugs, and histamine H₂ antagonists.

◆ NURSING DIAGNOSES

- Imbalanced nutrition, less than body requirements, as a result of the disease process and adverse effects of medication
- Reduced knowledge resulting from the infection and its drug treatment
- Inadequate therapeutic regimen management by patient and family, resulting from poor adherence to treatment and lack of knowledge about the infection and its treatment

◆ PLANNING

◆ Goals

- Patient will maintain balanced nutrition during drug therapy.
- Patient, family members, and significant others will demonstrate adequate knowledge regarding the infection and its treatment.
- Patient, family members, and others in the home environment will experience improved therapeutic regimen management and compliance.

◆ Expected Patient Outcomes

- Patient states measures to enhance balanced nutrition, taking into account recommendations for increased caloric and protein intake.
- Patient identifies menu planning strategies appropriate to meet increased nutritional demands.
- Patient lists foods to be included in daily diet to improve overall nutritional status, incorporating recommendations from Canada's Food Guide along with prescribed dietary changes.
- Patient states the impact of infectious process on the human body and its functioning.
- Patient states the various measures to prevent worsening of lesions and minimize tissue injury, such as washing hands thoroughly; reporting any worsening of lesions, drainage, fever, or joint pain; and taking medication as prescribed.
- Patient states the importance of reporting the worsening of symptoms of the infection, including fever, lethargy, and loss of appetite.
- Patient states the rationale for continuing with treatment for the prescribed length of time.
- Patient states the importance of effective therapeutic regimen management by and for the family, including adhering to therapy, returning for follow-up visits to the health care provider to monitor progress, being aware of any adverse drug reactions, and reporting any new symptoms in members of the family or household.

◆ IMPLEMENTATION

With antimalarials, encourage adequate dietary and fluid intake while the patient is fighting the infection and taking medication. Take oral doses with at least 180 to 240 mL of water or other fluid and increase fluid intake unless contraindicated. Because antimalarials concentrate in the liver first, emphasize to the patient the importance of follow-up visits to the health care provider so that liver function may be monitored during therapy.

Chloroquine and hydroxychloroquine are administered orally and are to be given exactly as prescribed. Follow dosing orders and instructions as prescribed, with specific attention to the loading doses, subsequent doses, and prophylactic dosing. Photosensitivity may occur with the use of quinine sulphate; provide adequate teaching about sun safety and the use of sunscreen. Sun protection must include protection from both UVA and UVB rays. See the Patient Teaching Tips for more information. Most of the antiprotozoal drugs (e.g., atovaquone, metronidazole) are given with food when taken orally. Infuse IV doses of metronidazole as indicated in the manufacturer's instructions. During use of this drug, report to the health care provider any changes in neurological status (e.g., dizziness, confusion). All anthelmintic drugs are to be administered as ordered and for the prescribed length of time. Warn patients that the use of primaquine may lead to dark discoloration of the urine. Perform collection of stool specimens as ordered. The stool must not come in contact with water, urine, or chemicals because of the risk of destroying the parasitic worms or altering the test results. See the Patient Teaching Tips for more information on anthelmintic drugs.

CASE STUDY

Metronidazole

Kelis, a 28-year-old graduate student, just returned from an archeology internship in a developing country. She has had severe diarrhea for several days and has been diagnosed with intestinal amoebiasis. She will receive fluids for rehydration and metronidazole as part of her treatment.

1. What specific laboratory test must be ordered before the initiation of the metronidazole therapy? List other laboratory studies that will be performed.
2. Kelis is started on oral metronidazole treatment and after a day she reports that her diarrhea has decreased and that she feels a little better. During afternoon rounds, she tells the nurse that she has some nausea and feels dizzy and tired. She asks, "Is this because of my infection?" How will the nurse respond?
3. Kelis is discharged to home with a prescription to take the metronidazole for 8 more days (for a total of 10 days). The nurse knows that one serious adverse effect of this medication is leukopenia. What symptoms will the nurse tell Kelis to report?

4. A week later, Kelis calls to tell the nurse that she went out to a bar with some friends and became very ill after having one drink. Explain what happened. For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

EVALUATION

Monitor patients for the therapeutic effects of antimalarials, antiprotozoals, and anthelmintic drugs, such as improved energy levels and decrease in or eventual resolution of all symptoms. Evaluation of proper hygiene and prevention of the spread of the infestation or infection is also important. With these three groups of drugs, evaluate for the adverse effects associated with each type of drug (see [Tables 48.1, 48.6, and 48.10](#)). Some antimalarials and anthelmintics may precipitate hemolysis in patients with G6PD deficiency (mostly patients of African descent and those of Mediterranean ancestry); therefore, closely monitor these patients for this complication during the treatment protocol. See [Chapter 2](#) for further discussion of G6PD deficiency.

PATIENT TEACHING TIPS

- Antimalarials are known to cause GI upset; however, this may be decreased if the medication is taken with food. Encourage patients to inform the health care provider if there is unresolved nausea, vomiting, profuse diarrhea, or abdominal pain. Patients should immediately report any visual disturbances, dizziness, or respiratory difficulties.
- Educate patients about the need for prophylactic doses of antimalarials, as prescribed, before visiting malaria-endemic countries, as well as the need to receive appropriate treatment upon return.
- As with other medications, patients should know to keep antimalarials out of the reach of children.
- Instruct patients to take the entire course of medication as directed.
- Patients should be aware that oral dosage forms of metronidazole are to be taken with food.
- Inform patients taking metronidazole for a sexually transmitted infection to avoid sexual intercourse until the health care provider indicates that it is safe.
- When a patient is taking metronidazole for amoebiasis, include in your instructions how to check stool samples correctly and safely, as well as how to dispose of samples properly.
- Apply topical forms of drugs with a finger cot or gloved hand, and caution patients to avoid contact of the drug with the eyes.
- Metronidazole may precipitate dizziness. Encourage patients to be cautious with all activities until response to the drug is noted and consistent.
- Anthelmintics are to be taken exactly as prescribed; emphasize to patients the importance of adherence to the drug regimen.

KEY POINTS

- Malaria is caused by *Plasmodium*, a particular genus of protozoa, and is transmitted through the bite of an infected female mosquito. The drug primaquine attacks the parasite when it is outside the exoerythrocytic (tissue) phase.
- Other common protozoal infections are amoebiasis, giardiasis, toxoplasmosis, and trichomoniasis. Protozoa are parasites that are transmitted by person-to-person contact, ingestion of contaminated water or food, direct contact with the parasite, or the bite of an insect (mosquito or tick). Pneumocystosis is now classified as a fungal infection, but it is treated with antiprotozoal drugs.
- Antiprotozoals include atovaquone and pentamidine isethionate. Metronidazole is an antibacterial, antiprotozoal, and anthelmintic. Paromomycin sulphate directly kills protozoa such as *Entamoeba histolytica*.
- Anthelmintics are drugs used to treat parasitic worm infections caused by cestodes (tapeworms), nematodes (roundworms), and trematodes (flukes).
- Nursing considerations with the use of any of the antimalarials, antiprotozoals, and anthelmintics include assessment for contraindications, cautions, and drug interactions.

EXAMINATION REVIEW QUESTIONS

- The nurse is reviewing the medication history of a patient who is taking hydroxychloroquine. The patient's history does not reveal a history of malaria or travel out of the country. The patient is most likely taking this medication for which condition?
 - Plasmodium*
 - A thyroid disorder
 - Roundworms
 - Rheumatoid arthritis
- What teaching point would be appropriate for the nurse to include when informing a patient about the adverse effects of antimalarials?
 - The skin may turn blotchy while these medications are taken.
 - These medications may cause anorexia and abdominal distress.
 - These medications may cause increased urinary output.
 - You may experience periods of diaphoresis and chills.
- When teaching a patient about potential drug interactions with antiprotozoal drugs, the nurse will include information about which drug or type of drug?
 - acetaminophen
 - warfarin sodium
 - Decongestants
 - Antibiotics
- Before administering antiprotozoal drugs, the nurse will review which baseline assessment?
 - Complete blood count
 - Serum magnesium level
 - Creatinine clearance
 - Arterial blood gas concentration
- The nurse knows that antimalarial drugs are used to treat patients with infections caused by which microorganism?
 - Plasmodium* spp.
 - Candida albicans*
 - Pneumocystis jirovecii*
 - Mycobacterium* spp.
- When giving metronidazole, which of these appropriate administration techniques does the nurse implement? (Select all that apply.)
 - Giving oral forms with food
 - Giving oral forms on an empty stomach with a full glass of water
 - Infusing IV doses over 30 to 60 minutes
 - Administering IV doses by bolus over 5 minutes
 - Obtaining ordered specimens before starting the medication
- A 5-year-old patient has been diagnosed with malaria after returning from a trip. The patient is to receive one dose of mefloquine hydrochloride (Lariam), 25 mg/kg PO. The child weighs 20 kg. How much mefloquine hydrochloride will this child receive? Is this a safe dose?
- Praziquantel (Biltricide) is prescribed for a patient with a tapeworm infection. The nurse prepares to administer the medication via which route?
 - Rectal
 - Oral
 - Intravenous
 - Inhalation

CRITICAL THINKING ACTIVITIES

- You are preparing to give pyrantel pamoate (Combantrin) to a patient who is infected with intestinal roundworms. The patient is worried about this infection and its treatment and asks you, "What will this drug do to me? Does it have bad effects? I'm already sick enough!" What is your priority when answering the patient's questions?
 - Your friend is travelling to a country where there is high potential for malaria infection. The friend asks you what you think her nurse practitioner will order, if anything at all. What is your best response to this question?
 - A patient with a history of AIDS has severe *Pneumocystis jirovecii* pneumonia. As you prepare the ordered intravenous pentamidine, the patient asks you, "What are you doing? Why can't you give that to me in a pill?" What is your priority when answering the patient's questions?
- For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Anti-inflammatory and Antigout Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Discuss the inflammatory response and the role it plays in the generation of pain.
2. Compare disease processes (pathologies) that are inflammatory in nature.
3. Discuss the mechanisms of action, indications, adverse effects, dosage ranges, routes of administration, cautions, contraindications, drug interactions, and toxicities of the various anti-inflammatory and antigout drugs.
4. Develop a collaborative plan of care that includes all phases of the nursing process for patients receiving anti-inflammatory or antigout drugs.

KEY TERMS

Done nomogram A standard plot of graphic data, originally published in 1960 in the journal *Pediatrics*, for rating the severity of aspirin toxicity following overdose; serum salicylate levels are plotted against time elapsed since ingestion. (p. 793)

Gout Hyperuricemia (elevated blood uric acid level); the arthritis caused by tissue buildup of uric acid crystals. (p. 796)

Inflammation A localized protective response stimulated by injury to tissues that serves to destroy, dilute, or wall off (sequester) both the injurious agent and the injured tissue. (p. 789)

Nonsteroidal anti-inflammatory drugs (NSAIDs) A large, chemically diverse group of drugs that possess analgesic, anti-inflammatory, and antipyretic activity. (p. 790)

Salicylism The syndrome of salicylate toxicity, including symptoms such as tinnitus, nausea, and vomiting. (p. 792)

DRUG PROFILES

	acetylsalicylic acid, p. 794
	allopurinol, p. 796
	celecoxib, p. 795
	colchicine, p. 797
	ibuprofen, p. 795
	indomethacin, p. 794
	ketorolac (ketorolac tromethamine)*, p. 795
	probenecid, p. 797
	Key drug

* Full generic name is given in parentheses. For the purposes of this text, the more common, shortened name is used.

OVERVIEW

Inflammation is defined as a localized protective response stimulated by injury to tissues, which serves to destroy, dilute, or wall off (sequester) both the injurious agent and the injured tissue. Classic signs and symptoms of inflammation include pain, fever, loss of function, redness, and swelling. These symptoms result from arterial, venous, and capillary dilation; enhanced blood flow and vascular permeability; exudation of fluids, including plasma proteins;

and leukocyte migration into the inflammatory focus. The inflammatory response is mediated by a host of endogenous compounds, including proteins of the complement system, histamine, serotonin, bradykinin, leukotrienes, and prostaglandins, the latter two being major contributors to the symptoms of inflammation.

Arachidonic acid is released from phospholipids in cell membranes in response to a triggering event (e.g., an injury). It is metabolized in either the prostaglandin pathway or the leukotriene pathway, both of which are branches of the arachidonic acid pathway, as shown in [Figure 49.1](#). Both of these pathways lead to inflammation, edema, headache, and other pain characteristic of the body's response to injury or inflammatory illnesses such as arthritis.

In the prostaglandin pathway, arachidonic acid is converted by the enzyme cyclooxygenase into various prostaglandins. Prostaglandins mediate inflammation by inducing vasodilation and enhancing vasopermeability. These effects in turn potentiate the action of proinflammatory substances such as histamine and bradykinin in the production of edema and pain. These symptoms arise as a result of prostaglandin-induced hyperalgesia (excessive sensitivity). In this situation, stimuli that normally would not be painful, such as the movement of a joint through its natural range of motion, become painful because of the inflammatory process at work. Fever occurs when prostaglandin E₂ is synthesized in the preoptic hypothalamic region, the area of the brain that regulates temperature.

Fig. 49.1 Arachidonic acid pathway. PGI₂, prostaglandin I₂; PLT, platelet; TXA₂, thromboxane A₂.

The leukotriene pathway utilizes lipoxygenases to metabolize the arachidonic acid and convert it into various leukotrienes. Although leukotrienes were discovered more recently than prostaglandins and are thus not as well studied, they are also mediators of inflammation, promoting vasoconstriction, bronchospasm, and increased vascular permeability with resultant edema (see Chapter 38).

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Nonsteroidal anti-inflammatory drugs (NSAIDs) are among the most commonly prescribed drugs. Every year, over 10 million prescriptions are written for NSAIDs in Canada (Kümmerer, 2013). This figure represents over 4% of all prescriptions. NSAIDs remain a popular medication; however, there are no current data to support the number of prescriptions written for NSAIDs or use of over-the-counter (OTC) medications. Currently, more than 15 different NSAIDs are available in Canada; many of these are available to be purchased OTC as well as by prescription. Some are used more commonly than others. Any one patient may respond better to one NSAID than to others, in terms of both symptom relief and adverse effects.

NSAIDs comprise a large, chemically diverse group of drugs that possess analgesic, anti-inflammatory, and antipyretic activity. They are also used for the relief of mild-to-moderate headaches, myalgia, neuralgia, and arthralgia; alleviation of postoperative pain; relief of the pain associated with arthritic disorders such as rheumatoid arthritis, juvenile arthritis, ankylosing spondylitis, and osteoarthritis; and treatment of gout and hyperuricemia (discussed later in the chapter). Aspirin is an NSAID used for its effect in inhibiting platelet aggregation, which has been shown to have protective qualities against certain cardiovascular events such as myocardial infarction (MI) and stroke. Corticosteroid anti-inflammatory drugs (e.g.,

prednisone, dexamethasone) are also used for similar purposes and were discussed in Chapter 34. NSAIDs have generally more favourable adverse effect profiles than corticosteroidal anti-inflammatory drugs.

In 1899, acetylsalicylic acid (ASA; aspirin) was marketed and rapidly became the most widely used drug in the world. The success of aspirin established the importance of drugs with antipyretic, analgesic, and anti-inflammatory properties, properties that all NSAIDs share. The widespread use of aspirin also yielded evidence of its potential for causing major adverse effects. Gastrointestinal (GI) intolerance, bleeding, and kidney impairment became major factors limiting its long-term administration. As a result, efforts were mounted to develop drugs that did not have the adverse effects of aspirin. This led to the discovery of other NSAIDs, which in general are associated with less serious adverse effects and a lower incidence for those effects; they are often better tolerated than aspirin in patients with chronic diseases. If aspirin were to be a newly discovered drug today, it would require a prescription.

As a single class, NSAIDs constitute an exceptional variety of drugs, and they are used for an equally wide range of indications. Box 49.1 categorizes these drugs into a number of distinct chemical classes. NSAIDs have been approved for a variety of indications and are considered the drug of choice for most of the conditions listed in Box 49.2. Almost all NSAIDs are used for the treatment of rheumatoid arthritis and degenerative joint disease (osteoarthritis). Several of these drugs are available in sustained-release formulations. This formulation allows once- or twice-daily dosing, which is known to improve patients' adherence to prescribed drug therapy regimens.

Mechanism of Action and Drug Effects

NSAIDs act through inhibition of the leukotriene pathway, the prostaglandin pathway, or both. More specifically, NSAIDs

BOX 49.1 Chemical Categories of NSAIDs**Salicylates**

aspirin
diflunisal

Acetic Acid Derivatives

diclofenac sodium (Voltaren®)
indomethacin sulindac
etodolac
ketorolac (Toradol®)
mefenamic acid (Ponstan®)

Cyclooxygenase-2 Inhibitors

celecoxib (Celebrex®)

Enolic Acid Derivatives

nabumetone
meloxicam (Mobicox®)
piroxicam

Propionic Acid Derivatives

flurbiprofen
ibuprofen (Advil®, Motrin®)
ketoprofen (Apo-Keto-E®)
naproxen (Naprolen®, Naprosyn®, Aleve®)
oxaprozin tiaprofenic acid

NSAIDs, nonsteroidal anti-inflammatory drugs.

BOX 49.2 NSAIDs: Health Canada–Approved Indications

- Acute gout
- Acute gouty arthritis
- Ankylosing spondylitis
- Bursitis
- Fever
- Juvenile rheumatoid arthritis
- Mild to moderate pain
- Osteoarthritis
- Primary dysmenorrhea
- Rheumatoid arthritis
- Tendinitis
- Various ophthalmic uses

NSAIDs, nonsteroidal anti-inflammatory drugs.

relieve pain, headache, and inflammation by blocking the chemical activity of the *cyclooxygenase* (COX) enzymes. It is now recognized that there are at least two types of cyclooxygenase. Cyclooxygenase-1 (COX-1) is the isoform of the enzyme that promotes the synthesis of prostaglandins, which have primarily beneficial effects on various body functions. One example is their role in maintaining an intact intestinal mucosa. In contrast, the cyclooxygenase-2 (COX-2) isoform promotes the synthesis of prostaglandins that are involved in inflammatory processes. In 1999, the newest class of NSAIDs, the COX-2 inhibitors, was approved. Drugs in this class work by specifically inhibiting the COX-2 isoform of cyclooxygenase and theoretically have limited or no effects on COX-1. Previous NSAIDs nonspecifically inhibited both COX-1 and COX-2 activities. This greater enzyme specificity of the COX-2

inhibitors allows for beneficial anti-inflammatory effects while reducing the prevalence of adverse effects associated with the nonspecific NSAIDs, such as GI ulceration. The leukotriene pathway is inhibited by some anti-inflammatory drugs, but not by salicylates.

All NSAIDs can be ulcerogenic and induce GI bleeding due to their activity against tissue COX-1. One notable effect of aspirin is the inhibition of platelet aggregation, also known as its *antiplatelet activity*. Aspirin has the unique property among NSAIDs of being an irreversible inhibitor of COX-1 receptors within platelets themselves. This in turn results in reduced formation by the platelets of thromboxane A₂, a substance that normally promotes platelet aggregation. This antiplatelet action has made aspirin, along with thrombolytic drugs (see Chapter 27), a primary drug in the treatment of acute MI and many other thromboembolic disorders. Other NSAIDs lack these antiplatelet effects.

Indications

Some of the therapeutic uses of this broad class of drugs are listed in Table 49.1; however, NSAIDs are used primarily for their analgesic, anti-inflammatory, and antipyretic effects, and for platelet inhibition.

NSAIDs are also widely used for the treatment of rheumatoid arthritis and osteoarthritis, as well as other inflammatory conditions, rheumatic fever, mild-to-moderate pain, and acute gout. They have proven beneficial as adjunctive pain relief medications in patients with chronic persistent pain syndromes, such as pain from bone cancer and chronic persistent back pain. For the relief of pain, NSAIDs are sometimes combined with an opioid (see Chapter 11). They tend to have an opioid-sparing effect when given together with opioids because the drugs attack pain using two different mechanisms. This often allows less of the opioid to be used. Unlike opioids, NSAIDs show a ceiling effect that limits their effectiveness; that is, any further increase in the dosage beyond a certain level increases the risk of adverse effects without a corresponding increase in therapeutic effect. Refer to manufacturers' instructions for maximum dosages. In contrast, opioid doses may be titrated almost indefinitely to increasingly higher levels, especially in terminally ill patients with severe pain.

The appropriate selection of an NSAID is a clinical judgment based on consideration of the patient's history, including any previous medical conditions, the intended use of the drug, the patient's previous experience with NSAIDs, the patient's preference, and the cost.

Contraindications

Contraindications to NSAIDs include known drug allergy and conditions that place the patient at risk for bleeding, such as rhinitis (due to possible epistaxis [nosebleed]), vitamin K deficiency, and peptic ulcer disease. NSAIDs should not be administered to a patient with a current hemorrhagic stroke. Patients with documented aspirin allergy must not receive NSAIDs. Other common contraindications are those that apply to most drugs and include severe kidney or liver disease. NSAIDs are considered relatively safe to use during pregnancy and do not increase the risk of spontaneous abortion (Daniel, Koren, Lunenfeld, et al., 2014). Women

TABLE 49.1 Suggested NSAIDs for Patients With Various Medical Conditions

Medical Condition	Recommended NSAID
Ankylosing spondylitis	indomethacin, naproxen, sulindac, piroxicam
Dysmenorrhea	Fenamates, naproxen, ibuprofen
Gout	indomethacin, naproxen, sulindac
Headaches	aspirin, ibuprofen, naproxen
Hepatotoxicity	naproxen, ibuprofen, piroxicam, fenamates
History of aspirin or NSAID allergy	Avoid NSAIDs if possible; if deemed necessary, consider a nonacetylated salicylate
Hypertension	sulindac, nonacetylated salicylate, ibuprofen, etodolac
Osteoarthritis	diclofenac sodium, oxaprozin, indomethacin, piroxicam
Risk for gastrointestinal toxicity	celecoxib, nonacetylated salicylate, enteric-coated aspirin, diclofenac sodium, nabumetone, etodolac, ibuprofen, oxaprozin
Risk for nephrotoxicity	sulindac, nonacetylated salicylate, nabumetone, etodolac, diclofenac sodium, oxaprozin

NSAIDs, nonsteroidal anti-inflammatory drugs.

who are pregnant should avoid using NSAIDs after 32 weeks' gestation, owing to the possibility of antiplatelet or prolonged bleeding effects. Although prenatal ductal constriction and closure have been described with the maternal use of NSAIDs, frequently no clear underlying cause is found (Lopes, Carrilho, Francisco, et al., 2016). Interestingly, NSAIDs (ibuprofen or indomethacin) are used to close patent ductus arteriosus in newborns. NSAID use has also been associated with neonatal NSAID toxicity during the perinatal period. These drugs are also not recommended for nursing mothers because they are known to be excreted into human milk. Because of the potential of NSAIDs to increase bleeding, patients undergoing elective surgery need to stop taking NSAIDs at least 1 week prior to surgery.

Adverse Effects

Although NSAIDs are the most widely used class of drugs, and some are available without prescription, their potential for causing serious adverse effects has been underemphasized. Among the more common and potentially serious adverse effects of NSAIDs is their impact on the GI tract. Symptoms can range from mild, such as heartburn, to the most severe GI complication, GI bleeding. Most fatalities associated with NSAID use are related to GI bleeding. In addition, acute kidney injury is quite common with NSAID use, especially if the patient is dehydrated. The potential adverse effects of NSAIDs are listed in Table 49.2. Not all of the adverse effects necessarily apply to all drugs, but many do. In 2006, Health Canada began requiring warnings on all of the NSAIDs' packaging (Box 49.3) (Health Canada, 2006). In 2014, Health Canada updated its warning on diclofenac (based on a 2013 study by Bhala, Emberson, Merhi, et al.) to include the increased risk of cardiovascular disease, particularly at higher doses (150 mg per day or more) and with longer duration of use. Patients with a history of or risk factors for heart disease, stroke, or uncontrolled high blood pressure

TABLE 49.2 NSAIDs: Adverse Effects

Body System	Adverse Effects
Cardiovascular	Moderate-to-severe noncardiogenic pulmonary edema
Gastrointestinal	Dyspepsia, heartburn, epigastric distress, nausea, vomiting, anorexia, abdominal pain, gastrointestinal bleeding, mucosal lesions (erosions or ulcerations)
Hematological	Altered hemostasis through effects on platelet function
Hepatic	Acute reversible hepatotoxicity
Renal	Reduction in creatinine clearance, acute tubular necrosis with acute kidney injury
Other	Skin eruption, sensitivity reactions, tinnitus, hearing loss

NSAIDs, nonsteroidal anti-inflammatory drugs.

BOX 49.3 Health Canada–Required Warnings on All NSAIDs

The following warnings must now be included in the packaging for all NSAIDs:

Cardiovascular Risk

- NSAIDs may cause an increased risk of serious cardiovascular thrombotic events, MI, and stroke, which can be fatal. This risk may increase with duration of use. Patients with cardiovascular disease or risk factors for cardiovascular disease may be at greater risk.
- NSAIDs are contraindicated for the treatment of perioperative pain in the setting of coronary artery bypass graft surgery.

Gastrointestinal Risk

- NSAIDs cause an increased risk of serious GI adverse events, including bleeding, ulceration, and perforation of the stomach or intestines, which can be fatal. These events can occur at any time during use and without warning symptoms. Older adult patients are at greater risk for serious GI events.
- See Chapter 3 for more information on drug warnings.

GI, gastrointestinal; MI, myocardial infarction; NSAIDs, nonsteroidal anti-inflammatory drugs.

may be at greater risk if they use diclofenac. This increased risk is also associated with high doses of ibuprofen (see discussion on ibuprofen).

Kidney function depends partly on prostaglandins; the use of NSAIDs can compromise existing kidney function. Disruption of prostaglandin function by NSAIDs is sometimes strong enough to precipitate acute kidney injury or chronic kidney failure, depending on the patient's current level of kidney function. Kidney toxicity can occur in patients who are dehydrated, those with heart failure or liver dysfunction, and those taking diuretics or angiotensin-converting enzyme (ACE) inhibitors.

Toxicity and Management of Overdose

Salicylate toxicity, usually from aspirin, is not as common as it once was; however, there are both chronic and acute manifestations of salicylate toxicity. Chronic salicylate intoxication is known as **salicylism** and results from either short-term administration of high dosages or prolonged therapy with high or even lower doses. The most common signs and symptoms of acute or chronic salicylate intoxication are listed in Table 49.3.

TABLE 49.3 Acute or Chronic Salicylate Intoxication: Signs and Symptoms

Body System	Signs and Symptoms
Cardiovascular	Increased heart rate
Central nervous	Tinnitus, hearing loss, dimness of vision, headache, dizziness, mental confusion, lassitude, drowsiness
Gastrointestinal	Nausea, vomiting, diarrhea
Metabolic	Sweating, thirst, hyperventilation, hypoglycemia or hyperglycemia

The most common manifestations of chronic salicylate intoxication in adults are tinnitus and hearing loss. Common manifestations in children are hyperventilation and central nervous system (CNS) effects such as dizziness, drowsiness, and behavioural changes. Metabolic complications such as metabolic acidosis and respiratory alkalosis often occur to varying degrees in cases of chronic salicylate intoxication. Metabolic acidosis can also occur with acute intoxication, but it is usually less severe than that in patients with chronic intoxication. Hypoglycemia may also arise and can be life-threatening. The treatment of chronic salicylate intoxication is based on the presenting symptoms.

Serum salicylate concentrations may be determined but are not as useful in estimating the severity of toxicity because severe intoxication can occur with a concentration as low as 150 mg/kg.

The signs and symptoms of acute salicylate toxicity are similar to those of chronic intoxication, but the effects are often more pronounced and occur more quickly. Acute salicylate overdose usually results from the ingestion of a single toxic dose, and its severity can be judged on the basis of estimated amount ingested (in milligrams per kilogram of body weight), as follows:

- Little or no toxicity: less than 150 mg/kg
- Mild to moderate toxicity: 150 to 300 mg/kg
- Severe toxicity: 300 to 500 mg/kg
- Life-threatening toxicity: over 500 mg/kg

However, doses lower than 150 mg/kg have resulted in fatal toxicity. A serum salicylate concentration measured 6 hours or longer after the ingestion may be used in conjunction with the Done nomogram to estimate the severity of intoxication and help guide treatment. The **Done nomogram** is a graphic plot of serum salicylate level as a function of time since salicylate ingestion (Done, 1960). It was first published in a 1960 issue of the journal *Pediatrics* and is still widely used today for gauging acute salicylate toxicity. This nomogram is intended for estimating the severity only of acute intoxications and not chronic salicylate intoxication. Table 49.4 describes, in general terms, the treatment for cases of varying severity. Treatment goals include removing salicylate from the GI tract and preventing its further absorption; correcting fluid, electrolyte, and acid-base disturbances; and implementing measures to enhance salicylate elimination, including hemodialysis.

An acute overdose of nonsalicylate NSAIDs (e.g., ibuprofen) causes effects similar to those of salicylate overdose, but they are generally not as extensive or as dangerous. Symptoms include CNS toxicities such as drowsiness, lethargy, mental confusion, paresthesias (abnormal touch sensations), numbness, aggressive behaviour, disorientation, seizures, and GI toxicities such as

TABLE 49.4 Acute Salicylate Intoxication: Treatment

Severity	Treatment
Mild	1. Dosage reduction or discontinuation of salicylates 2. Symptomatic and supportive therapy
Severe	1. Discontinuation of salicylates 2. Intensive symptomatic and supportive therapy 3. Dialysis if high salicylate levels, unresponsive acidosis (pH less than 7.1), impaired kidney function or kidney failure, pulmonary edema, persistent CNS symptoms (e.g., seizures, coma), progressive deterioration despite appropriate therapy

CNS, central nervous system.

nausea, vomiting, and GI bleeding. Intense headache, dizziness, cerebral edema, cardiac arrest, and death have also been known to occur in extreme cases. For suspected overdose, consultation with a poison control centre is recommended. Treatment consists of the administration of activated charcoal, with supportive and symptomatic treatment initiated thereafter. Unlike with salicylates, hemodialysis appears to be of no value in enhancing the elimination of nonsalicylate NSAIDs.

Interactions

Drug interactions associated with the use of salicylates and other NSAIDs can result in significant complications and morbidity. One significant drug interaction occurs with the use of NSAIDs and angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin-receptor inhibitors (ARBs). NSAIDs inhibit renal prostaglandins, resulting in afferent arteriole vasoconstriction, and ACEI/ARBs cause efferent arteriole vasodilation. The combination of both results in a drastic decrease in glomerular filtration rate (GFR) which can lead to kidney failure (especially in patients with already compromised kidneys or in older adults). Some of the more common interactions are listed in Table 49.5.

NSAIDs can also interfere with laboratory test results. Specifically, salicylates can cause what are usually minor and transient elevations in liver enzymes (alanine aminotransferase [ALT], aspartate aminotransferase [AST]), but, unlike with acetaminophen (see Chapter 11), cases of severe hepatotoxicity are rare. Hematocrit, hemoglobin level, and red blood cell (RBC) count can drop if there is any drug-induced GI bleeding, and bleeding time may be prolonged. NSAID-induced hyperkalemia or hyponatremia can also occur.

Dosages

For the recommended dosages of selected NSAIDs, refer to the table on p. 796.

DRUG PROFILES

Salicylates

Aspirin is the most commonly used of all salicylates. Although aspirin is available over the counter, many of the other salicylate drugs, such as diflunisal, do require a prescription. Salicylates are most commonly used in solid oral dosage forms (e.g., tablets,

TABLE 49.5 Salicylates and Other NSAIDs: Drug Interactions

Drug	Mechanism	Result
Alcohol	Additive effect	Increased GI bleeding
Anticoagulants	Platelet inhibition, hypoprothrombinemia	Increased bleeding tendencies
ASA and other salicylates with NSAIDs	Reduce NSAID absorption, additive GI toxicities	Increased GI toxicity with no therapeutic advantage
Bisphosphonates	Additive GI effects	Increased GI bleeding risk
Corticosteroids and other ulcerogenic drugs	Additive toxicities	Increased ulcerogenic effects
Ciclosporin	Inhibition of kidney prostaglandin synthesis	Increased nephrotoxic effects of cyclosporine; kidney failure
Diuretics and ACE inhibitors	Inhibition of prostaglandin synthesis	Reduced hypotensive and diuretic effects
lithium carbonate	Increased lithium absorption	Increased lithium concentrations
Protein-bound drugs	Compete for binding	More pronounced drug actions
Uricosurics	Antagonism	Decreased uric acid excretion
Natural health products: feverfew, garlic, ginger, ginkgo	Interference with platelet function	Increased bleeding risk

ACE, angiotensin-converting enzyme; ASA, acetylsalicylic acid; GI, gastrointestinal; NSAIDs, nonsteroidal anti-inflammatory drugs.

capsules). Other available dosage forms include topical cream (Aspercreme®), oral liquids, and rectal suppositories. Aspirin is also contained in many combination products, including with antacids (e.g., Alka Seltzer®), with the antidiabetic pravastatin, and with the antiplatelet dipyridamole. Many of the available analgesic combinations contain caffeine, which provides an adjunctive analgesic effect. Aspirin is also available in special dosage forms, such as enteric-coated aspirin (Praxis ASA EC®), designed to protect the stomach mucosa by dissolving in the duodenum.

acetylsalicylic acid

Aspirin is known chemically as acetylsalicylic acid (ASA). It is the prototype salicylate and NSAID and is the most widely used drug in the world. A daily aspirin tablet (81 mg or 325 mg) continues to be routinely recommended as prophylactic therapy for adults who have strong risk factors for developing coronary artery disease or stroke, even if they have no prior history of such an event. The American College of Cardiology (Arnett, Blumenthal, Albert, et al., 2019) has recommended that caution be exercised with the use of daily aspirin in patients with increased risk of bleeding and in individuals greater than 70 years of age; however, no new recommendations from the Canadian Cardiovascular Society have addressed changes to the use of daily aspirin. The 81-mg dose (which is traditionally thought of as “children’s” aspirin) effectively inhibits thromboxane A₂, and the 325-mg strengths appear to be equally beneficial for the prevention of thrombotic events. For this reason, the lower strength is often chosen for patients who have any elevated risk of bleeding, such as those with prior stroke history, those with a history of peptic ulcer disease, or those taking the anticoagulant warfarin (Coumadin®). Aspirin is also often used to treat pain associated with headache, neuralgia, myalgia, and arthralgia, as well as other pain syndromes resulting from inflammation, including arthritis, pleurisy, and pericarditis. The 81-mg dose, however, is not appropriate for treating pain in adults. Patients with systemic lupus erythematosus may benefit from aspirin therapy because of its antirheumatic effects. Aspirin is also used for its antipyretic action.

Aspirin and other salicylates all have one specific contraindication. This drug class is contraindicated in children with flulike symptoms because the use of these drugs has been strongly associated with Reye’s syndrome. This is an acute and potentially life-threatening condition involving progressive neurological deficits that can lead to coma and may also involve liver damage. It is believed to be triggered by viral illnesses such as influenza as well as by salicylate therapy itself in the presence of a viral illness. Survivors of this condition may or may not suffer permanent neurological damage.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	15–30 min	1–2 hr*	3–6 hr; anti-platelet effects last ~10 d	4–6 hr

*chewing non-enteric coated tablets (like in the setting of an acute coronary syndrome) ASA has a peak of 20 minutes whereas chewing enteric-coated tabs peaks in 2 hours

Acetic Acid Derivatives

There are several acetic acid derivatives, which are listed in Box 49.1. Indomethacin and ketorolac are the most commonly used.

indomethacin

As with the other NSAIDs, indomethacin has analgesic, anti-inflammatory, antirheumatic, and antipyretic properties. Its therapeutic actions are of particular use in the treatment of rheumatoid arthritis, osteoarthritis, acute bursitis or tendinitis, ankylosing spondylitis, and acute gouty arthritis. The drug is available for both oral and rectal use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	30 min	2 hr	2.6–11.2 hr	4–6 hr

ketorolac tromethamine

Ketorolac tromethamine (Toradol) is unique in that although it does have some anti-inflammatory activity, it is used primarily for its powerful analgesic effects. Its analgesic effects are comparable to those of narcotic drugs such as morphine sulphate, which can make it a desirable choice for patients who are opiate addicted and have acute pain control needs, as ketorolac lacks the addictive properties of the opioids. Ketorolac is indicated for the treatment of moderate-to-severe acute pain such as that resulting from orthopedic injuries or surgery. Ketorolac can be given orally or by injection, and there is also a dosage form for ophthalmic use (see Chapter 57). It is available only by prescription. It is indicated for short-term use to manage moderate-to-severe acute pain. It is not indicated for treatment of minor pain or chronic pain. The most common adverse effects of ketorolac include kidney impairment, edema, GI pain, dyspepsia, and nausea. Ketorolac is not recommended for use in children under age 16, as safety and efficacy in children have not been established. It is important to note that the drug can be used only for up to 5 days for postsurgical patients and for up to 7 days for patients with musculoskeletal pain because of its potential adverse effects on the kidney and GI tract. If supplementary analgesia is required, a concomitant low dose of an opiate can be used.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Unknown	45 min	4–6 hr	4–6 hr or longer
IV/IM	0.5 hr	1–3 min (IV); 30–60 min (IM)	2–9 hr	4–6 hr

Propionic Acids

ibuprofen

Ibuprofen (Motrin, Advil) is the prototype NSAID in the propionic acid category, which also includes flurbiprofen, ketoprofen, naproxen, and oxaprozin. Ibuprofen is the most commonly used of the propionic acid drugs because of the numerous indications for its use and because of its relatively safe adverse effect profile. It is often used for its analgesic effects in the management of rheumatoid arthritis, osteoarthritis, primary dysmenorrhea, dental pain, and musculoskeletal disorders; in addition, it is used for its antipyretic actions. In 2015, Health Canada issued a warning about the risk of serious cardiovascular effects (e.g., stroke, MI) associated with high doses of ibuprofen, at least 2 400 mg/day. The risk increases with dose size and duration of use (Health Canada, 2018).

Naproxen is the second most commonly used NSAID, with an adverse effect profile reported to be somewhat better than that of ibuprofen, as well as fewer drug interactions with ACE inhibitors given for hypertension. Evidence indicates that ibuprofen is more likely than naproxen to interact with these drugs and hinder their desired hypotensive effects. Both drugs are available for oral use in both OTC and prescription strengths. In 2011, an injectable form of ibuprofen became available.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	30–60 min (analgesic); 7 days (anti-inflammatory)	1–2 hr	2 hr	4–6 hr

Cyclooxygenase-2 Inhibitors

The COX-2 inhibitors were developed primarily to decrease the GI adverse effects characteristic of other NSAIDs because of their COX-2 selectivity. However, they are not totally devoid of GI toxicity. Gastritis and upper GI bleeding have been reported with their use, although much less frequently than with the use of older NSAIDs. Originally, there were three COX-2 inhibitors; however, they were removed from the Canadian market because the use of rofecoxib (Vioxx®) and valdecoxib (Bextra®) was found to be associated with an increased risk of adverse cardiovascular events, including MI, stroke, and death.

celecoxib

Celecoxib (Celebrex®) was the first COX-2 inhibitor and is the only one remaining on the market. It is indicated for the treatment of osteoarthritis, rheumatoid arthritis, acute pain symptoms, ankylosing spondylitis, and primary dysmenorrhea. Its use was recently approved by Health Canada for symptoms associated with ankylosing spondylitis. There is evidence that celecoxib use may pose a risk of cardiovascular events similar to that associated with rofecoxib and valdecoxib. However, there is inconsistency in the literature regarding the true potential for these effects. Other adverse effects associated with celecoxib include headache, sinus irritation, diarrhea, fatigue, dizziness, lower extremity edema, and hypertension. COX-2 inhibitors have little effect on platelet function. Celecoxib is not to be used in patients with known sulfa allergy.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1 hr	3 hr	11 hr	Unknown

Enolic Acid Derivatives

The enolic acid derivatives include piroxicam, meloxicam, and nabumetone. Piroxicam and meloxicam are potent drugs that are commonly used in the treatment of mild-to-moderate osteoarthritis, rheumatoid arthritis, and gouty arthritis. Both are available only in oral dosage formulations and have contraindications similar to those of the other NSAIDs.

Nabumetone is better tolerated than some of the other enolic acid derivatives in terms of GI adverse effects; it is relatively nonacidic compared with most of the other NSAIDs, which may account for its better GI tolerance. Currently, it is indicated only for the treatment of osteoarthritis and rheumatoid arthritis.

DOSAGES Most Commonly Used NSAIDs

Drug	Pharmacological Class	Usual Dosage Range	Indications
acetylsalicylic acid (ASA, aspirin)	Salicylate	<i>Adults</i> PO/PR: 325–650 mg q4h (max 4 gm/day) PO: 3.6–5.4 gm/day, divided PO: 80–325 mg once daily	Fever, pain Anti-inflammatory Thromboprevention
celecoxib (Celebrex)	COX-2 inhibitor	<i>Adults over 18 yr</i> PO: 100–200 mg/day given in 1 or 2 doses PO: Initial 400 mg (day 1); then 200 mg/day × 7 days PO: 400 mg bid	Rheumatoid arthritis, osteoarthritis, ankylosing spondylitis Acute pain Reduction of number of hereditary colon polyps in familial adenomatous polyposis
ibuprofen (Motrin, Advil, others)	Propionic acid derivative	<i>Infants (< 6 months) and Children</i> 5–10 mg/kg/dose every 6–8 hours (maximum 40 mg/kg/day OR 400 mg/dose max) <i>Adults and children over 12 yr</i> 200–400 mg q4h (max 1 200 mg/day)	Fever, pain Arthritis, fever, pain, dysmenorrhea
indomethacin (Indocid P.D.A.®, Nu-Indo®)	Acetic acid derivative	<i>Adults and children over 14 yr</i> PO: 25–50 mg bid–tid (max 200 mg/day) PR: 50–100 mg bid (max 200 mg)	Arthritis including acute gouty arthritis, bursitis, or tendinitis
ketorolac tromethamine (Toradol)	Acetic acid derivative	<i>Adults</i> PO: 10 mg q4–6h (max 40 mg/day) × 5–7 days IM: 10–30 mg q4–6h (max 120 mg/day if under 65 yr; max 60 mg/day if older than 65 yr)	Acute painful conditions that would otherwise require opioid-level analgesia

IM, intramuscular; PO, oral; PR, rectal.

ANTIGOUT DRUGS

Gout is caused by the overproduction of uric acid, decreased uric acid excretion, or both. This overproduction or decreased excretion can often result in hyperuricemia (too much uric acid in the blood). When the body contains too much uric acid, deposits of uric acid crystals, an end product of purine metabolism, collect in tissues and joints. This causes an inflammatory response and extreme pain because these crystals are like small needles that jab and stick into sensitive tissues and joints. Purines are part of normal dietary intake and are used to make the essential structural units of deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). During purine metabolism, they are converted from hypoxanthine to xanthine and eventually to uric acid. The normal pathway for purine metabolism is depicted in [Figure 49.2](#). This pathway is overactive in patients with gout and is reduced by antigout drug therapy. The goals of gout treatment are to decrease the symptoms of an acute attack and prevent recurrent attacks.

DRUG PROFILES

Although specific antigout drugs are available, the NSAIDs (described earlier) are considered first-line therapy for most patients with gout. The specific antigout drugs, allopurinol, febuxostat, probenecid, and sulfinpyrazone, are targeted at the underlying defect in uric acid metabolism, which causes either overproduction or underexcretion of uric acid (see

[Figure 49.2](#)). Both of these pathological processes lead to tissue accumulations of uric acid crystalline deposits (gouty deposits) and symptoms of gout. Not all gouty deposits occur within joints. Gouty arthritis is the condition in which one or more joints are inflamed from the collection of gouty deposits inside the joint anatomy. This is also called *articular gout*, whereas gout that occurs in tissues outside of the joints is called *abarticular gout*.

allopurinol

The beneficial effect of allopurinol (Zyloprim®) in the relief of gout is the inhibition of the enzyme xanthine oxidase, which thereby prevents uric acid production. Allopurinol is indicated for patients whose gout is caused by excess production of uric acid (hyperuricemia). Allopurinol is also used to prevent acute tumour lysis syndrome (see [Chapter 52](#)).

Allopurinol is contraindicated in patients with a hypersensitivity to it. Significant adverse effects of the drug include agranulocytosis, aplastic anemia, and serious and potentially fatal skin conditions such as exfoliative dermatitis, Stevens–Johnson syndrome, and toxic epidermal necrolysis. Azathioprine and mercaptopurine both significantly interact with allopurinol, and as a result, their dosages may have to be adjusted. Allopurinol is available only for oral use. The usual recommended adult dosage is 200 to 800 mg/day, depending on the severity of the gout experienced by the patient, with the maximum dosage being 800 mg/day. In renal impairment, allopurinol is not

Fig. 49.2 Uric acid production. XO, xanthine oxidase.

contraindicated but lower maximum doses should be observed. For patients with CrCl 10–20 mL/min, the maximum dose would be 200 mg/day. For patients with a CrCl 3–10 mL/min the maximum dose would be 100 mg/day. In renal impairment, doses should be initiated at 50 mg daily and titrated more slowly. Potential benefits of allopurinol may warrant the use of the drug in pregnant women despite potential risks. The new drug febuxostat (Uloric®) is a nonpurine selective inhibitor of xanthine oxidase. It is the first new drug approved for the treatment of gout since the 1960s. Febuxostat is more selective for xanthine oxidase than allopurinol and may pose a greater risk of cardiovascular events than allopurinol. It is not to be given along with theophylline, azathioprine, or mercaptopurine. It is dosed at 80 mg/day.

PHARMACOKINETICS (Allopurinol)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	2–3 days	1.5 (allopurinol)–4.5 hr (oxypurinol)	1–2 hr (allopurinol); 15 hr (oxypurinol)	Unknown

colchicine

Colchicine is the oldest available drug for the treatment of acute gout and is considered second-line therapy, after the NSAIDs. Colchicine appears to be effective in the treatment of gout by reducing the inflammatory response to deposits of urate crystals in joint tissue. Its mechanism of action is not clearly defined, but it is thought to inhibit the metabolism, mobility, and chemotaxis of polymorphonuclear leukocytes. Chemotaxis is the chemical attraction of leukocytes to the site of inflammation, which worsens an inflammatory response.

Colchicine is a powerful inhibitor of cell mitosis and can cause short-term leukopenia. For this reason, it is generally used for the short-term treatment of acute attacks of gout. However, it may be used for prophylaxis of acute attacks in dosages of 0.6 mg once or twice a day. The more severe adverse effects of colchicine can include bleeding into the GI or urinary tracts; the drug must be discontinued if such effects appear. Colchicine is contraindicated in patients with a known hypersensitivity to it and in those with blood dyscrasias or severe kidney, GI, liver, or cardiac disorders. There is no specific antidote for colchicine poisoning. The drug is available in oral forms only.

The usual adult dosage of colchicine for an acute gout flare is an initial dose of 1 to 1.2 mg initially, followed by 0.6 mg 1 hour later and every 2 hours until the gout pain disappears or until nausea, vomiting, or diarrhea develops. It is classified as pregnancy category D. The patient must wait 12 hours to resume prophylaxis (0.6 mg once or twice daily). When colchicine is used for the treatment of acute gout, 3 days must pass before a second course of therapy is initiated. Colchicine dosages must be reduced in patients with kidney impairment. There is evidence of fetal risk with the use of colchicine, but the potential benefits of the drug may outweigh the risk.

PHARMACOKINETICS (Colchicine)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	18–24 hr	0.5–3 hr	27–31 hr	~24 hr

probenecid

Probenecid (Benuryl®) inhibits the reabsorption of uric acid in the kidney and thus increases the excretion of uric acid. Drugs that promote uric acid excretion are known as *uricosurics*. Probenecid acts by binding to the special transporter protein in the proximal convoluted kidney tubule that takes uric acid from the urine and places it back into the blood. The probenecid is then reabsorbed back into the bloodstream while the uric acid remains in the urine, from where it is excreted. Besides being used to treat the hyperuricemia associated with gout and gouty arthritis, it also has the ability to delay the renal excretion of penicillin, which increases serum levels of penicillin and prolongs its effect (see Chapter 43). Probenecid is available as a 500-mg oral tablet. The usual adult dosage is 250 mg, twice a day, with food, milk, or antacids, for 1 week, followed by 500 mg twice daily thereafter. This dosage may be adjusted as needed to maintain desirable serum uric acid levels. Contraindications to the use of probenecid include peptic ulcer disease and blood dyscrasias. Probenecid is ineffective in patients with kidney impairment and is not to be used in these patients. There is no risk to the fetus if the drug is required during pregnancy.

❖ NURSING PROCESS

◆ ASSESSMENT

Prior to giving anti-inflammatory, antigout, and related drugs, it is crucial to patient safety and drug effectiveness to assess for drug allergies, contraindications, cautions, and drug interactions associated with each drug in these major groups. Before administering anti-inflammatory drugs, perform a thorough head-to-toe physical assessment, including a baseline pain assessment when appropriate; measure vital signs; and take a thorough medication history, noting any prescription medications, OTC medications, and natural health products the patient is taking (see Natural Health Products: Glucosamine and Chondroitin). Analyze results of laboratory tests reflecting hematological, kidney, and liver functioning, before initiation of therapy as ordered, especially if long-term use is indicated. These tests will include RBC count, hemoglobin level, hematocrit, white blood cell count, platelet count, blood urea nitrogen (BUN), and liver enzymes such as alkaline phosphatase (ALP), aspartate aminotransferase (AST), and lactate dehydrogenase (LDH). If NSAIDs are used in the short term for other conditions (e.g., fever, acute pain), laboratory studies are not usually indicated since these drugs are available over the counter and are self-administered.

NATURAL HEALTH PRODUCTS

Glucosamine and Chondroitin

Overview

Glucosamine is chemically derived from glucose. Its chemical name is *2-amino-2-deoxyglucose sulphate*. Glucosamine is thought to enhance the production of cartilage matrix components, increase hyaluronic production, and prevent collagen degeneration.

Chondroitin is a protein usually isolated from bovine (cow) cartilage. To date, there are no reports of disease transmission from cows to humans with chondroitin. It increases the hyaluronic production by human synovial cells, which maintains viscosity in synovial fluid.

Common Uses

These two supplements are often used in combination for synergistic effect, and sometimes individually, to treat pain from osteoarthritis. Although most commonly taken orally, injectable forms are commercially available (e.g., for administration by a naturopathic health care provider).

Adverse Effects

Glucosamine: Usually mild adverse effects that are comparable to those of a placebo in clinical studies, including GI discomfort, drowsiness, headache, and skin reactions.

Chondroitin: No major ill effects in studies lasting from 2 months to 6 years; GI discomfort is the most common adverse effect, but is usually well tolerated.

Potential Drug Interactions

Both supplements: May enhance the anticoagulant effects of warfarin. (The patient's INR needs to be measured more frequently during glucosamine/chondroitin therapy and the warfarin dosage adjusted if indicated.)

Glucosamine: May cause an increase in insulin resistance, necessitating the need for higher dosages of oral hypoglycemics or insulin.

Contraindications

Both supplements: No specific contraindications listed, but avoidance in pregnancy is recommended because of lack of firm safety data.

Prior to the use of aspirin, NSAIDs, other anti-inflammatory drugs, and antigout drugs, assess and document the duration, onset, location, and type of inflammation and pain the patient is experiencing, as well as any precipitating, exacerbating, or relieving factors. Note any interference of the symptoms with the patient's ability to perform activities of daily living (ADLs). Inspect all joints with attention to deformities, immobility or limitations in mobility, overlying skin condition, and presence of any heat or swelling over the joint. Age is important to assess because aspirin and many of the other NSAIDs are not to be used in children and adolescents because of the associated increased risk of Reye's syndrome (see the Special Populations: Children box). These drugs are also to be used cautiously in older adults who have reduced liver and kidney function (See Special Populations: Older Adults box). Assessing the odour of aspirin is also important because a vinegary odour is associated with chemical breakdown of the drug. Prior to the use of aspirin, assess the patient for a history of asthma, wheezing, or other respiratory problems because of increased incidence of allergic reactions to aspirin in individuals with such a history. As well, identify patients who have been diagnosed with what is called the *aspirin triad*, which includes asthma, nasal polyps, and rhinitis; these conditions are considered to put the patient at risk for reactions to aspirin. Other contraindications, cautions, and drug interactions relevant to the use of aspirin and other NSAIDs have been discussed previously. Remember that acetylsalicylic acid (aspirin) and other NSAIDs have anti-inflammatory, antipyretic, analgesic, and antiplatelet activity but also carry a risk for ulcerogenic adverse effects and GI bleeding. NSAIDs carry the risk of acute reversible hepatotoxicity, kidney failure, hearing loss, and noncardiogenic pulmonary edema, so a review of patients' history of pre-existing medical conditions is important.

In addition to patient assessment, the use of ketorolac requires assessment of the drug order to ensure that the drug has been ordered for a short term (i.e., no more than 5 to 7 days) and only for patients experiencing moderate to severe acute pain. Assess patients for underlying signs of infection before the use of any NSAID or other anti-inflammatory drug because these drugs may mask symptoms. Prior to the use of celecoxib, document any cardiovascular disorders or symptoms because use of this drug carries a risk of cardiovascular events.

Prior to the use of antigout drugs, perform a thorough assessment of hydration status and baseline serum uric acid levels. Closely assess urinary output prior to and during drug therapy to ensure an output of at least 30 to 60 mL/hour. Determine and assess renal function through monitoring of GFR, BUN, and serum creatinine, as well as liver function through monitoring of ALP, AST, ALT, and LDH. If a patient is receiving febuxostat (Uloric), assess for any history of cardiovascular disease due to the risk of adverse effects linked to the cardiac system. Additionally, drug interactions may occur with theophylline, azathioprine, or mercaptopurine. If a patient is taking allopurinol, assess the integrity of the skin due to potentially life-threatening skin adverse effects, including exfoliative dermatitis, Stevens-Johnson syndrome, and toxic epidermal necrolysis. Assess blood counts because of the potential for aplastic anemia and agranulocytosis. Prior to the use of colchicine, conduct a thorough assessment for a history of GI distress; ulcers; or

SPECIAL POPULATIONS: CHILDREN

Reye's Syndrome

Reye's syndrome is associated with the administration of aspirin to children and adolescents and is a potentially life-threatening illness. Encephalopathy and liver damage are two of the serious complications resulting from Reye's syndrome, which usually occurs after a viral infection, such as chicken pox or influenza B, during which aspirin is often given to decrease fever. To reduce the risk for Reye's syndrome, aspirin or medications that contain aspirin should not be given to children or adolescents to treat viral illnesses or fever. Other names for aspirin include acetylsalicylic acid, acetylsalicylate, salicylic acid, and salicylate. Other drugs that can be used instead to reduce fever and relieve pain include acetaminophen and ibuprofen. Check the label on any medication that is to be given to a child because aspirin is contained in at least 50 over-the-counter drugs, including, for example, Alka-Seltzer® and Anacin®. Aspirin is also found in numerous cold and flu preparations.

Signs and Symptoms of Reye's Syndrome

- Altered liver function
- Encephalopathy and fatty degeneration of the viscera, primarily in children and adolescents
- Changes in level of consciousness
- Coma, flaccid paralysis, loss of deep tendon reflexes
- Hypoglycemia
- Seizures
- Vomiting

Medical Management

- Provide supportive treatment in the Critical Care Unit
- Maintain life functions, restore metabolic balance, and control cerebral edema

- Administer intravenous glucose (10% or higher) for treatment of hypoglycemia
- Monitor blood glucose level; insulin may be needed
- Administer vitamin K for clotting problems
- Give fresh frozen plasma if needed for significant bleeding
- Provide prophylactic antiepileptic drugs
- Monitor intracranial pressure
- Initiate cautious fluid administration
- Administer osmotic diuretics with steroids if needed to treat cerebral edema

Nursing Management

- Critical care setting often indicated for care of these patients
- Assess neurological status, vital signs, and arterial and central venous pressures
- Monitor blood gas concentrations and intracranial pressure as ordered
- Control temperature to prevent elevations and increased O₂ demands
- Elevate the head of the bed
- Monitor intake and output
- Initiate hyperventilation (if patient is intubated and if ordered) to reduce intracranial pressure by lowering CO₂ levels and increasing O₂ levels
- Provide a quiet environment
- Handle gently
- Provide family support during critical phase of the illness
- Provide physical and emotional support for the child and family with recovery
- Ensure appropriate spiritual care is provided
- Educate the public about Reye's syndrome and its life-threatening complications

Source: Mayo Foundation for Medical Education and Research. (2014). *Reye's syndrome*. Retrieved from <http://www.mayoclinic.org/diseases-conditions/reyes-syndrome/basics/definition/con-20020083>.

cardiac, kidney, or liver disease. Also worthy of mention regarding antigout drugs (e.g., allopurinol, colchicine, probenecid) is that these drugs may be used for either their short-term or long-term effects. Therefore, assess the order and indication for the antigout drug to ensure that the patient is receiving the appropriate treatment. Also assess for all contraindications, cautions, and drug interactions (see earlier discussion).

◆ NURSING DIAGNOSES

- Potential risk for acute pain as a result of disease process or injury to joints and other disease-affected areas
- Inadequate knowledge as a result of first-time drug therapy for treatment of a disease process
- Potential risk for injury as a result of the effects of the disease and treatment on mobility and the performance of ADLs

◆ PLANNING

◆ Goals

- Patient will experience pain relief or relief of symptoms within the expected time frame.
- Patient will demonstrate increased knowledge about the disease process, medication regimen, and beneficial lifestyle changes.
- Patient will remain free from injury related to the disease process or drug regimen.

◆ Expected Patient Outcomes

- Patient remains pain free or nearly pain free with adequate drug and nondrug therapy.
- Patient states that pain and changes in joints and mobility are characteristic of inflammation, injury, or related disease processes and will decrease with effective therapy.
- Patient identifies factors that aggravate or alleviate pain, such as movement, activity, exercise, and changes in the weather or atmosphere.
- Patient states nonpharmacological measures to use to promote comfort, increase joint function and mobility, and improve performance of ADLs (e.g., biofeedback, imagery, massage, application of hot or cold packs, physiotherapy, relaxation therapy).
- Patient describes disease process requiring treatment with an NSAID or antigout drug therapy.
- Patient states the expected impact of effective and consistent drug therapy in the prevention of damage to the part of the musculoskeletal system being affected by the disease process (of injury, gout, arthritis, etc.).
- Patient states adverse effects associated with NSAIDs or antigout drug therapy.
- Patient states symptoms that should be reported to the health care provider immediately, such as fever, increase in symptoms or joint pain, jaundice, changes in skin, or severe rash.

SPECIAL POPULATIONS: OLDER ADULTS

NSAIDs

It is anticipated that, by 2036, there will be more than 10.4 million Canadians 65 years of age and older, exceeding 23% of the population. It is also anticipated that the use of over-the-counter NSAIDs will be widespread and increasing in this population and requiring special attention and education to prevent or minimize adverse effects. Understanding the physiological changes that older adult patients experience will help ensure safe and effective use of these medications.

The underlying pharmacokinetic characteristics and physical and biological changes in older adult patients must be understood. Even if older adults have normal kidney and liver function, they have a reduced rate of drug metabolism and drug elimination compared with younger adults.

Patients 65 years of age and older do not have to be ill for NSAIDs to adversely affect them, because of normal age-related physiological changes. The presence of chronic or multiple illnesses may result in an increased incidence of adverse reactions.

Some changes noted in older adult patients that affect drug treatment include changes in kidney elimination, protein binding, body composition, drug distribution, drug clearance, and sensitivity to drugs, as well as an increased incidence of adverse reactions to all types of medications.

Older patients who are at risk for kidney insufficiency because of natural physiological changes may experience changes in fluid balance as well as changes in drug reabsorption, excretion, and filtration processes; these changes may lead to drug toxicity.

Cardiac output decreases by 25% between the ages of 25 and 65, which results in decreased blood flow to the kidneys and, consequently, reduced glomerular filtration rate (GFR). There is also an overall decline in circulating blood volume, which may affect overall pharmacokinetics and lead to decreased drug absorption, distribution, metabolism, and excretion.

Many individuals older than 65 years of age become slow metabolizers of medications, which affects the way NSAIDs are handled by the liver. In addition, the liver decreases in size and weight with advancing age. Blood flow to the liver is also decreased. Drug metabolism is affected by these changes, resulting in the possible need to decrease drug dosages for older adults or monitor these patients closely for toxicity.

Gastrointestinal (GI) functioning is affected by aging, with older adults having more acidic gastric juices and decreased gastric motility. These changes may lead to slower emptying of the stomach and result in decreased intestinal drug absorption. Serum levels of drugs, including NSAIDs, may be higher on account of these factors, and overall drug dosages may need to be decreased. Older adults may also be at increased risk for developing NSAID-related GI problems.

Interventions to help decrease NSAID-related adverse reactions include asking the patient pertinent questions; listing all drugs; teaching about all medications; and assessing GI, cardiovascular, and neurological systems according to patient concerns and symptoms. In addition, it is important to teach older adult patients about the maximum doses of NSAIDs.

Source: Hunt, R. (2014). *The elderly patient taking NSAIDs and aspirin*. Retrieved from <http://www.medscape.org/viewarticle/458018> <http://www.medscape.org/viewarticle/458018>; Wooten, J. M. (2012). Pharmacotherapy considerations in elderly adults. *Southern Medical Journal*, 105(8), 437–445.

NSAID, nonsteroidal anti-inflammatory drug.

- Patient takes medication regimen as prescribed.
 - Patient contacts health care provider if there is a lack of improvement in injury or disease process.
 - Patient maintains follow-up appointments with health care provider to enhance therapeutic effectiveness and minimize injury.

◆ IMPLEMENTATION

If aspirin is used, the oral dosage forms are given with food, milk, or meals. Advise patients that sustained-released or enteric-coated tablets are not to be crushed or broken. Monitor serum levels of aspirin if aspirin therapy is used for its anti-inflammatory effect in the treatment of arthritis; however, this indication is rare. Because of its associated high risk of potentially severe adverse effects, aspirin is mainly used in lower doses (e.g., 81 mg) when it is indicated for cardioprotective reasons. If used in higher doses, monitor for clinical presentation as well as serum salicylate levels to help distinguish between mild, moderate, and severe toxicity (see pharmacology discussion). In such situations, it is important to be aware of signs and symptoms of toxicity, such as GI bleeding, other bleeding, and abdominal pain. If any of these occur, report the findings to the health care provider and ensure immediate treatment. If aspirin is used as an antipyretic, the patient's temperature generally begins to decrease within 1 hour. See the Patient Teaching Tips for more information on the safe use of aspirin.

Non-aspirin NSAIDs or other anti-inflammatory drugs may also come in enteric-coated or sustained-release preparations; stress to patients that these are not to be crushed or chewed. Oral dosage forms of these drugs, including ketorolac, may be taken

with antacids or food to decrease GI upset or irritation. Instruct patients to report to the health care provider immediately any moderate to severe GI upset, dyspepsia with nausea, vomiting, abdominal pain, or blood in the stool or vomitus. During therapy with NSAIDs, continuously monitor the patient for bowel patterns, stool consistency, and any occurrence of GI symptoms or dizziness, and document the findings. Monitor laboratory tests during high-dose or long-term treatment, including complete blood count (CBC); BUN levels; platelet counts; and serum bilirubin, ALP, AST, and ALT levels. Emphasize the importance of safe ambulation with NSAID use as well as with the use of any other anti-inflammatory drugs or analgesics. With ketorolac, know that dosing is not to exceed a 5- to 7-day time period with either the oral or intramuscular dosage forms. Administer intramuscular injections slowly into a large muscle mass. Educate patients prescribed celecoxib to take the drug only as ordered and, as with other NSAIDs, to avoid using alcohol, aspirin, salicylates, and OTC drugs containing any of these drugs. Celecoxib may be taken without regard to meals; however, taking the drug with food and fluids may decrease GI upset. Instruct patients to report immediately to a health care provider any stomach or abdominal pain, other GI problems, unusual bleeding, blood in the stool or vomitus, edema, chest pain, or palpitations.

The antagout drugs are somewhat different from the NSAIDs, with different mechanisms of action and different nursing considerations. Colchicine needs to be taken on an empty stomach for optimally complete absorption but is best tolerated if given with food. Educate the patient with gout on the importance of increasing fluid intake, up to 3 L/day, unless contraindicated. Advise patients to avoid using alcohol and any OTC cold-relief

products that contain alcohol while taking colchicine. In addition, inform patients with gout that adherence to the complete medical regimen, both pharmacological and nonpharmacological, is crucial to successful treatment. If allopurinol is prescribed, it is to be given with meals to minimize the occurrence of GI symptoms such as nausea, vomiting, and anorexia. If allopurinol is to be administered in conjunction with chemotherapy (in an attempt to decrease hyperuricemia associated with malignancy and cell death from successful treatment), it should be given a few days before the chemotherapy. Patients taking allopurinol must also increase fluid intake to 3 L/day in order to maintain a urinary output of 2 L/day. This daily fluid intake will also assist in preventing the development of uric acid kidney stones. Patients need to avoid hazardous activities (e.g., driving) if dizziness or drowsiness occurs with the medication. Alcohol and caffeine must also be avoided because these substances will increase levels of uric acid and decrease levels of allopurinol; the intake of even one to two alcoholic drinks per day is associated with higher levels of uric acid. A healthy, balanced diet is recommended for patients with gout; however, patient education should include limiting foods high in purine. Foods high in purine include seafood and red meats (especially organ meats), meat extracts, yeast, beer, beans, peas, oatmeal, lentils, spinach, asparagus, cauliflower, and mushrooms. Patients who are overweight or obese should be encouraged to lose weight, as they are at higher risk of developing gout.

EVALUATION

Aspirin and NSAIDs may vary in their potency and anti-inflammatory and analgesic effects. Therapeutic responses to NSAIDs include the following: decrease in acute pain; decrease in swelling, pain, stiffness, and tenderness of a joint or muscle area; improved ability to perform ADLs; improved muscle grip and strength; reduction in fever; return to normal laboratory values for CBC and sedimentation rate; and return to a less inflamed state, as evidenced by sedimentation rates, X-ray examination, computed tomography (CT) scan, or magnetic resonance

imaging (MRI). Monitoring for the occurrence of adverse effects and toxicity is essential to the safe and effective use of anti-inflammatory drugs (aspirin, celecoxib, other NSAIDs) and antigout drugs (see [Box 49.3](#) and [Tables 49.2 and 49.3](#)).

Therapeutic responses to the antigout drug colchicine include decreased pain in affected joints and increased sense of well-being. Monitor closely patients taking this drug for any increased pain, blood in the urine, excessive fatigue and lethargy, or chills or fever, and contact the health care provider immediately should any of these occur. A therapeutic response to allopurinol includes a decrease in pain in the joints, a decrease in uric acid levels, and a decrease in stone formation in the kidneys.

CASE STUDY

NSAIDs

Jana, a 35-year-old writer, has developed severe pain in her right wrist and has been unable to make her publisher's deadlines because of the pain she is having. After magnetic resonance imaging and a physical examination, she is diagnosed with tendonitis and started on extended-release diclofenac (Voltaren®-XR), 75 mg twice a day. She is also given a wrist orthosis and instructed to resume work slowly once she is feeling better.

1. What instructions are important for Jana at this time?
2. After 1 week of therapy, Jana calls the office and says, "There has been no change! My wrist still hurts. I need to get better quickly!" What is the nurse's best response?

At her 1-month checkup, Jana is happy that her wrist has stopped hurting and that she has been able to resume her writing part-time. She mentions, however, that she has felt extremely tired recently and has had increased abdominal discomfort. She also tells the nurse that her bowel movements have been darker and asks if that could be an adverse effect of the medicine.

3. Explain what is possibly happening, and what steps will be taken next.

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

PATIENT TEACHING TIPS

- Instruct patients that anti-inflammatory drugs, if in sustained-release or enteric-coated forms, are not to be crushed or chewed. Educate patients that the full anti-inflammatory effect of the drug may not be apparent immediately, depending on the specific drug. For example, the onset of full therapeutic anti-inflammatory action of ibuprofen may take 7 days and its analgesic effects may take 30 to 60 minutes.
- Advise patients to provide a list of all medications to all health care providers, including dentists, especially if they are taking high dosages of aspirin or have been taking aspirin or another NSAID for prolonged periods. Aspirin and NSAIDs are generally discontinued 1 week prior to any type of surgery, including oral or dental surgery, per the health care provider's or surgeon's orders.
- Patients should know to always keep aspirin and other drugs out of the reach of children. If a child (or adult) has consumed large or unknown quantities of aspirin or another NSAID, contact a poison control centre and seek emergency medical

attention immediately. Children and adolescents must never take aspirin because of the risk of Reye's syndrome (see the Special Populations: Children box on p. 799). Acetaminophen in the recommended dosage range is usually preferred.

- Educate patients about the adverse effects of aspirin, such as GI upset, nausea, vomiting, diarrhea, dizziness, and tinnitus. [Table 49.3](#) lists the signs and symptoms of acute or chronic salicylate intoxication. Instruct patients to report to a health care provider immediately any black or tarry stools, bleeding around the gums, petechiae, ecchymosis, or purpura.
- Inform patients about the most common adverse effects of NSAIDs (see [Table 49.2](#)). Advise patients to take NSAIDs with food, milk, or antacids to help minimize GI distress.
- Educate patients about the many drug interactions that can occur with aspirin, other NSAIDs, and antigout drugs.
- Alert the patient to look-alike, sound-alike drugs, especially Celebrex (celecoxib), which may be confused with Cilex (citalopram) or Cerebyx (fosphenytoin).

KEY POINTS

- Anti-inflammatory drugs include aspirin, NSAIDs, and COX-2 inhibitors.
- NSAIDs are one of the most commonly prescribed categories of drugs. The first drug in this category to be synthesized was salicylic acid or aspirin. Aspirin is often included in the discussion of anti-inflammatory drugs and identified as such. NSAIDs have analgesic, anti-inflammatory, and antipyretic activities; aspirin also has antiplatelet activity. NSAIDs are thus often used in the treatment of gout, osteoarthritis, juvenile arthritis, rheumatoid arthritis, dysmenorrhea, and musculoskeletal injuries such as strains and sprains.
- The three main adverse effects of NSAIDs are GI intolerance, bleeding (often GI bleeding), and kidney impairment. Misoprostol may be given to prevent GI intolerance and ulcers resulting from NSAID use. It is classified as a prostaglandin analogue. There are also many contraindications to the use of NSAIDs, such as GI tract lesions, peptic ulcers, and bleeding disorders.
- Most oral NSAIDs are better tolerated if taken with food to minimize GI upset.
- When NSAIDs are used to decrease joint inflammation in patients with arthritis, full therapeutic effects may not be experienced for 1 week or longer.
- Antigout drugs are indicated for either acute or chronic gout or gout prophylaxis. Diarrhea and abdominal pain are common adverse effects. Antigout drugs are often given to patients during cancer chemotherapy that causes cell death, to avoid goutlike syndromes and pain.

EXAMINATION REVIEW QUESTIONS

1. A client has been prescribed long-term NSAID therapy. Which of the following drugs may be given to prevent serious GI adverse effects of NSAIDs?
 - a. misoprostol
 - b. metoprolol tartrate
 - c. metoclopramide hydrochloride
 - d. magnesium sulphate
2. The nurse is caring for a patient prescribed NSAID. The nurse should monitor the patient for which symptom indicating NSAID toxicity?
 - a. Constipation
 - b. Nausea and vomiting
 - c. Tremors
 - d. Urinary retention
3. The nurse is providing teaching to a patient about antigout drugs. Which of the following statements indicates the nurse's understanding about the mechanism of action of these drugs?
 - a. "Antigout medications increase blood oxygen levels."
 - b. "Antigout medications decrease leukocytes and platelets."
 - c. "Antigout medications increase protein and rheumatoid factors."
 - d. "Antigout medications decrease serum uric acid levels."
4. The nurse is completing teaching with a patient about newly prescribed antigout medications. Which statement by the nurse would be most accurate when teaching about antigout drugs?
 - a. "Drink only limited amounts of fluids with the drug."
 - b. "This drug may cause limited movement in your joints."
 - c. "There are few drug interactions with this medication."
 - d. "Colchicine is best taken on an empty stomach."
5. A parent calls the clinic to ask about what medication to give a 5-year-old child for a fever during a bout of chicken pox. The nurse's best response would be:
 - a. "Your child is 5 years old, so it would be okay to use children's aspirin to treat his fever."
 - b. "Start with acetaminophen or ibuprofen, but if these do not work, then you can try aspirin."
 - c. "You can use children's dosages of acetaminophen or ibuprofen, but aspirin is not recommended."
 - d. "It is best to wait to let the fever break on its own without medication."
6. A patient has been admitted with possible chronic salicylate intoxication after self-treatment for arthritis pain. The nurse should monitor for which symptom of salicylate intoxication?
 - a. Tinnitus
 - b. Headache
 - c. Constipation
 - d. Nausea
 - e. Bradycardia
7. An order for a child reads: "Give ibuprofen suspension 30 mg/kg/day, divided into four doses, for pain." The child weighs 15 kg. How many milligrams will this child receive per dose?
8. The nurse is reviewing a patient's medication list during a preoperative visit. The patient is scheduled for diagnostic laparoscopy in 2 weeks. He asks the nurse, "I hope I can continue the ibuprofen, because I really ache if I don't take it. It's just minor surgery, right?" What is the nurse's best response?
 - a. "You can continue to take it as the laparoscopy is considered minor surgery."
 - b. "You will need to take a lower dosage during the preoperative period."
 - c. "I'll check with your prescriber, but this drug is usually stopped a week before the surgery because it can cause increased bleeding tendencies."
 - d. "You can switch to aspirin before the surgery; both aspirin and ibuprofen are over-the-counter pain relievers."

CRITICAL THINKING ACTIVITIES

1. A 68-year-old patient has been instructed to take aspirin, 81 mg every morning with breakfast, as part of treatment after having an MI. When discussing the aspirin therapy, he asks the nurse, “Will this also help my arthritis?” What is the nurse’s best answer?
2. A patient has been taking ibuprofen (Motrin), 800 mg three times a day, for treatment of arthritis. She is scheduled for a laparoscopy. She asks you, “I hope I can continue the Motrin because I really ache if I don’t take it. It’s just minor surgery,

right?” What is the nurse’s priority when answering the patient’s question?

3. A patient has been diagnosed with gout and will be taking colchicine. When reviewing the instructions for the medication, he asks, “I like to take my pills with breakfast.” What is the nurse’s priority when providing teaching?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Immunosuppressant Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Discuss the role of immunosuppressive therapy in organ transplant recipients and in the treatment of autoimmune diseases.
2. Discuss the mechanisms of action, contraindications, cautions, adverse effects, routes of administration, drug interactions, and toxicities associated with the most commonly used immunosuppressants.
3. Develop a collaborative plan of care that includes all phases of the nursing process for patients receiving immunosuppressants after organ transplantation or for the treatment of autoimmune diseases.

KEY TERMS

Autoimmune diseases A large group of diseases characterized by the alteration of the immune system's function, in which immune response affects normal body tissue(s), resulting in pathological conditions. (p. 798)

Grafts Transplanted tissues or organs. (p. 801)

Immune-mediated diseases A large group of diseases that result when the cells of the immune system react to a variety

of situations, such as transplanted organ tissue or drug-altered cells. (p. 798)

Immunosuppressants Drugs that decrease or prevent an immune response. (p. 798)

Immunosuppressive therapy Drug treatment used to suppress the immune system. (p. 798)

DRUG PROFILES

- ▶ azathioprine (azathioprine sodium)*, p. 807
- ▶ basiliximab p. 807
- ▶ cyclosporin, p. 807
- ▶ fingolimod hydrochloride, p. 809
- ▶ glatiramer (glatiramer acetate)*, p. 809
- ▶ mycophenolate mofetil, p. 809
- ▶ sirolimus and tacrolimus, p. 809
- ▶ Key drug

* Full generic name is given in parentheses. For the purposes of this text, the more common, shortened name is used.

IMMUNE SYSTEM

The purpose of the immune system is to distinguish self from nonself and to protect the body from foreign material (antigens). There are three layers of barriers or lines of defence to protect the body (Figure 50.1). The first line of defence is a combination of physical (e.g., skin, mucous membranes, hair, and cilia) and chemical (e.g., gastric secretions, vaginal secretions,

urine, tears, sweat, saliva, and cerumen) means. The second line of defence is the leukocytes. The third line of defence is the specific immune response. There are two types of immunity: humoral immunity, which is mediated by B lymphocytes, and cellular immunity, which is mediated by T lymphocytes. This chapter focuses on drugs that suppress the T lymphocytes.

The immune system defends the body against invading pathogens, foreign antigens, and its own cells that become cancerous, or neoplastic. Aside from performing this beneficial function, it can also attack itself and cause what are known as **autoimmune diseases** and **immune-mediated diseases**. The immune system also participates in hypersensitivity, or anaphylactic, reactions, which can be life-threatening. The rejection of kidney, lung, pancreas, liver, and heart (whole organ) transplants is directed by the immune system as well.

Drugs that decrease or prevent an immune response, and hence suppress the immune system, are known as **immunosuppressants**. Treatment with such drugs is referred to as **immunosuppressive therapy**. Immunosuppressants are used for many immune-related disorders, including rheumatoid arthritis, systemic lupus erythematosus, Crohn's disease, multiple sclerosis, myasthenia gravis,

Fig. 50.1 A simplified depiction of the complicated immune system. (From: Patton, K. T., & Thibodeau, G. A. (2010). *Anatomy and physiology* (7th ed.). St. Louis, MO: Mosby.)

psoriasis, and others. Examples of these drugs include cyclophosphamide (see Chapter 52), glatiramer, fingolimod hydrochloride, and many immunomodulators, which are discussed in Chapter 53. This chapter focuses on the drugs used in organ transplantation.

Transplantation is one of the most complex areas of modern medicine. Currently, there are approximately over 4 500 patients awaiting organ donation in Canada, with 76% of those patients waiting for a kidney transplant (Canadian Institute for Health Information, 2018). Many different types of transplants are routinely performed, including, but not limited to, kidney, heart, liver, lung, pancreas, small bowel, bone marrow, and cornea transplantation. The primary concern with transplantation is rejection, which could necessitate that the transplanted organ be removed. Rejection occurs due to an immune response targeted against the transplanted organ. There are three categories of rejection. A hyperacute rejection (or antibody-mediated or humoral rejection) occurs within minutes to hours after a transplant, with an immediate systemic inflammatory response. An acute rejection can occur within the first 3 months, mediated by macrophages and T cytotoxic lymphocytes. This type of rejection often occurs at least once after transplantation and is often reversible with an adjustment to immunosuppressant therapy or increased doses of corticosteroids. Chronic rejection occurs months to years post-transplantation and is considered irreversible. It is the result of a chronic, low-grade immune T cell- and B cell-mediated response. It is often not treatable. Immunosuppressants are used to inhibit the immune system and prevent organ rejection. Patients who have undergone a transplant remain on immunosuppressant therapy for the duration of their lives.

IMMUNOSUPPRESSANT DRUGS

Mechanism of Action and Drug Effects

All immunosuppressants have similar mechanisms of action in that they selectively suppress certain T lymphocyte cell

lines. By doing so, they prevent their involvement in the immune response. This suppression results in a pharmacologically immunocompromised state. Each drug differs in the exact way in which it suppresses certain cell lines involved in an immune response. The major classes of immunosuppressant drugs used in preventing organ rejection include glucocorticoids, calcineurin inhibitors, mammalian target of rapamycin (mTOR) inhibitors, antimetabolites, and biologics. Corticosteroids inhibit all stages of T cell activation and are used for induction (intense immunosuppressive therapy at the time of transplant), maintenance immunosuppression, and acute rejection. Corticosteroids are discussed in depth in Chapter 34 and are not discussed further in this chapter. Calcineurin inhibitors (e.g., cyclosporin, tacrolimus) inhibit the action of phosphatase required for interleukin-2 production. Sirolimus does not inhibit calcineurin but instead forms a complex with an intracellular protein that binds to mTOR, which ultimately inhibits interleukin-2 communication. mTOR is a protein kinase that has a variety of functions related to the regulation of cell growth and proliferation. Antimetabolites (e.g., azathioprine, mycophenolate acetate) inhibit cell proliferation. Biologics (e.g., basiliximab) inhibit cytotoxic T-killer cell function. [Table 50.1](#) outlines the mechanisms of action and indications of the available immunosuppressant drugs.

Indications

The therapeutic uses of immunosuppressants are many and vary from drug to drug, as noted in [Table 50.1](#). Two of these drugs, cyclosporin and tacrolimus, are indicated primarily for both prevention of rejection and treatment of organ rejection. Fingolimod hydrochloride and glatiramer are immunosuppressants that are indicated for the reduction of the frequency of relapses (exacerbations) in a type of multiple sclerosis known as *relapsing–remitting multiple sclerosis*.

TABLE 50.1 Classification and Mechanisms of Action for Available Immunosuppressant Drugs

Drug Names	Mechanism of Action	Indications/Uses
azathioprine sodium (Imuran®)	Blocks metabolism of purines, inhibiting the synthesis of T cell DNA, RNA, and proteins, thereby blocking immune response	Prevention of organ rejection in kidney transplantation; treatment of rheumatoid arthritis
basiliximab* (Simulect®)	Suppresses T cell activity by blocking the binding of the cytokine mediator IL-2 to a specific receptor	Prevention of organ rejection in kidney transplantation
cyclosporin (Sandimmune®, Neoral®, Cyclosporin®)	Inhibits synthesis of T cells by blocking the production and release of the cytokine mediator IL-2	Prevention of graft rejection following solid organ and bone marrow transplantation; treatment of rheumatoid arthritis and psoriasis
fingolimod hydrochloride (Gilenya®)	Decreases the number of lymphocytes available to the CNS	Reduction of relapse frequency in patients with relapsing–remitting MS
glatiramer acetate (Copaxone®)	Precise mechanism unknown; believed to somehow modify immune system processes that are associated with symptoms of MS	Reduction of relapse frequency in patients with relapsing–remitting MS
mycophenolate mofetil (CellCept®), mycophenolate sodium (Myfortic®)	Prevents proliferation of T cells by inhibiting intracellular purine synthesis	Mycophenolate mofetil is indicated for the prevention of organ rejection in kidney, liver, and heart transplantation; mycophenolate sodium is indicated for the prevention of organ rejection in kidney transplantation
sirolimus (Rapamune®)	Inhibits T cell activation by binding to an intracellular protein known as <i>FK-binding protein 12</i> that subsequently prevents cellular proliferation	Prevention of organ rejection in kidney transplantation
tacrolimus (Advagraf®, Prograf®)	Inhibits T cell synthesis, possibly by binding to an intracellular protein known as <i>FK-binding protein 12</i>	Prevention of organ rejection in liver, kidney, and heart transplantation; unlabelled uses† include rejection in bone marrow, pancreas, pancreatic islet cell, and small intestine transplantation, as well as treatment of autoimmune diseases and severe psoriasis

CNS, Central nervous system; DNA, deoxyribonucleic acid; IL-2, interleukin-2; MS, multiple sclerosis; RNA, ribonucleic acid.

*Note that “ab” in any drug name usually indicates that it is a monoclonal antibody synthesized using recombinant DNA technology.

†Use not approved by Health Canada but under investigation.

Contraindications

The main contraindication for all immunosuppressants is known drug allergy. Relative contraindications, depending on the patient's condition, may include kidney or liver failure, hypertension, uncontrolled infection, and concurrent radiation therapy. While pregnancy is not necessarily a contraindication to these drugs, immunosuppressants should be used in pregnant women only in urgent situations, under close care of a transplant team that includes pharmacists, nurses, and surgeons.

Adverse Effects

Immunosuppressant drugs have many significant adverse effects, which are listed in Table 50.2. Immunosuppressants place patients at increased risk for opportunistic infections. They may also increase the risk of certain types of cancers; for instance, patients on immunosuppressant therapy are at a greater risk of developing skin cancers than the general population. Other adverse effects are specific to the immunosuppressant drug. For example, cyclosporin and tacrolimus can cause nephrotoxicity. Corticosteroids, cyclosporin, and tacrolimus can cause post-transplant diabetes mellitus. Additionally, patients on immunosuppressant drugs need to avoid live vaccines.

Interactions

Patients who have undergone a transplant are placed on immunosuppressant drugs for their lifetime and are often on combination therapy, increasing their risk for drug interactions.

Immunosuppressants have narrow therapeutic windows, and drug interactions can be significant. Drugs that cause increased levels of immunosuppressant drugs can cause toxicity, whereas drugs that reduce immunosuppressant drug levels may lead to organ rejection. The most significant drug interactions with immunosuppressant drugs are listed in Table 50.3. Many of these drugs are metabolized by the cytochrome P450 enzyme system; thus, drug interactions are common and can be significant. Grapefruit can inhibit metabolizing enzymes and thus can increase the levels of cyclosporin, tacrolimus, and sirolimus. Foods that are high in potassium, such as bananas and tomatoes, can increase cyclosporin nephrotoxicity. Meals that have high fat content can increase sirolimus levels.

Cyclosporin, tacrolimus, and sirolimus can be involved in many drug interactions, several of which can be harmful. Drugs that may increase their actions are diltiazem, verapamil, fluconazole, itraconazole, clarithromycin, allopurinol, metoclopramide, amphotericin B, cimetidine, and ketoconazole. Grapefruit (including its juice), because of its inhibition of key metabolizing enzymes, can also increase the bioavailability of these three immunosuppressants. For example, cyclosporin can have a profound interaction with grapefruit juice; when they are taken together, there is an increase in the bioavailability of cyclosporin, from 20 to 200%. Drugs that may reduce the effects of these immunosuppressants include carbamazepine, phenobarbital, phenytoin, and rifampin; these interactions occur because some of the same cytochrome P450 metabolizing enzymes are

TABLE 50.2 Immunosuppressant Drugs: Common Adverse Effects

Body System	Adverse Effects
Azathioprine	
Hematological	Leukopenia, thrombocytopenia
Hepatic	Hepatotoxicity
Cyclosporin	
Cardiovascular	Moderate hypertension in as many as 50% of patients
Central nervous	Neurotoxicity, including tremors, in 20% of patients
Hepatic	Hepatotoxicity with cholestasis and hyperbilirubinemia
Renal	Nephrotoxicity is common and dose limiting
Other	Post-transplant diabetes mellitus, gingival hyperplasia, and hirsutism
Tacrolimus	
Central nervous	Agitation, anxiety, confusion, hallucinations, neuropathy
Renal	Albuminuria, dysuria, acute kidney injury, kidney tubular necrosis
Other	Post-transplant diabetes mellitus
Antibody immunosuppressants (basiliximab)	
Multiple body systems	Cytokine release syndrome, which includes such immune-mediated symptoms as fever, dyspnea, tachycardia, sweating, chills, headache, nausea, vomiting, diarrhea, muscle and joint pain, and general malaise

shared among these drugs and the immunosuppressant drugs. Although these are the most significant interactions, there are many more of less significance.

Because of its antibodies, basiliximab is generally given in a relatively short, single course of therapy; it has a few recognized drug interactions. The potential for interactions between immunosuppressant drugs and natural health products also should not be overlooked. For example, the enzyme-inducing properties of St. John's wort have been demonstrated to reduce the therapeutic levels of cyclosporin and cause organ rejection. The immunostimulant properties of cat's claw and echinacea may be similarly undesirable in transplant recipients; these products have effects that are opposite those of the immunosuppressants.

Dosages

For the recommended dosages of selected immunosuppressants, see the table on p. 804. Immunosuppressants must be taken exactly as directed, at precise times and with a specific dietary plan. While adhering to dosage schedules can be a challenge for most patients, immunosuppressants should be taken continuously, with direct supervision from the transplant team. Cyclosporin and tacrolimus should not be taken at the same time. Sirolimus should be taken 4 hours after cyclosporin. If a

dose is missed, it should be taken as soon as the patient remembers, unless it is close to the time the next dose is due; in this type of situation, patients must contact their transplant teams.

DRUG PROFILES

azathioprine

Azathioprine (Imuran) is a chemical analogue of the physiological purines, such as adenine and guanine. It blocks T cell proliferation by inhibiting purine synthesis, which in turn prevents deoxyribonucleic acid (DNA) synthesis. Azathioprine is used for prophylaxis of organ rejection concurrently with other immunosuppressant drugs, such as cyclosporin and corticosteroids. It is available in both oral and injectable forms.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	2–4 days*	1–2 hr	5 hr	Unknown

*6–8 wk for rheumatoid arthritis

basiliximab

Basiliximab (Simulect) is a monoclonal antibody that acts by inhibiting the binding of the cytokine mediator interleukin-2 (IL-2) to the high-affinity IL-2 receptor. Basiliximab is used to prevent rejection of transplanted kidneys (**grafts**) and is most often used as part of a multidrug immunosuppressive regimen that includes cyclosporin and corticosteroids. It has a tendency to cause the allergiclike reaction known as *cytokine release syndrome*, which can be severe and involve anaphylaxis. Patients are often premedicated with corticosteroids (e.g., intravenous [IV] methylprednisolone), in an effort to avoid or alleviate this problem. Basiliximab is available only in injectable form.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	1 day	3–4 days	7–9 days	Unknown

cyclosporin

Cyclosporin (Sandimmune, Cyclosporin, Neoral) is an immunosuppressant drug indicated for the prevention of organ rejection following solid organ transplantation and bone marrow transplantation. Cyclosporin is classified as a calcineurin inhibitor and works by inhibiting the production and release of IL-2. Similar to azathioprine, cyclosporin may also be used for the treatment of other autoimmune disorders, such as rheumatoid arthritis, nephrotic syndrome, psoriasis, and irritable bowel syndrome.

Cyclosporin is available in both oral and injectable forms. Neoral is available as an oral solution and capsules, while Sandimmune is the injectable form. Patients who are unable

TABLE 50.3 Immunosuppressant Drugs: Selected Drug Interactions

Drug	Mechanism	Result
Cyclosporin		
clarithromycin fluconazole amiodarone hydrochloride verapamil hydrochloride allopurinol protease inhibitors	Inhibit metabolism of cyclosporin	Increased levels of cyclosporin and toxicity
phenytoin phenobarbital carbamazepine rifampin St. John's wort	Induce metabolism of cyclosporin	Decreased levels of cyclosporin and reduced effect
NSAIDs	Inhibit synthesis of renal prostaglandin	Increased nephrotoxic effects of cyclosporin; renal failure
Grapefruit juice	Increase absorption of cyclosporin	Increased levels of cyclosporin and toxicity
Sirolimus		
cyclosporin	Unknown	Increased concentration of sirolimus and nephrotoxic risk
fluconazole ketoconazole clarithromycin erythromycin Protease inhibitors verapamil hydrochloride Grapefruit juice	Inhibit metabolism of sirolimus	Increased levels of sirolimus and toxicity
rifampin phenytoin phenobarbital carbamazepine St. John's wort	Induce metabolism of sirolimus	Decreased concentration and effect of sirolimus
Tacrolimus		
amphotericin gentamicin tobramycin	Increase nephrotoxicity of tacrolimus	Kidney failure
clarithromycin fluconazole ketoconazole voriconazole Protease inhibitors verapamil hydrochloride diltiazem Grapefruit juice	Inhibit metabolism of tacrolimus	Increased levels of tacrolimus and toxicity
rifampin phenytoin phenobarbital carbamazepine St. John's wort	Induce metabolism of tacrolimus	Decreased effect of tacrolimus
Mycophenolate		
Antacids Iron cholestyramine	Reduce absorption of mycophenolate mofetil	Decreased effect of mycophenolate mofetil
Oral contraceptives	Mycophenolate mofetil decreases progesterone levels	Possible pregnancy
rifampin	Induce metabolism of mycophenolate mofetil	Decreased effect of mycophenolate mofetil
Azathioprine		
allopurinol	Decrease metabolism of azathioprine	Bone marrow suppression

NSAIDs, Nonsteroidal anti-inflammatory drugs.

to take Neoral soft gelatin capsules or oral solution may be treated with Sandimmune intravenously, at one-third of the oral dose. Cyclosporin has a narrow therapeutic range, and for this reason, laboratory monitoring of drug levels may be implemented to ensure therapeutic plasma concentrations and to avoid toxicity.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	1–3 hr	3.5 hr	1–2 hr (parent compound) 10–40 hr (metabolites)	Unknown

fingolimod hydrochloride

A new drug, fingolimod hydrochloride (Gilenya®), a sphingosine-1-phosphate receptor (S1PR) modulator, failed as an antirejection drug but was approved for multiple sclerosis. It is an oral drug available for relapsing forms of multiple sclerosis. It has significant adverse effects, including headache, hepatotoxicity, flu-like symptoms, back pain, atrioventricular block, bradycardia, hypertension, and macular edema. For these reasons, there is an extensive patient medication guide for all patients dispensed fingolimod hydrochloride.

glatiramer acetate

Glatiramer acetate (Copaxone) is a mixture of random polymers of four different amino acids. This mixture results in a compound that is antigenically similar to myelin basic protein (a protein found on the myelin sheath of nerves). The drug is believed to work by blocking T cell autoimmune activity against this protein, which reduces the frequency of the neuromuscular exacerbations associated with multiple sclerosis. Each 1 mL of Copaxone® solution contains 20 mg or 40 mg of glatiramer acetate and 40 mg of the inactive ingredient, mannitol. This drug is contraindicated in patients who have a sensitivity to glatiramer or to mannitol. It is available only in injectable form. Monitor for adverse events such as flushing, urticaria, chest pain, dyspnea, and throat constriction.

mycophenolate mofetil

Mycophenolate mofetil (CellCept) is an antimetabolite and suppresses T cell proliferation. It is indicated for the prevention as well as the treatment of organ rejection. Mycophenolate mofetil is associated with an increased risk of congenital malformations and spontaneous abortions when used during pregnancy. It is available in oral and IV forms. Common adverse effects include hypertension (28 to 77% incidence), hypotension, peripheral edema, tachycardia, pain, headache, hyperglycemia, dyslipidemia, electrolyte disturbances, abdominal pain, leukopenia, thrombocytopenia, cough, and dyspnea.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	4 wk	0.8–1.8 hr	8–16 hr	Unknown

sirolimus and tacrolimus

Sirolimus (Rapamune) is an immunosuppressant drug that is similar in structure to tacrolimus (Prograf). Sirolimus is a macrocyclic immunosuppressive, antifungal, and antitumour drug, and tacrolimus is used to prevent organ rejection and to treat rejection once it occurs. Sirolimus works by inhibiting T lymphocyte activation in response to antigenic stimulation and inhibits antibody production, which in turn suppresses cytokine-mediated T cell proliferation. Sirolimus and tacrolimus are structurally related and act through similar mechanisms. Sirolimus is classified as an mTOR kinase inhibitor, whereas tacrolimus is classified as a calcineurin inhibitor. Sirolimus is available only for oral use, whereas tacrolimus is available in both oral and injectable forms. Sirolimus levels are increased when the drug is taken with high-fat meals.

Everolimus, an analogue of sirolimus, was originally approved for the treatment of certain forms of advanced cancer, such as advanced breast cancer, pancreatic neuroendocrine tumours, and renal cell carcinoma. It is available as Afinitor® and Afinitor Disperz™, which are not interchangeable drugs. Afinitor is used for the treatment of patients 18 years of age and older with renal angiomyolipoma associated with tuberous sclerosis complex (TSC) who do not require immediate surgery, for hormone receptor-positive, HER2-negative advanced breast cancer, for differentiated neuroendocrine tumours of pancreatic origin, for metastatic kidney cancer, and for angiomyolipoma of the kidney associated with TSC. Both Afinitor® and Afinitor Disperz® are indicated for the treatment of patients with subependymal giant cell astrocytoma (SEGA) associated with TSC who are not candidates for surgical resection and who do not require immediate surgical intervention. Afinitor® is a tablet and Afinitor Disperz™ is a tablet for oral suspension.

PHARMACOKINETICS (SIROLIMUS)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Rapid	1–3 hr	60–80 hr	Unknown

PHARMACOKINETICS (TACROLIMUS)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Variable	0.5–4 hr	21–61 hr	Unknown

Dosages

Selected Immunosuppressant Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications/Uses
azathioprine (Imuran)	Antimetabolite	<i>Adults and children</i> IV/PO: 3–5 mg/kg/day to start, then 1–3 mg/kg/day maintenance	Prevention of rejection of kidney transplants
basiliximab (Simulect)	Monoclonal antibody	<i>Children 2–15 yr, less than 35 kg</i> IV: 10 mg within 2 hr of transplant surgery, then 10 mg, 4 days afterward <i>Adults</i> IV: 20 mg within 2 hr of transplant surgery, then 20 mg, 4 days afterward	Prevention of rejection of kidney transplants
cyclosporin (Sandimmune, Neoral)	Calcineurin inhibitor	<i>Adults</i> PO: 10–15 mg/kg as a single dose, 4–12 hr preoperatively; continue same dose daily postoperatively for 1–2 wk, then reduce by 5%/wk to a maintenance dose of 2–6 mg/kg/day IV: 3–5 mg/kg as a single dose, 4–12 hr preoperatively and continued daily postoperatively until patient can tolerate PO dosing	Prevention and treatment of rejection of kidney, liver, and heart transplants
fingolimod hydrochloride	SP-1 receptor modulator	<i>Adults and Pediatrics greater than 40 kg</i> - 0.5 mg PO once daily <i>Pediatrics 40 kg or less</i> - 0.25 mg PO once daily	Treatment of RRMS
glatiramer acetate (Copaxone)	Miscellaneous biologic	<i>Adults only</i> Subcut: 20 mg once daily	Treatment of RRMS
mycophenolate mofetil (CellCept)	Antimetabolite	<i>Children 2–18 yr</i> IV/PO: 600 mg/m ² twice daily (maximum daily dose: 1.5–2 g daily) <i>Adults</i> IV/PO: 1–1.5 g twice daily	Prevention of rejection of kidney, liver, or heart transplants
mycophenolate sodium (Myfortic®)	Antimetabolite	<i>Adults</i> PO: 720 mg twice daily	Prevention of rejection of kidney transplants
sirolimus (Rapamune)	mTOR kinase inhibitor	<i>Children over 13 yr, less than 40 kg</i> IV/PO: 3-mg/m ² loading dose on day 1, followed by maintenance of 1 mg/m ² /day <i>Adults</i> IV/PO: 6-mg loading dose on day 1, followed by maintenance dose of 2 mg/day	Prevention of rejection of kidney transplants
tacrolimus (Advagraf, Prograf)	Calcineurin inhibitor	<i>Adults and children</i> IV: 0.01–0.05 mg/kg/day as continuous IV infusion; then PO: 0.075 mg/kg/day–0.3 mg/kg/day divided doses q12h	Prevention and treatment of rejection of liver, kidney, heart, lung, pancreas, and small bowel transplants

IV, Intravenous; mTOR, mammalian target of rapamycin; PO, oral; RRMS, relapsing–remitting multiple sclerosis; Subcut, subcutaneous.

NURSING PROCESS

ASSESSMENT

Transplantation is a highly specialized area of medicine that brings forth complexity in both medical and ethical domains of health care. The primary concern for patients is organ rejection, which comes with the possibility of removal of the transplanted organ. Immunosuppressant therapy is used to inhibit the patient's immune system, to prevent organ rejection. Patients are placed on immunosuppressant drugs for the duration of the transplanted organ's life. Prior to any administration of immunosuppressants, perform a thorough patient assessment focused on obtaining baseline measurements that include vital signs and weight. Conduct a detailed health history, including past and present medical conditions, and document the following specific systemic information:

(1) pre-existing diseases that impact the patient's immune status, such as diabetes, hypertension, and cancer; (2) urinary functioning and patterns; (3) presence of jaundice, edema, or ascites; (4) history of heart disease or dysrhythmias, chest pain, or heart failure; (5) level of central nervous system (CNS) functioning, with attention to any seizure disorders, alteration of motor or sensory function, paresthesias, or changing levels of consciousness; (6) respiratory status and baseline respiratory functioning, breath sounds, presence of asthma, pulmonary diseases, wheezing, cough, activity intolerance, dyspnea, or sputum production; (7) gastrointestinal (GI) functioning and patterns and bowel disease; (8) musculoskeletal intactness, with attention to range of motion, appearance of joints and any deformities, and ability to perform activities of daily living; and (9) presence and location of any inflammatory reactions as well as any pain, redness, or drainage. In addition, the

following laboratory and diagnostic tests may be ordered: kidney function tests with glomerular filtration rate, blood urea nitrogen (BUN) and creatinine levels; liver function tests with ALP, AST, ALT, and bilirubin levels; and cardiovascular function with baseline electrocardiogram. See [Table 50.2](#) for information on other systems affected by the immunosuppressant drugs. Assess for and document all cautions, contraindications, and drug interactions, as well as any concerns that the patient may have.

Azathioprine requires assessment of white blood cell (WBC) and platelet counts, noting any signs and symptoms of infection as well as any bleeding tendencies because of the risk of drug-related leukopenia and thrombocytopenia. Assess liver function prior to administering this drug. A significant drug interaction occurs between azathioprine and allopurinol; thus, it is important to assess for this interaction to avoid the resultant effect of bone marrow suppression. Prior to the use of cyclosporin, specifically assess the functional level of all organs as well as for any underlying cardiovascular, CNS, liver, or kidney disease because of potential drug-related toxicities involving these systems and the physiological impact of the organ transplant process on multiple systems. Perform a baseline oral assessment because of the possible adverse effect of drug-induced gingival hyperplasia with the use of this drug. Assess and document baseline blood pressures, because as many as 50% of patients on this drug experience subsequent moderate hypertension. Common drug, food, and natural health product interactions with cyclosporin for which to assess include protease inhibitors, HMG-CoA reductase inhibitors, clarithromycin, phenytoin, phenobarbital, St. John's wort, nonsteroidal anti-inflammatory drugs, and grapefruit juice (see [Table 50.3](#)).

Prior to the administration of tacrolimus, obtain a thorough patient history with attention to medication use, and perform a physical assessment with close attention to renal functioning, through monitoring of BUN, serum creatinine, and serum electrolyte levels. When the drug is administered, closely assess the patient for the first 30 minutes following the first dose of the medication. Concern regarding anaphylactic reactions also continues past this first 30 minutes and the first dose. It is important to monitor for symptoms of anaphylaxis, confirm that resuscitative equipment is accessible and functioning and that appropriate doses of epinephrine and oxygen are also readily available. Drug interactions with tacrolimus for which to assess are listed in [Table 50.3](#). Prior to the use of basiliximab (an antibody immunosuppressant), complete a thorough documentation of baseline vital signs and other presenting manifestations because of the possible occurrence of cytokine release syndrome, with resultant fever, dyspnea, tachycardia, sweating, chills, vomiting, diarrhea, muscle or joint pain, and general malaise.

◆ NURSING DIAGNOSES

- Pain (e.g., joint and muscle aches, flu-like symptoms) as a result of adverse effects of immunosuppressant medications
- Potential risk for injury as a result of the physiological effects of the disease, overall weakness, and the adverse effects of immunosuppressants
- Potential risk for infection as a result of altered immune status caused by chronic disease, treatment with immunosuppressants, or the transplantation process

◆ PLANNING

◆ Goals

- Patient will experience maximal comfort during drug therapy with immunosuppressants.
- Patient will remain free from injury during drug therapy with immunosuppressants.
- Patient will remain free from infection during therapy with immunosuppressants.

◆ Expected Patient Outcomes

- Patient states measures to help maximize comfort and minimize adverse effects of drug therapy, such as taking acetaminophen for fever and joint pain; reporting unusually high blood pressure readings; and participating in relaxation therapy, massage, diversional activities, hypnosis, imagery, and biofeedback.
- Patient states measures to decrease injury to self, such as reporting to the health care provider the onset of fever, rash, sore throat, fatigue, breaks in skin (rashes, sores), or other unusual problems or symptoms that may develop during therapy.
- Patient maintains immune system and prevents infection with a healthy diet inclusive of an increase in caloric and protein intake, as deemed necessary during nutritional consultation, during drug therapy.
- Patient reports any fever, chills, increased malaise, productive cough, lethargy, fatigue, or confusion to the health care provider.
- Patient minimizes contact with large crowds and with individuals with known bacterial or viral infections while on immunosuppressive therapy.

◆ IMPLEMENTATION

Oral immunosuppressants need to be taken with food to minimize GI upset. It is also important, because of the immunosuppressed state of patients receiving immunosuppressants, that oral forms of the drugs be used whenever possible to decrease the risk of infection associated with parenteral injections and subsequent injury to the first line of defence (skin). An oral antifungal medication may be ordered to treat any oral candidiasis that occurs as a consequence of the treatment and the disease process; however, significant drug interactions may occur between the immunosuppressant and antifungal drug, so always check for drug interactions. Therefore, this possible interaction should be considered and avoided prior to giving the medications. With the use of any of the immunosuppressants, it is also important to be sure that supportive treatment equipment and related drugs are available in case of an anaphylactic or allergic reaction. Be aware of the high risk for such an occurrence, and be constantly prepared. The use of premedication protocols involving various antihistamines and anti-inflammatory drugs is also common. Depending on the immunosuppressant being administered, the nurse may wear gloves, a mask, protective goggles, or a gown.

Cyclosporin is available in both oral and injectable formulations; do not refrigerate oral solutions. For the safe administration of oral liquid dosage forms, a graduated syringe for dispensing is provided with them. The oral solution may be mixed in a glass container with apple juice or orange juice and served at room temperature. The use of grapefruit juice as a diluent should be avoided, owing to its possible interference

with the cytochrome P450 enzyme system. Once the solution is mixed, make sure that it is stirred well and the patient drinks it immediately. Other drinks, such as soft drinks, can be administered following administration of the drug. The syringe should not come into contact with the diluent and should be used only for medication administration. If the syringe is to be cleaned, do not rinse it but wipe the outside with a dry tissue. Neoral soft gelatin capsules are to be swallowed whole. They are available in blister packs, which, when opened, have a characteristic odour that is normal. With intravenously administered cyclosporin, the dose must be diluted as recommended by the manufacturer and given according to standards of care and institutional policy. Always infuse this drug using an infusion pump and over the recommended period. Especially during the first 30 minutes, monitor the patient closely during the infusion for any allergic reactions manifested by facial flushing, urticaria, wheezing, dyspnea, or rash. Record vital signs frequently and document these. It is also important to closely monitor the patient's BUN, LDH, AST, and ALT during therapy, as ordered, to detect possible kidney and liver impairment. Oral hygiene may be performed frequently to prevent dry mouth and subsequent infections. The health care provider will also order blood tests to confirm therapeutic serum levels of cyclosporin.

Sirolimus and tacrolimus need to be administered as ordered, by either the IV or oral route. If IV tacrolimus is to be discontinued and maintenance dosing is needed, oral tacrolimus is usually ordered to be given 8 to 12 hours after discontinuation of the IV drug. Do not store IV solution in polyvinyl chloride containers. It must be administered in appropriately designed containers and tubing. Oral dosages of tacrolimus are given on an empty stomach. As with cyclosporin, the oral dosage of tacrolimus are not to be put in Styrofoam containers. Inform patients to avoid the consumption of grapefruit while taking sirolimus or tacrolimus. Both drugs have long half-lives, so toxicity is a concern because of possible cumulative effects.

Because immunosuppressant therapy is lifelong and expensive, it is important for patients to receive adequate and appropriate emotional, spiritual, social, and financial support. Additionally, specifics of therapy must be emphasized with patients, family members, and significant others, such as the complexity of dosing and the need to always have a 1-week supply of medication available so that there is never a risk of running out. Continuous monitoring of drug serum levels is required.

PATIENT TEACHING TIPS

- Educate patients who have undergone a transplant about the need for lifelong immunosuppressant therapy with often complex therapeutic regimens.
- Emphasize to patients taking immunosuppressants the importance of avoiding situations that pose an increased risk of exposure to infection, such as being in crowds, malls, or movie theaters.
- Stress to patients the importance of reporting any headache, fever, sore throat, chills, joint pain, chest pain, dizziness, fatigue, problems with urination, or rash to the health care provider, as these may indicate infection and require immediate medical attention.

CASE STUDY

Cyclosporin

Valerie, a 62-year-old retired orchestra conductor, moved to another city after her husband died. Over the past few years, she has developed kidney problems, and 3 years ago she was told that she needed a kidney transplant. After 3 years of waiting and undergoing hemodialysis, she was told that her niece was a match and was willing to donate a kidney. She has had the transplant, and after 1 week, the transplant seems to be successful so far.

Cyclosporin is one of the immunosuppressants she will be receiving. She was given her first dose of cyclosporin 12 hours before surgery and is now receiving oral doses. The nurse has provided instructions on how to take the oral doses at home.

1. The next day, when another nurse comes in with Valerie's morning medications, Valerie says, "You can't give me the medicine like that. Don't you know how to mix it?" What do you think the nurse did wrong?
2. What important measures will be taken to prevent toxicity?
3. Valerie tells the nurse that she can't wait to get home and relax by her pool. She is also looking forward to getting her strength back and going shopping with her friends. How will the nurse respond to these statements?
4. After Valerie gets home, she calls the office to ask about eating grapefruit. "The pill bottle says no grapefruit, but I thought the doctor said I could have a little bit. I bought some wonderful organic grapefruits, and I love fresh grapefruit juice. What should I do?" What is the nurse's best answer?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

EVALUATION

Continuously evaluate and re-evaluate goals and expected outcomes related to administration of immunosuppressants and the nursing process. In addition, evaluate therapeutic responses to immunosuppressants, including acceptance of the transplanted organ or graft and improved symptoms in those with autoimmune diseases. Complete blood count; erythrocyte sedimentation rate; C-reactive protein level; liver, kidney, and heart function tests; pulmonary function tests; chest X-ray; and analysis of T-lymphocyte surface phenotyping are a few of the tests performed to evaluate patients during and after drug therapy. Evaluation of drug-specific adverse effects and toxicities (see Table 50.2) and specific therapeutic drug levels (as indicated) should be ongoing.

- Educate patients about signs of rejection such as flu-like symptoms, fever above 38°C, decreased urine output, weight gain, pain or tenderness over the transplant area, and fatigue. Patients must report these to the health care provider immediately, as rejection can often be managed with adjustments to dosages of immunosuppressant.
- Encourage patients to wear medical alert jewellery that clearly indicates what was transplanted and the time of transplantation.
- Educate female patients of childbearing age who are receiving immunosuppressants about the need to use some form of contraception during treatment and for up to 12 weeks after therapy ends.

- For most immunosuppressant drugs, advise patients to take them at the same time every day and, if a dose is omitted, to contact the health care provider for further instructions.
- Patients should be aware that follow-up appointments are important because of the need to monitor status through examinations and blood testing.
- Educate patients about the adverse effects of cyclosporin, (e.g., headache, tremor), and instruct patients to avoid consumption of grapefruit or grapefruit juice because of the related potential for an increase in blood concentrations of cyclosporin, tacrolimus, or sirolimus. This effect can last for over 24 hours and the effect can occur even when grapefruit juice is taken at a different time from the medication.
- Inform patients that gelatin capsules are to be stored in a cool, dry environment and must not be exposed to light. The dosage form must be kept in its original packaging.
- A possible adverse effect of cyclosporin is photosensitivity, which can cause patients to sunburn more easily. Instruct patients to avoid prolonged exposure to the sun, and encourage them to use sunscreen and wear protective clothing when outdoors.
- Inform patients who are to undergo transplant surgery that several days before surgery they may be told to take cyclosporin with corticosteroids. They may also be given an oral antifungal as prophylaxis for candidiasis infections.
- Encourage patients to inspect the oral cavity frequently for any white patches on the tongue, mucous membranes, or oropharynx; these patches may indicate oral candidiasis.
- Advise patients taking oral forms of cyclosporin to take the medication with meals or mixed with milk to minimize GI upset.
- Inform patients taking azathioprine that several days before transplant surgery they are to take all their medication by the oral route if possible and avoid trauma as well as subcutaneous and intramuscular injections, which increase the risk for infection.
- Provide patients on tacrolimus or sirolimus with a list of foods, especially those high in fats and carbohydrates, that could negatively impact the absorption of the medication. Nutritional counselling can be extremely beneficial to patients and improve their understanding of food interactions as well as any concerns related to dyslipidemia and increased triglycerides associated with many of the immunosuppressive drugs.
- All immunosuppressants taken at home are to be taken exactly as ordered and at the same time every day. Educate patients about the adverse effects of the medication.

KEY POINTS

- Immunosuppressants decrease or prevent the body's immune response. Some of the clinical uses for immunosuppressants are suppression of immune-mediated disorders or malignancies and improvement of short-term and long-term allograft survival.
- Oral antifungals are generally given with immunosuppressant medications to treat oral candidiasis that occurs as a result of immunosuppression and fungal overgrowth.
- Monitor the results of laboratory studies ordered by the health care provider, such as hemoglobin level and hematocrit, as well as red blood cell, WBC, and platelet counts. If values indicated in these tests drop below normal ranges, notify the health care provider.

EXAMINATION REVIEW QUESTIONS

1. The nurse is caring for a patient who has been prescribed glatiramer. The patient has not had an organ transplant. The nurse understands the patient is receiving this drug for what condition?
 - a. Psoriasis
 - b. Rheumatoid arthritis
 - c. Irritable bowel syndrome
 - d. Relapse–remitting multiple sclerosis
2. The nurse assesses a patient who is prescribed cyclosporin. What condition would the nurse identify as a contraindication for taking this drug?
 - a. Acute myalgia
 - b. Kidney disease
 - c. Fluid overload
 - d. Polycythemia
3. The nurse is caring for a client prescribed to take azathioprine (Imuran). What adverse event would prompt further attention by the nurse?
 - a. Bradycardia
 - b. Diarrhea
 - c. Vomiting
 - d. Thrombocytopenia
4. The nurse is completing patient teaching for a client prescribed an immunosuppressant drug. Which of the following statements should the nurse include?
 - a. “It is better to use oral forms of these drugs to prevent the occurrence of thrush.”
 - b. “You will remain on antibiotics to prevent infections.”
 - c. “It is important to use some form of contraception during treatment and for up to 12 weeks after the end of therapy.”
 - d. “Be sure to take your medications with grapefruit juice to increase absorption.”
5. A client has been prescribed basiliximab. Which of the following symptoms would prompt the nurse that the patient has developed cytokine release syndrome?
 - a. Fever, dyspnea, and general malaise
 - b. Neurotoxicity and peripheral neuropathy
 - c. Hepatotoxicity with jaundice
 - d. Thrombocytopenia with increased bleeding tendencies

6. The nurse is assessing a patient who is about to begin therapy with an immunosuppressant drug. Which of the following conditions should be monitored by the nurse? (Select all that apply.)
 - a. Pregnancy
 - b. Glaucoma
 - c. Anemia
 - d. Myalgia
 - e. Kidney dysfunction
 - f. Liver dysfunction
7. The order reads: "Give tacrolimus IV 0.03 mg/kg/day as a continuous IV infusion." The patient weighs 110 pounds. How many milligrams per day will this dose provide?
8. The nurse is reviewing cyclosporin and recognizes that this drug works by which mechanism of action?
 - a. Suppressing viral replication
 - b. Enhancing the action of macrophages
 - c. Inhibiting activation of T-lymphocyte cells
 - d. Increasing the number of T-lymphocyte cells

CRITICAL THINKING ACTIVITIES

1. The nurse is explaining the purpose of cyclosporin to a 58-year-old patient who has had a heart transplant. The patient asks, "How does this keep my immune system from attacking my new heart?" What is the nurse's best answer?
 2. A patient is about to receive basiliximab as part of post-transplant drug therapy. Before the nurse administers the basiliximab, what action is most important to take in order to prevent adverse effects? Explain your answer.
 3. A patient is on call for lung transplant surgery—she has been told the procedure could occur within 24 hours. The surgeon writes an order that says, "Avoid injections as much as possible." A new nurse questions this order, asking another nurse, "What does the surgeon mean by that?" What is the nurse's best answer?

Immunizing Drugs and Pandemic Preparedness

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Discuss the importance of immunity as it relates to immunizing drugs and their use in patients of all ages.
2. Identify the diseases that are treated or prevented with toxoids or vaccines.
3. Compare the mechanisms of action, indications, cautions, contraindications, adverse effects, toxicities, drug interactions, and routes of administration of various toxoids and vaccines.
4. Develop a collaborative plan of care that includes all phases of the nursing process related to the administration of immunizing drugs across the lifespan.
5. Develop a collaborative plan of care covering aspects of the nursing process related to pandemic preparedness, with emphasis on the nurse's role.

KEY TERMS

Active immunization A type of immunization that causes development of a complete and long-lasting immunity to a certain infection through exposure of the body to the associated disease antigen; it can be natural active immunization (i.e., having the disease) or artificial active immunization (i.e., receiving a vaccine or toxoid). (p. 817)

Active immunizing drugs Toxoids or vaccines that are administered to a host to stimulate host production of antibodies. (p. 819)

Antibodies Immunoglobulin molecules that have an antigen-specific amino acid sequence and are synthesized by the humoral immune system (B cells) in response to exposure to a specific antigen; their purpose is to attack and destroy molecules of this antigen. (p. 816)

Antibody titre The amount of an antibody needed to react with and neutralize a given volume of a specific antigen. (p. 819)

Antigens Substances, usually proteins and usually foreign to a host, that stimulate the production of antibodies and that react specifically with those antibodies; examples include bacterial exotoxins and viruses. An allergen (e.g., dust, pollen, mould) is an antigen that can produce an immediate-type hypersensitivity reaction or allergy. (p. 816)

Antiserum A serum that contains antibodies; it is usually obtained from an animal that has been immunized against a specific antigen. (p. 819)

Antitoxin An antiserum against a toxin (or toxoid); it is most often a purified antiserum obtained from animals (usually horses) by injection of a toxin or toxoid, so that antibodies to the toxin (i.e., antitoxin) can be collected from the animals and used to provide artificial passive immunity to humans exposed to a given toxin (e.g., tetanus immunoglobulin). (p. 819)

Antivenin An antiserum against a venom (poison produced by an animal) used to treat humans or other animals that have been envenomed (e.g., by snakebite or spider bite). (p. 819)

Biological antimicrobial drugs Substances of biological origin used to prevent, treat, or cure infectious diseases (e.g., vaccines, toxoids, immunoglobulins); these drugs are often simply referred to as *biologics*. (p. 817)

Bivalent vaccine A vaccine that stimulates an immune response against two different antigens (e.g., two different viruses or microorganisms). (p. 824)

Booster shot A repeat dose of an antigen, such as a vaccine or toxoid, usually administered in an amount smaller than that used in the original immunization, given to maintain the immune response of a previously immunized patient at, or return the response to, a clinically effective level. (p. 819)

Cell-mediated immune system The immune response that is mediated by T cells (as opposed to B cells, which produce antibodies); T cells mount their immune response through activities such as the release of cytokines (chemicals that stimulate other protective immune functions) as well as through direct cytotoxicity (e.g., phagocytosis of an antigen). (p. 817)

Herd immunity Resistance to a disease on the part of an entire community or population because a large proportion of its members are immune to the disease. (p. 819)

Immune response A cascade of biochemical events that occurs in response to entry of an antigen (foreign substance) into the body; key processes of the immune response include phagocytosis ("eating of cells") of foreign microorganisms and synthesis of antibodies that react with specific antigens to inactivate them. Immune response centres around the blood but may also involve the lymphatic system and the reticuloendothelial system (see later in Key Terms). (p. 816)

Immunization The induction of immunity by administration of a vaccine or toxoid (active immunization) or antiserum (passive immunization). (p. 817)

Immunizing biologics Toxoids, vaccines, or immunoglobulins that are targeted against specific infectious microorganisms or toxins. (p. 817)

Immunoglobulins Glycoproteins synthesized and used by the humoral immune system (B cells) to attack and kill all substances foreign to the body. (Synonymous with *immune globulins*.) (p. 816)

Passive immunization A type of immunization in which immunity to an infection occurs by injecting a person with antiserum or concentrated antibodies that directly give the host the means to fight off an invading microorganism (artificial passive immunization). The host's immune system therefore does not have to manufacture these antibodies. This process also occurs when antibodies pass from mother to infant during breastfeeding or through the placenta during pregnancy (natural passive immunization). (p. 817)

Passive immunizing drugs Drugs containing antibodies or antitoxins that can kill or inactivate pathogens by binding to the associated antigens. These are directly injected into a person (host) and provide that person with the means to fend off infection, bypassing the host's own immune system. (p. 819)

Quadrivalent vaccine A vaccine that stimulates an immune response against four different antigens (e.g., four different viruses or microorganisms). (p. 824)

Recombinant Relating to or containing a combination of genetic material from two or more organisms. Such genetic recombination is one of the key methods of biotechnology

and is often used to manufacture immunizing drugs and various other medications. (p. 819)

Reticuloendothelial system Specialized cells located in the liver, spleen, lymphatics, and bone marrow that remove miscellaneous particles from the circulation, such as aging antibody molecules. (p. 819)

Trivalent vaccine A vaccine that stimulates an immune response against three different antigens (e.g., three different viruses or microorganisms). (p. 822)

Toxin Any poison produced by a plant, animal, or microorganism that is highly toxic to other living organisms. (p. 817)

Toxoids Bacterial exotoxins that are modified or inactivated (by chemicals or heat) so that they are no longer toxic but can still bind to host B cells in order to stimulate the formation of antitoxin; toxoids are often used in the same manner as vaccines to promote artificial active immunity in humans. They are one type of active immunizing drug (e.g., tetanus toxoid). (p. 817)

Vaccines Suspension of live, attenuated, or killed microorganisms that can promote an artificially induced active immunity against a particular microorganism. They are one type of active immunizing drug (e.g., tetanus vaccine). (p. 817)

Venom A poison that is secreted by an animal (e.g., snake, insect, or spider). (p. 819)

DRUG PROFILES

diphtheria and tetanus toxoids and acellular pertussis vaccine tetanus (adsorbed), p. 821

Haemophilus influenzae type b conjugate vaccine, p. 821

IMMUNITY AND IMMUNIZATION

Centuries ago, it was noticed that people who contracted certain diseases acquired an immune tolerance to the disease so that, when exposed to the disease again, they did not experience a second incidence of the illness. This basic observation prompted scientists to investigate ways of artificially producing this tolerance. With this line of inquiry came insight into the way in which the immune system functions normally. Knowledge regarding how healthy immune systems work is essential to understanding how immunizing drugs work. Briefly, when the body first comes into contact with **antigens** (foreign proteins or polysaccharides) from an invading organism, specific information is imprinted into a cellular “memory bank” of the immune system. The body can then effectively fight any future invasion by mounting an **immune response**. This cellular memory bank consists of specialized immune cells known as *memory cells*. When an antigen presents itself to a person's humoral immune system (B lymphocytes or B cells) by binding to B cells, the B cells differentiate into two other types of cells—memory cells are one type, and the other is plasma cells. Plasma cells produce large volumes of antibodies against the antigen in question. **Antibodies** are immunoglobulin molecules that have antigen-specific amino acid sequences. **Immunoglobulins**, or immune globulins, are glycoprotein molecules synthesized by the humoral immune system for the purpose of destroying all substances that the body recognizes as foreign. Immunoglobulins can be general or specific. A general immunoglobulin lacks a specific amino acid sequence that allows

TABLE 51.1 Active Versus Passive Immunity

Characteristic	Active	Passive
Artificial		
Type of immunizing drug	Toxoid or vaccine	Immunoglobulin or antitoxin
Mechanism of action	Results from an antigen–antibody response similar to that after antigen exposure in the natural disease process	Results from direct administration of exogenous antibodies; antibody concentration will decrease over time, so if re-exposure is expected, it is good judgement to continue passive immunizations
Use	To prevent development of active disease in the event of exposure to a given antigen in individuals who have at least a partially functioning immune system	To provide temporary protection against disease in individuals who are immunocompromised, those for whom active immunization is contraindicated, and those who have been exposed to or anticipate exposure to the organism or toxin; an antibody response is not stimulated in the host
Natural		
Mechanism of action	Production of one's own antibodies during actual infection	Transmission of antibodies from mother to fetus through the placenta or from mother to infant during breastfeeding

it to recognize a specific antigen. An immunoglobulin with such a specific amino acid sequence is known as an *antibody*. It is because of this ability of the immune system to recognize specific antigens that individuals are rarely subjected twice to certain diseases, such as mumps, chicken pox, and measles. Instead, they have a complete and long-lasting immunity to those infections.

In contrast to the humoral immune system, which is the focus of this chapter, the **cell-mediated immune system** is the branch of the immune system that does not synthesize antibodies. Rather, it is driven by T cells (T lymphocytes) and works by the release of cytokines (chemicals that promote other immune system functions, e.g., inflammatory responses, runny nose) and by phagocytosis (engulfment and destruction of antigens by the T cells). The cell-mediated immune system is discussed in [Chapter 54](#) because it is the target of immunosuppressant drugs. To varying degrees, these two immune system branches work simultaneously, even interdependently. The humoral immune system is also activated and driven partly by cytokines from the cell-mediated immune system.

There are two ways of developing immunity to certain infections: **active immunization** and **passive immunization**. Each can be an artificial or natural process. In artificial active immunization, the body is clinically exposed to a relatively harmless form of an antigen that does not cause an actual infection. Information about the antigen is then imprinted into the memory of the immune system and the body's defences are stimulated to resist any subsequent exposure (by producing antibodies). In contrast, natural active immunization occurs when a person acquires immunity by surviving the disease and producing antibodies to the disease-causing organism. Artificial passive immunization involves clinical administration of serum or concentrated immunoglobulins. This directly gives the inoculated individual the substance needed to fight off the invading microorganism. This type of **immunization** bypasses the host's immune system. Finally, natural passive immunization occurs when antibodies are transferred from a mother to her infant through the bloodstream via the placenta during pregnancy. This protection is temporary and lasts for only a few weeks or months. The major differences between active and passive immunity are summarized in [Table 51.1](#) and are discussed in greater depth in the following sections.

Active Immunization

In general, **biological antimicrobial drugs** (also referred to simply as *biologics*) are substances such as antitoxins, antisera, toxoids, and vaccines that are used to prevent, treat, or cure infectious diseases. Toxoids and vaccines are known as **immunizing biologics**, and they target a particular infectious microorganism.

Toxoids

Toxoids are substances that contain antigens, most often in the form of bacterial exotoxins. These substances have been detoxified or weakened with chemicals or heat, which renders them nontoxic and unable to revert back to a toxic form. Nonetheless, they remain highly antigenic and can stimulate an artificial active immune response (production of antitoxin antibodies) when injected into a host patient. These antibodies can then neutralize the same exotoxin upon any future exposure. Toxoids were first developed in 1923, at the Pasteur Institute, by Gaston Ramon and his associates, and modern versions are effective against diseases that are caused by **toxin**-producing bacteria, such as diphtheria and tetanus.

Vaccines

Vaccines are suspensions of live, attenuated (weakened), or killed (inactivated) microorganisms that can stimulate the production of antibodies against the particular organism. Subunit vaccines are similar to inactivated whole-cell vaccines but they contain only the antigenic parts of the vaccine. They can be protein-based (e.g., acellular pertussis, hepatitis B), polysaccharide (e.g., meningococcal disease caused by *Neisseria meningitidis* groups A, C, W135 and Y), or conjugate (e.g., *Haemophilus influenzae* type b [Hib] and pneumococcal). Most vaccines in the childhood immunization schedule require two or more doses in order to prompt the development of an adequate and persisting antibody response. The *Canadian Immunization Guide* recommends ages and the intervals between doses of the same antigen(s) that will offer optimal protection or have the best evidence of efficacy ([Public Health Agency of Canada, 2020a](#)). As with toxoids, slight alterations in the bacteria and viruses prevent the person injected from contracting the disease. They are still able to promote active immunization against the organism,

including an antibody response. People vaccinated with viruses or live bacteria (as well as those who recover from an infection) may endure long-term immunity against that particular disease. However, protection provided by inactivated vaccines normally will diminish over time, and for this reason periodic booster shots must be given to maintain immune system protection against infection with the specific organism.

It was Edward Jenner who noticed that milkmaids who had contracted cowpox infections were rarely victims of smallpox and was the first to study the relationship of cowpox to smallpox immunity. His observation led to the development of the smallpox vaccine, using the cowpox virus. With the help of the modern version of this vaccine, smallpox was considered to be eradicated by 1980. Routine smallpox vaccination of Canadians was discontinued in 1972. However, there is a Canadian Smallpox Contingency Plan that is updated as necessary by the Office of Emergency Preparedness, the Centre of Emergency Preparedness and Response, and the Public Health Agency of Canada, with recommendations for actions to be taken if a case of smallpox occurs in Canada or elsewhere in the world.

Today, there are vaccines available for more than 20 infectious diseases. Because of the complexities of developing a safe and effective vaccine, new vaccines appear periodically but not with the rapidity of other types of drugs. Most modern vaccines are produced in a laboratory by genetic engineering methods and contain some extract of the pathogen, or a synthetic extract, rather than the microbe itself. Some vaccines, such as the influenza vaccine, may contain actual whole or split virus particles. Most, however, contain a smaller fraction of the organism, such as the bacterial capsular polysaccharides that are used to make pneumococcal vaccine. The attenuating or killing agent is usually a chemical such as formaldehyde or a physical mechanism such as heat. Attenuation may also be accomplished with the repeated passage of the microbe through some medium, such as a fertile hen egg or a special tissue culture.

The search for new and better drugs will never end. Current goals include finding vaccines against HIV/AIDS and malaria; the ultimate goal in the area of immunization is to develop an effective vaccine against all infectious diseases. A promising vaccine against *Ebolavirus*, developed in Canada (and supported by the World Health Organization), is the recombinant, replication-competent vesicular stomatitis virus–based vaccine expressing a surface glycoprotein of *Zaire Ebolavirus* (rVSV-ZEBOV®; [Public Health Agency of Canada, 2020b](#)). A single injection of the vaccine produces a rapid immune response against *Ebolavirus*. The currently available immunizing vaccines are listed in [Box 51.1](#). Note that the drug given to prevent serious respiratory syncytial virus (RSV) infection is not an immunizing drug per se but is a specialized antiviral drug. It is discussed in [Chapter 45](#). The RSV immunoglobulin is no longer available.

People who travel to different parts of the world may require specific vaccines. This information can be found on the Health Canada website. Individuals can also call or visit travel clinics that specialize in travel vaccination consultations. It is also important to recognize that many individuals who immigrate to Canada may have been vaccinated against diseases that are not

BOX 51.1 Available Immunizing Drugs

Active Immunizing Drugs	Active Immunizing Drugs
Bacille Calmette-Guérin vaccine (tuberculosis)	Measles virus* vaccine (live, attenuated)
	Measles, mumps, and rubella virus vaccine (live)
	Meningococcal bacterial vaccine
Cholera/traveller's diarrhea (oral)	Pneumococcal 13-valent conjugate vaccine
	Pneumococcal 23-valent conjugate vaccine
Diphtheria and tetanus toxoids (adsorbed)	Rabies virus vaccine
Diphtheria and tetanus toxoids, and acellular pertussis vaccine (adsorbed)	Rotavirus
Diphtheria and tetanus toxoids, acellular pertussis, inactivated poliovirus, and <i>Haemophilus influenzae</i> type b conjugate vaccines	Rubella virus vaccine (live)
	Smallpox virus vaccine
Diphtheria, tetanus, acellular pertussis (adsorbed), inactivated poliovirus, <i>Haemophilus influenzae</i> type b, hepatitis B (recombinant) vaccine, combined	Tetanus toxoid vaccine (adsorbed)
	Tetanus immune globulin
	Typhoid (oral and injection)
<i>Haemophilus influenzae</i> type b conjugate vaccine	Varicella vaccine
Hepatitis A virus vaccine (inactivated)	Yellow fever virus vaccine
Hepatitis B virus vaccine (recombinant)	Passive Immunizing Drugs
Hepatitis A virus vaccine (inactivated) and hepatitis B vaccine (recombinant)	Botulism antitoxin
	Botulism immune globulin
Herpes zoster virus (live, attenuated)	Cytomegalovirus immunoglobulin
Human papillomavirus vaccine (attenuated)	Diphtheria antitoxin

	Tetanus immunoglobulin
	Vaccinia immunoglobulin
	Varicella-zoster immunoglobulin

*Also known as rubeola virus.

part of the Canadian immunization schedule. They may also not have received vaccinations that those born in Canada typically receive in childhood and may thus require a “catch-up” vaccination schedule.

The National Advisory Committee on Immunization (NACI) provides the [Public Health Agency of Canada \(2020c\)](#) with ongoing medical, scientific, and public health advice regarding vaccines approved for use in humans in Canada and recommendations for immunization. All recommendations on vaccine use are published every 4 years in the *Canadian Immunization*

Guide, which is available online. Within the immunization guide is detailed information about vaccines. There is also a catch-up schedule for people who may have missed immunizations as children.

Passive Immunization

In passive immunization, the host's immune system is bypassed, and the person is inoculated with serum containing immunoglobulins obtained from humans or animals. These substances provide the individual the means to fight off the invading organism. This is known as *artificially acquired passive immunity* and it confers temporary immunity against a particular antigen following exposure to the antigen. It differs from active immunization in that it produces a transitory (short-lived) immune state and the antibodies are already prepared for the host; the host's immune system does not have to synthesize its own antibodies. This allows for more rapid prevention or treatment of disease. Important examples include immunization with tetanus immunoglobulin, hepatitis immunoglobulin, rabies immunoglobulin, and snakebite antivenin.

Passive immunization occurs naturally between a mother and fetus or nursing infant, when the mother passes maternal antibodies directly, either through the placenta to the fetus or through breast milk to the nursing infant. This is called *naturally acquired passive immunity*.

There are specific populations that can benefit from passive immunization but not from active immunization (see Table 51.1). These include individuals who have been rendered immunodeficient for one reason or another (e.g., by drugs or disease) and who therefore cannot mount an immune response to a toxoid or vaccine injection because their immune systems are suppressed. **Passive immunizing drugs** are also used in individuals who already have the given disease, especially those with diseases that are rapidly harmful or fatal, such as rabies, tetanus, and hepatitis. Because these diseases can progress rapidly, the body does not have time to mount an adequate immune defence against them before death occurs. The passive immunization of such individuals confers a temporary protection that is usually sufficient to keep the invading organism from killing them, even though it does not stimulate an antibody response.

The passive immunizing drugs are divided into three groups: antitoxins, immunoglobulins, and snake and spider antivenins. An **antitoxin** is a purified **antiserum** that is usually obtained from horses inoculated with the toxin. An immunoglobulin is a concentrated preparation containing predominantly immunoglobulin G and is harvested from a large pool of blood donors. An **antivenin**, often referred to as an *antivenom*, is an antiserum containing antibodies against a **venom**, which is a poison secreted by an animal such as a reptile or an insect or other arthropod (e.g., spider). Most antivenins are obtained from animals (usually horses) that have been injected with the particular venom; however, the newer antivenins are produced by **recombinant** technology. The serum contains immunoglobulins that can neutralize the toxic effects of the venom.

IMMUNIZING DRUGS

Mechanism of Action and Drug Effects

Active immunizing drugs consist of vaccines and toxoids that may be administered either orally or intramuscularly and work by stimulating the humoral immune system. This system synthesizes immunoglobulins, of which there are five distinct types, designated as M, G, A, E, and D. These immunoglobulins attack and kill foreign substances that invade the body. When this occurs, the foreign substances are referred to as *antigens*, and the immunoglobulins are called *antibodies*.

Vaccines contain substances that trigger the formation of these antibodies against specific pathogens. They may contain the actual live or attenuated pathogen or a killed pathogen. The **antibody titre** is a measure of how many antibodies to a given antigen are present in the blood and is used to assess whether enough antibodies are present to protect the body effectively against the particular pathogen. Sometimes levels of antibodies decline over time. When this happens, another dose of the vaccine is given to restore the antibody titres to a level that can protect the person against the infection. This repeat dose is referred to as a **booster shot**.

Toxoids are altered forms of bacterial toxins that stimulate the production of antibodies in the same way as vaccines. Because both toxoids and vaccines rely on the immunized host to mount an immune response, the host's immune system must be intact. Therefore, patients who are immunocompromised may not benefit from receiving vaccines or toxoids. Instead, their clinical situations may warrant giving them passive immunizing drugs such as immunoglobulins.

Passive immunizing drugs are the actual antibodies (immunoglobulins) that can kill or inactivate the pathogen. The process is called *passive* because the person's immune system does not participate in the synthesis of antibodies; the antibodies are provided by the immunizing drug. Immunity acquired in this way generally lasts for a much shorter time than that produced by active immunization. Passive immunization lasts only until the injected immunoglobulins are removed from the person's immune system by the **reticuloendothelial system**. The reticuloendothelial system is composed of specialized cells in the liver, spleen, lymphatics, and bone marrow.

Indications

Vaccines and toxoids are active immunizing drugs that have been developed for the prevention of many illnesses caused by bacteria and their toxins, as well as those caused by viruses. Antivenins, antitoxins, and immunoglobulins are passive immunizing drugs. Such drugs can inactivate spider and snake venom, bacterial toxins (exotoxins), and potentially lethal viruses, respectively. Box 51.1 lists the currently available immunizing drugs. The successful immunization of a high proportion of individuals within a population confers protection from infection on the remaining proportion of individuals who are non-immune because the number of susceptible people is small. This type of protection is called **herd immunity**.

Antivenins, also known as *antisera*, are used to prevent or minimize the effects of poisoning by the venoms of crotalids

(e.g., rattlesnakes, copperheads, cottonmouths, water moccasins), black widow spiders, and coral snakes. Of concern in Canada are the crotalids (rattlesnakes are found in northern Ontario, Manitoba, Alberta, Saskatchewan, and some parts of British Columbia) and black widow spiders, whose poison can be lethal. Most healthy adults do not die from the bites of spiders or snakes if they receive the appropriate treatment (i.e., administration of the appropriate antivenin). However, young children and older adults with health problems are particularly susceptible to the effects of the venom of some of these animals; for either group, an antivenin is needed to neutralize the venom following poisoning.

Contraindications

Contraindications to the administration of immunizing drugs include immediate or anaphylactic reaction to the vaccine or to any component of the vaccine or its container (e.g., latex). Live attenuated vaccines are generally contraindicated in individuals with severe asthma, immunocompromised persons, and pregnant women. Live and inactivated vaccines are also generally contraindicated in those who developed Guillain-Barré syndrome within 6 weeks of receiving a vaccine. Anaphylactic reactions to vaccine components such as egg, gelatin, latex, or thiomersal are rare. Those with a proven anaphylactic reaction to these components may be vaccinated in a setting where appropriate management of the reaction can be undertaken. In the case of a potentially fatal illness such as rabies, the drug may still need to be given and any allergic reaction controlled with other medications. Administration of some immunizing drugs is best deferred until after recovery from a febrile illness or a temporary immunocompromised state (e.g., following cancer chemotherapy), if possible. However, the decision about when to administer the drugs is often a matter of clinical judgement—the individual patient’s condition and risk factors for serious illness may be arguments for or against administration of a given immunizing drug at a given time.

Adverse Effects

The undesirable effects of the various immunizing drugs can range from mild and transient to life-threatening and are listed in Table 51.2. The overwhelming majority of adverse effects are minor. Minor reactions can be treated with acetaminophen and rest. More severe reactions, such as fever higher than 39.4°C, can be treated with acetaminophen and tepid baths. Serum sickness sometimes occurs after repeated injections of equine-derived immunizing drugs. The signs and symptoms of serum sickness consist of edema of the face, tongue, and throat; rash; urticaria; arthritis; adenopathy; fever; flushing; itching; cough; dyspnea; cyanosis; vomiting; and cardiovascular collapse. Serum sickness is best treated with analgesics, antihistamines, epinephrine, or corticosteroids; hospitalization may be required.

Any serious or unusual reactions to immunizing drugs need to be reported to the Canadian Adverse Events Following Immunization Surveillance System (CAEFISS), a national vaccine safety surveillance program. There is also a collaboration between the Canadian Paediatric Society (CPS) and pediatric infectious disease specialists, called Immunization Monitoring

TABLE 51.2 Immunizing Drugs: Minor and Severe Adverse Effects

Body System	Adverse Effects
Minor Effects	
Central nervous	Fever, adenopathy, malaise, headache
Integumentary	Minor rash, soreness at injection site, urticaria, arthritis
Severe Effects	
Central nervous	Fever higher than 39.4°C, encephalitis, convulsions, peripheral neuropathy, anaphylactic reaction, shock, unconsciousness
Integumentary	Rash
Respiratory	Dyspnea
Other	Cyanosis

Program ACTIVE (IMPACT), a pediatric hospital-based, national active surveillance system, to monitor serious adverse events following immunization, vaccination failures, and selected infectious diseases. IMPACT was established in 1990 to support the timely reporting of adverse events, particularly the most serious reactions in children. The Public Health Agency of Canada website provides extensive information on reporting systems and the data collected by these agencies. Such data are used to improve the quality of immunizing drugs and can even be possible grounds for a Health Canada recall of biologics that demonstrate adverse effects exceeding acceptable safety thresholds.

In the early 1980s, in response to vaccine-related injuries, many parents became reluctant to immunize their children against common, and even potentially fatal, childhood illnesses. There has also been controversy in the national news pertaining to a possible link between immunizations and autism in children. It was thought that thiomersal (a mercury-containing preservative used in vaccines) may have been a causative link. In Canada, the influenza vaccine and most hepatitis B vaccines are the only ones that contain thiomersal. In 2011, the medical community declared that the original study suggesting a link between vaccines and autism was fraudulent. It was suggested that the original author falsified the medical histories of the patients in his study and that he was “hoping to create a vaccine scare.” Although there is no evidence to support a link between autism and vaccines, many parents are still reluctant to vaccinate their children.

Interactions

Drug interactions are not generally a problem with the majority of immunizing drugs, probably because immunizing drugs are normally given in a single dose or a relatively small number of doses. One drug class of note that can potentially reduce the efficacy of immunizing drugs is immunosuppressant drugs, including corticosteroids (see Chapter 34), transplant antirejection drugs (see Chapter 50), and cancer chemotherapy drugs (see Chapters 52 and 53). All of these drugs can, to varying degrees, hinder the generation of active immunity that would normally occur following vaccine or toxoid administration. The

bacille Calmette-Guérin vaccine for tuberculosis (used in certain vulnerable groups in Canada and in developing countries) can cause false-positive results on the tuberculin skin test (see [Chapter 46](#)).

Some vaccines are not to be given close in time to one another. For example, the meningococcal vaccine, whole-cell pertussis vaccine, and typhoid vaccine together have an undesirably large bacterial endotoxin content and should not be administered simultaneously. The effectiveness of measles, mumps, and rubella vaccines may be reduced by concurrent interferon therapy (see [Chapter 54](#)). Influenza vaccines may also theoretically lose efficacy if given while antiviral influenza drugs are being taken (see [Chapter 45](#)). It is recommended to give the influenza vaccine at least 48 hours after stopping such antiviral drug therapy. In general, immunizations requiring intramuscular (IM) injection are given with particular caution (and with appropriate monitoring) to patients receiving anticoagulant drugs such as warfarin sodium (see [Chapter 27](#)). Review the package inserts of any immunizing drugs given to obtain the latest information and identify other specific drug interactions that may occur. Hepatitis B immunoglobulin interacts with live vaccines; defer administration of such vaccines until 3 months after the dose of immunoglobulin is given.

Dosages

For the recommended dosages of selected immunizing drugs, refer to the appropriate drug profile. Readers are referred to the *Canadian Immunization Guide* for specifics.

DRUG PROFILES

Some of the more commonly used vaccines, toxoids, and immunoglobulins are described in the following sections. The immunizing drugs currently available commercially in Canada, including several combination vaccines for the prevention of more than one disease, are listed in [Box 51.1](#). Combination vaccines obviously reduce the number of injections that the patient receives, and thus their use is desirable when possible, especially in children.

Active Immunizing Drugs

diphtheria and tetanus toxoids, acellular pertussis vaccine (adsorbed)

The active immunizing drugs include diphtheria and tetanus toxoids and the acellular pertussis vaccine (adsorbed). *Adsorption* refers to the laboratory techniques used to make most vaccines and toxoids. The biological materials (i.e., virus or toxin particles) are adsorbed (separated out of solution and dried) onto carrier media such as alum, from which they are later removed for packaging into final dosage forms. Pertussis, also known as *whooping cough*, is highly contagious and is spread through contact with respiratory secretions. It has recently increased in incidence. Pertussis vaccine is available only as an acellular preparation in a combination vaccine, and the amount of acellular pertussis antigen present varies by product. Acellular pertussis consists of a single weakened toxoid, whereas previous pertussis vaccines contained multiple toxoids. Diphtheria

toxoid is also available only in a combination vaccine. The vaccine combination *diphtheria and tetanus toxoids with acellular pertussis vaccine adsorbed* (DTaP[®]) was approved for the full childhood immunization series and has replaced the older tetanus, diphtheria, and pertussis vaccine, DPT. In Canada, a number of combination vaccines are available, including pentavalent and hexavalent vaccines. The pentavalent vaccine combines diphtheria, tetanus, pertussis, polio (inactivated polio virus [IPV]), and *Haemophilus influenzae* b conjugate (Hib; Pentacel[®], Pediacel[®], Infanrix-IPV/Hib[®]) while the hexavalent vaccine adds hepatitis B (HB) to the pentavalent combination (Infanrix-Hexa[®]).

Acellular pertussis vaccine is recommended for routine infant immunization, beginning at 2 months of age. DTaP-IPV (with or without Hib) vaccine is used for children under 7 years of age. DTaP-HB-IPV-Hib vaccine is used for children 6 weeks to 23 months of age and can be given to children aged 24 months to under 7 years, if necessary. DTaP-IPV or Tdap-IPV vaccine should be used as the booster dose for children at 4 to 6 years of age. Children 7 years of age and older receive the adult formulation of diphtheria-tetanus-pertussis-containing vaccine, with or without polio (Tdap or Tdap-IPV), for primary immunization or booster doses as it contains less diphtheria toxoid than preparations given to younger children and is less likely to cause reactions in older children. Tdap (Adacel[®], Boostrix[®]) vaccine is administered to adolescents at 14 to 16 years of age as the first 10-year booster dose; Tdap-IPV (Adacel-Polio[®], Boostrix-Polio[®]) vaccine should be used if IPV vaccine is also indicated. Infants and children receive a series of 0.5-mL injections at 2, 4, 6, and 18 months, followed by a booster of DTaP-IPV or Tdap-IPV at 4 to 6 years and a booster of Tdap at 14 to 16 years.

These toxoids (DTaP, Tdap, Td [vaccine containing tetanus and diphtheria]) are available only as parenteral preparations to be given as deep IM injections. Their use is contraindicated in people who have had a prior systemic hypersensitivity reaction or a neurological reaction to one of the ingredients. Some manufacturers indicate that use is contraindicated in cases of concurrent acute or active infections but not in cases of minor illness. Although there have been few, if any, studies documenting the safety of their use in pregnant women, it is generally considered safe to give diphtheria, tetanus, and pertussis toxoids after the first trimester.

Haemophilus influenzae type b vaccine

Haemophilus influenzae type b (Hib) vaccine (Act-HIB[®], Hiberix[®]) is a noninfectious, bacteria-derived vaccine. It is made by extracting *H. influenzae* particles that are antigenic and then chemically attaching these particles to a protein carrier medium for use in injections. All Canadian provinces and territories include Hib conjugate vaccine in their immunization programs for children. The vaccine is given by injection to previously unimmunized adults and children 5 years of age or older who are considered at high risk for acquiring *H. influenzae* infection. Conditions with increased risk of invasive Hib disease include the following: congenital (primary) immunodeficiency, malignant hematological disorders, HIV, anatomic or functional asplenia (including sickle cell disease), all transplant

recipients, and recipients of cochlear implants. *H. influenzae* type b infection occurs worldwide and is most prevalent in children aged 2 months to 2 years. Before this vaccine was developed, infections caused by Hib were the leading cause of bacterial meningitis in children 3 months to 5 years of age; this form of bacterial meningitis has a mortality rate of 5 to 10%. This bacterium can also cause several other serious infections in children and adults. Severe neurological deficits occur in 10 to 15% of survivors and deafness in 15 to 20% ([Public Health Agency of Canada, 2017a](#)). All Hib vaccine products are parenteral formulations that are administered intramuscularly. It is administered as part of the routine immunization of infants as discussed in the previous section. Hib-containing vaccine is not routinely indicated in children 5 years of age and older.

hepatitis B virus vaccine (inactivated)

Hepatitis B virus vaccine (inactivated; Recombivax HB[®], Engerix-B[®]) is a noninfectious viral vaccine containing hepatitis B surface antigen (HBsAg). It is made from viral particles and yeast, using recombinant deoxyribonucleic acid (DNA) technology. DNA from two or more organisms is combined, and yeast cells then produce this viral antigenic substance in mass quantities. The substance is attached to a carrier medium (alum) and made into a vaccine injection preparation. This antigenic HBsAg is used to promote active immunity to hepatitis B infection in people considered at high risk for potential exposure to the hepatitis B virus (HBV) or HBsAg-positive materials (e.g., blood, plasma, serum). Health care providers, for example, are considered at high risk, and many hospitals require this vaccination upon employment. It is recommended that all children receive this vaccine, and it is usually started shortly after birth. It is also recommended that adults with diabetes receive hepatitis B vaccination because of defective phagocytic and neutrophil function. The vaccine does not interfere with insulin levels or control of plasma glucose. NACI recommends that all individuals without contraindications, including those living with Type 1 or 2 diabetes, can receive hepatitis B vaccination ([Public Health Agency of Canada, 2017b](#)).

Use of the hepatitis B vaccine is contraindicated in individuals who have a history of anaphylactic hypersensitivity to the vaccine or any component of the vaccine (e.g., yeast). Pregnancy is not considered a contraindication to use. The vaccine is administered by IM injection and is given as a series of three injections (0.5 mL each). Hepatitis B vaccines are approved for use in Canada for pre-exposure and postexposure prophylaxis. Adults 19 years of age and older receive three 10-mcg doses of Engerix-B on day 0, 1 month, and 6 months. A combination hepatitis A and hepatitis B vaccine (Twinrix[®], Twinrix Junior[®]) is preferred for individuals travelling to countries where both hepatitis A and hepatitis B are endemic.

influenza virus vaccine

The influenza virus vaccine is used to prevent influenza. Agriflu[®], Flud[®], Fluviral[®], Fluzone[®], Influvac[®], Intanza[®], and Vaxigrip[®] are seasonal trivalent vaccines. *Valent* refers to the number of serotypes of viruses or bacteria included in the vaccine. Flulaval[®] and Fluzone[®] are quadrivalent vaccines. Agriflu,

Fluviral, Fluzone, Influvac, and Vaxigrip are administered intramuscularly. Flud[®] is recommended for patients who are 65 years of age and older; it is administered intramuscularly. Intanza is administered intradermally. FluMist[®] is a live attenuated vaccine and is usually a **trivalent vaccine** (contains three virus strains). A new quadrivalent vaccine (FluMist Quadrivalent[®]) has been introduced and contains four vaccine virus strains: an A/H1N1 strain, an A/H3N2 strain, and two B strains. Both are administered intranasally. FluMist Quadrivalent is claimed to be 47% more effective in children aged 2 to 17 (according to the drug monograph). FluMist contains three live attenuated viruses, rather than killed viruses, as in the injectable influenza vaccine and is recommended for healthy children between the ages of 2 and 17. Each dose is 0.2 mL, given as 0.1 mL in each nostril. Children 6 months to less than 24 months of age should be given 0.25 mL of Flud Pediatric[®], a trivalent vaccine, administered intramuscularly.

NACI recommends that all individuals over the age of 6 months be vaccinated with the influenza vaccine, which is given each year prior to the beginning of the influenza season. Such inoculation is the single most important influenza control measure. Each year, a new influenza vaccine is developed by virology researchers. The vaccine usually contains three or, more recently, four different influenza virus strains. These strains are chosen from among the hundreds of influenza virus strains in the environment, based on the latest epidemiological data indicating which influenza viruses will most likely circulate in North America in the upcoming winter. The effectiveness of a vaccine can vary considerably from season to season and depends on how well matched the vaccine is to the circulating viruses; in some years, there may be no benefit. Researchers attempt to determine the effectiveness of the vaccines in order to assess and confirm the value of influenza vaccination as a public health intervention. In addition, the effects of the vaccine can wear off, so a yearly vaccination is required. The vaccine is made from highly purified, egg-grown viruses that have been rendered noninfectious (inactivated).

Influenza is characterized by abrupt onset of fever, myalgia, sore throat, and nonproductive cough. Severe malaise may last several days. More severe illness can occur in certain populations. Older adults, children, and adults with underlying serious health problems (e.g., HIV infection, asthma, cardiopulmonary disease, cancer, diabetes) are at increased risk for complications from influenza infections. [The Canadian Nurses Association \(2020\)](#) position is that all registered nurses should receive a yearly influenza vaccine. Many health care institutions strongly encourage influenza immunization, as health care providers are considered a high-risk group. In recent years, there has been a debate over whether receiving the influenza vaccine should be a mandatory requirement for employment. It is argued that such policies pressure nurses (and other health care providers) regarding their right to choose whether or not they are immunized (or should be forced to wear a mask if unvaccinated).

Mortality can result not only from influenza but also from cardiopulmonary and other chronic diseases that can be exacerbated by influenza. More than 90% of the deaths attributed to pneumonia and influenza occur among individuals 65 years of

age or older. Another fairly unusual but important at-risk group is children and adolescents who are receiving long-term aspirin therapy (e.g., for juvenile arthritis) and who therefore might be at risk for developing Reye's syndrome after influenza (see Chapter 49).

Factors that may alter a vaccine's effectiveness are the age and immunocompetence of the vaccine recipient and the degree of similarity between the virus strains included in the vaccine and those that actually predominate during a given influenza season. Healthy individuals younger than 65 years of age have a 70% chance of avoiding illness caused by influenza when there is a good match between the vaccine and the circulating viruses.

Older adults, especially those residing in long-term care facilities, can avoid severe illness, secondary complications, and death by receiving the influenza vaccine. In older adults, the vaccine can prevent hospitalization and pneumonia up to 50 to 60% of the time and death up to 80% of the time. Achieving a high rate of vaccination among residents can reduce the spread of infection in a facility, thus preventing disease through herd immunity.

measles, mumps, and rubella virus vaccine (live, attenuated)

The measles, mumps, and rubella (MMR) vaccine (M-M-R[®], Priorix[®]) is virus preparation consisting of live measles, mumps, and rubella viruses that are weakened (attenuated). The vaccine promotes active immunity to these diseases by inducing the production of virus-specific immunoglobulin G and immunoglobulin M antibodies. The antibody response to initial vaccination resembles that caused by primary natural infection.

Administration of the measles vaccine or any of the combination products that include the measles virus is contraindicated in people with a history of anaphylactic reactions or some other immediate reaction to vaccine components. The measles and mumps component of the vaccine is prepared in chick embryo cell culture and may contain traces of egg protein. According to NACI, the trace amount of egg protein in the vaccine appears to be insufficient to cause an allergic reaction in egg-allergic individuals. Use of these vaccine products is also contraindicated in people who have had an anaphylactic reaction to topically or systemically administered neomycin because this antibiotic is used as a preservative in some preparations. These vaccines are not to be administered to pregnant women, and pregnancy needs to be avoided for 4 weeks following vaccination with a live virus. This precaution is based on the theoretical risk that the live virus vaccine may cause a fetal infection.

The measles vaccine is available in MMR or measles-mumps-rubella-varicella (MMRV) vaccines. Children receive a single dose subcutaneously at 12 to 15 months of age, and a second dose at 18 months or any time thereafter, but should be given it no later than around school entry.

meningococcal vaccine

There are three meningococcal vaccines in use in Canada: (1) monovalent conjugate meningococcal vaccines (Men-C-C, Mejugate[®], NeisVac-C[®]), (2) quadrivalent conjugate meningococcal vaccines (Men-C-ACYW-135, Menactra[®], Menveo[®],

Nimenrix[®]), and (3) a quadrivalent polysaccharide meningococcal vaccine (Men-P-ACYW-135) (Menomune[®]). These three vaccines are indicated for active immunization to prevent invasive meningococcal disease caused by *Neisseria meningitidis*. Men-C-C vaccine is recommended for all children at 12 to 23 months of age regardless of any doses given at less than 12 months of age. It is routinely given at 12 months and is recommended in unimmunized children less than 5 years of age. Men-C-C vaccine may be considered for children 5 to 11 years of age if not previously immunized as infants or toddlers. Men-C-C or Men-C-ACYW-135 vaccine is recommended for adolescents and young adults between 12 years and 24 years of age. The powder must be diluted with the included liquid conjugate component. Adverse effects include a 50% incidence of pain at the injection site and headache. Other adverse effects include myalgia, malaise, and nausea. Caution must be used to prevent sound-alike errors among the different brand names. The most current recommendations indicate a two-dose series should be given to individuals who are considered high risk because they are immunocompromised or have underlying medical conditions such as asplenia. All other patients receive a one-time dose.

Bexsero[®] is a multicomponent meningococcal B vaccine indicated for active immunization of individuals from 2 months to 17 years of age against *Neisseria meningitidis* serogroup B strain. The number of injections given depends on the age of the patient. It is available as a suspension for IM injection provided in a prefilled glass syringe.

pneumococcal vaccine, polyvalent and 13-valent

Two forms of vaccine against pneumococcal pneumonia are available that also protect against any illness caused by *Streptococcus pneumoniae*. *Pneumococcus* is the common name for the bacterium *S. pneumoniae*, the causative organism of this common bacterial infection. The polyvalent type of vaccine (Pneumovax 23[®], Pneumo 23[®], Pneu-P-23[®]) is used primarily in adults. (The term *polyvalent* refers to the fact that the vaccine is designed to be effective against the many [23] strains of pneumococcus most commonly implicated in adult cases of pneumonia.) This vaccine may also sometimes be recommended for children at higher risk for pneumonia as a result of serious chronic illnesses, especially those who are immunocompromised. However, the 13-valent conjugate vaccine is the pneumococcal vaccine that is routinely recommended for children. Its official full name is *13-valent conjugate vaccine* (Pneu-C-13[®] or Prevnar 13[®]). The term *13-valent* refers to the fact that the vaccine is designed to immunize against the top 13 pneumococcal strains found in pneumonia cases in children. The pneumococcal 13-valent conjugate vaccine is included in the publicly funded immunization program of all provinces and territories in Canada. Routine infant immunization consists of the administration of three doses of Pneu-C-13 vaccine at a minimum of 8-week intervals, beginning at 2 months of age, followed by a fourth dose at 12 to 15 months of age. For healthy infants, a three-dose schedule may be used, with doses at 2 months, 4 months, and 12 months of age. It is recommended that healthy adults

65 years and older receive one dose of Pneu-P-23. Each dose is 0.5 mL, administered intramuscularly.

Contraindications to the use of either pneumococcal vaccine include known drug allergy to components of the vaccine itself, as well as the presence of current significant febrile illness or an immunosuppressed state as a result of drug therapy (e.g., cancer chemotherapy). The vaccine may sometimes still be given in such cases, if it is felt that withholding it poses an even greater risk to the patient.

poliovirus vaccine (inactivated)

The use of live oral polio vaccine (OPV) is no longer routine in Canada, due to case reports of vaccine-acquired polio. Since 1980, the only indigenous cases of poliomyelitis reported in Canada (11 cases) have been associated with use of the live OPV. Injected doses of inactivated polio vaccine (IPV) are instead recommended for routine use and are available in numerous preparations. All provinces and territories include IPV as part of routine immunization programs. It is administered intramuscularly (0.5 mL) as part of DTaP-IPV-Hib vaccine formulation at 2, 4, 6 and 18 months of age, or the DTaP-HB-IPV-Hib vaccine may be used to add protection against hepatitis B. A booster dose is administered at 4 to 6 years of age.

rabies virus vaccine

Vaccination against the rabies virus is not normally a routine immunization. Situations requiring this vaccine occur periodically in many practice settings. Rabies is a virus that can infect a variety of mammals, including skunks, foxes, raccoons, bats, dogs, and cats. The virus is usually transferred to humans by an animal bite and almost universally causes fatal brain tissue destruction if the patient is not treated with rabies vaccine and immunoglobulin (discussed later). Rabies virus vaccine (Imovax[®], RabAvert[®]) is produced using laboratory techniques involving infected human cell cultures and selected antimicrobial drugs. Current recommendations call for a total of five IM injections of 1 mL on days 0, 3, 7, 14, and 28, following an animal bite that raises concern for rabies transmission. This includes a bite by any animal whose rabies immunization status is unknown or that escapes and cannot be observed for signs of rabies. This type of treatment is known as *postexposure prophylaxis*. Pre-exposure prophylaxis is recommended for people who are at high risk for exposure to the rabies virus (e.g., veterinarians). The pre-exposure course consists of only three injections (1 mL intramuscularly or 0.1 mL intradermally) on day 0, day 7, and between days 21 and 28. Periodic booster shots are also recommended for such individuals approximately every 2 to 5 years, or based on the levels of the patient's rabies virus antibody titres. Contraindications to the administration of rabies vaccine include a history of allergic reaction to the vaccine itself or to the drugs neomycin, gentamicin, or amphotericin B. However, given the life-threatening nature of rabies infection, treatment may still be required, with supportive therapy (e.g., epinephrine, diphenhydramine hydrochloride, corticosteroids) provided to minimize allergic reactions. Patients with any kind of febrile illness should delay occupational pre-exposure prophylaxis treatment until the illness has subsided.

human papillomavirus vaccine

Human papillomavirus virus (HPV) is a common cause of genital warts and cervical cancer. Genital HPV is a common virus that is transmitted through genital contact, most often during sex. Most sexually active people will get HPV at some time in their lives, although most will never even know it. It is most common in people in their late teens and early 20s. Every year, about 1 450 women are diagnosed with cervical cancer, and almost 380 women die from this disease in Canada. The papillomavirus vaccines (Gardasil[®], Cervarix[®]) are the first and only vaccines known to prevent cancer. Cervarix is a **bivalent vaccine**, whereas Gardasil is a **quadrivalent vaccine**. Cervarix provides protection against two HPV types that cause approximately 70% of all cervical cancers—HPV-16 and HPV-18. Cervarix is approved for use only in females aged 10 to 25 and is not approved for use in males. Gardasil vaccine protects against four types of HPV—HPV-16 and HPV-18, as well as two types known to cause 90% of genital warts in females and males, HPV-6 and HPV-11. Gardasil is recommended for all females and males between the ages of 9 and 26. It is also approved for use in women up to the age of 46. Maximum benefit is achieved in females before they become sexually active. The vaccine is also beneficial in females aged 14 to 26 regardless of previous sexual activity, Pap abnormalities, cervical cancer, anogenital warts, or known HPV infection. In addition to being recommended for males between 9 and 26 years of age, Gardasil is also recommended for men of any age who have sex with men. In males, maximum benefit occurs between the ages of 9 and 13, prior to the onset of sexual activity. As with females, males between the ages of 14 and 26 who are sexually active benefit from Gardasil as they may not yet have HPV infection and it is unlikely that they have been infected with all four types of HPV present in the vaccine.

The vaccine is given in three injections of 0.5 mL, administered intramuscularly. After the first dose, two more doses follow at 1 month and 6 months later. It is contraindicated in patients who show hypersensitivity to yeast or to their first injection of the vaccine. The Gardasil 9 vaccine is also now available in Canada. It helps to prevent against diseases associated with the HPV types 6, 11, 16, 18, 31, 33, 45, 52, and 58. These nine HPV types are known to cause approximately 90% of cervical cancers, 80% of cervical precancers, 75% of HPV-related vulvar, vaginal, and anal cancers and precancers, and over 90% of genital warts. [The Society of Obstetricians and Gynecologists of Canada \(2020\)](#) recommends HPV vaccination using Gardasil 9 for all girls and women aged 9 to 45 and for boys and men aged 9 to 26. The HPV vaccine is not recommended for pregnant patients, because appropriate studies have not been completed. Pain on injection is common.

herpes zoster vaccine

Zoster vaccine (Zostavax[®] and Shingrix[®]) is a vaccine available for the prevention of herpes zoster. Herpes zoster, also known as *shingles*, is an extremely painful condition (also producing intense pruritus) caused by the varicella-zoster virus that also causes chicken pox. The vaccine is recommended for patients without complications who are 60 years of age or older and may

be used in patients 50 years of age and older to prevent reactivation of the zoster virus that causes shingles. It is a one-time vaccine, and it can be given to patients who have already had shingles. The vaccine does not prevent postherpetic neuralgia. Herpes-zoster virus vaccine is a live attenuated vaccine. Its use is contraindicated in patients with hypersensitivity to neomycin, gelatin, or any component of the vaccine. It is also contraindicated in immunocompromised patients and those receiving immunosuppressant therapies, as well as in pregnant women. Because it is a live vaccine, there is a risk of transmission of the virus from the person who is vaccinated to other people. The vaccine is not to be used for the prevention of chicken pox and is not given to children. The drug must be stored in the freezer. Reactions at the injection site are usually mild and involve pain, swelling, or redness in 48% of recipients.

varicella virus vaccine

The live attenuated varicella virus vaccine (Varivax III[®], Varilrix[®]) is used to prevent varicella (chicken pox). Varicella occurs primarily in children younger than 12 years of age or in individuals with compromised immune systems, such as older adults or patients with HIV. It is estimated that only 10% of children older than 12 years of age are still susceptible to varicella. Only 2% of adults develop varicella virus infections. However, 50% of the deaths associated with varicella infections are in adults. Half of these are in patients who are immunocompromised. The virus in varicella vaccine is attenuated by the passage of virus particles through human and embryonic guinea pig cell cultures. Varicella vaccine is stored in the refrigerator. It is not to be administered to patients who are immunocompromised or to patients who have received high doses of systemic steroids in the previous month. It is also recommended that salicylates be avoided for 6 weeks after administration of varicella vaccine because of the association between wild-type varicella, salicylate therapy, and Reye's syndrome (see [Chapter 49](#)). The varicella vaccine is given at 12 months of age, and then a second dose is given at 4 to 6 years of age. All patients receiving the vaccine need to receive a second dose. It is administered as a 0.5-mL dose, subcutaneously.

rotavirus oral vaccine

There are two oral rotavirus vaccines available in Canada: RotaTeq[®], a live pentavalent vaccine, and Rotarix[™], a live monovalent, attenuated human vaccine. Rotavirus is a highly infectious virus transmitted via the fecal-oral route and possibly the respiratory route. It survives on environmental surfaces and can be transmitted as fomites. The majority of cases occur during the winter and spring months. The rotavirus causes severe gastroenteritis with associated fever, vomiting, diarrhea, and electrolyte imbalance in children. The diarrhea can be so severe that it quickly leads to dehydration. Infants and children aged 3 months to 5 years of age are the most susceptible. Rotavirus vaccines are recommended for infants starting at 6 weeks to 14 weeks of age, with the vaccination series complete before 8 months of age. RotaTeq requires three doses 4 to 10 weeks apart while Rotarix requires 2 doses with at least 4 weeks between doses.

Passive Immunizing Drugs

The currently available antivenins, antitoxins, and immunoglobulins that comprise the passive immunizing drugs are listed in [Box 51.1](#). Those that are commonly used are described in the following profiles.

hepatitis B immunoglobulin

Hepatitis B immunoglobulin (HBIG; HepaGam B[®], HyperHEP B[®]) is used to provide passive immunity against hepatitis B infection in the postexposure prophylaxis and treatment of people exposed to HBV or HBsAg-positive materials (e.g., blood, plasma, serum). It is prepared from the plasma of human donors with high titres of antibody to HBsAg. All donors are tested for HIV antibodies to prevent HIV transmission.

Because of the possible devastating consequences of hepatitis B infection, pregnancy is not considered a contraindication to the use of hepatitis B immunoglobulin when there is a clear need for its use. All infants born to mothers infected with hepatitis B need to be given one dose (0.5 mL) HBIG intramuscularly within 12 hours after birth. Adults need to receive 0.06 mg/kg intramuscularly within 48 hours after exposure.

immunoglobulin

Immune globulin (GamaSTAN S/D[®]) is available in IM, subcutaneous, and intravenous dosage forms. It provides passive immunity by increasing antibody titre and antigen-antibody reaction potential. Immunoglobulin preparations contain immune antibodies directed against a broad range of pathogens and foreign antigens. Immunoglobulins are given to help prevent certain infectious diseases in susceptible persons or to ameliorate the diseases in those already infected. Immunoglobulins are pooled from the blood of several thousand human donors. This plasma is prepared by cold alcohol fractionation and usually washed with a detergent to destroy any harmful viruses, such as hepatitis or HIV. Health Canada-approved uses for immunoglobulins are primary humoral immunodeficiency syndrome, HIV in children, idiopathic thrombocytopenic purpura, B-cell chronic lymphocytic leukemia, and allogeneic bone marrow transplant. Dosages vary widely.

Rh₀(D) immunoglobulin

Rh₀(D) immunoglobulin (RhoGAM[®], WinRho[®]) is used to suppress the active antibody response and the formation of anti-Rh₀(D) antibodies in an Rh₀(D)-negative person exposed to Rh-positive blood. Because an Rh₀(D)-negative person reacts to Rh-positive blood as if it were a foreign, “nonself” substance, an immune response develops against it and an antigen-antibody reaction occurs. This reaction can be fatal. The administration of this immunoglobulin helps to prevent the reaction. The most common use of this product is in cases of maternal-fetal Rh incompatibility (postpartum). Only the mother is normally dosed. The objective is to prevent a harmful maternal immune response to a fetus during a future pregnancy, if an Rh-negative mother becomes pregnant with an Rh-positive child.

Rh₀(D) immunoglobulin is prepared from the plasma or serum of adults with a high titre of anti-Rh₀(D) antibody to the red blood cell antigen Rh₀(D). Administration of this

immunoglobulin is contraindicated in people who have been previously immunized with this drug and in Rh₀(D)-positive or Du-positive patients. It is administered intramuscularly or intravenously at 28 weeks gestation, and 600 units are administered within 72 hours after delivery. After spontaneous or elective abortion of a pregnancy of 12 weeks gestation or less, 600 units is administered intramuscularly.

rabies immunoglobulin

Rabies immunoglobulin (Imogam Rabies Pasteurized®, HyperRab S/D®) is a passive immunizing drug that is administered concurrently with rabies virus vaccine following suspected exposure to the rabies virus. In humans, this usually occurs following an animal bite. Rabies immunoglobulin is derived from human cells that are harvested from people who have been immunized with rabies vaccine. The only contraindication to its use is drug allergy, although a patient with an allergy may still need to be dosed rather than face infection with the almost universally fatal rabies virus. The decision to dose a patient in such a case would be based on the probability of rabies infection given the particular circumstances surrounding the animal bite. Rabies immunoglobulin is administered as a single dose (20 units per kg). Infiltrate as much of the dose as possible into the bite wound area and give the remainder intramuscularly in the gluteal region; do not administer into the same site as the rabies vaccine.

tetanus immunoglobulin

Tetanus immune globulin (Hypertet S/D®) is a passive immunizing drug effective against tetanus. It contains tetanus antitoxin antibodies that neutralize the bacterial exotoxin produced by *Clostridium tetani*, the bacterium that causes tetanus. The antitoxin neutralizes circulating toxins and competes with and partially binds with loosely bound toxin. However, the antitoxin has no effect on tissue-bound toxins. Optimum passive immunity occurs early in the disease process. Tetanus immunoglobulin is prepared from the plasma of adults who are hyperimmunized with the tetanus toxoid and is given as prophylaxis to people with tetanus-prone wounds (250 units intramuscularly as a single dose). It may also be used to treat active tetanus (3 000 to 6 000 units intramuscularly as a single dose).

varicella-zoster immunoglobulin

Varicella-zoster immunoglobulin (VZIG; VariZIG®) can be used to modify or prevent chicken pox in susceptible individuals who have had recent significant exposure to the disease. VZIG is best administered within 96 hours of exposure. Candidates for therapy with VZIG are those at high risk of serious disease or complications if they become infected with the varicella-zoster virus. Two examples are newborn children, including premature infants with significant exposure, and immunocompromised adults. If the infection manifests in a pregnant woman within 5 days of delivery, a dose of VZIG is recommended for the infant. It may also be beneficial to both mother and infant when given to the mother during pregnancy, preferably as soon as possible after diagnosis of infection. Healthy adults, including pregnant women, are evaluated on a case-by-case basis. The

duration of protection against infection provided by VZIG is at least 3 weeks. VZIG is prepared from the plasma of normal blood donors with high antibody titres to varicella-zoster virus. It is administered intravenously or intramuscularly, 125 to 625 units within 96 hours of varicella exposure.

PANDEMIC PREPAREDNESS AND RESPONSE

In anticipation of an influenza pandemic in the near future, pandemic planning for the health care sector involves a federal, provincial, and territorial framework to provide a planned, coordinated, efficient, and effective public health response—the Canadian Pandemic Influenza Preparedness (CPIP): *Planning Guidance for the Health Sector*. The plan is a collaborative effort put forth by public health and emergency preparedness and response experts from the government of Canada and provincial and territorial governments, as well as other expert stakeholders. The Canadian pandemic plan has two overall goals: (1) to minimize overall illness and deaths and (2) to minimize societal disruption associated with an influenza pandemic. The plan offers guidance and information to help support planning for and responding to an influenza pandemic. The original plan is regularly updated to reflect current thinking and new knowledge. Two key components to the plan are preparedness and response. *Preparedness* involves prevention strategies and activities to prepare for the pandemic, including guidelines for planning activities that would aid in managing an influenza pandemic. Surveillance, vaccine programs, the use of antivirals, health services, public health measures, and communication are all examples of such activities. *Response* involves high-level operational activities for an effective national health sector response, including roles and responsibilities for health care providers. A recovery plan would focus on the coordination of a postpandemic response for health care and emergency response sectors. Additional information about the CPIP is available at <http://www.phac-aspc.gc.ca/cpip-pclcpi/>.

The [Global Preparedness Monitoring Board \(2019\)](#) of the World Health Organization reviewed recommendations following the 2009 H1N1 influenza pandemic and the 2014–2016 Ebola outbreak and identified seven urgent actions to prepare the world for global health emergencies such as a potential novel coronavirus. The World Health Organization was notified on December 31, 2019 of a mysterious pneumonia of unknown cause affecting the population of Wuhan in Hubei province, China; however, the COVID-19 virus would later affect the global population. On March 11, 2020, the World Health Organization made an assessment of COVID-19 and declared a global pandemic. At the time of this text's publication, treatments and vaccines for COVID-19 are in progress, with more knowledge being discovered and published. A more fulsome discussion will occur in the subsequent edition of this book.

❖ NURSING PROCESS

◆ ASSESSMENT

Before administering a toxoid or vaccine, gather complete information about the patient's health history, including medications

taken (prescription, over-the-counter, and natural health products), reactions to drugs, present and past health status, previous allergy test results, use of any immunosuppressants, presence of autoimmune or immunosuppressing diseases or infections, pregnancy and lactation status, and any unusual reaction to any substance. When children are to receive a vaccine or toxoid, assess and follow the prescribed immunization schedule and dose. [The Public Health Agency of Canada \(2020d\)](#) and the NACI provide the latest recommendations for adult and child immunizations in Canada. These recommendations, along with cautions, are easily accessible on the Internet and are available for referral to gain updated information prior to giving vaccines.

Because passive immunizing drugs may precipitate serum sickness, carefully assess patients who have chronic illnesses, are debilitated, or are older adults. This includes measuring vital signs, completing a physical assessment, and obtaining a medication history, as well as examining the results of any laboratory testing ordered by the health care provider. Document the patient's general health status with attention to overall well-being and any illnesses. See the discussion on passive vaccines as well as [Box 51.1](#) and [Table 51.1](#) for further information.

For the various active immunizing drugs, the Immunity and Immunization section and [Tables 51.1 and 51.2](#) provide more specific insight and information, including contraindications, cautions, and drug interactions. It is also important to note that the use of these drugs in the following patient groups must be considered carefully: patients who are pregnant; those with active infection (especially infections caused by the same pathogen or an organism producing the same toxin); patients with severe febrile illnesses excluding minor illnesses such as a cold, mild infection, ear infection, or low-grade fever; and patients with a history of reactions or serious adverse effects related to the drug. In addition, research has shown that patients who are already immunocompromised (e.g., those with AIDS, older adults, those with chronic diseases or cancer, neonates) are at increased risk for serious adverse effects to toxoids or vaccines; therefore, use these drugs cautiously or not at all in such patients. Many adults assume that the vaccines they received as children will protect them for a lifetime. This is usually the case; however, many vaccines may require an additional dose of vaccine periodically to “boost” the immune system (e.g., every 10 years for the tetanus vaccine). Always check with a reliable source such as the public health unit or a family health care provider. Some adults, however, were never vaccinated as children, or newer vaccines were not available at the time they were vaccinated. In addition, immunity may fade over time, and as patients age, they may become more susceptible to serious diseases caused by common infections, such as *Pneumococcus* infections.

Tetanus, diphtheria, and pertussis vaccines are to be used in patients 6 weeks to 6 years of age and are contraindicated in those with previous vaccine reactions. In addition, the use of these toxoids is contraindicated in patients with any type of neurological reaction to the vaccine. Pertussis, or whooping cough, is contagious—spread through respiratory secretions—and can certainly become a widespread problem. Assess the age of the patient because DTaP is the preferred preparation in children from 6 weeks to 7 years of age unless the pertussis component is contraindicated. In adolescents and adults, Tdap is indicated.

The *H. influenzae* type b vaccine is administered to adults and children considered at high risk for acquiring *H. influenzae* infection, such as congenital (primary) immunodeficiency; malignant hematological disorders; HIV; anatomic or functional asplenia (including sickle cell disease); all transplant recipients; and recipients of cochlear implants. In addition, the influenza vaccine should be administered yearly to adults and children over the age of 6 months. It is important to note that, each year, a new influenza vaccine is developed (see the earlier discussion on influenza vaccine). Assess whether the patient belongs in a high-risk group for exposure, such as health care providers. Assessment of age and medical history is important with these vaccines because individuals 65 years of age and older and those with chronic diseases are at risk for increased mortality from influenza. The influenza virus vaccine is contraindicated in those with a known hypersensitivity to it. Hepatitis B virus vaccines are indicated for those at high risk for exposure to the HBV or HBsAg-positive materials (e.g., blood, plasma, serum), such as health care providers. This vaccine is contraindicated in those allergic to yeast. Assess the needs of the patient receiving the vaccine because there are different formulations for children, adults older than 20 years of age, and individuals receiving dialysis or who are otherwise immunocompromised.

The MMR vaccine is contraindicated in pregnant women, in persons with a history of anaphylactic reaction or other immediate reaction to egg ingestion, and in those with an anaphylactic reaction to topically or systemically administered neomycin. Prior to the administration of the meningococcal vaccine, gather data about any history of allergies. The pneumococcal vaccine is contraindicated in those with known allergy to the drug or its components or in those patients with significant febrile illness or an immunosuppressed state as a result of drug therapy (e.g., chemotherapy).

Do not give the papillomavirus vaccine (Gardasil, Cervarix) to patients with allergies to yeast or patients who have had a documented allergic reaction to the first injection of the vaccine. This vaccine is also contraindicated in pregnancy. The zoster vaccine (Zostavax) is for the prevention of herpes zoster. Assessment of age is an important factor in the administration of this vaccine. It is recommended for patients 50 years of age and older to prevent shingles and is not to be given to patients with a history of allergic reactions to neomycin, gelatin, or any component of the vaccine. Assessment of immune status is also important because it is not to be given to those who are pregnant, immunocompromised, or receiving immunosuppressant therapies. The varicella virus vaccine, Varivax, is used to prevent chicken pox, which occurs mainly in those younger than 8 years of age or in those who are immunocompromised. Assess the patient's medical and medication history because this vaccine should not be given to individuals who have received high doses of systemic steroids in the previous month. Advise patients receiving the vaccine to avoid salicylates for 6 weeks after its administration because of the risk of Reye's syndrome (see [Chapter 49](#)). Age of the patient is important because it is given at 12 months of age and then again at 4 to 6 years of age.

Vaccine hesitancy is a concept nurses will need to consider during their assessment of pediatric and adult populations in Canada. [The World Health Organization \(2020\)](#) defines vaccine hesitancy as “the reluctance or refusal to vaccinate despite the availability of vaccines.” Currently, the [WHO \(2020\)](#) lists vaccine

hesitancy as one of the top ten threats to world health for 2019, contributing globally to 1.5 million deaths a year. The Childhood National Immunization Coverage Survey (Public Health Agency of Canada, 2016) reports only 1.5% of Canadian children have never received a vaccine; however, growing concerns from parents about the safety of vaccines and potential risks associated from receiving vaccines was also reported through the survey. The Canadian Nurses Association recommends that nurses provide evidence-based, accurate, timely and non-judgemental information to the public so individuals may make an informed decision about their own health. Therefore, it is important to complete a thorough immunization history during a health history addressing previous immunizations as well as attitudes pertaining to vaccinations.

◆ NURSING DIAGNOSES

- Potential for pain as a result of local or systemic effects of the injection of a toxoid, vaccine, or passive immunizing drug
- Ineffective knowledge as a result of the use of toxoids, vaccines, or passive immunizing drugs

◆ PLANNING

◆ Goals

- Patient will experience minimal pain associated with the injection of a toxoid, vaccine, or immunizing drug.
- Patient will demonstrate adequate and updated knowledge regarding the use of toxoids, vaccines, or immunizing drugs.

◆ Expected Patient Outcomes

- Patient uses measures to increase comfort associated with injection, such as the application of warm packs to the site of injection, as indicated and as ordered by the health care provider, to help relieve localized discomfort or alleviate any localized reactions.
 - Patient uses additional comfort measures such as eating small meals, controlling the environmental temperature, decreasing stimuli, increasing opportunity for rest, and using analgesics and anti-inflammatory drugs as prescribed or recommended.
- Patient states rationale for and benefits versus risks of the use of toxoids, vaccines, or immunizing drugs.
 - Patient describes symptoms to report to the health care provider immediately should they occur, such as fever higher than 38.3°C, infection, wheezing, increasing weakness, or any other unusual reaction.

◆ IMPLEMENTATION

When any immunizing drug is administered, always check and then recheck the specific protocols and schedules of administration to ensure accuracy and patient safety. Provide individuals receiving any immunizing drug with the proper instructions and updated written materials about the medication, technique and route of administration, adverse effects, and potential complications. Inform patients receiving vaccines that they will not “get” the

disease in question from receiving the attenuated or dead virus. It is also important to follow the manufacturer's recommendations for storage and administration of the drug, routes and site of administration, and dosage, as well as precautions and contraindications pertaining to the drug's use. Always provide patients with a written record of immunization with the date of administration and a reminder of when a booster is needed. Encourage parents to keep and maintain an accurate journal of their child's immunization status, including dates of immunization and any reactions, if they occur. Canada is working toward the development of a national electronic Immunization Tracking System. Prior to giving a vaccine, always inquire about any previous reaction. Administer all immunizing drugs as prescribed, using the route specified. The midlateral muscle of the thigh is the preferred site for infants. The deltoid muscle is preferred for older children and adults. If a patient experiences discomfort at the injection site, apply warm compresses to the site, or administer an analgesic, antipyretic, or anti-inflammatory drug, as ordered. Have epinephrine 1:1 000 readily available at the time of injection due to the risk of hypersensitivity reactions. Epinephrine is available in an autoinjector as 0.15 mg/0.15 mL (Allerject®) or in vials. Epinephrine solutions for injection (vials or autoinjectors) have a short shelf life of 12 to 18 months and, past this time, will start to break down to inactive substances. Replace epinephrine when outdated. Additionally, if fever (38.3°C or higher), convulsions with or without fever, altered consciousness, neurological symptoms, collapse, or somnolence occur, report them immediately to the health care provider, monitor the patient, and initiate emergency treatment as needed.

In regard to the possibility of an influenza pandemic, keep patients well informed and be aware of the need to minimize anxiety at all times. See the Patient Teaching Tips for more information.

CASE STUDY

Varicella Vaccination

Alicia has taken her daughter, 12-month-old Jamie, for a well-baby checkup. Jamie has been healthy overall and is due for the varicella virus vaccination. The nurse reviews the vaccination process with Alicia and gives her information about what to expect after the vaccination.

1. Alicia looks at the information sheet and then asks, “This is just one shot, right? After this, she’ll be immune to chicken pox. What a relief that will be!” What is the nurse’s best response?
2. The nurse reviews the information with Alicia and tells her that a slight fever may develop. She asks Alicia what she has at home to give to Jamie if a fever or discomfort at the injection site develops. Alicia replies, “Oh, I have children’s aspirin.” What instructions will the nurse give regarding this?
3. The next morning, the skin around Jamie’s injection site is slightly swollen, red, and warm to the touch. Alicia calls the office to “make sure everything is all right.” What further assessment questions will the nurse ask Alicia?
4. Alicia’s grandmother is visiting and tells Alicia, “Oh, I had that same vaccine 2 months ago! I don’t ever want to get shingles.” Is she correct? Did she receive the same vaccine that Jamie did?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

◆ EVALUATION

The therapeutic response in patients receiving immunizing drugs is the prevention or amelioration of the specific disease being targeted. Adverse reactions for which to monitor in patients receiving immunizing drugs are specific to the drug, but there may be a localized reaction, including swelling, redness, discomfort, and heat at the site of injection or a more serious reaction that must be reported immediately to

the health care provider (e.g., high fever, lymphadenopathy, rash, itching, joint pain, severe flu-like symptoms, decreased level of consciousness, shortness of breath). For a complete list of expected reactions and adverse effects, both minor and severe, see Table 51.2. As immunizing drugs improve and newer ones are developed, it is hoped that fewer adverse effects and fewer adverse drug events and complications will be seen.

PATIENT TEACHING TIPS

- A localized reaction to the injection sometimes occurs when toxoids and vaccines are administered. Inform patients that the discomfort can be relieved by placing warm compresses on the injection site, resting, and taking acetaminophen or diphenhydramine hydrochloride, as directed by the health care provider. Instructions for the care of infants or children with such reactions are generally given by the child's health care provider when the immunizing drug is administered.
- Advise patients, parents, and caregivers to notify the health care provider if rash, itching, high or prolonged fever, or shortness of breath occurs after the vaccination.
- Stress that patients, parents, or caregivers should always keep a double record (two copies kept in separate places) of all medications being taken, including all vaccinations received.
- A vaccine adverse event reporting system is available through Health Canada (<http://www.phac-aspc.gc.ca/im/ae-fi-essi-form-eng.php>).
- Patients are to be monitored for any adverse reactions for at least 15 minutes after receiving an immunization; 30 minutes is preferred if there is a specific concern about a possible vaccine reaction.

KEY POINTS

- A foreign substance in the body is termed an *antigen*; the body creates a substance called an *antibody* to specifically bind to it.
- B lymphocytes (B cells), when stimulated by the binding of an antigen molecule, begin to differentiate into memory cells and plasma cells.
- Memory cells remember what a particular antigen looks like in case the body is exposed to the same antigen in the future. Plasma cells manufacture antibodies and will mass-produce clones of antibodies upon re-exposure to a particular antigen.
- The two types of immunity are active and passive immunity. Different types of drugs are used to induce each, and these drugs are indicated for different populations, as follows:
 - Active immunization involves administration of a toxoid or a vaccine that exposes the body to a relatively harmless form of the antigen (foreign invader) to imprint cellular memory and stimulate the body's defences to fight any subsequent exposure. It provides long-lasting or permanent immunity. The recipient must have an active, functioning immune system to benefit.
 - Passive immunization involves the administration of immunoglobulins, antitoxins, or antivenins. Serum or concentrated immunoglobulins are obtained from humans or animals and, after screening and testing, are injected into the patient, directly giving the individual the ability to fight off the invading microorganism or inactivate a toxin. Passive immunization provides temporary protection and does not stimulate an antibody response in the host. It is used in patients who are immunocompromised or who have been exposed to, or anticipate exposure to, an organism or toxin.
- Patients who should not receive immunizing drugs include those with active infections, febrile illnesses, or history of a previous reaction to the drug. Use of these drugs in pregnant women is usually contraindicated.
- Patients who are immunocompromised are at greater risk of experiencing serious adverse effects from immunizing drugs.
- Encourage parents to keep updated records of their children's and their own immunizations with any toxoids or vaccines.

EXAMINATION REVIEW QUESTIONS

1. The nurse is assessing a patient who has been prescribed the measles vaccine. Which of the following conditions would the nurse indicate as a contraindication to the vaccine??
 - a. Anemia
 - b. Pregnancy
 - c. Ear infection
 - d. Common cold
2. An infant is to receive a vaccination. Which of the following adverse events would the nurse teach the parent of the infant to monitor?
 - a. Fever over 38.3°C
 - b. Rash
 - c. Soreness at the injection site
 - d. Chills

3. A client presents with a suspected hepatitis B exposure. Which of the following would the nurse anticipate will be given to the client?
 - a. Immune serum globulin
 - b. Hepatitis B virus vaccine
 - c. Hepatitis B immunoglobulin
 - d. Rh₀(D) immunoglobulin
4. During a routine checkup, a 72-year-old patient is advised to receive an influenza vaccine injection. The client questions this, saying, “I had one last year. Why do I need another one?” What of the following would be the most appropriate response by the nurse?
 - a. “The effectiveness of the vaccine wears off after 6 months.”
 - b. “Each year a new vaccine is developed on the basis of flu strains that are likely to be in circulation.”
 - c. “When you reach 65 years of age, you need boosters on an annual basis.”
 - d. “Taking the flu vaccine each year allows you to build your immunity to a higher level each time.”
5. A client presents to an urgent care centre after stepping on a rusty tent nail. The nurse evaluates the patient’s immunity status and notes that the patient last received the tetanus booster 10 years ago. Which of the following immunizations would be most appropriate for the client?
 - a. Immunoglobulin intravenous
 - b. DTaP (diphtheria, tetanus, and acellular pertussis)
 - c. Tdap (tetanus, diphtheria, and acellular pertussis)
 - d. No immunizations are necessary at this time.
6. The nurse is providing teaching after an adult receives a booster immunization. Which adverse reactions should the patient report immediately to the health care provider? (Select all that apply.)
 - a. Swelling and redness at the injection site
 - b. Fever of 37.8°C
 - c. Joint pain
 - d. Heat over the injection site
 - e. Rash over the arms, back, and chest
 - f. Shortness of breath
7. The order for an adult who needs passive hepatitis B prophylaxis reads: “Give hepatitis B immunoglobulin, 0.06 mg/kg IM now and then again in 30 days.” The patient weighs 176 pounds. How many milligrams will this patient receive per dose?
8. An animal control officer was bitten by a stray dog that showed signs of rabies. Which statement by the nurse is correct regarding the treatment for rabies prophylaxis?
 - a. “You will receive treatment if you begin to show symptoms of rabies.”
 - b. “You will receive one oral dose of medication today, and one more in 1 week.”
 - c. “You will need to receive 3 subcutaneous injections over the next week.”
 - d. “You will need to receive 5 intramuscular injections over the next 28 days.”

CRITICAL THINKING ACTIVITIES

1. A patient is in the emergency department after receiving a bite from a black widow spider (*Latrodectus mactans*). As you administer the antivenin for the black widow spider bite, he asks you, “Now will I be immune to black widow spiders after this shot? That’s good, because we have a lot of them around the barn.” What is the nurse’s best response? Explain your answer.
 2. Within 2 hours after a patient receives a tetanus booster vaccination, his wife calls the clinic. “He says that he is feeling weird and a little short of breath. You said to call if he is having a reaction, but it’s hard to tell what is happening.” What is the first instruction the nurse should give to this patient’s wife?
 3. You are working as a staff nurse on a medical–surgical unit in a suburban area. A coworker asks you, “What are we supposed to do if there is an influenza pandemic?” What is the nurse’s best answer?
- For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Antineoplastic Drugs Part 1: Cancer Overview and Cell Cycle–Specific Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Briefly describe concepts related to carcinogenesis.
2. Define the different types of malignancy.
3. Discuss the purpose and role of various treatment modalities in the management of cancer.
4. Define the term *antineoplastic*.
5. Discuss the role of antineoplastic therapy in the treatment of cancer.
6. Contrast the cell cycle of normal cells and malignant cells in regard to growth, function, and response of the cell to chemotherapeutic drugs and other treatment modalities.
7. Compare the characteristics of highly proliferating normal cells (including cells of the hair follicles, gastrointestinal tract, and bone marrow) with the characteristics of highly proliferating cancerous cells.
8. Briefly describe the specific differences between cell cycle–specific and cell cycle–nonspecific antineoplastic drugs
9. Identify the drugs that are categorized as cell cycle–specific, including mitotic inhibitors, topoisomerase inhibitors, and antineoplastic enzymes.
10. Describe the common adverse effects and toxic reactions associated with the various antineoplastic drugs, including the causes for their occurrence and methods of treatment, such as antidotes for toxicity.
11. Discuss the mechanisms of action, indications, dosages, routes of administration, cautions, contraindications, and drug interactions of cell cycle–specific drugs, including mitotic inhibitors, topoisomerase inhibitors, and antineoplastic enzymes.
12. Apply knowledge about antineoplastic drugs to the development of a comprehensive collaborative plan of care for patients receiving cell cycle–specific drugs, mitotic inhibitors, topoisomerase inhibitors, and antineoplastic enzymes.

KEY TERMS

Analogue A chemical compound with a structure similar to that of another compound but differing from it with respect to some component. (p. 841)

Anaplasia The absence of the cellular differentiation that is part of the normal cellular growth process (see *differentiation*; adjective: *anaplastic*). (p. 837)

Antineoplastic drugs used to treat cancer. Also called *cancer drugs*, *anticancer drugs*, *cancer chemotherapy*, and *chemotherapy*. (p. 837)

Benign Denoting a neoplasm that is noncancerous and therefore not an immediate threat to life. (p. 834)

Cancer A malignant neoplastic disease, the natural course of which is fatal (see *neoplasm*). (p. 833)

Carcinogen Any cancer-producing substance or organism. (p. 836)

Carcinomas Malignant epithelial neoplasms that tend to invade surrounding tissue and metastasize to distant regions of the body. (p. 834)

Cell cycle–nonspecific Denoting antineoplastic drugs that are cytotoxic in any phase of the cellular growth cycle. (p. 838)

Cell cycle–specific Denoting antineoplastic drugs that are cytotoxic during a specific phase of the cellular growth cycle. (p. 839)

Clone A cell (or group of cells) that is genetically identical to a given parent cell. (p. 833)

Differentiation An important part of normal cellular growth in which immature cells mature into specialized cells. (p. 833)

Dose-limiting adverse effects Adverse effects that prevent an antineoplastic drug from being given in higher dosages, often restricting the effectiveness of the drug. (p. 839)

Emetic potential The potential of a drug to cause nausea and vomiting. (p. 839)

Extravasation The leakage of any intravenously or intra-arterially administered medication into the tissue space surrounding the vein or artery. Such an event can cause serious tissue injury, especially with antineoplastic drugs. (p. 840)

Gene expression How a cell expresses a receptor or gene; the process in which information from a gene is used in the synthesis of a gene product. (p. 835)

Growth fraction The percentage of cells in mitosis at any given time. (p. 837)

Intrathecal A route of drug injection through the theca of the spinal cord and into the subarachnoid space. This route is used to deliver certain chemotherapy medications to kill cancer cells in the central nervous system. (p. 844)

Leukemias Malignant neoplasms of blood-forming tissues, characterized by the replacement of normal bone marrow cells with leukemic blasts, resulting in abnormal numbers and forms of immature white blood cells in the circulation. (p. 834)

Lymphomas Malignant neoplasms of lymphoid tissue. (p. 834)

Malignant Tending to worsen and cause death; anaplastic, invasive, and metastatic. (p. 834)

Metastasis The process by which a cancer spreads from the original site of growth to a new and remote part of the body (adjective: *metastatic*). (p. 833)

Mitosis The process of cell reproduction occurring in somatic (nonsexual) cells and resulting in the formation of two genetically identical daughter cells containing the diploid (complete) number of chromosomes characteristic of the species. (p. 836)

Mitotic index The number of cells per unit (usually 1 000) undergoing mitosis at a given moment. (p. 837)

Mutagen A chemical or physical agent that induces or increases genetic mutations by causing changes in deoxyribonucleic acid (DNA). (p. 836)

Mutation A permanent change in DNA that is transmissible to future cellular generations. Mutations can transform normal cells into cancer cells. (p. 833)

Myelosuppression Suppression of bone marrow function, which can result in dangerously reduced numbers of red blood cells, white blood cells, and platelets. (p. 839)

Nadir Lowest point in any fluctuating value over time; for example, the lowest white blood cell count measured after the count has been depressed by chemotherapy. (p. 840)

Neoplasm Any new and abnormal growth, specifically growth that is uncontrolled and progressive; a synonym for *tumour*; a malignant neoplasm or tumour is synonymous with *cancer*. (p. 833)

Nucleic acids Molecules of DNA and RNA in the nucleus of every cell (hence the name *nucleic acid*). Chromosomes are made up of DNA and encode all of the genes necessary for cellular structure and function. (p. 836)

Oncogenic Cancer producing; often applied to tumour-inducing viruses. (p. 836)

Paraneoplastic syndromes (PNSs) Symptom complexes arising in patients with cancer that cannot be explained by local or distant spread of their tumours. (p. 835)

Primary lesion The original site of growth of a tumour. (p. 833)

Sarcomas Malignant neoplasms of the connective tissues arising in bone, fibrous, fatty, muscular, synovial, vascular, or neural tissue; often first presenting as painless swellings. (p. 834)

Tumour A new growth of tissue characterized by a progressive, uncontrolled proliferation of cells. Tumours can be solid (e.g., brain tumour) or circulating (e.g., leukemia or lymphoma) and benign (noncancerous) or malignant (cancerous); circulating tumours are more precisely called *hematological tumours* or *hematological malignancies*; a tumour is also called a *neoplasm*. (p. 834)

Tumour lysis syndrome A common metabolic complication of chemotherapy for rapidly growing tumours. It is characterized by the presence of excessive cellular waste products and electrolytes, including uric acid, phosphate, and potassium, and by reduced serum calcium levels. (p. 842)

DRUG PROFILES

asparaginase, p. 849

capecitabine, p. 844

Key drug

Full generic name is given in parentheses. For the purposes of this text, the more common, shortened name is used.

OVERVIEW

Cancer is a broad term encompassing a group of diseases that are characterized by cellular transformation (e.g., by genetic **mutation**), uncontrolled cellular growth, possible invasion into surrounding tissue, and metastasis to other tissues or organs distant from the original body site. This cellular growth differs from normal cellular growth in that cancerous cells do not possess a growth control mechanism. Lack of cellular **differentiation** or maturation into specialized, productive cells is also a common characteristic of cancer cells. **Figure 52.1** illustrates the multiple steps involved in the development of cancer. Cancerous cells will continue to grow and invade adjacent structures. They may break away from the original tumour mass and travel by means of the blood or lymphatic system to establish a new clone of cancer cells and create a metastatic growth elsewhere in the body. A **clone** is a cell (or group of cells) that is genetically identical to a given parent cell. In the remainder of this chapter and the next chapter, the term *cancer* will be used to refer to any type of malignant neoplasm.

Metastasis refers to the spreading of a cancer from the original site of growth (**primary lesion**) to a new and remote part of the body (secondary or metastatic lesion). The terms *malignancy*, *neoplasm*, and *tumour* are often used as synonyms for *cancer*. A **neoplasm** (from Latin roots meaning new tissue) is

Fig. 52.1 Process of cancer development. (From Lewis, S. L., Bucher, L., Heitkemper, M. M., et al. (2019). In M. A. Barry, J. Lok, J. Tyerman, & S. Goldsworthy (Canadian Eds.), *Medical-Surgical nursing in Canada: Assessment and management of clinical problems* (4th Canadian ed., p. 319). Toronto, ON: Elsevier.)

a mass of new cells. It is another term for **tumour**. There are two types of tumours: benign and malignant. A **benign** tumour is of a uniform size and shape and displays no invasiveness (in terms of infiltrating other tissues) or metastatic properties. The terms *nonmalignant* and *benign* suggest that these tumours may be harmless, which is true in most cases. However, a benign tumour can be lethal if it grows large enough to mechanically interrupt the normal function of a crucial tissue or organ. **Malignant** neoplasms consist of cancer cells that invade (infiltrate) surrounding tissues and metastasize to other tissues and organs. Some of the various characteristics of benign and malignant neoplasms are listed in Table 52.1.

Various tumour types based on tissue categories include sarcomas, carcinomas, lymphomas, leukemias, and tumours of nervous tissue origin. Examples of these common malignant tumours are listed in Table 52.2. It is important to know the tissue of origin because this determines the type of treatment, the likely response to therapy, and the prognosis.

Carcinomas arise from epithelial tissue, which is located throughout the body. This tissue covers or lines all body surfaces, both inside and outside the body. Examples are the skin,

TABLE 52.1 Tumour Characteristics: Benign and Malignant		
Characteristics	Benign	Malignant
Potential to metastasize	No	Yes
Encapsulated	Yes	No
Similar to tissue of origin	Yes	No
Rate of growth	Slow	Unpredictable and unrestrained
Recurrence after surgical removal	Rare	Common

TABLE 52.2 Tumour Classification Based on Specific Tissue of Origin	
Tissue of Origin	Malignant Tissue
Epithelial = Carcinomas	
Glands or ducts	Adenocarcinomas
Respiratory tract	Small and large cell carcinomas
Kidney	Kidney cell carcinoma
Skin	Squamous cell, epidermoid, and basal cell carcinoma; melanoma
Connective = Sarcomas	
Fibrous tissue	Fibrosarcoma
Cartilage	Chondrosarcoma
Bone	Osteogenic sarcoma (Ewing's tumour)
Blood vessels	Kaposi's sarcoma
Synovia	Synoviosarcoma
Mesothelium	Mesothelioma
Lymphatic = Lymphomas	
Lymph tissue	Lymphomas (Hodgkin's, non-Hodgkin's)
Glia	Glioma
Adrenal medulla nerves	Pheochromocytoma
Blood and Bone Marrow	
White blood cells	Leukemia
Bone marrow	Multiple myeloma

the mucosal lining of the entire gastrointestinal (GI) tract, and the lining of the bronchial tree (lungs). The purpose of these epithelial tissues is to protect the body's vital organs. **Sarcomas** are malignant tumours that arise primarily from connective tissues, although some sarcomas are tumours of epithelial cell origin. Connective tissue is the most abundant and widely distributed of all tissues and includes bone, cartilage, muscle, lymphatic, and vascular structures. Its purpose is to support and protect other tissues. **Lymphomas** are cancers within the lymphatic tissue. **Leukemias** arise from the bone marrow and are cancers of blood and bone marrow. Leukemias differ from carcinomas and sarcomas in that the cancerous cells do not form solid tumours but are interspersed throughout the lymphatic or circulatory system and interfere with the normal functioning of these systems. For this reason, they are sometimes referred to as *circulating tumours*, although *hematological malignancy* is a more precise term. Lymphomas can be quite bulky and are usually classified as solid tumours.

TABLE 52.3 Paraneoplastic Syndrome Associated With Some Cancers

Paraneoplastic Syndrome	Associated Cancer
Hypercalcemia, sensory neuropathies, syndrome of inappropriate antidiuretic hormone secretion (SIADH)	Lung
Disseminated intravascular coagulation	Leukemia
Cushing's syndrome	Lung, thyroid, testes, adrenal
Addison's disease	Adrenal, lymphoma

Patients with cancer may also experience various groups of symptoms that cannot be directly attributed to the spread of a cancerous tumour. Such symptom complexes are referred to as **paraneoplastic syndromes (PNSs)**. They are estimated to occur in up to 15% of patients with cancer and may even be the first sign of malignancy. *Cachexia* (general ill health and malnutrition) is the most common such symptom complex. Examples of other common PNSs are listed in [Table 52.3](#). These syndromes are believed to result from the effects of biologically or immunologically active substances, such as hormones and antibodies, secreted by the tumour cells. Many patients also exhibit generalized symptoms such as anorexia, weight loss, fatigue, and fever.

Etiology of Cancer

The etiology of cancer remains a mystery for the most part, and cancer researchers have made slow progress toward identifying possible causes. Certain etiological factors have been identified, and some of these factors and the cancers with which they are causally associated are listed in [Table 52.4](#). Causative factors that have been identified include age-related and sex-related characteristics; genetic and ethnic factors; oncogenic viruses; environmental and occupational factors; radiation; and immunological factors.

Age- and Gender-Related Differences

The probability that a neoplastic disease will develop generally increases with advancing age. A number of rare cancers, such as acute lymphocytic leukemia and Wilms tumours, occur predominantly in children.

With the exception of cancers affecting the reproductive system, few cancers exhibit a sex-related difference in incidence. Urinary cancers are more common in men than in women, with a relatively equal number of lung cancer diagnoses in men and women; however this may have more to do with exogenous factors such as smoking and occupational exposure to environmental toxins than to sex-related characteristics ([Canadian Cancer Society, 2018](#)). The incidence of colon, rectal, pancreatic, and skin cancers, as well as leukemia, is comparable in men and women. A number of hematological cancers have a slight male predominance.

Genetic and Ethnic Factors

Few cancers have been confirmed to have a hereditary basis (some types of breast, colon, and stomach cancers are exceptions). Improved understanding of tumour biology has helped guide therapy tremendously. Two related advancements are

TABLE 52.4 Cancer: Proposed Etiological Factors

Risk Factor	Associated Cancer
Environment	
Radiation (ionizing)	Leukemia, breast, thyroid, lung
Radiation (ultraviolet)	Skin, melanoma
Viruses	Leukemia, lymphoma, nasopharyngeal
Food	
Aflatoxin	Liver
Dietary factors	Colon, breast, endometrial, gallbladder
Lifestyle	
Alcohol	Esophageal, liver, stomach, laryngeal
Tobacco	Lung, oral, esophageal, laryngeal, bladder
Medical Drugs	
Diethylstilbestrol	Vaginal in second generation, breast, testicular, ovarian
Estrogens	Endometrial, breast
Alkylating drugs	Leukemia, bladder
Occupational	
Asbestos	Lung, mesothelioma
Aniline dye	Bladder
Benzene	Leukemia
Vinyl chloride	Liver
Reproductive History	
Late first pregnancy, early menses	Breast
Multiple sexual partners	Cervical, uterus
Nulliparity (no children)	Ovarian

determination of hormone receptor status and identification of specific **gene expression** in various types of tumour cells. For example, some tumour cells express themselves on their cell membrane surfaces, either estrogen receptors or progesterone receptors, and some tumour cells express specific genes such as the *HER2/neu* gene. Because these indicators aid in the classification of a patient's tumour, they also help in choosing appropriate drug therapy, predicting response to therapy, and anticipating a prognosis. Discovery of the *BRCA1* and *BRCA2* genes has allowed identification of women who are at risk of breast cancer because they have a certain alteration in one of these *BRCA* genes. Many women with a family history of breast cancer choose to be tested for the presence of a *BRCA* gene mutation, which has led some women to undergo prophylactic breast removal. Tumours with identifiable gene expression patterns can show a familial pattern of inheritance. For example, Burkitt lymphoma is endemic in children aged 4 to 7 years, in certain regions of equatorial Africa and other tropical locations. Outside Africa, adults with the sporadic form of this lymphoma are typically younger than 35 years. Another example of an ethnic predisposition is the high incidence of nasopharyngeal

cancer in people of South Asian descent as well as among the Inuit population of Alaska and Canada. These associations with race are complicated by a well-recognized viral pathogenesis for both diseases.

Oncogenic Viruses

Extensive research has indicated that there are cancer-causing (**oncogenic**) viruses that can affect most mammalian species. Examples include human papillomavirus (HPV), feline leukemias, the Rous sarcoma virus in chickens, and the Shope papillomavirus in rabbits.

The herpesviruses are common examples of oncogenic viruses. Epstein–Barr virus is a type of herpesvirus. It is most commonly recognized as the cause of infectious mononucleosis (commonly referred to as *mono* or “the kissing disease”). However, it is also associated with the development of Burkitt lymphoma and nasopharyngeal cancer. Infection with HPV has been linked to cervical, anal, and oropharyngeal cancers.

Occupational and Environmental Carcinogens

A **carcinogen** is any substance that can cause cancer. In the nucleus of every cell are found molecules of **nucleic acids**, so named because of their location in the cell nucleus. The two types of nucleic acids are deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). DNA molecules are the master molecules of genetic material within cells and contain the approximately 30 000 genes of the human genome. Genes are transcribed into messenger RNA molecules, which in turn are translated into protein molecules necessary for cellular structure and function. This process is discussed further in the section on alkylating drugs in [Chapter 53](#). Environmental carcinogens include air and water pollution, pesticides, certain chemicals in foods, and many more. Occupational exposure is defined as any contact between the human body and a potentially harmful agent or environment in the workplace. Examples of such agents include asbestos, cadmium, benzene, radon, and vinyl chloride. A **mutagen** is any substance (e.g., chemicals in cigarette smoke, pesticides) or physical agent (e.g., radiation) that induces changes in DNA molecules. Mutations often transform normal cells into cancer cells.

Radiation

Radiation is a well-known and potent carcinogenic agent. There are two basic types of radiation: (1) ionizing, or high-energy, radiation and (2) nonionizing, or low-energy, radiation. Both types can be carcinogenic. Ionizing radiation is potent and can penetrate deeply into the body. It is called *ionizing* because it causes the formation of ions within living cells. This type of radiation (used in X-ray studies) is also used to treat (irradiate) cancerous tumours (e.g., radium implants). Nonionizing radiation is much less potent and cannot penetrate deeply into the body. Ultraviolet light is an example of this type of radiation and is the cause of skin cancer. In contrast to chemotherapy, radiation therapy is considered a locoregional and not a systemic cancer treatment. Adverse effects of radiation therapy (e.g., radiation burns; nausea with GI tract irradiation) tend to be more localized to the site of treatment as well. Scientific specialists known

as *radiation oncologists* are involved in the planning of radiation treatments, including calculation of the appropriate dose (dosimetry).

Immunological Factors

The immune system plays an important role in the body in cancer surveillance and in the elimination of neoplastic cells. Neoplastic cells are believed to develop in everyone; however, a healthy person's immune system recognizes them as abnormal and eliminates them through cell-mediated immunity (cytotoxic T lymphocytes; see [Chapter 54](#)). It has also been shown that the incidence of cancer is much higher in immunocompromised individuals. The relationship between cancer and a suppressed immune system has also been noted in patients with cancer being treated with immunosuppressive drugs after organ transplantation. The higher rates of cancers such as skin cancer and lymphoma in transplant patients are a result of this aggressive use of drugs to prevent organ rejection.

Cell Growth Cycle

Normal cells in the body divide (proliferate) in a controlled and organized fashion. This growth is regulated by means of various mechanisms. In contrast, cancer cells lack regulatory mechanisms and divide uncontrollably. Often, the growth of cancer cells is also more constant or continuous than that of nonmalignant cells. Thus, one important growth index for malignant tumours is the time it takes for the tumour to double in size. This doubling time varies greatly for different types of cancers and is directly related to and important for determining the prognosis. Cancer treatment that cannot destroy every neoplastic cell does not prevent the regrowth of the tumour. The time it takes for regrowth to occur depends on the doubling time of the particular cancer. For example, Burkitt lymphoma has an extremely short doubling time. This shorter doubling time is associated with a tumour that, although it may be chemosensitive, is often difficult to cure due to rapid regrowth.

The cell growth characteristics of normal and neoplastic cells are similar. Both types of cells pass through five distinct growth phases: G_0 , the resting phase, in which the cell is considered out of the cell cycle; G_1 , the first gap phase; S, the synthesis phase; G_2 , the second gap phase; and M, the **mitosis** phase ([Figure 52.2](#)).

During mitosis, one cell divides into two genetically identical daughter cells. Mitosis is further subdivided into four distinct subphases associated with the time periods before and during the alignment and separation of the chromosomes (DNA strands): prophase, metaphase, anaphase, and telophase. A complete cycle from one mitosis to the next is called the *generation time*. It is different for all tumours, ranging from hours to days. The cell growth cycle and the events that occur in the different phases are summarized in [Table 52.5](#). [Figure 52.3](#) shows at which points in the general phases of the cell cycle the cell cycle-specific chemotherapeutic drugs show their greatest activity.

The growth activity in a mass of tumour cells has an important bearing on the killing power of chemotherapy drugs. The

Fig. 52.2 Cell life cycle and metabolic activity. Generation time is the period from M phase to M phase. Cells not in the cycle but capable of division are in the resting phase (G₀). (Adapted from Kumar, V., Fausto, N., & Aster, J. C. (2010). *Robbins and Cotran pathologic basis of disease* (8th ed., p. 86) Philadelphia, PA: Saunders.)

TABLE 52.5 Cell Cycle Phases

Phase	Description
G ₀ : Resting phase	Most normal human cells exist predominantly in this phase. Cancer cells in this phase are not susceptible to the toxic effects of cell cycle–specific drugs.
G ₁ : First gap phase or postmitotic phase	Enzymes necessary for deoxyribonucleic acid (DNA) synthesis are produced.
S: DNA synthesis phase	DNA synthesis takes place, from DNA strand separation to replication of each strand to create duplicate DNA molecules.
G ₂ : Second gap phase or premitotic phase	RNA and specialized proteins are made.
M: Mitosis phase	Divided into four subphases: prophase, metaphase, anaphase, and telophase; cell divides (reproduces) into two daughter cells.

percentage of cells undergoing mitosis at any given time is called the **growth fraction** of the tumour. The actual number of cells that are in the M phase of the cell cycle is called the **mitotic index**. Chemotherapy is most effective in a rapidly dividing or highly proliferative tumour.

Hematopoietic stem cells are cells in bone marrow that have the capacity for self-renewal and repopulation of the different types of blood and bone marrow cells. In bone marrow, the hematopoietic stem cell divides asynchronously, regenerating itself while producing a cell that will go through a series of cell divisions to produce mature blood cells. Tumours in the bone marrow that affect a cell close to the stem cell are unable to mature and are considered poorly differentiated. The level of differentiation within a tumour, whether solid or circulating, becomes important in the treatment of neoplasms. This is because more highly differentiated tumours generally have a better therapeutic response (tumour shrinkage) to treatments such as

chemotherapy and radiation. In contrast, some cancers, such as leukemia, involve proliferation of immature white blood cells (WBCs) known as **blast cells**. Cancers with a high proportion of such undifferentiated cells are less responsive to chemotherapy or radiation and are thus more difficult to treat. Lack of normal cellular differentiation is known as **anaplasia**, and such undifferentiated cells are said to be **anaplastic** cells.

Cancer Drug Nomenclature

The more technical term for cancer is **malignant neoplasm**. Drugs used to treat cancer are known as **antineoplastic drugs** but are also called *cancer drugs*, *anticancer drugs*, and, most commonly, *cytotoxic chemotherapy* or just *chemotherapy*. The nomenclature (naming system) of cancer drugs can be somewhat more complex and confusing than that of other drug classes. Cancer treatment is an intensively researched area in health care, with many active research protocols. Multiple names are often used for the same drug, depending on its stage of development.

Recall from **Chapter 2** that medications have a chemical name, a generic name, and a trade name. This section introduces yet another name for medications, especially cancer drugs: the investigational or protocol name. A drug's chemical name is used by the chemists who first discover and work with the drug. The generic name is frequently first assigned to a chemical compound after a pharmaceutical manufacturer has determined that it is worthy of continued clinical research. It is often at this point that the chemical compound becomes an investigational drug. The trade name is a marketing name of a given drug used by the manufacturer primarily to market the drug. During the time before marketing and while a given medication is undergoing clinical research, it is frequently referred to by its protocol name. The protocol name is often a code name that consists of a combination of letters and numbers separated by one or more dashes. Although investigational drugs for all disease classes usually have some kind of protocol name, in patient care settings, protocol names tend to be used more

Fig. 52.3 General phase of the cell cycle in which the cell cycle-specific chemotherapeutic drugs accomplish their greatest proportionate kill of cancer cells.

commonly for cancer drugs than for other drug classes. Here are two typical examples that illustrate these concepts:

Other Name	Generic Name	Trade Name
STI-571 (protocol name)	imatinib mesylate	Gleevec®
5-fluorouracil* (chemical name)	fluorouracil	Same as generic

*The "5" refers to the position of a fluorine atom in the cyclic ring structure of the uracil molecule.

Because antineoplastic drugs can be carcinogenic, Health Canada mandates that carcinogenic studies be performed before any new drug is approved for use. However, no amount of clinical testing can fully reveal all of a drug's possible carcinogenic effects. Carcinogenic effects may not be observed in the laboratory animals on which the drug was tested but may become obvious only when the drugs are used in human

subjects. Given the relatively small numbers of patients in clinical research trials, the carcinogenic potential of a given drug may not be observed until after the drug is marketed for use in the general population. If patterns of carcinogenicity begin to emerge during this period of postmarketing surveillance (or in postmarketing studies), the drug may be recalled from the market.

Drug Therapy

Cancer is normally treated with one or more of these major medical approaches: surgery, radiation therapy, targeted drug therapy, biologic therapy, and chemotherapy. *Chemotherapy* is a general term that technically can refer to chemical (drug) therapy for any kind of illness. In practice, however, it usually refers to the pharmacological treatment of cancer. Figure 52.4 shows how various combinations of cancer treatment may succeed, or fail, over time.

Cancer chemotherapy drugs can be subdivided into two main groups based on where in the cell cycle they have their effects. Antineoplastic drugs that are cytotoxic (cell killing) in any phase of the cycle are called **cell cycle-nonspecific** drugs. Those drugs that are cytotoxic during a specific cell cycle phase

Fig. 52.4 Relationship between tumour cell burden and phases of cancer treatment. (From McCance, K. L., & Heuther, S. (2006). *Pathophysiology: The biologic basis for disease in adults and children* (5th ed.). St Louis, MO: Mosby.)

are called **cell cycle–specific** drugs. These are broad categories that describe the activity of a drug within the cell cycle. Individual drugs may have actions that fall into both of these categories. Regardless of the cell cycle characteristics of a drug, it is more effective on rapidly growing tumours. This chapter discusses the cell cycle–specific drugs. **Chapter 53** focuses on cell cycle–nonspecific drugs as well as various miscellaneous antineoplastic drugs.

The ultimate goal of any anticancer regimen is to kill every neoplastic cell and produce a cure, yet this goal is not achieved in most cases. Fortunately, some patients' immune systems may be able to clear any remaining tumour. Factors that affect the chances of cure and the length of patient survival include the cancer stage at time of diagnosis, the type of cancer and its doubling time, the efficacy of the cancer treatment, the development of drug resistance, and the general health of the patient. When a total cure is not possible, the primary goal of therapy is to control the growth of the cancer while maintaining the best possible quality of life for the patient, with the least possible level of discomfort and minimal adverse effects of treatment.

Cancer care and treatment involve many rapidly evolving medical sciences. Cancer is an intensively researched area, with the ultimate goals of research being to prevent cancer and prevent premature death. Chemotherapy medications are often dosed as part of complex, specific treatment protocols that are subject to frequent revision by oncology clinicians and researchers. For these reasons, the drug dosing information provided in this chapter is intended only to be representative of current cancer treatment and is not absolute or comprehensive. Furthermore, the indications listed for each specific drug are the primary, current Health Canada–approved indications. These, too, may change with time as a given drug is determined to be

more (or less) effective for treating certain types of cancer. Also, in clinical practice, patients are often treated with one or more antineoplastic medications for “off-label” uses; that is, the drug is not currently approved for those particular uses by Health Canada.

No antineoplastic drug is effective against all types of cancer. Most cancer drugs have a low therapeutic index, which means that there is a narrow margin between the therapeutic effect and toxicity. Clinical experience has shown that a combination of drugs is usually more effective than single-drug therapy. Because drug-resistant cells often develop in tumours as a result of the tumour's genetic instability, exposure to multiple drugs with multiple mechanisms and sites of action will destroy more subpopulations of cells. The delayed onset of resistance to a particular antineoplastic drug is one benefit of combination drug therapy. To be most effective, however, the drugs used in such a combination regimen would ideally possess the following characteristics:

- Some efficacy even as single drugs in the treatment of the particular type of cancer
- Different mechanisms of action so that the cytotoxic effect is maximized; this includes differences in cell cycle specificity
- No or minimal overlapping toxicities

One major drawback to the use of antineoplastic drugs is that the majority cause adverse effects. These toxicities generally stem from the fact that chemotherapy drugs affect rapidly dividing cells—both harmful cancer cells and healthy, normal human cells. Three types of rapidly dividing human cells are the cells of hair follicles, GI tract cells, and bone marrow cells. Because most of today's antineoplastic drugs cannot differentiate between cancer cells and healthy cells, healthy cells are also destroyed, so hair loss, nausea and vomiting, and bone marrow toxicity are their undesirable consequences. Effects on the GI tract and bone marrow are often **dose-limiting adverse effects**; that is, the patient can no longer tolerate an increase in dosage that may be necessary to adequately treat the cancer and achieve good disease response.

Hair follicle cells are rapidly dividing cells. Cancer drugs that affect these cells often cause the adverse effect of **alopecia**, or hair loss. Many patients, particularly women, choose to wear wigs, hats, or scarves to disguise this adverse effect. Some antineoplastic drugs are harmful to the epithelial cells of the stomach and intestinal tract, which often leads to diarrhea and mucositis, and may also increase the risk of nausea and vomiting. The likelihood that a given drug will produce vomiting is known as its **emetic potential**. Anticancer drugs cause nausea and vomiting by stimulating the cells in the chemoreceptor trigger zone. Several antiemetic drugs are used to prevent these symptoms and are described in **Chapter 41**. **Box 52.1** lists the relative emetic potential of selected chemotherapy drugs.

Myelosuppression, also known as **bone marrow suppression** or **bone marrow depression**, is another unwanted adverse effect of certain antineoplastics. It commonly results from drug- or radiation-induced destruction of certain rapidly dividing cells in the bone marrow, primarily the cellular precursors of WBCs, red blood cells (RBCs), and platelets. Myelosuppression can also occur secondary to the disease processes of the cancer itself. It,

BOX 52.1 Relative Emetic Potential of Selected Antineoplastic Drugs**Low (Less Than 10 to 30%)**

ifosfamide (more than 1 500 mg/m²)
lomustine
methotrexate (more than 1 000 mg/m²)
mitoxantrone hydrochloride (more than 15 mg/m²)
oxaliplatin
procarbazine hydrochloride
streptozocin

in turn, leads to leukopenia, anemia, and thrombocytopenia. Cancer patients are often at great risk for infection because of leukopenia (reduced WBC count) secondary to chemotherapy. Patients often need antibiotics intravenously, either to prevent or treat bacterial infections. Such patients are referred to as being *neutropenic*. Drug-induced anemia (reduced RBC count) often leads to hypoxia and fatigue, whereas thrombocytopenia (reduced platelet count) makes patients more susceptible to bleeding.

The lowest level of WBCs in the blood following chemotherapy (or radiation) treatment is called the **nadir**. The time until the nadir is reached in a patient may become shorter and the recovery time for the bone marrow may become longer with multiple courses of antineoplastic treatment. The nadir normally occurs approximately 10 to 28 days after dosing, depending on the particular cancer drug or combination of drugs used to treat the patient. Anticipation of the nadir based on known cancer drug data can be used to guide the use of blood stimulants known as *hematopoietic growth factors* (see [Chapter 54](#)).

Common indications for various antineoplastic drug classes are listed in the Dosages table. Also provided in various locations in this chapter and in [Chapter 53](#) (Table 53.2 and Box 53.1) are drug-specific guidelines for the treatment of

extravasation—unintended leakage of a chemotherapy drug (with vesicant potential) into the surrounding tissues outside of the intravenous line.

Because of the often severe toxicity of cancer medications, a current major focus of cancer drug research is the development of targeted drug therapy. Targeted drug therapy utilizes drugs that recognize a specific molecule involved in the growth of cancer cells while sparing healthy cells. Examples of targeted drugs include the following: imatinib (tyrosine kinase inhibitor), vorinostat (histone deacetylase inhibitors), temsirolimus (mTOR pathway inhibitors), erlotinib (EGFR inhibitors), sunitinib, sorafenib (multikinase inhibitors), bortezomib (proteasome inhibitors), crizotinib, and vismodegib. One example of biologic therapy is the class of cancer drugs known as *monoclonal antibodies* (see [Chapter 54](#)).

Pharmacokinetic data for antineoplastic medications is seldom used to guide dosing. Assay complexity coupled with a poor correlation between blood concentration and toxicity and efficacy limits its value. Only a handful of anticancer drugs benefit from therapeutic drug monitoring. For these reasons, pharmacokinetic data are not included with the drug profiles in this chapter. In spite of their notorious toxicity, given the often fatal outcome of neoplastic diseases, most cancer drugs are only

rarely considered absolutely contraindicated. Even if a patient has a known allergic reaction to a given antineoplastic medication, the urgency of treating the patient's cancer still necessitates administering the medication and treating any allergic symptoms with premedications such as antihistamines, corticosteroids, and acetaminophen. For these reasons, no specific contraindications are listed for any of the drugs in this chapter.

Common relative contraindications for cancer drugs include weakened status of the patient as manifested by indicators such as extremely low WBC count, ongoing infectious process, severe compromise in nutritional and hydration status, reduced kidney or liver function, or a decline in function in any system that may be further affected by the toxic effects of the drug being administered. These are situations in which chemotherapy treatment is commonly delayed until the patient's status improves. In general, most chemotherapy is held when the patient's absolute neutrophil count (ANC) is less than 0.05×10^9 (severe neutropenia; see [Chapter 53](#)). Alternatively, dosages are often reduced for frail older adults or others with significantly compromised organ system function, depending on the drugs used.

Reduction in fertility is often a major concern in postpubertal patients. Cancer also complicates 1 in 1 000 pregnancies. All chemotherapy drugs are not recommended during pregnancy because of positive evidence of fetal risk. The choice to use chemotherapy in a pregnant woman is based on risk versus benefit. Both radiation and chemotherapy treatments can cause significant permanent fetal harm or death. The greatest risk is during the first trimester. Chemotherapy treatment during the second or third trimester is more likely to improve maternal outcome without significant fetal risk. However, radiation treatment poses great risk to the fetus throughout pregnancy and is reserved for the postpartum period if possible. Patients who are prepubertal are more resilient, however, and can have normal puberty and fertility following chemotherapy.

In older adults, *frailty* refers to loss of most of the patient's functional reserve and limited ability to tolerate even minimal physiological stress (e.g., chemotherapy treatment). More robust older adult patients are better candidates for cancer treatment, although frail patients often benefit as well, especially in terms of palliative (noncurative) symptom control.

CELL CYCLE–SPECIFIC ANTINEOPLASTIC DRUGS

Cell cycle–specific drug classes include antimetabolites, mitotic inhibitors, topoisomerase I inhibitors, and antineoplastic enzymes. These drugs are collectively used to treat a variety of solid and circulating tumours, although some drugs have much more specific indications than others.

Antimetabolites

A compound that is structurally similar to a normal cellular metabolite is known as an **analogue** of that metabolite. Analogues may have agonist or antagonist activity relative to corresponding cellular compounds. An antagonist analogue is also known as an *antimetabolite*.

Mechanism of Action and Drug Effects

Antineoplastic antimetabolites are cell cycle–specific analogues that work by antagonizing the actions of key cellular metabolites. More specifically, antimetabolites inhibit cellular growth by interfering with the synthesis or actions of several compounds crucial to cellular reproduction: the vitamin folic acid, purines, and pyrimidines. Purines and pyrimidines make up the bases contained in nucleic acid molecules (DNA and RNA). Antimetabolites work via two mechanisms: (1) by falsely substituting for purines, pyrimidines, or folic acid and (2) by inhibiting critical enzymes involved in the synthesis or function of these compounds. Thus, they ultimately inhibit the synthesis of DNA, RNA, and proteins, all of which are necessary for cell survival. Antimetabolites work primarily in the S phase of the cell cycle, during which DNA synthesis is most active. The available antimetabolites and the metabolites they antagonize are as follows:

Folate Antagonists

- methotrexate
- pemetrexed disodium
- raltitrexed disodium

Purine Antagonists

- cladribine
- fludarabine phosphate (F-AMP)
- mercaptopurine (6-MP)
- thioguanine (6-TG)

Pyrimidine Antagonists

- capecitabine
- cytarabine (ara-C)
- fluorouracil (5-FU)
- gemcitabine

Folic Acid Antagonism. The antimetabolite methotrexate is an analogue of folic acid. It inhibits dihydrofolate reductase, an enzyme responsible for converting folic acid to its active form, folate, which is needed for the synthesis of DNA. The result is that DNA is not produced and the cell dies. The drug also inhibits thymidine synthase and glycinamide ribonucleotide formyltransferase that may assist to reduce the risk of drug resistance. In practice, the terms *folic acid* and *folate* are often used interchangeably. Pemetrexed disodium is a newer folate antagonist with a mechanism of action similar to that of methotrexate. Pralatrexate (Foloty®) is the newest dihydrofolate reductase inhibitor, specifically indicated for T cell lymphoma. It is available in Canada through Health Canada's Special Access Programme.

Purine Antagonism. The purine bases present in DNA and RNA are adenine and guanine (see the discussion in [Chapter 53](#)). They are required for the synthesis of the purine nucleotides that are incorporated into nucleic acid molecules. Fludarabine phosphate is a synthetic analogue of adenine, while mercaptopurine and thioguanine are synthetic analogues of guanine. Cladribine is a more general purine antagonist. Cladribine is unique in that it actually lacks cell cycle specificity, unlike other drugs in its class. It is included in this section because of its similar pharmacology and mechanism of action. All of these drugs work by ultimately interrupting the synthesis of both DNA and RNA.

Although allopurinol is chemically similar to purines, it does not disrupt DNA synthesis. Instead, it inhibits xanthine

TABLE 52.6 Common Manifestations of Antineoplastic Toxicity

Type of Toxicity	Common Manifestations
Neurological	Fatigue, weakness, depression, agitation, euphoria, insomnia, sedation, headache, reduced libido, confusion, amnesia, hallucinations (visual and auditory), dizziness, loss of taste or altered taste sensations, dysarthria (difficult articulation of speech), polyneuropathy (numbness in extremities), neuritis, paresthesia (abnormal touch sensations), facial paralysis, migraine, tremor, hemiplegia, loss of consciousness, seizures, ataxia, encephalopathy
Cardiovascular	Hot flushes, edema, thrombophlebitis and bleeding (e.g., near infusion site), chest pain, tachycardia, bradycardia, other dysrhythmias, angina, venous or arterial thrombosis, transient ischemic attacks, heart failure, myocardial ischemia, pericarditis, pericardial effusion, pulmonary embolism, aneurysm, cardiomyopathy, myocardial infarction, stroke, cardiac arrest, sudden cardiac death
Pulmonary–respiratory	Cough, rhinorrhea (runny nose), sore throat, sinusitis, bronchitis, pharyngitis, laryngitis, epistaxis (nosebleed), abnormal breath sounds, asthma, bronchospasm, atelectasis, pleural effusion, hemoptysis, hypoxia, respiratory distress, pneumothorax, diffuse interstitial pneumonitis, fibrosis, anaphylaxis, generalized allergic reactions
Hepatobiliary	Increased bilirubin and liver enzyme levels, jaundice, cholestasis, acalculic cholecystitis (inflamed gallbladder without stones), hepatitis, sclerosis, fibrosis, fatty liver changes, veno-occlusive liver disease, cirrhosis, hepatic coma
Gastrointestinal	Dyspepsia (heartburn), hiccups, gingivitis (inflamed gums), glossitis (inflamed tongue), abdominal pain, nausea, vomiting, diarrhea, constipation, gastroenteritis, stomatitis (painful mouth sores), oral candidiasis (thrush), ulcers, proctalgia (rectal pain), hematemesis, gastrointestinal hemorrhage, melena (blood in the stool), toxic intestinal dilation, ileus (bowel paralysis), ascites, necrotizing enterocolitis
Genitourinary	Oliguria, nocturia, dysuria, proteinuria, crystalluria, hematuria, urinary retention, abnormal kidney function test results, hemorrhagic cystitis, kidney failure
Dermatological	Rash, erythema, pruritus, ecchymosis, dryness, edema, photosensitivity, sweating, discoloration (pigmentation changes), freckling, petechiae, purpura, numbness, tingling, hypersensitivity, fissuring, scaling, seborrhea, acne, eczema, psoriasis, skin hypertrophy, subcutaneous nodules, alopecia, nail disorders including onycholysis (loss of nails), dermatitis, cellulitis, excoriation, maceration, ulceration, urticaria, abscesses, benign skin neoplasm, hemorrhage (at injection site), palmar–plantar dysesthesia–paresthesia, toxic epidermal necrolysis, Stevens-Johnson syndrome
Ocular	Eye irritation, increased lacrimation, nystagmus, photophobia, visual changes, conjunctivitis, keratitis, dacryostenosis (narrowing of lacrimal duct)
Otic	Hearing loss
Metabolic	Weight loss or gain, anorexia, dehydration, hypokalemia, hypocalcemia, hypomagnesemia, hypertriglyceridemia, hyperglycemia, syndrome of inappropriate secretion of antidiuretic hormone, hypoadrenalism, protein-losing enteropathy, hyperuricemia, tumour lysis syndrome
Musculoskeletal	Back pain, limb pain, bone pain, myalgia, joint stiffness, arthralgia, muscle weakness, fibromyositis

oxidase, which reduces serum and urinary levels of uric acid. Rasburicase is an enzyme that degrades uric acid to more soluble end products. Uric acid is a common waste product that often accumulates in the blood following lysis of tumour cells, part of a condition known as **tumour lysis syndrome** (see Adverse Effects).

Pyrimidine Antagonism. The pyrimidine bases, cytosine and thymine, occur in the structure of DNA molecules. Cytosine and uracil are part of the structure of RNA molecules. These bases are essential for DNA and RNA synthesis. Fluorouracil is a synthetic analogue of uracil, and cytarabine is a synthetic analogue of cytosine. Capecitabine is actually a prodrug of fluorouracil and is converted to that drug in the liver and other body tissues. Because of its prodrug form, it can be given orally. Gemcitabine inhibits the action of two essential enzymes, DNA polymerase and ribonucleotide reductase. Overall, these drugs act in a way that is similar to that of the purine antagonists, incorporating themselves into the metabolic pathway for the synthesis of DNA and RNA, thereby interrupting synthesis of both of these nucleic acids.

Indications

Antimetabolite antineoplastic drugs are used for the treatment of a variety of solid tumours and some hematological cancers. They may also be used in combination chemotherapy regimens

to enhance the overall cytotoxic effect. Methotrexate is also used to treat severe cases of psoriasis (a skin condition) as well as rheumatoid arthritis (see [Chapter 54](#)). Because some of these drugs are available in both oral and topical preparations, they are sometimes used for low-dose maintenance and palliative cancer therapy.

Allopurinol and rasburicase are both indicated for the hyperuricemia associated with tumour lysis syndrome and are usually given in anticipation of this condition during chemotherapy regimens associated with the syndrome. Allopurinol is also used commonly in oral form to treat gout (see [Chapter 49](#)). The commonly used drugs and their common specific therapeutic uses are listed in the Dosages table on p. 845.

Adverse Effects

As with most antineoplastic drugs, antimetabolites can cause hair loss, nausea, vomiting, diarrhea, and myelosuppression. The relative emetic potentials for some of these drugs are listed in [Box 52.1](#). In addition, these drugs can cause other major types of toxicity, including neurological, cardiovascular, pulmonary, hepatobiliary, GI, genitourinary (GU), dermatological, ocular, otic, and metabolic toxicity. Common manifestations of these toxicities are listed in [Table 52.6](#), approximately in order of increasing severity. Note that a single drug may not

TABLE 52.7 Selected Antimetabolites: Common Drug Interactions

Antimetabolite	Interacting Drug	Observed and Reported Effects*
capecitabine	warfarin sodium	Altered coagulation test results with potential for fatal bleeding
	phenytoin	Reduced phenytoin clearance and toxicity
	leucovorin calcium	Potential of capecitabine with possible toxicity
cladribine	None listed	None listed
cytarabine	Digoxin	Reduced absorption likely due to cytarabine-induced damage to intestinal mucosa; elixir form may be better absorbed
	Aminoglycoside antibiotics	Reduced antibiotic efficacy against <i>Klebsiella pneumoniae</i> infections
fludarabine phosphate	Cytarabine	Increased antitumor activity of cytarabine
fluorouracil	warfarin sodium	Enhanced anticoagulant effects
	leucovorin calcium	Same as for capecitabine
	cimetidine	Increases toxicity of fluorouracil
gemcitabine	None listed	None listed
mercaptopurine (6-MP)	allopurinol	Inhibition of 6-MP metabolism by inhibition of xanthine oxidase enzyme, with possible enhanced 6-MP toxicity; reduce the dose one third to one fourth
	warfarin sodium	6-MP reported to both enhance and inhibit effects of warfarin
	Hepatotoxic drugs	Increased risk of liver toxicity
methotrexate (MTX)	Protein-bound drugs and weak organic acids (e.g., salicylates, sulfonamides, sulfonylureas, phenytoin)	Possible displacement of MTX from protein-binding sites, enhancing its toxicity
	Penicillins, nonsteroidal anti-inflammatory drugs	Possible reduced renal elimination of MTX with potentially fatal hematological and gastrointestinal toxicity
	Live virus vaccines	Viral infection (true for any immunosuppressive drug)
	folic acid	Reduced MTX efficacy (theoretical only)
	theophylline	Reduced theophylline clearance
	Hepatotoxic drugs	Increased risk of liver toxicity
thioguanine	busulfan	Reports of hepatotoxicity, esophageal varices, and portal hypertension
	Other cytotoxic drugs in general	Reports of hepatotoxicity

*Not all mechanisms for these drug interactions have been clearly identified. The information in this table is based on reported clinical observations, with mention of known or theorized mechanisms when available.

cause all of the specific symptoms that are listed for each toxicity category, and actual symptoms may vary widely in severity among patients. The most common general symptoms are fever and malaise. Metabolic toxicity also includes tumour lysis syndrome, a common postchemotherapy condition. This syndrome is often associated with induction (initial) chemotherapy for rapidly growing hematological malignancies. It may include hyperphosphatemia, hyperkalemia, and hypocalcemia. These electrolyte abnormalities are often treated with diuretics such as mannitol, IV calcium supplementation, oral or rectal potassium exchange resin, and oral aluminum hydroxide. Hyperuricemia can lead to nephropathy, and hemodialysis may be required in severe cases of tumour lysis syndrome.

A severe, but usually reversible, form of dermatological toxicity is known as *palmar-plantar dysesthesia* or paresthesia (also called *hand-foot syndrome*). It can range from mild symptoms such as painless swelling and erythema to painful blistering of the patient's palms and soles. Other severe, but fortunately

uncommon, dermatological syndromes that can similarly affect the skin in more generalized regions include Stevens-Johnson syndrome and toxic epidermal necrolysis.

Interactions

As is true for cancer drugs in general, the administration of one antimetabolite drug with another that causes similar toxicities may result in additive toxicities. Therefore, the respective risks and benefits must be weighed carefully before therapy is initiated with either another antimetabolite or any other drug possessing a similar toxicity profile. Table 52.7 lists some known common examples of drugs that cause interactions with antimetabolites.

Dosages

For dosage information on selected antimetabolite chemotherapeutic drugs, refer to the table on p. 845. It is important to note that dosages of antineoplastics are highly variable, based on type of cancer, prior therapy, and planned coadministration of other agents.

DRUG PROFILES

Folate Antagonists

methotrexate

Methotrexate is the prototypical antimetabolite antineoplastic of the folate antagonist group and is currently one of three antineoplastic folate antagonists used clinically. It has proved useful for the treatment of solid tumours such as those found in breast, head and neck, and lung cancers and for the management of acute lymphocytic leukemia and non-Hodgkin's lymphomas. Methotrexate also has immunosuppressive activity because it can inhibit lymphocyte multiplication. For this reason, it may be useful for the treatment of rheumatoid arthritis (see [Chapter 54](#)). Its combined immunosuppressant and anti-inflammatory properties also make it useful for the treatment of psoriasis.

High-dose methotrexate is associated with severe bone marrow suppression and is always given in conjunction with the “rescue” drug leucovorin. Leucovorin is an antidote for folic acid antagonists. The body produces active folic acid via metabolic steps utilizing the enzyme dihydrofolate reductase. Because methotrexate inhibits this enzyme, healthy cells die due to lack of folic acid. Giving leucovorin (which is rapidly converted to the active form of folic acid) provides the body with active folic acid, which prevents the death of normal cells. Methotrexate is available in both injectable and oral (tablet) form. A preservative-free injectable formulation is required for [intrathecal](#) administration (into the subarachnoid space), used in the treatment of some cancers. One other folate antagonist is pemetrexed disodium, which acts similarly to methotrexate. However, it is used less commonly because its indication is limited to lung cancer.

raltitrexed disodium

Raltitrexed disodium (Tomudex®) is a quinazoline folate analogue that selectively inhibits a key enzyme (thymidylate synthase) required for the synthesis of DNA in cells, resulting in DNA fragmentation and cell death. It is actively transported into the cells via a reduced folate carrier and then extensively metabolized to polyglutamate forms without metabolic degradation. This particular property of raltitrexed facilitates a conventional dosing schedule of infusion every 3 weeks. Raltitrexed is cell cycle phase-specific for the S phase and is also a radiation-sensitizing agent. Raltitrexed is currently indicated for the treatment of advanced colorectal cancer.

Purine Antagonists

The currently available purine antagonists are cladribine, fludarabine, mercaptopurine, and thioguanine. Mercaptopurine and thioguanine are administered orally, whereas the other two are available only in injectable form. These drugs are used primarily in the treatment of leukemia and lymphoma.

cladribine

Cladribine is indicated specifically for the treatment of a specific type of leukemia known as *hairy-cell leukemia*, so named because of the appearance of its cancerous cells under the microscope.

fludarabine phosphate

Fludarabine phosphate (Fludara®), as with cladribine, also has a specific single indication, chronic lymphocytic leukemia. It is also commonly used in the treatment of follicular lymphoma and as part of salvage therapy in acute myelogenous leukemia.

Pyrimidine Antagonists

The currently available pyrimidine antagonists are capecitabine, cytarabine, fluorouracil, and gemcitabine. These drugs are used more commonly than the purine antagonists. They are available only in parenteral formulations, except for capecitabine, which is currently available only in tablet form. Dosage and other information appear in the table below.

capecitabine

Capecitabine (Xeloda®) is indicated primarily for the treatment of metastatic breast cancer and metastatic colorectal cancer.

cytarabine

Cytarabine (ara-C; Cytosar®) is used primarily for the treatment of leukemias (acute myelocytic, lymphocytic, and meningeal) and non-Hodgkin's lymphomas. It is available only in injectable form and may be administered intravenously, subcutaneously, or intrathecally. It is also now available in a special encapsulated liposomal form (Depocyt®), for intrathecal use only, in treating meningeal leukemia. Cytarabine has a unique set of adverse reactions, called “cytarabine syndrome.” Cytarabine syndrome is characterized by fever, muscle and bone pain, maculopapular rash, conjunctivitis, and malaise. It usually occurs 6 to 12 hours following cytarabine administration. The syndrome may be treated or prevented with the use of corticosteroids.

fluorouracil

Fluorouracil (5-FU) is used in a variety of treatment regimens, including the palliative treatment of cancers of the colon, rectum, stomach, breast, and pancreas. It also is used in the adjuvant setting in the treatment of breast and colorectal cancers.

gemcitabine hydrochloride

Gemcitabine hydrochloride (Gemzar®) is an antineoplastic drug structurally related to cytarabine. Gemcitabine is believed to have antitumour activity superior to that of cytarabine. It is used as first-line therapy for locally advanced or metastatic cancer of the pancreas, for non-small cell lung cancer, and for advanced bladder cancer. Gemcitabine is increasingly used to treat other solid tumours, including breast cancer.

Dosages

Selected Antimetabolites**

Drug	Pharmacological Class	Usual Dosage Range*	Indications
capecitabine (Xeloda)	Pyrimidine antagonist (analogue)	PO: 1 250 mg/m ² bid for 2 wk, followed by 1-wk rest period; this 3-wk cycle repeatable as ordered	Metastatic colorectal and breast cancer
Cladribine	Purine antagonist (analogue)	IV: 0.09 mg/kg/day by continuous infusion for 7 consecutive days	Hairy-cell leukemia
cytarabine (Cytosar)	Pyrimidine antagonist (analogue)	IV: 100 mg/m ² /day by continuous infusion for 7 days (other regimens as well)	Leukemias (several varieties), non-Hodgkin's lymphoma
fludarabine phosphate (Fludara)	Purine antagonist (analogue)	IV: 25 mg/m ² /day for 5 consecutive days; PO: 40 mg/m ² /day x 3 days; repeatable every 28 days	Acute and chronic leukemias, non-Hodgkin's lymphoma
fluorouracil (5-FU)	Pyrimidine antagonist (analogue)	IV: short infusion (variable): 300–480 mg/m ² ; continuous infusion: 1 000–2 000 mg/m ² over 24 hr, daily for 5 days; dosage varies afterward depending on patient response	Colon, rectal, breast, esophageal, head and neck, cervical, and kidney cancer
gemcitabine hydrochloride (Gemzar)	Pyrimidine antagonist (analogue)	IV: 1 000 mg/m ² once weekly or as protocol dictates; cycle may be repeated or modified according to patient tolerance	Pancreatic, non–small cell lung, and bladder cancer
methotrexate (Metoject®)	Folate antagonist (analogue)	IV: 30–40 mg/m ² /wk PO: 15–30 mg/day 5 days, repeated every 7 days, 3–5 courses	Acute lymphocytic† leukemia; gestational choriocarcinoma; breast, head and neck, and many other cancers

IV, Intravenous; PO, oral.

*All dosages are for adults, unless indicated otherwise.

†The term *lymphocytic* is synonymous in the literature with the term *lymphoblastic*.

**Doses may vary depending on indication.

Mitotic Inhibitors

Mitotic inhibitors include natural products obtained from the periwinkle plant and semisynthetic drugs obtained from the mandrake plant (also known as the “may apple”). These vinca alkaloids include vinblastine, vincristine, and vinorelbine. Two newer plant-derived drugs are the *taxanes*. These include paclitaxel, once derived from the bark of the slow-growing Western (Pacific) yew tree, and docetaxel, a semisynthetic taxoid produced from the needles of the European yew tree. The current process of isolating the starting material for paclitaxel from the needles has made the drug supply more abundant than previously. Docetaxel is pharmacologically similar to paclitaxel. The newest taxanes are cabazitaxel (Jevtana®), which is indicated for prostate cancer, and eribulin mesylate (Halaven®), which is indicated for breast cancer.

Mechanism of Action and Drug Effects

Depending on the particular drug, these plant-derived compounds can work in various phases of the cell cycle (late S phase, throughout G₂ phase, M phase), but they all work shortly before or during mitosis, and thus they slow cell division. Each different subclass inhibits mitosis in a unique way.

The vinca alkaloids (vincristine, vinblastine, and vinorelbine) bind to the protein tubulin during the metaphase of mitosis (M phase). This action prevents the assembly of key structures called *microtubules*. This action, in turn, results in the dissolution of other important structures known as *mitotic spindles*. Without these mitotic spindles, cells cannot reproduce properly. This condition results in inhibition of cell division and cell death.

The taxanes paclitaxel, docetaxel, and cabazitaxel act in the late G₂ phase and M phase of the cell cycle. They promote the

assembly of tubulin into stable microtubules, while simultaneously inhibiting their disassembly preventing anaphase.

Indications

Mitotic inhibitors are used to treat a variety of solid tumours and some hematological malignancies. They are often used in combination chemotherapy regimens to enhance the overall cytotoxic effect.

Adverse Effects

Like many of the antineoplastic drugs, mitotic inhibitor antineoplastic drugs can cause hair loss, nausea and vomiting, and myelosuppression (see Table 52.6). The emetic potential of some of the drugs is given in Box 52.1.

Toxicity: Management of Extravasation. Most of the mitotic inhibitor antineoplastics are administered intravenously, and extravasation of these drugs is potentially serious. Specific antidotes and additional measures to be taken for the treatment of extravasation of the mitotic inhibitors are given in Table 52.8.

Interactions

A variety of drug interactions are possible with most antineoplastic drugs, some more significant than others. A few basic principles apply to all antineoplastic drug classes. Any drug that reduces the clearance of an anticancer drug also increases the risk of toxicity, whereas a drug that increases the elimination of an anticancer drug reduces its efficacy. The use of multiple antineoplastic drugs can cause severe neutropenia and infection, due to additive bone marrow suppression. Monitor and treat patients accordingly for hematological toxicity and infections. Observed drug interactions specific for mitotic inhibitor drugs are summarized in Table 52.9.

TABLE 52.8 Mitotic Inhibitor and Etoposide Extravasation: Listed Specific Antidote

Drug	Antidote Preparation	Method
etoposide vinblastine vincristine	hyaluronidase (Wydase®) 150 units/mL: add 1 mL NaCl (150 units/mL; available via the Special Access Programme)	1. Inject 1 to 6 mL into the extravasated site with multiple subcutaneous injections. 2. Repeat subcutaneous dosing over the next few hours. 3. Apply warm compresses.* No total dose established.

*Important: Administration of corticosteroids and topical cooling appear to worsen toxicity.

TABLE 52.9 Selected Mitotic Inhibitors and Etoposide: Common Drug Interactions

Drug	Interacting Drug	Observed and Reported Effects*
etoposide	warfarin sodium	Enhanced anticoagulation
	cyclosporin	Reduced etoposide clearance
docetaxel	CYP3A4 inhibitors (e.g., azole antifungals, ciprofloxacin, clarithromycin, imatinib, verapamil, many others)	Enhanced docetaxel effect (possible toxicity)
	CYP3A4 inducers (e.g., carbamazepine, rifampin, phenytoin)	Reduced docetaxel effect
paclitaxel	doxorubicin hydrochloride	Increased cardiotoxicity
	CYP3A4 inhibitors and inducers	Same as for docetaxel
Vincristine	phenytoin	Reduced phenytoin concentrations with consequent enhanced seizure risk
	asparaginase	Reduced vincristine clearance and increased neurotoxicity (give vincristine 12–24 hours before asparaginase)
	mitomycin	Increased risk of pulmonary toxicity
	CYP3A4 inhibitors and inducers	Same as for docetaxel

CYP3A4, Cytochrome P450 subtype 3A4.

*Not all mechanisms for these drug interactions have been clearly identified. The information in this table is based on reported clinical observations, with mention of known or theorized mechanisms when available.

Alkaloid Topoisomerase II Inhibitors

Etoposide and teniposide are derivatives of epipodophyllotoxin. They exert their cytotoxic effects by inhibiting the enzyme topoisomerase II, which causes breaks in DNA strands. These drugs work during the late S phase and the G₂ phase of the cell cycle.

Dosages

For dosage information on selected mitotic inhibitors and topoisomerase II inhibitors, refer to the table on p. 847.

DRUG PROFILES

Selected Mitotic Inhibitors and Etoposide

etoposide

Etoposide (VePesid®) is a topoisomerase II inhibitor. Its structure, mechanism of action, and adverse effect profile are similar to those of teniposide. It is believed to kill cancer cells in the late S phase and the G₂ phase of the cell cycle. Etoposide is indicated for the treatment of non-small cell and small cell lung cancer, histiocytic lymphoma, and testicular cancer. It is available in oral and injectable forms. The oral form is poorly absorbed and has fallen out of favour because it produces significant toxicities without therapeutic benefit. The intravenous (IV) drug is formulated in a hydroalcoholic diluent, which can cause toxicity (hypotension) if administered in too high a concentration.

paclitaxel

Paclitaxel (Abraxane®) is a natural mitotic inhibitor originally isolated from the bark of the Pacific yew tree. The European

yew tree is the source of another mitotic inhibitor, docetaxel (Taxotere). Paclitaxel is currently approved for the treatment of breast cancer, non-small cell lung cancer, and Kaposi's sarcoma, among other cancers. Paclitaxel is extremely water insoluble (hydrophobic), and for this reason it is put into a solution containing oil rather than water. The particular oil is a type of castor oil called Kolliphor® EL (formerly known as Cremophor), the same oil with which cyclosporin is formulated. Many patients tolerate it poorly and show hypersensitivity associated with infusion. For this reason, before patients receive paclitaxel, they are premedicated with a steroid (dexamethasone), H₁ receptor antagonist (diphenhydramine hydrochloride), and H₂ receptor antagonist (ranitidine hydrochloride). Paclitaxel is available only in injectable form. There is an albumin-bound form of the drug (Abraxane®) that is not associated with severe infusion reactions.

vincristine

Vincristine is an alkaloid isolated from the periwinkle plant and is indicated for the treatment of acute lymphocytic leukemia and other cancers. It is available only in a parenteral form. It is an M phase-specific drug that inhibits mitotic spindle formation. Vincristine is the most significantly neurotoxic of the cytotoxic drugs, but it continues to be used, in part because of its relative lack of bone marrow suppression. Special care must be taken not to inadvertently give vincristine via the intrathecal route. Several deaths have been reported due to this error. The World Health Organization (WHO) and the Institute for Safe Medication Practices suggest that vincristine be diluted in 25 mL of fluid and never dispensed via a syringe to prevent this lethal error from occurring. A special warning is

required for all vincristine products dispensed that states “For Intravenous Use Only—Fatal If Given by Other Routes.” (See the Preventing Medication Errors box.)

Topoisomerase I Inhibitors

Topoisomerase I inhibitors comprise a relatively new class of chemotherapy drugs. The two drugs currently available in this class are topotecan and irinotecan. Both are semisynthetic analogues of the compound camptothecin, which was originally isolated in the 1960s from *Camptotheca acuminata*, a Chinese shrub. For this reason, they are also referred to as *camptothecins*.

Mechanism of Action and Drug Effects

The camptothecins inhibit proper DNA function in the S phase by binding to the DNA–topoisomerase I complex. This complex normally allows DNA strands to be temporarily cleaved and then reattached, in a critical step known as *relegation*. The

binding of the camptothecin drugs to this complex slows this relegation process, which results in a DNA strand break.

Indications

The two currently available topoisomerase I inhibitors are used primarily to treat ovarian and colorectal cancer. Topotecan has been shown to be effective in cases of metastatic ovarian cancer that have failed to respond to platinum-containing regimens (e.g., cisplatin, carboplatin) and paclitaxel. Topotecan is also used to treat small cell lung cancer. Irinotecan is currently approved for the treatment of metastatic colorectal cancer, small cell lung cancer, and cervical cancer.

Adverse Effects

The main adverse effect of topotecan is bone marrow suppression. Topotecan is not to be given to patients with baseline neutrophil counts of less than $1.5 \times 10^9/L$. Other adverse effects are relatively minor compared with those of the other antineoplastic drug classes. These include mild to moderate nausea, vomiting, diarrhea, headache, rash, muscle weakness, and cough.

Irinotecan causes more severe adverse effects than topotecan. In addition to producing similar hematological adverse effects, it has been associated with severe diarrhea, known as *cholinergic diarrhea*. It is recommended that this condition be treated with atropine sulphate unless use of this drug is strongly contraindicated. Delayed diarrhea may occur 2 to 10 days after infusion of irinotecan. This diarrhea can be severe and even life-threatening due to dehydration and severe electrolyte imbalance. Delayed diarrhea should be treated aggressively with loperamide hydrochloride. There is a moderate risk of nausea and vomiting with irinotecan, which requires appropriate supportive care, such as IV rehydration and antiemetic drug therapy.

Interactions

Topotecan has a unique drug interaction involving the granulocyte colony–stimulating factor filgrastim (see Chapter 54). Filgrastim is commonly used to enhance neutrophil recovery

⚡ PREVENTING MEDICATION ERRORS

Vincristine: Right Route Is Essential

For several years, the Institute for Safe Medication Practices has recommended changes in procedures to ensure that vincristine and other vinca alkaloids are not given intrathecally (via the spinal route) or by any route other than parenterally. Administering these drugs through the spinal route is almost always fatal, causing a slow and excruciating death. Mistakes occur when the drug is drawn up in a syringe for IV administration and then is inadvertently given via the intrathecal route. These errors are preventable. The WHO has suggested that pharmacies prepare vincristine in a diluted volume, such as in a 50-mL minibag of normal saline, to deter practitioners from giving the drug intrathecally. Drugs given intrathecally are not normally dispensed in a minibag. Nurses, who may assist health care providers with intrathecal procedures, need to be aware of the potential fatal error that may occur if vincristine is given via the wrong route. The Institute for Safe Medication Practices (2019) has called upon the U.S. Food & Drug Administration to take the lead and change best practice standards requesting the removal of syringes for administration of vinca alkaloids.

Data from: Institute for Safe Medication Practices. (2019). *ISMP calls on FDA—No more syringes for vinca alkaloids!* Retrieved from <https://www.ismp.org/resources/ismc-calls-fda-no-more-syringes-vinca-alkaloids>.

Dosages

Selected Mitotic Inhibitors and Etoposide

Drug	Pharmacological Class	Usual Dosage Range*	Indications
Epipodophyllotoxin Derivative			
etoposide (Etoposide Injection®, VePesid®)	Topoisomerase II inhibitor	IV: 50–100 mg/m ² /day for 5 days PO: 100–200 mg/m ² /day for 5 days	Testicular, small cell and non–small cell lung cancer, histiocytic lymphoma
Taxane			
nab-paclitaxel (Abraxane®)	Mitotic inhibitor	IV (Abraxane): 260 mg/m ² q3wk (breast cancer); 125 mg/m ² day 1, 8, 15, 28 day cycle (pancreatic cancer)	Metastatic breast cancer, pancreatic cancer
Vinca Alkaloid			
vincristine	Inhibitor of tubulin polymerization	<i>Children</i> IV: 2 mg/m ² <i>Adults</i> IV: 1.4 mg/m ² ; fatal if given intrathecally	Acute leukemia, Hodgkin's lymphoma, rhabdomyosarcoma, breast cancer, small cell lung cancer, cervical cancer, malignant melanoma, colorectal cancer, non-Hodgkin's lymphoma, Wilms tumour

IV, Intravenous; PO, oral.

*Note: Dosages may vary widely among treatment protocols.

TABLE 52.10 Irinotecan: Common Drug Interactions

Interacting Drug	Observed and Reported Effects*
CYP2B6 inhibitors (e.g., paroxetine hydrochloride, sertraline hydrochloride)	Increased effects and toxicity of irinotecan
CYP3A4 inhibitors (e.g., azole antifungals, ciprofloxacin hydrochloride, clarithromycin, imatinib, isoniazid, verapamil hydrochloride)	Increased effects and toxicity of irinotecan; concurrent use not recommended
CYP2B6 inducers (e.g., carbamazepine, phenytoin, nevirapine)	Reduced effects of irinotecan
CYP3A4 inducers (e.g., aminoglutethimide, carbamazepine, nevirapine, phenytoin)	Reduced effects of irinotecan
St. John's wort	Reduced effects of irinotecan; stop St. John's wort 2 wk before initiating irinotecan therapy

CYP2B6, Cytochrome P450 liver enzyme subtype 2B6; CYP3A4, cytochrome P450 subtype 3A4.

*Note that not all mechanisms of these drug interactions have been clearly identified. The information in this table is based on reported clinical observations, with mention of known or theorized mechanisms when available.

Dosages

Selected Topoisomerase I Inhibitors

Drug	Pharmacological Class	Usual Dosage Range*	Indications
irinotecan hydrochloride (Camptosar)	Synthetic camptothecin	IV: 125 mg/m ² on various days depending on protocol	Metastatic colorectal cancer
topotecan hydrochloride (Hycamtin)	Semisynthetic camptothecin	IV: 1.5 mg/m ² once daily for 5 consecutive days on a repeatable 21-day course	Ovarian and small cell lung cancer

IV, Intravenous.

*Dosages listed are for adults.

after chemotherapy. When topotecan is given concurrently with filgrastim, myelosuppression has been shown to worsen. It is recommended that filgrastim be administered 24 hours after completion of a topotecan infusion. Laxatives and diuretics are not given with irinotecan because of their potential to worsen the dehydration resulting from the severe diarrhea that this drug can produce. Severe cardiovascular toxicity, including thrombosis; pulmonary embolism; stroke; and acute, fatal myocardial infarction (MI), has been reported when irinotecan is given with fluorouracil and leucovorin. The role of irinotecan in this toxicity syndrome is unclear, because fluorouracil is a well-recognized cause of myocardial ischemia, including MI and sudden death. Such drug combinations are given with careful monitoring. Several additional recognized drug interactions occur with irinotecan, and these are summarized in Table 52.10.

Dosages

For dosage information on selected topoisomerase I inhibitors, refer to the table on p. 848.

DRUG PROFILES

Selected Topoisomerase I Inhibitors

irinotecan hydrochloride

Irinotecan hydrochloride (Camptosar®) is often given with both fluorouracil and leucovorin. It is available only in injectable form.

topotecan hydrochloride

After initial therapy with other antineoplastics, cancer cells commonly become resistant to their effects. The use of topotecan

hydrochloride (Hycamtin®) to treat ovarian cancer and small cell lung cancer has been studied extensively. As noted earlier, it produces therapeutic responses even in cases in which powerful drugs such as cisplatin and paclitaxel have failed. Topotecan is available only in injectable form.

Antineoplastic Enzymes

Two antineoplastic enzymes are commercially available in Canada: pegaspargase and asparaginase. There are two asparaginase products: Kidrolase® and Erwinase®. Kidrolase is an *Escherichia coli*-based asparaginase. *Erwinia* asparaginase (Erwinase) is available for patients who have developed allergic reactions to Kidrolase. Pegaspargase and the two asparaginase drugs are synthesized from cultures of certain bacteria, using recombinant DNA technology.

Indications

The antineoplastic enzymes are approved exclusively for the treatment of acute lymphocytic leukemia.

Adverse Effects

Of particular note for the antineoplastic enzymes is a fairly unique adverse effect of impaired pancreatic function. This can lead to hyperglycemia and severe or fatal pancreatitis. Other types of adverse effects associated with these drugs involve the dermatological, liver, GU, neurological, musculoskeletal, GI, and cardiovascular systems.

Interactions

Commonly reported drug interactions involving antineoplastic enzymes are summarized in Table 52.11.

TABLE 52.11 Selected Antineoplastic Enzymes: Common Drug Interactions

Enzyme	Interacting Drug	Observed and Reported Effects*
asparaginase	cyclophosphamide, mercaptopurine, vincristine	Interference with efficacy or clearance of asparaginase
	mercaptopurine, methotrexate, prednisone	Enhanced liver toxicity of asparaginase
	methotrexate	Reduced antineoplastic effect when given concurrently, but possibly enhanced antineoplastic effect when given 9 to 10 days before or shortly after methotrexate
	prednisone	Hyperglycemia (give asparaginase after prednisone)
	vincristine	Neuropathy (give asparaginase after vincristine)
	aspirin, nonsteroidal anti-inflammatory drugs, dipyridamole, heparin sodium, warfarin sodium	Use with caution due to possible coagulation abnormalities

*Note that not all mechanisms for these drug interactions have been clearly identified. The information in this table is based on reported clinical observations, with mention of known or theorized mechanisms when available.

Dosages

Selected Antineoplastic Enzymes

Drug	Pharmacological Class	Usual Dosage Range*	Indications
asparaginase (Kidrolase)	<i>Escherichia coli</i> -derived L-asparagine amidohydrolase enzyme	IM/IV: 200–1 000 units/kg/day for 28 successive days; may continue for an additional 14 days if remission not induced	Acute lymphocytic leukemia
pegaspargase (Oncaspar)	Pegylated version of asparaginase	IV/IM: 2 500 units/m ² q14d	Acute lymphocytic leukemia (usually in patients who have developed an allergy to asparaginase)

IM, Intramuscular; IV, intravenous.

*All dosages listed are for adults.

Dosages

For dosage information on antineoplastic enzymes, refer to the table above.

DRUG PROFILES

asparaginase

Asparaginase (Kidrolase) is for the treatment of acute lymphocytic leukemia. Its mechanism of action is slightly different from that of traditional antineoplastics in that it is an enzyme that catalyzes the conversion of the amino acid asparagine to aspartic acid and ammonia. Leukemic cells are then unable to synthesize the asparagine required for synthesis of DNA and proteins needed for cell survival.

The only commercially available asparaginase products in Canada are Kidrolase and Erwinase. Kidrolase is derived from *E. coli* bacteria, and it is common for patients to develop allergic reactions to it. When this occurs, one alternative is to use the asparaginase synthesized from *Erwinia* bacteria, Erwinase. Another treatment alternative is pegaspargase, described in the following drug profile. All antineoplastic enzymes are available only in injectable form.

pegaspargase

Pegaspargase (Oncaspar®) has a mechanism of action, indications, and contraindications similar to those of asparaginase. It is essentially the same enzyme that has been formulated so as to reduce its allergenic potential. This process involves chemical

conjugation of the enzyme with units of a relatively inert compound known as monomethoxypolyethylene glycol. Because polyethylene glycol is abbreviated PEG, this process is known as *pegylation*. Pegylation is a process that is increasingly used in formulating various drugs that are described in other chapters (e.g., see [Chapter 54](#)). These drugs are recognized by the prefix *peg* in their generic names. Pegaspargase is usually prescribed for patients who have developed an allergy to asparaginase, which is a common occurrence, especially with repeated treatment.

NURSING PROCESS

ASSESSMENT

With antineoplastic therapy, perform the following components of a thorough physical assessment: nursing history; past and present medical history; family history; medication profile with a notation of allergies as well as a listing of all prescription drugs, over-the-counter (OTC) drugs, and natural health products; height, weight, and vital signs; and baseline hearing and vision testing (as ordered). Also assess bowel and bladder patterns, neurological status, heart sounds, heart rhythm, breath sounds, and lung function. Examine the skin and mucosa, paying attention to turgor, hydration, colour, and temperature. Note any signs and symptoms of fear and anxiety with attention to reports of insomnia, irritability, shakiness, restlessness, and palpitations. Include an assessment of cultural, emotional, spiritual, sexual, and financial influences, concerns, and issues.

BOX 52.2 Effects of Antineoplastic Drugs on Normal Cells and Related Adverse Effects

Antineoplastic drugs are designed to kill rapidly dividing *cancer* cells, but they also kill rapidly dividing *normal* cells. Such normal cells include cells of the oral and GI mucous membranes, hair follicles, reproductive germinal epithelium, and components of bone marrow (WBCs, RBCs, and platelets). The more common adverse effects of normal cell death are as follows:

- Killing of normal cells of the GI mucous membranes may result in adverse effects such as altered nutritional status, stomatitis with inflammation and ulceration of the mucosa throughout the GI tract, altered bowel function, poor appetite, nausea, vomiting (often intractable and requiring aggressive antiemetic treatment), and diarrhea.
- Killing of the normal cells of hair follicles leads to alopecia.
- Killing of normal cells in the bone marrow results in dangerously low (life-threatening) blood cell counts. Because of the drugs' impact on these normal cells, the nurse must carefully assess patients' WBC counts (leukocytes, neutrophils, and band neutrophils), RBC counts, hemoglobin level, hematocrit, and platelet counts (see the Lab Values box). In addition, monitoring of patients' absolute neutrophil count (ANC) is needed ($\text{ANC} = \% \text{ of neutrophils} + \% \text{ bands} \times \text{WBC}$). Monitoring ANC values allows nurses and other health care providers to identify the nadir, the lowest count, when the patient is most vulnerable. An ANC of $0.05 \times 10^9/\text{L}$ or lower indicates high risk for infection.
- Killing of germinal epithelial cells (also rapidly dividing) leads to sterility (irreversible) in males, damage to the ovaries with subsequent amenorrhea in females, and teratogenic effects with possible fetal death in pregnant women.

Assess the patient's ability to perform activities of daily living (ADLs) and the patient's mobility status and gait. Perform a pain assessment using objective methods such as a numeric rating scale (e.g., 0 to 10, where 0 = no pain and 10 = worst pain ever). Note the pattern of pain, focusing on location, quality, onset, duration, and precipitating or alleviating factors. Document any oral, pharyngeal, esophageal, or abdominal pain; painful swallowing; epigastric or gastric pain, especially after eating spicy or acidic foods; achiness in joints or lower extremities; numbness or tingling; and any burning or sharp pain. Question the patient about past experiences with pain and about any drug, nondrug, or alternative therapies used, as well as about any previous successes or failures in pain management. Take into account cultural considerations relating to a cancer diagnosis.

Assess contraindications, cautions, and drug interactions; document the findings prior to the use of antineoplastic drugs. Laboratory tests that are usually ordered prior to their use include levels of electrolytes and minerals, uric acid levels, complete blood count, platelet count, bleeding time, and cardiac enzyme levels, as well as tests of liver and kidney function (see the Lab Values box). Assays of tumour markers may also be ordered to establish baseline levels and determine the impact of the disease and subsequent therapeutic effectiveness. See [Box 52.2](#) for more information about the specific adverse effects associated with destruction of populations of normal cells due to chemotherapy. Specific areas of assessment related to some of the more common adverse effects of chemotherapy on normal, rapidly dividing cells include the following:

- For altered nutritional status and impaired oral mucosa: Assess signs and symptoms of altered nutrition with a focus

on weight loss, abnormal serum protein–albumin and blood urea nitrogen (BUN) levels (a negative nitrogen status due to low protein levels would be indicated by a decreasing BUN level), weakness, fatigue, lethargy, poor skin turgor, and pale conjunctiva. Assess oral mucosa for any signs and symptoms of stomatitis, such as pain or burning in the mouth, difficulty swallowing, taste changes, viscous saliva, dryness, cracking, and fissures with or without bleeding of the mucosa.

- For effects on the GI mucosa: Assess bowel sounds (hyperactive or hypoactive versus normoactive). Assess for signs and symptoms of diarrhea, such as frequent, loose stools (more than three stools per day), urgency, and abdominal cramping. Obtain information about the presence of blood in the stool as well as consistency, colour, odour, and amount. Assess for nausea and vomiting and determine whether symptoms are acute, delayed, or anticipatory; if vomiting occurs, determine the colour, amount, consistency, frequency, and odour, as well as whether blood is present. The severity of nausea and vomiting may be rated using a scale of 1 to 10 (where 10 indicates the worst symptoms) or using the terms *mild*, *moderate*, and *severe*.
- For alopecia: Assess the patient's views, concerns, and emotions about potential hair loss. Assess the patient's need to prepare for hair loss, either by leaving the hair as it is and allowing it to fall out on its own; having the hair cut short; or wearing a scarf, hat, bandanna, or hair wrap or purchasing a wig before the hair is actually lost. Purchasing a wig prior to chemotherapy will allow for a closer match to a patient's pre-chemotherapy hairstyle.
- For bone marrow suppression: Assess for signs and symptoms of anemia or decrease in RBCs, hemoglobin level, and hematocrit (e.g., pallor of the skin, oral mucous membranes, and conjunctiva; fatigue; lethargy; loss of interest in activities; shortness of breath; intolerance of activity; and inability to concentrate). Assess for signs and symptoms of leukopenia (decrease in WBCs [see [Chapter 53](#)] and an ANC below the normal range of $1.5 \times 10^9/\text{L}$, with severe neutropenia being less than $0.05 \times 10^9/\text{L}$), including fever; chills; tachycardia; abnormal breath sounds; productive cough with purulent, green- or rust-coloured sputum; change in the colour of urine; lethargy or fatigue; and acute confusion. (For more information, see Lab Values on p. 851). Assess for signs and symptoms of thrombocytopenia (decrease in thrombocytes [usually less than $100 \times 10^9/\text{L}$] and platelet clotting factors), including indications of unusual bleeding such as petechiae; purpura; ecchymosis; gingival (gum) bleeding; excessive or prolonged bleeding from puncture sites (e.g., intramuscular [IM] or IV sites or blood draw sites); unusual joint pain; blood in the stool, urine, or vomitus; and a decrease in blood pressure with elevated pulse rate (see the Lab Values box on p. 851 in this chapter as well as Chapters 27 and 28; see also [Box 52.2](#)). Always assess for the normal ranges of laboratory values.
- For possible sterility, teratogenesis, damage to ovaries with amenorrhea: In adult male patients, assess baseline reproductive history with attention to sexual functioning, fathering of children, and past and current reproductive or sexual

LAB VALUES RELATED TO DRUG THERAPY

Rationales for Assessment and Monitoring of Blood Cell Counts With Antineoplastics

Antineoplastic drugs kill both normal and abnormal cells that are rapidly dividing, and thus the bone marrow and its rapidly dividing cellular constituents are negatively impacted. Because of this characteristic of chemotherapeutic drugs, RBCs, WBCs, and platelets are suppressed, and therefore their levels require frequent monitoring. Presented here is information specifically on RBCs and subsequent hemoglobin (Hgb) and hematocrit (Hct) levels as well as platelet levels. [Chapter 46](#) contains more information on WBCs, with neutrophil counts and nadir levels.

Laboratory Test	Normal Ranges	Rationale for Assessment
RBC count	M: $4.5\text{--}6 \times 10^{12}/\text{L}$ F: $4.2\text{--}5.4 \times 10^{12}/\text{L}$	Bone marrow suppression from antineoplastics affects RBC values, leading to severe anemia. RBCs carry oxygen—attached to hemoglobin—from the lungs to the rest of the body. RBCs also help carry carbon dioxide back to the lungs for exhalation. Therefore, if RBC counts are low (e.g., with anemia), the body does not get the oxygen it needs, which leads to lack of energy, fatigue, intolerance of activity, shortness of breath, and hypoxemia. For patients with cancer who may already be experiencing the effects of bone marrow suppression from the disease and then from the treatment, this loss of oxygen saturation will be exacerbated, resulting in decreased ability to get up and about and perform activities of daily living.
Hct	M: 0.4–0.5% F: 0.38–0.47%	Hct measures the volume of RBCs in the blood, so if the RBC value is low, the Hct is also low. The impact of this low value is discussed above, under RBCs.
Hgb level	M: 135–180 g/L F: 120–160 g/L	Hgb is the major substance in RBCs. It carries oxygen and is responsible for the red colour of the blood cell. With low levels of Hgb, the consequence to the patient is the same as noted with RBCs.
Platelets	$150\text{--}400 \times 10^9/\text{L}$	Platelets are the smallest type of blood cell and play a large role in the process of blood clotting. When bleeding occurs, the platelets swell, clump, and form a plug that helps stop the bleeding. Therefore, if platelet levels are lower than $10 \times 10^9/\text{L}$, the patient is at high risk for uncontrolled bleeding or hemorrhage. Some guidelines may use a platelet count of $5 \times 10^9/\text{L}$ and above as the criterion. Seek out further information in policies and procedures, or contact the health care provider.

F, Female; M, male; RBCs, red blood cells; WBCs, white blood cells.

problems or concerns. In adult female patients, in addition to the relevant aspects already mentioned, inquire about fertility, menstrual and childbearing history, and age of onset of menses and menopause, if applicable.

Prior to the use of cell cycle–specific drugs, document all allergies, cautions, contraindications, and drug interactions. Most antimetabolite drugs do not produce severe emesis for most patients (i.e., it occurs in fewer than 10% of cases). Some of the pyrimidine analogues have emetic potential, so perform an assessment of baseline GI functioning. In addition, the folate antagonists are not as likely as other drugs to cause emesis but may be associated with GI abnormalities, such as ulcers and stomatitis. Because these drugs are generally administered parenterally, assessing peripheral access areas or central venous sites is crucial to preventing risk of damage to surrounding tissue, joints, and tendons. Assess IV sites every hour, as needed, or as per facility protocol, for redness, swelling, heat, and pain. One specific assessment consideration associated with use of the antimetabolite cytarabine is monitoring for the occurrence of cytarabine syndrome. This syndrome usually occurs within 6 to 12 hours after drug administration and is characterized by fever, muscle and joint pain, maculopapular rash, conjunctivitis, and malaise. Assessment and quick identification of this syndrome can lead to its prevention and appropriate treatment.

In patients receiving mitotic inhibitors (e.g., vinblastine, vincristine) and alkaloid topoisomerase II inhibitors (e.g., etoposide), perform baseline liver and kidney function studies as ordered. Serum uric acid levels are usually ordered because these levels rise with increased cell death from cancer or its treatment.

Other mitotic inhibitors, docetaxel and paclitaxel, are associated with severe neutropenia and a decrease in platelet counts (see the Lab Values box on p. 851 as well as [Chapter 54](#)); therefore, perform blood counts before, during, and after drug therapy. Constantly assess the patient for severe hypersensitivity reactions, characterized by dyspnea, severe hypotension, angioedema, and generalized urticaria (during treatments). A drop in blood cell counts may even occur before any clinical evidence is present. Note baseline neurological functioning as well as the presence of any peripheral neuropathies. Because these drugs have multiple incompatibilities and are irritants (irritating the IV site and vein) and vesicants (causing cell death with extravasation and necrosis with ulcerations), the nurse must be familiar with potential solution and drug interactions. It is appropriate to consult with the health care provider and pharmacist as well as refer to authoritative resources. Documentation must include initial and frequent follow-up assessments of the IV site.

Topoisomerase I inhibitors are associated with hematological adverse effects; thus, perform baseline WBC counts as ordered. Bone marrow suppression is predictable, noncumulative, reversible, and manageable; therefore, do not give drugs such as topotecan to patients with baseline neutrophil counts of less than $1.5 \times 10^9/\text{L}$. Irinotecan causes more severe adverse effects than topotecan, so assess related systems and note the findings. The potential for irinotecan-related cholinergic diarrhea requires continuous assessment of the GI tract. Diarrhea may appear 2 to 10 days after the irinotecan infusion, and further medical treatment may be required if severe forms of diarrhea occur; the diarrhea can be life-threatening. There is only moderate risk of nausea

and vomiting with irinotecan, which requires immediate and appropriate assessment and care. Drug interactions for which to assess include the concurrent administration of topotecan with filgrastim, which results in a worsening of myelosuppression. Do not give laxatives or diuretics with irinotecan due to the potential for severe diarrhea, fluid volume loss, and subsequent dehydration. When given with fluorouracil and leucovorin, severe cardiovascular toxicity (including thrombosis), pulmonary embolism, stroke, and acute fatal MI may occur. Perform a cautious and skillful assessment of related systems. See [Table 52.10](#) for more drug interactions.

With the use of natural enzyme drugs (e.g., asparaginase, pegasparase), assess pancreatic function because of the potential for severe or even fatal pancreatitis. Because of this risk of pancreatitis, assess the patient closely for moderate to severe abdominal pain (upper left quadrant), nausea, vomiting, and hyperglycemia. Serum alkaline phosphatase and WBC counts, if elevated, may indicate possible pancreatitis if also supported by clinical presentation. Additionally, assessment and documentation of dermatological, hepatic, GU, neurological, musculoskeletal, GI, and cardiovascular systems is important due to the impact of natural enzyme drugs on these systems.

Genetic considerations are an area of importance in the treatment of cancer with antineoplastics, as with all drug therapy. Assess individuals for the presence of the following characteristics before chemotherapy is initiated: (1) genetic markers for oral cancers, (2) genetic determinants of testosterone or estrogen metabolism, and (3) genetically linked enzyme system abnormalities such as those involving specific cytochrome P450 enzymes that metabolically convert nicotine to a carcinogenic substance. These genetic factors are extremely complex; nevertheless, be aware of the possible influence of genetic differences, and be forward thinking regarding the impact of drug research and genetics. See [Chapter 5](#) for more information on genetics as related to drug therapy and the nursing process.

◆ NURSING DIAGNOSES

- Potential risk of diarrhea as a result of the adverse effects of antineoplastic drugs
- Potential risk for acute pain as a result of the disease process and drug-induced joint pain, stomatitis, GI distress, and other discomforts associated with antineoplastic cell cycle-specific therapy
- Potential risk for infection as a result of drug-induced bone marrow suppression with possible leukopenia and neutropenia

◆ PLANNING

◆ Goals

- Patient will regain as near normal as possible bowel elimination patterns during antineoplastic therapy.
- Patient will achieve improved comfort levels with improved pain control and management of symptoms and adverse effects.
- Patient will remain free from infection.

◆ Expected Patient Outcomes

- Patient states measures to minimize diarrhea.
 - Patient states foods and beverages to avoid, such as hot, spicy foods and beverages; alcohol; foods high in fibre; gaseous foods such as cruciferous vegetables; and raw seafood.
 - Patient takes antidiarrheal medication, as instructed and if indicated, to avoid dehydration and electrolyte loss.
- Patient experiences improved pain relief through use of pharmacological and nonpharmacological measures to manage chemotherapy-related adverse effects, such as joint pain, stomatitis, and GI distress.
 - Patient requests medication(s) for comfort before pain is uncontrollable and severe.
 - Patient uses a numeric scale of 0 to 10 for identification of pain level, with 0 being no pain and 10 representing the worst pain ever experienced.
 - Patient uses nonpharmacological measures (e.g., relaxation, music therapy, pet therapy, biofeedback, massage, therapeutic touch, diversion) concurrently with drug therapy to increase comfort levels.
- Patient states measures to assist in supporting the immune system and preventing infection, such as frequent hand-washing; performance of deep breathing exercises; increased intake of fluids; consumption of a well-balanced diet; avoidance of malls and other crowded places; and avoidance of people with colds, flu, or communicable respiratory illnesses.
 - Patient states ways to minimize oral mucosal breakdown and infection, such as frequent mouth care and dental hygiene measures; using mild toothpaste, gentle sponge toothettes, and non-alcohol-based mouthwash, as well as frequent fluid intake.
 - Patient demonstrates the use of various measures to enhance skin integrity, such as keeping skin clean, dry, and lubricated.
- Patient adheres to daily regimen for increasing urinary health, such as increasing fluid intake and consuming fluids that minimize urinary infections (e.g., cranberry juice). (Note that the nursing diagnoses, goals, and expected patient outcomes presented here are appropriate to treatment with many antineoplastic drugs.)

◆ IMPLEMENTATION

Antineoplastic drugs are some of the most toxic medications given to patients because they cause the death of normal cells along with the death of cancer cells. The high potency of these drugs also places patients at higher risk for toxicity, serious complications, and adverse effects. The possibility of such adverse effects and toxicities require skillful nursing care based on cautious and thorough assessment and subsequent critical thinking. Consequently, chemotherapy administration requires specialized education. The Canadian Association of Nurses in Oncology had developed standards for the practice, education, and continuing competence of registered nurses. General considerations in nursing implementation applicable to most

antineoplastic drugs, as well as some specific aspects of implementation related to cell cycle-specific drugs, are discussed in the following paragraphs. Other nursing process information related to cell cycle-nonspecific drugs is presented in [Chapter 53](#).

For antineoplastic therapy in general, nursing considerations related to reducing fear and anxiety include establishing a therapeutic relationship, beginning with trust and empathy. Approach the patient in a warm, empathic, and supportive manner while projecting confidence in providing nursing care. Provide individualized explanations and teaching about the patient's illness, care, and treatments that are appropriate to the patient's educational level. Collaborate with all members of the health care team. Encourage patients to consider relaxation techniques such as listening to music, performing meditation, or engaging in guided imagery. To support the patient's emotional, mental, and physical health, it may be necessary to call on other sources of support, including social services, counselling services, financial assistance services, home support, and religious-spiritual support. Also necessary may be appropriate consults with other health care providers such as social workers, discharge planners, psychiatrists, mental health nurses, nurse practitioners, and oncology nurse specialists, as well as with support groups for the patient, family members, or significant others. A referral to palliative care may also be appropriate.

A variety of interventions that may be indicated for the management of stomatitis or excessive oral mucosa dryness and irritation include the following: (1) Instruct the patient to perform oral hygiene before and after eating or as needed to help provide cleanliness and comfort; also advise the patient to avoid lemon, glycerin, undiluted peroxide, or alcohol-containing products because they are drying and irritating to the oral mucosa. (2) Recommend that the patient use a soft-bristle toothbrush or soft-tipped toothette or swab with solutions of diluted, warm saline. (3) If dentures are used, encourage the patient to remove and clean them frequently and, if stomatitis is severe, to insert them only at mealtimes. (4) Advise the patient to use OTC saliva substitutes, keep the lips moist, and use sugarless candy or gum to stimulate saliva flow. (5) Stress to the patient that spicy, acidic, or hot foods; alcohol; and tobacco should be avoided because they are irritants. (6) Oral antifungal suspensions (e.g., nystatin) may be ordered if white patches are noted on the oral mucosa; the patient may use analgesic solutions (e.g., lidocaine swish and swallow), as ordered, to help manage discomfort.

Nausea and vomiting occur commonly with antineoplastic drugs. Emetic potential varies depending on the drug or treatment protocol (see earlier discussion and [Box 52.1](#)). Educate the patient on measures to enhance comfort during times of nausea and vomiting, including restricting oral intake as ordered; removing noxious odours or sights to avoid stimulating the vomiting centre; performing oral hygiene as needed; promoting relaxation through slow, deep breathing; consuming small, frequent meals and eating slowly; and consuming clear liquids and a bland diet. Use of IV fluids may be indicated for hydration purposes if nausea and vomiting

are severe. Antiemetics are also a vital part of antineoplastic therapy (see [Chapter 41](#) for a brief review of the pathophysiology of nausea and vomiting and more specific drug-related information). Premedication with antiemetics 30 to 60 minutes before administration of the antineoplastic(s) is the preferred treatment protocol to help reduce nausea and vomiting, prevent dehydration and malnutrition, and promote comfort. Combination antiemetic drug therapy may be more effective than single-drug therapy. An antiemetic may be given with the chemotherapeutic regimen as well as prescription medication for at-home use. Ginger ale and ginger-based teas may also be helpful.

Diarrhea is also a common adverse effect of antineoplastic therapy. Perform the following nursing interventions: (1) Advise patients to avoid or limit oral intake of irritating, spicy, and gas-producing foods; caffeine; high-fibre foods; alcohol; extremely hot or cold foods or beverages; and lactose-containing foods and beverages. (2) Consult appropriate personnel, as ordered, to help patients and family members plan meals and arrange ways to meet the patients' dietary and bowel elimination needs. (3) Administer opioids (e.g., paregoric), synthetic opioids (e.g., loperamide, diphenoxylate hydrochloride), or other antidiarrheals, as prescribed. Adsorbents-protectants and antisecretory drugs may also help reduce GI upset and diarrhea (see [Chapter 40](#)).

To address nutritional concerns, the following measures may prove beneficial in improving oral intake and nutritional status: (1) Perform a 24-hour recall of food intake, and report the typical week's diet for patients. (2) Use antiemetic therapy, pain management, mouth care, and hydration, as ordered, to reduce the adverse effects of therapy and improve appetite. (3) To ease taste alterations, advise patients to consume mild-tasting foods and to use chicken, turkey, cheese, Greek yogourt, nondairy yogourt or pudding, or tofu as protein sources, as tolerated. (4) Provide plastic rather than metal utensils if patients report a metallic taste. (5) Encourage patients to eat foods that are easy to swallow, such as custards; gelatins; puddings; milkshakes; eggnog; commercially prepared high-protein, high-calorie supplemental shakes; mashed white or sweet potatoes; blended drinks with crushed ice, fruit, and yogourt; nutritional supplement drinks and snacks; and lactose-free ice cream. (6) Instruct patients to avoid sticky or dry foods. (7) Encourage the consumption of small, frequent meals in environments that are conducive to eating (e.g., free of odours and excessive noise). (8) Appetite stimulants such as megestrol acetate or dronabinol may be used. (9) Encourage patients to practice energy conservation, including frequent rest periods before and after meals.

Alopecia is a common adverse effect of antineoplastics and is disturbing to patients regardless of age or gender. Warn patients and family members about the possibility of hair loss, and tell them when it will occur (usually 7 to 10 days after treatment begins, but this is dependent upon the specific drug used) and that it is reversible. Inform patients that new hair growth is often a different colour and texture from that of the hair lost. Provide information before the actual hair loss about the options of acquiring a wig or hairpiece, or wearing scarves or hats.

The Canadian Cancer Society may be a resource for items such as wigs, scarves, and hats.

Antineoplastic-induced bone marrow suppression leads to anemia, leukopenia, neutropenia, and thrombocytopenia (see previous discussion and Lab Values boxes in this chapter and [Chapter 53](#)). Anemia results in fatigue and loss of energy and is a common adverse effect of therapy and the disease process of cancer. Anemia may require blood transfusions, peripheral blood stem cell treatment, or treatment with prescribed medications such as iron preparations, folic acid, or erythropoietic growth factors (e.g., darbepoietin alfa). Injections of these substances may be given at home and may be administered at the first sign of a decrease in RBC levels. Conservation of energy and planning of care are very important in minimizing patient fatigue.

Risk of infection from leukopenia or neutropenia and immunosuppression is one of the more significant adverse effects of antineoplastic drugs and requires close attention. Inform the patient, family members, and caregivers that when WBC counts are low, the patient is at high risk for infection and that defences remain low until the counts recover. Following standard precautions/routine practices and using good hand-washing technique are essential in preventing transmission of infection in the hospital and home settings. Patients may also need to be placed on reverse isolation, especially if they have neutropenia. Because fever is a principal early sign of infection, take patients' oral or axillary temperature at least every 4 hours during periods in which they are at risk. Avoid taking the temperature rectally to minimize tissue trauma and breaks in skin integrity, and thus loss of the first line of defence and increased risk to infection. Encourage the patient to immediately report to the health care provider a temperature of 38.1°C or higher so that appropriate treatment may be initiated and complications avoided. Many facilities recommend taking special precautions during the care of a patient who is receiving chemotherapy (see [Chapter 53](#) for details). If needed, and as ordered, administration of colony-stimulating factors may be beneficial. Filgrastim, pegfilgrastim, and sargramostim are examples of drugs given to accelerate WBC recovery during antineoplastic drug therapy. Use these drugs, as ordered, to minimize neutropenia. These medications act on the bone marrow to enhance neutrophil production and help decrease the incidence, severity, and duration of neutropenia. These drugs must be administered within a certain time frame (see [Chapter 54](#)). Encourage patients with immune suppression to be aware of environments and people to avoid, such as individuals who have recently been vaccinated (who may have a subclinical infection) or who have a cold or flu or other symptoms of an infection. Maintaining a "low-microbe" diet by washing fresh fruits and vegetables and making sure foods are well cooked is also recommended. Educate patients on the importance of performing oral care frequently (see discussion of stomatitis) and to turn frequently, cough, and breathe deeply to help prevent stasis of respiratory secretions.

Thrombocytopenia is also an adverse effect of antineoplastic therapy and puts patients at risk for bleeding. Monitor platelet

counts, coagulation studies, RBC counts, hemoglobin levels, and hematocrit values, and report any decreases (see the Lab Values box). Avoid injections if possible, and utilize alternative routes of administration. If injections or venipunctures are absolutely necessary, always use the smallest gauge needle possible and apply gentle, prolonged pressure to the site afterward. Monitor closely patients who have undergone bone marrow aspiration after the procedure, for bleeding at the aspiration site. Perform blood pressure monitoring as needed. Be efficient and quick and do not overinflate the cuff to avoid bruising. Monitor patients for bleeding from the mouth, gums, and nose. Check for bleeding after tooth brushing and report excessive bleeding to the health care provider.

Inform patients that antineoplastics may have a negative impact on the reproductive tract, causing destruction of the germinal epithelium of the testes and damage to the ovaries and to a fetus (teratogenesis). Other problems may include sterility; amenorrhea; premature menopausal symptoms of hot flashes, decreased vaginal secretions, mood changes, or irritability; and decreased libido or sexual dysfunction. Counsel male patients about the risk for sterility, which may be irreversible. Discuss with male patients the option and topic of sperm banking before chemotherapy, if deemed appropriate. Stress that female patients of childbearing age who are sexually active need to protect themselves against pregnancy because of the risk of embryonic death. Encourage contraceptive measures during chemotherapy and for up to 8 weeks after discontinuation of therapy; however, some antineoplastic drugs require use of contraceptives for up to 2 years after completion of treatment because of the risk for genetic abnormalities.

With antimetabolites, always follow the practitioner's orders regarding premedication with antiemetics and antianxiety drugs. Follow orders or protocol for the use of other symptom-control medications, as prescribed. GI adverse effects are common with antimetabolites and usually occur on about the fourth day following their administration; these effects require preplanning for specific pharmacological interventions (e.g., antiemetics, antispasmodics, analgesics) and nonpharmacological measures (e.g., dietary changes, oral care). Antibiotic therapy may also be ordered prophylactically. See earlier discussion of nursing considerations associated with stomatitis, loss of appetite, diarrhea, nausea, vomiting, and anemia. For further discussion of the handling of antimetabolites and other IV antineoplastic drugs, see Box 53.2.

Use extreme caution in the handling and administration of cytarabine by the various routes (IV, subcutaneous, or intrathecal). Major concerns with cytarabine therapy include bone marrow suppression (see earlier discussion) and cytarabine syndrome (see the Assessment section). If high dosages are used, cytarabine may also cause central nervous system, GI, or pulmonary toxicity, so closely monitor these systems to ensure patient safety and comfort. For intrathecal administration, the drug may be reconstituted with sodium chloride, or the health care provider may use the patient's spinal fluid. Do not add fluorouracil to any other IV infusions; administer the drug by itself in the appropriate diluent. When an infusion port is not used, do not use IV sites over joints, tendons,

or small veins, or in extremities that are edematous. Give IV dosages exactly as ordered, and constantly monitor the IV site, infusion port, and infusion solution and equipment. If IV infiltration occurs, follow the protocol for management of infiltration and contact the health care provider. Follow all hospital or infusion protocols without exception because treatment of extravasation is handled differently depending on the specific drug. If extravasation of a vesicant occurs, the drug is usually discontinued immediately; leave the IV cannula in place (for possible use of antidotes through the cannula to access the affected area), and follow facility protocol. The use of antidotes and other drugs, as well as hot or cold packs, is usually outlined in the protocol for managing extravasation (see Box 53.1). If topical forms of cytarabine are used, inform patients that it is important to apply the drug exactly as ordered, to the affected area only. Use gloves or a finger cot to apply the topical dosage form.

Gemcitabine, another antimetabolite, is dosed based on absolute granulocyte counts and platelet nadirs and is given if the counts exceed $1.5 \times 10^9/L$ and $1 \times 10^9/L$, respectively. Keep IV solutions at room temperature to avoid crystallization and use within 24 hours. Give infusions as ordered. Antiemetics and antidiarrheals may be needed. Mercaptopurine is available in oral dosage forms; give it as ordered. Finally, the antimetabolite methotrexate has numerous toxicities and adverse effects that may be minimized by appropriate medical treatment. For example, there may be orders for boosting immune status and blood cell counts before aggressive therapy is initiated. Cytoprotective drugs are used. Continue to monitor creatinine clearance, as ordered, to detect any nephrotoxicity. Nutritional status may be enhanced by increasing the intake of foods high in folic acid, including bran, dried beans, nuts, fruits, asparagus, and other fresh vegetables, if tolerated. Consumption of these foods is yet another measure to help minimize the possibility of methotrexate toxicity. If GI upset or stomatitis occurs, the patient may need to decrease any sources of irritation (e.g., high-fibre food). Methotrexate is usually given orally or intravenously. Wear gloves when giving the drug. If any of the solution comes in contact with the skin, wash the area immediately and thoroughly with soap and water. (See Box 53.2 for discussion of concerns in the handling and administration of vesicant drugs.)

For the mitotic inhibitors, specifically the taxane family of drugs, and docetaxel in particular, premedication protocols are usually specified and include administration of oral corticosteroids (e.g., dexamethasone) beginning several days before day 1 of therapy, to help decrease the risk of hypersensitivity. Closely monitor patients for the sudden onset of bronchospasms, flushing of the face, and localized skin reactions; these may indicate a hypersensitivity response requiring immediate treatment. In such situations, contact the health care provider immediately. These symptoms may occur within just a few minutes of beginning the infusion. In addition, any dyspnea, abdominal distension, crackles in the lungs, or dependent edema during therapy require immediate attention. Cutaneous reactions may also appear during therapy, such as rash on the hands and feet; these

reactions also need immediate attention and treatment. With paclitaxel, the patient may also be premedicated with diphenhydramine hydrochloride, corticosteroids, and H_2 antagonist drugs. Take all measures to minimize tissue trauma (e.g., avoidance of IM injections and taking temperature rectally, if possible) to promote comfort and prevent bleeding and infection.

With the topoisomerase I inhibitors irinotecan and topotecan, monitor blood counts closely with every treatment. A drop in blood counts or severe diarrhea may cause a temporary postponement of therapy. Treat any extravasation of the solution immediately, and follow protocol. Ensuring that IV sites remain patent is crucial to the prevention of tissue damage secondary to extravasation of antineoplastic drugs that are considered irritants or vesicants. Nausea and vomiting may lead to dehydration and electrolyte disturbances. Advise patients and family members to report these symptoms immediately before adverse consequences occur (see previous discussion for specific interventions). IV incompatibilities are numerous for both of these drugs and are of constant concern. With topotecan, IV extravasation is usually accompanied by a mild local reaction such as erythema or bruising. If these symptoms are noted, they must be managed immediately to avoid further trauma and risk for loss of skin integrity (the first line of defence against infection). Headache and difficulty breathing may be more common with topotecan than with irinotecan; therefore, closely and frequently monitor patients for these symptoms. The enzyme antineoplastics asparaginase and pegaspargase should be handled with extreme caution and care. Patients may receive an intradermal test dose of asparaginase before therapy begins or when a week or longer has passed between doses. With asparaginase and pegaspargase, if the solution comes in contact with the skin, thoroughly wash or rinse the area with copious amounts of water for a minimum of 15 minutes. During therapy, if there are signs and symptoms of oliguria, anuria (renal failure), or pancreatitis, the drug will most likely be discontinued. The IM route of administration is usually preferred because it carries a lower risk of causing clotting abnormalities, GI disorders, and kidney and liver toxicity. If solutions are cloudy, do not use them. If more than 2 mL is ordered or required for intramuscular dosing, use two injections. Pancreatitis is problematic with the use of these drugs and can be serious. Pay close attention to symptoms such as severe abdominal pain with nausea and vomiting. Constantly monitor serum lipase and amylase levels. If any signs or symptoms of pancreatitis occur, the health care provider will usually discontinue the drugs immediately. Use of cytoprotective drugs has been briefly discussed (p. 855), with further discussion provided in [Chapter 53](#).

◆ EVALUATION

Focus evaluation of nursing care on reviewing whether goals and outcome criteria are being met, as well as on monitoring for therapeutic responses and adverse and toxic effects of antineoplastic therapy. Therapeutic responses may manifest as clinical improvement, decrease in tumour size, and

decrease in metastatic spread. Evaluation of nursing care, with reference to goals and outcome criteria, may reveal improvements related to a decrease in adverse effects and a decrease in the impact of the cancer on the patient's well-being. With therapeutic effectiveness, there will be increases in comfort, nutrition, hydration, energy levels, and ability to carry out ADLs, as well as improved quality of life. Revisit goals and outcome criteria to identify more specific areas to monitor. In addition, certain laboratory studies, such as tumour markers levels, levels of carcinoembryonic antigens, RBC and WBC counts, and platelet counts, may be performed to aid in determining how well the treatment protocol has worked and to monitor adverse effects of bone marrow suppression. Also, if ANC drops below 0.05×10^9 , the health care provider may discontinue chemotherapy but then reinstitute it when the level is above 1×10^9 , or as facility policy dictates. Other blood counts are considered, too. As part of the evaluation, health care providers may also order additional X-rays, computed tomographic scans, magnetic resonance images, tissue analysis, or other studies appropriate to the diagnosis, both during and after antineoplastic therapy, at time intervals related to the anticipated tumour response.

CASE STUDY

Facing Chemotherapy

Phuong, a 48-year-old bank teller and mother of two adolescent daughters, has been diagnosed with breast cancer. She has undergone lumpectomy to remove the tumour and is about to start adjuvant chemotherapy. She states that she has "faced the facts" about her disease and the threat to her life but says, "I know this is silly, but I hate the thought of losing my hair with the treatment."

1. What measures can be taken to help Phuong deal with her hair loss?

2. Ten days after her chemotherapy, Phuong's neutrophil count drops to $2 \times 10^9/L$. She has been hospitalized because she has developed a cough, and several of her friends have come in to visit and have brought a fresh fruit basket. What actions will be taken to protect her from infection?

3. During rounds, the nurse finds Phuong curled up in the bed and sobbing. Phuong says that she feels "so afraid" and is worried about who will care for her family if she dies. What actions will the nurse take at this time?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

PATIENT TEACHING TIPS

- Educate patients that GI adverse effects and irritation to the oral and GI mucosa may be decreased by avoiding intake of alcohol, tobacco, spicy and high-fibre foods, juices or foods containing citric acid, and foods that are very hot or cold or have a rough texture. Perishable foods that have been left out of refrigeration for more than 1 hour should not be consumed.
- Stress to patients that daily mouth care is important. Instruct them to report sores, pain, or white patches in the mouth to the health care provider immediately. Headache, fatigue, faintness, and shortness of breath (possibly indicative of anemia); bleeding and easy bruising (possibly indicative of a drop in platelet count); and sore throat and fever (possibly indicative of infection) also need to be reported immediately to the appropriate health care provider. Fever and chills may be the first signs of an oncoming infection.
- Discuss contraception, sperm banking, and other reproductive issues with postpubescent male patients and women of childbearing age.
- Emphasize to patients receiving antineoplastic drugs which OTC medications they should avoid (e.g., aspirin, ibuprofen, any combination products containing these drugs).
- Antineoplastics may cause alopecia. Before therapy, provide patients with the opportunity to discuss options for hair and scalp care. These options may include, but are not limited to, having the hair cut short before treatment; selecting, purchasing or renting a wig or hairpiece comparable to the patient's existing hair in colour, texture, length, and style; or having bandanas, scarves, or hats on hand before the hair is actually

lost. Although hair loss is temporary, inform patients that it will occur and that hair will appear different upon growing back. The Canadian Cancer Society may be a resource for wigs and hairpieces.

- The following websites are helpful online resources for patients and their family members and significant others: <http://www.cancer.ca/>, <http://www.hc-sc.gc.ca/hc-ps/dc-ma/cancer-eng.php>, <http://www.wellspring.ca>, <http://www.bccancer.bc.ca>, and <http://www.oncolink.org/>.
- With the use of cytarabine, encourage patients to increase fluid intake to help decrease the risk of dehydration and hyperuricemia.
- With the use of fluorouracil and gemcitabine, encourage patients to engage in frequent oral hygiene and to report to the health care provider immediately any bleeding, bruising, chest pain, diarrhea, nausea, vomiting, heart palpitations, infection, or changes in vision. Instruct patients to protect themselves from the sun while taking fluorouracil, including avoiding overexposure to sun or ultraviolet light and using protective clothing, sunscreen, and sunglasses.
- With the use of mercaptopurine, educate patients that alcohol must be avoided to help minimize drug toxicity.
- With the use of methotrexate, instruct patients to notify the health care provider if nausea and vomiting are problematic or uncontrollable, or if fever, sore throat, muscle aches and pains, or unusual bleeding occurs. Advise patients to avoid alcohol, salicylates, nonsteroidal anti-inflammatory drugs, and exposure to sunlight or ultraviolet light. Instruct both male and female patients to use

contraceptive measures for up to 3 months or longer following drug therapy, if appropriate.

- With the use of taxanes, counsel patients to contact the health care provider immediately if any signs or symptoms of neuropathy (e.g., numbness or tingling of extremities) appear.
- If WBC counts are low during therapy with etoposide or teniposide, caution patients to avoid individuals who are ill.

Additionally, advise them to report to the health care provider immediately any easy bleeding or bruising, difficulty breathing, fever, sore throat, or chills.

- With the use of the enzymes pegaspargase and asparaginase, encourage the patient to drink extra fluids and to report any severe nausea or vomiting, bleeding, excessive fatigue, fever, or other signs or symptoms of infection.

KEY POINTS

- Cancers are diseases that are characterized by uncontrolled cellular growth.
- *Malignancy* refers specifically to a neoplasm that is anaplastic, invasive, and metastatic, as opposed to benign.
- Tumours are generally classified by tissue of origin as follows: epithelial (carcinoma), connective (sarcoma), lymphatic (lymphoma), and leukocytic (leukemia).
- Antineoplastics are drugs used to treat malignancies. They may be either cell cycle–specific or cell cycle–nonspecific drugs or may have miscellaneous actions.
- Cell cycle–specific drugs kill cancer cells during specific phases of the cell growth cycle. Cell cycle–nonspecific drugs kill cancer cells during any phase of the cell growth cycle.
- Chemotherapy, or antineoplastic therapy, requires skillful and perceptive nursing care. It is important to act prudently and think critically when making decisions about the nursing care of patients receiving antineoplastic drugs.
- Cell cycle–specific drug classes include antimetabolites, mitotic inhibitors, alkaloid topoisomerase II inhibitors, topoisomerase I inhibitors, and antineoplastic enzymes.
- Antineoplastic antimetabolites are cell cycle–specific antagonistic analogues that work by inhibiting the actions of key cellular metabolites.
- Two plant-derived antineoplastic drugs are the taxanes: paclitaxel, derived from the bark of the slow-growing Western (Pacific) yew tree, and docetaxel, a semisynthetic taxoid produced from the needles of the European yew tree. Docetaxel is pharmacologically similar to paclitaxel.
- The topoisomerase I inhibitors, topotecan and irinotecan, comprise a relatively new class of chemotherapy drugs.
- Antineoplastic enzymes include asparaginase and pegaspargase.
- Several drugs that are available are classified as cytoprotective and help to reduce the toxicity of various antineoplastics.

EXAMINATION REVIEW QUESTIONS

1. A patient is experiencing stomatitis after a round of chemotherapy. Which intervention by the nurse would be most correct?
 - a. Clean the mouth with a soft-bristle toothbrush and room temperature club soda.
 - b. Rinse the mouth with commercial mouthwash twice a day.
 - c. Use lemon glycerin swabs to keep the mouth moist.
 - d. Keep dentures in the mouth between meals.
2. The nurse is caring for a patient who becomes severely nauseated during chemotherapy. Which nursing intervention is most appropriate?
 - a. Encourage light activity during chemotherapy as a distraction.
 - b. Provide antiemetic medications 30 to 60 minutes before chemotherapy begins.
 - c. Provide antiemetic medications only upon the request of the patient.
 - d. Hold fluids during chemotherapy to avoid causing vomiting.
3. The nurse monitors a patient who is experiencing thrombocytopenia from severe bone marrow suppression. Which of the following would the nurse recognize as this manifestation?
 - a. Severe weakness and fatigue
 - b. Elevated body temperature
 - c. Decreased skin turgor
 - d. Excessive bleeding and bruising
4. A patient receiving chemotherapy is experiencing severe bone marrow suppression. Which nursing diagnosis is most appropriate at this time?
 - a. Activity intolerance
 - b. Potential risk for infection
 - c. Disturbed body image
 - d. Impaired physical mobility
5. A patient has experienced extravasation of an antineoplastic medication. Which of the following nursing interventions should the nurse perform first?
 - a. Apply cold compresses to the site while elevating the arm.
 - b. Inject subcutaneous doses of epinephrine around the IV site every 2 hours.
 - c. Stop the infusion immediately, while leaving the catheter in place.
 - d. Inject the appropriate antidote through the IV catheter.
6. The nurse is assessing a patient who has experienced severe neutropenia after chemotherapy. Which of the following will the nurse monitor for possible signs of infection? (Select all that apply.)
 - a. Elevated WBC count
 - b. Fever
 - c. Nausea

- d. Sore throat
 - e. Chills
7. The order for chemotherapy reads: “Give asparaginase IV 200 units/kg/day.” The patient weighs 297 pounds. The pharmacy department will prepare the medication for IV infusion. How much drug will be given per dose? Is this a safe dose?
8. The nurse is assessing a patient who has developed anemia after two rounds of chemotherapy. Which of these may be indications of anemia? (Select all that apply.)
- a. Hypoxia
 - b. Fever
 - c. Infection
 - d. Bleeding
 - e. Fatigue

CRITICAL THINKING ACTIVITIES

1. A patient who has undergone three chemotherapy sessions is now experiencing stomatitis, and his wife exclaims, “He won’t eat! What kinds of food can I give him? I’m concerned because he has no appetite, and now he has these mouth sores.” What is the nurse’s priority response? Explain your answer.
 2. A patient is receiving irinotecan as part of his chemotherapy regimen. He will be receiving the dose shortly and then will be sent home. The nurse is providing patient teaching before giving him the medication. What is one of the most important problems for which the patient will need to be ready once he is home? Explain the nurse’s priority action.
 3. A patient is receiving chemotherapy that includes the anti-metabolite cytarabine. Several hours after the treatment, the patient reports shortness of breath. The nurse examines the patient and finds that his pulse rate is 118 beats/min, he has slight edema in his lower extremities, and crackles are audible over the bases of the lungs. In addition, his pulse oximetry reading is 92% on room air (previously it was 99%). What is the nurse’s immediate priority action?
- For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Antineoplastic Drugs Part 2: Cell Cycle–Nonspecific and Miscellaneous Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Review concepts related to carcinogenesis, types of malignancies and related terminology, and different treatment modalities, including the use of cell cycle–nonspecific and miscellaneous antineoplastic drugs.
2. Identify the various drugs that are classified as cell cycle–nonspecific or hormonal or that are considered miscellaneous drugs.
3. Discuss the common adverse effects and toxic effects of the cell cycle–nonspecific and miscellaneous antineoplastic drugs, including the reasons for their occurrence and methods of treatment, such as the use of any antidotes.
4. Describe the mechanisms of action, indications, dosages, routes of administration, cautions, contraindications, and drug interactions of the cell cycle–nonspecific drugs, hormonal drugs, and miscellaneous antineoplastic drugs.
5. Apply knowledge about the cell cycle–nonspecific, hormonal agonist–antagonist, and other miscellaneous antineoplastic drugs and their characteristics to the development of a comprehensive collaborative plan of care for patients with cancer who are receiving these drugs.
6. Briefly describe extravasation and other major adverse effects associated with the cell cycle–nonspecific and miscellaneous antineoplastics, including discussion of protocols and antidotes.

KEY TERMS

Alkylation A chemical reaction in which an alkyl group is transferred from one molecule to another. In chemotherapy, alkylation leads to damage of cancer cell deoxyribonucleic acid (DNA) and cell death. (p. 860)

Bifunctional Refers to alkylating drugs composed of molecules that have two reactive alkyl groups and are therefore able to alkylate at two sites on the DNA molecule. (p. 860)

Extravasation The leakage of any intravenously or intra-arterially administered medication into the tissue space surrounding the vein or artery; such an event can cause

serious tissue injury, especially with antineoplastic drugs. (p. 860)

Mitosis The process of cell reproduction occurring in somatic (nonsexual) cells and resulting in the formation of two genetically identical daughter cells, each containing the diploid (complete) number of chromosomes characteristic of the species. (p. 860)

Polyfunctional Refers to the action of alkylating drugs that can engage in several alkylation reactions with cancer cell DNA molecules per single molecule of drug. (p. 860)

DRUG PROFILES

bevacizumab, p. 864

cisplatin, p. 862

cyclophosphamide, p. 862

doxorubicin (doxorubicin hydrochloride)*, p. 863

hydroxyurea, p. 864

imatinib (imatinib mesylate)*, p. 865

mitotane, p. 865

mitoxantrone (mitoxantrone hydrochloride)*, p. 863

octreotide, p. 865

Key drug

* Full generic name is given in parentheses. For the purposes of this text, the more common, shortened name is used.

CELL CYCLE–NONSPECIFIC ANTINEOPLASTIC DRUGS

There are currently two broad classes of cell cycle–nonspecific cancer drugs: alkylating drugs and cytotoxic antibiotics.

Alkylating Drugs

Records of the use of drugs to treat cancer date back several centuries. However, truly successful systemic cancer chemotherapy treatments are not documented until the 1940s. At that time, the first alkylating drugs were developed from mustard gas agents that were used for chemical warfare, before and during World War I. The first drug to be developed was mechlorethamine hydrochloride, also known as *nitrogen mustard*. It is the prototypical drug of its class; however, it is no longer manufactured

in Canada. Since its antineoplastic activity was discovered in the mid-twentieth century, many analogues have been synthesized for use in the treatment of cancer, and they are collectively referred to as *nitrogen mustards*.

The alkylating drugs commonly used in clinical practice in Canada today fall into three categories: classic alkylators (the nitrogen mustards); nitrosoureas, which have a different chemical structure from that of the nitrogen mustards but also work by **alkylation**; and miscellaneous alkylators, which also have a different chemical structure from the nitrogen mustards but are known to work at least partially by alkylation. These drugs are used to treat a wide spectrum of malignancies. The drugs in each category are as follows:

Classic alkylators (nitrogen mustards)

- chlorambucil
- cyclophosphamide
- ifosfamide
- melphalan

Nitrosoureas

- carmustine
- lomustine
- streptozocin

Miscellaneous alkylators

- busulfan
- carboplatin
- cisplatin
- dacarbazine
- oxaliplatin
- procarbazine hydrochloride
- temozolomide

Mechanism of Action and Drug Effects

The alkylating drugs act by preventing cancer cells from reproducing. Specifically, they alter the chemical structure of the cells' deoxyribonucleic acid (DNA), which is essential to the reproduction of any cell, by causing alkyl groups rather than hydrogen atoms to be attached to the nucleic acid. DNA molecules consist of two adjacent strands, each consisting of alternating sequences of phosphate and sugar molecules (Figure 53.1). These components make up the "backbone" of the DNA strands. These two strands are chemically linked to each other by the third DNA structural element—nitrogen-containing bases (adenine, guanine, thymine, and cytosine, abbreviated A, G, T, and C, respectively). These bases are bound to the sugar molecules of the DNA backbone, and two bases, linked to each other by hydrogen bonds, form the molecular bridges between the two DNA strands that bring them into the double helix structure. A nucleotide, which consists of one molecule each of base as well as sugar and phosphate that are bound together, is the structural unit of the molecules of both DNA and ribonucleic acid (RNA), another nucleic acid that is important in cellular reproduction. Messenger RNA (mRNA) molecules are produced by DNA molecules during the complex process of transcription. These mRNA molecules differ from DNA molecules in at least three ways: they are single stranded (versus double stranded); they do not include thymine but instead include

another base, uracil (U); and their sugar molecules are ribose, which has a slightly different structure from that of the deoxyribose molecules of DNA.

During the normal process of reproduction, the double helix uncoils, and its two strands separate. A strand of RNA is then assembled next to each single DNA strand in a process known as *transcription*. RNA strands, in turn, are involved in both protein synthesis (translation) and replication of the original DNA structure before cell division, or **mitosis**. These processes ultimately result in the creation of a new cell with the same DNA sequence, and thus the same characteristics, as its parent cell.

Alkyl groups that are part of the structure of antineoplastic alkylating drugs attach to DNA molecules by forming covalent bonds with the bases described earlier. As a result, abnormal chemical bonds form between the adjacent DNA strands, which leads to the formation of defective nucleic acids that are then unable to perform the normal cellular reproductive functions mentioned previously. This leads to cell death.

Alkylating drugs can be characterized by the number of alkylation reactions in which they can participate. **Bifunctional** alkylating drugs have two reactive alkyl groups that are able to alkylate two sites on the DNA molecule. **Polyfunctional** alkylating drugs can participate in several alkylation reactions. Figure 53.2 shows the location along the DNA double helix where the alkylating drugs work.

Indications

The most commonly used alkylating drugs today are effective against a wide spectrum of malignancies, including both solid and circulating tumours. Common examples of the various types of cancer that different alkylating drugs are used to treat are listed in the Dosages table on p. 862.

Adverse Effects

Alkylating drugs are capable of causing all of the dose-limiting adverse effects described in Chapter 44. Other adverse effects are described in Table 53.1. The relative emetic potential of the alkylating drugs is given in Box 52.1. The adverse effects of these drugs are important because of their severity, but they can often be prevented or minimized by prophylactic measures. For instance, nephrotoxicity from cisplatin can often be prevented by adequately hydrating the patient with intravenous (IV) fluids.

Drug **extravasation** occurs when an IV catheter punctures the vein and medication leaks (infiltrates) into the surrounding tissues. With cancer chemotherapy drugs, in particular doxorubicin (a cytotoxic antibiotic), extravasation can cause severe tissue damage and necrosis (tissue death). Extravasation antidotes for selected drugs are listed in Table 53.2.

Interactions

Only a few alkylating drugs are capable of causing significant drug interactions. The most important guideline for preventing such drug interactions is to avoid administering an alkylating drug with any other drug capable of causing similar toxicities. For example, a major adverse effect of cisplatin is nephrotoxicity. Therefore, if possible, do not administer it with a drug such

Fig. 53.1 Deoxyribonucleic acid (DNA) double helix. (A). Diagrammatic model of the helical structure, showing its dimensions, the major and minor grooves, the periodicity of the bases, and the antiparallel orientation of the backbone chains (represented by ribbons). The base pairs (represented by rods) are perpendicular to the axis and lie stacked one on another. (B). The chemical structure of the backbone and bases of DNA, showing the sugar–phosphate linkages of the backbone and the hydrogen bonding between the base pairs. There are two hydrogen bonds between adenine and thymine and three between cytosine and guanine. (From: Dorland, W. A. N. (2012). *Dorland's illustrated medical dictionary* (32nd ed.). Philadelphia, PA: Saunders.)

Fig. 53.2 Organization of deoxyribonucleic acid (DNA) and site of action of alkylating drugs.

as an aminoglycoside antibiotic (gentamicin sulphate, tobramycin, or amikacin sulphate) because of the resulting additive nephrotoxic effects and hence the increased likelihood of kidney failure. Cyclophosphamide has a significant bone marrow-suppressing effect and ideally should not be administered with radiation therapy or with other drugs that suppress the bone marrow. In general, the nurse needs to work with available pharmacy and oncology staff to proactively anticipate (and avoid, if possible) undesirable drug and treatment interactions.

Dosages

For dosage information on selected alkylating drugs, refer to the Dosages table on p. 862. It is important to note that dosages are highly variable based on type of cancer, previous drugs used, and concurrent drug administration.

DRUG PROFILES

The most widely used alkylating drugs, based on standard treatment protocols, are profiled here. Information for drugs also appears in the Dosages table below.

TABLE 53.1 Commonly Used Alkylating Drugs: Severe Adverse Effects

Alkylating Drug	Severe Adverse Effects
busulfan	Pulmonary fibrosis
carboplatin*	Nephrotoxicity, neurotoxicity, bone marrow suppression
cisplatin	Nephrotoxicity, peripheral neuropathy, ototoxicity
Cyclophosphamide	Hemorrhagic cystitis

*Carboplatin has less nephrotoxicity and neurotoxicity but more bone marrow suppression than cisplatin.

cisplatin

Cisplatin is an antineoplastic drug that contains platinum in its chemical structure. It is classified as a probable alkylating drug because it is believed to destroy cancer cells in the same way as the classic alkylating drugs, by forming crosslinks with DNA, thereby preventing its replication. It is also considered a bifunctional alkylating drug.

Cisplatin is used for the treatment of many solid tumours, such as bladder, testicular, and ovarian tumours. It is available only in injectable form.

cyclophosphamide

Cyclophosphamide (Procytox*) is a nitrogen mustard derivative that was discovered during the course of research to improve mechlorethamine hydrochloride. It is a polyfunctional alkylating drug and is a prodrug requiring *in vivo* activation. It is used in the treatment of cancers of the bone and lymph nodes, as well as of other solid tumours. Cyclophosphamide is also used in the treatment of leukemias and multiple myeloma, as well as for non-cancer-related illnesses such as prophylaxis for rejection of kidney, heart, liver, and bone marrow transplants and the treatment of severe rheumatoid disorders. It is available in both oral and injectable dosage forms.

Cytotoxic Antibiotics

The cytotoxic antibiotics consist of natural substances produced by the mould *Streptomyces* as well as semisynthetic substances in which chemical changes have been made to the natural molecule. The most common toxicity of cytotoxic antibiotics is bone marrow suppression. The one exception is bleomycin, which instead causes pulmonary toxicity (pulmonary fibrosis and pneumonitis). Other severe toxicities

TABLE 53.2 Alkylating Drug Extravasation: Specific Antidotes

Alkylating Drug	Antidote Preparation	Method
carmustine	Mix equal parts 1 mmol/mL sodium bicarbonate (premixed) with sterile NS (1:1 solution); resulting solution is 0.5 mmol/mL	1. Inject 2–6 mL intravenously through the existing line with multiple Subcut injections into the extravasated site. 2. Apply cold compresses. 3. Total dose is not to exceed 10 mL of 0.5 mmol/mL solution.

NS, Normal saline; *Subcut*, subcutaneous.

Dosages

Selected Alkylating Drugs

Drug	Pharmacological Subclass	Usual Dosage Range*	Indications
 cisplatin	Platinum coordination complex	<i>Adults and children</i> IV: 50–75 mg/m ² q3–4 wk or 15–20 mg/m ² daily × 5 days q3–4 wk	Palliation for bladder cancer and for metastatic testicular and ovarian cancers
 cyclophosphamide (Procytox)	Classic alkylator	IV: 10–20 mg/kg daily × 2–5 days (many other regimens as well)	HL, NHL; leukemia, breast and ovarian cancer; retinoblastoma; almost every solid tumour

HL, Hodgkin's lymphoma; IV, intravenous; NHL, non-Hodgkin's lymphoma.

*Note: Dosages are highly variable unless indicated otherwise.

associated with the use of cytotoxic antibiotics are heart failure (daunorubicin hydrochloride) and, in rare cases, acute left ventricular failure (doxorubicin). The available cytotoxic antibiotics, categorized according to the specific subclass to which they belong, are as follows:

Anthracyclines

- daunorubicin hydrochloride
- doxorubicin hydrochloride
- epirubicin hydrochloride
- idarubicin hydrochloride
- valrubicin

Other cytotoxic antibiotics

- bleomycin sulphate (actually a cell cycle–specific drug)
- dactinomycin
- mitomycin hydrochloride
- mitoxantrone

Mechanism of Action and Drug Effects

Cytotoxic antibiotic antineoplastic drugs are cell cycle–nonspecific drugs. They interact with DNA through a process called *intercalation*, in which the drug molecule is inserted between the two strands of a DNA molecule, ultimately blocking DNA synthesis. These drugs inhibit the enzyme topoisomerase II, which leads to DNA strand breaks. Many of these drugs are able to generate free radicals, which also leads to DNA strand breaks and programmed cell death.

Indications

Cytotoxic antibiotics are used to treat a variety of solid tumours and some hematological malignancies as well. Commonly used examples of these drugs and the malignancies they are used to treat are given in the Dosages table on p. 862.

Adverse Effects

As with all of the antineoplastic drugs, cytotoxic antibiotics have the undesirable effects of hair loss, nausea and vomiting, and myelosuppression. The emetic potential of the drugs in this category is given in Box 52.1. Major adverse effects specific to the cytotoxic antibiotics are listed in Table 53.3.

Toxicity and Management of Overdose. Severe cases of cardiomyopathy are associated with large cumulative doses of doxorubicin. Routine monitoring of cardiac ejection fraction with multiple-gated acquisition (MUGA) scans, cumulative dose limitations, and the use of cytoprotectant drugs such as

dexrazoxane can decrease the incidence of this devastating toxicity. Box 53.1 outlines the management of doxorubicin extravasation.

Interactions

The cytotoxic antibiotics that are used in chemotherapy interact with many drugs. They all tend to produce increased toxicities when used in combination with other chemotherapeutic drugs or with radiation therapy. Some drugs, most notably bleomycin sulphate and doxorubicin, have been known to cause serum digoxin levels to increase. With patients receiving one of these drugs along with digoxin, observe for signs of digoxin toxicity. Dosage reduction or elimination of digoxin therapy may be indicated (see Chapter 25).

Dosages

For dosage information on selected cytotoxic antibiotics, refer to the Dosages table on p.862.

DRUG PROFILES

doxoryin hydrochloride

Doxorubicin hydrochloride (Adriamycin PFS®) is used in many combination chemotherapy regimens. The drug is contraindicated in patients with a known hypersensitivity to it, patients with severe myelosuppression, and patients who are at risk for severe cardiac toxicity because they have already received a large cumulative dose of any of the anthracycline antineoplastics. It is available only in injectable form. Doxorubicin is also available in a liposomal drug delivery system (Caelyx®, Myocet®). In this dosage formulation, the drug is encapsulated in a lipid molecule bilayer called a *liposome*. The advantages of liposomal encapsulation are reduced systemic toxicity and increased duration of action. Liposomal encapsulation extends the biological half-life of doxorubicin to 50 to 60 hours and increases its affinity for cancer cells. The liposomal dosage formulation is currently indicated for the treatment of ovarian cancer, metastatic breast cancer, and AIDS-related Kaposi's sarcoma.

mitoxantrone hydrochloride

Mitoxantrone hydrochloride is indicated for the treatment of acute nonlymphocytic leukemia and metastatic carcinoma of

TABLE 53.3 Cytotoxic Antibiotics: Severe Adverse Effects

Drug	Severe Adverse Effects
bleomycin sulphate	Pulmonary fibrosis, pneumonitis
dactinomycin, daunorubicin hydrochloride	Liver toxicity, tissue damage in the event of extravasation, heart failure
doxorubicin hydrochloride, idarubicin hydrochloride	Liver and cardiovascular toxicities
mitomycin hydrochloride	Liver, kidney, and lung toxicities
mitoxantrone	Cardiovascular toxicity

BOX 53.1 Treatment of Doxorubicin Hydrochloride Extravasation

1. Cool the site to patient tolerance for 24 hours.
2. Elevate and rest the extremity for 24 to 48 hours, and then have the patient resume normal activity as tolerated.
3. If pain, erythema, or swelling persists beyond 48 hours, discuss with the health care provider the need for surgical intervention or other treatment options.

For additional information, see OncoLink, <http://www.oncolink.com>.

Dosages

Selected Cytotoxic Antibiotics

Drug	Pharmacological Subclass	Usual Dosage Range*	Indications
Anthracycline Antibiotics			
 doxorubicin hydrochloride, conventional (Adriamycin®)	Anthracycline	IV: 60–75 mg/m ² as a single injection given q21 days	Multiple cancers, including breast, bone, and ovarian, and leukemia, neuroblastoma, HL, NHL
doxorubicin hydrochloride, liposomal (Caelyx, Myocet®)	Anthracycline	IV: 20–50 mg/m ² q3–4 wk for as long as tolerated and tumour is responsive to treatment	AIDS-related Kaposi's sarcoma when other chemotherapy drugs have failed or patient is intolerant of them; recurrent metastatic ovarian cancer
Anthracenedione Antibiotics			
mitoxantrone hydrochloride	Anthracenedione	IV: 14 mg/m ² q3 wk	Metastatic breast cancer, acute myelocytic leukemia, lymphoma, hepatoma

AIDS, Acquired immunodeficiency syndrome; HL, Hodgkin's lymphoma; IV, intravenous; NHL, non-Hodgkin's lymphoma.

*Dosages listed are for adults.

the breast. It is also indicated for relapsed adult leukemia and for patients with lymphoma or hepatoma. It is available only in injectable form.

MISCELLANEOUS ANTINEOPLASTICS

The miscellaneous antineoplastic drugs are those that, because of their unique structure and mechanism of action, cannot be classified into the previously described categories. However, some drugs that are originally classified as miscellaneous drugs are later reclassified as more is learned about their mechanisms of action and other characteristics. Drugs currently in the miscellaneous category include bevacizumab, everolimus, hydroxyurea (which is actually cell cycle-specific), imatinib, mitotane, ofatumumab, pazopanib hydrochloride, romidepsin, sorafenib tosylate, sunitinib malate, hormonal drugs, and radioactive and related antineoplastic drugs. Selected miscellaneous drugs are profiled in the following sections.

DRUG PROFILES

The various drugs in the miscellaneous category of antineoplastics are used to treat a wide range of cancers. Hydroxyurea and imatinib are administered orally. Bevacizumab and mitotane are available only in injectable form.

bevacizumab

Bevacizumab (Avastin®) was the first antineoplastic drug in a new category, that of the angiogenesis inhibitors. *Angiogenesis* is the creation of new blood vessels that supply oxygen and other blood nutrients to growing tissues. In the case of malignant tumours, angiogenesis that occurs within the tumour mass promotes continued tumour growth. As a tumour enlarges, its central tissues gradually die off (*necrosis*). However, its outer portion continues to grow, often to fatal proportions. Thus, inhibiting this process offers a promising new mechanism for antineoplastic drug action. Bevacizumab is a recombinant “humanized” monoclonal immunoglobulin G1 antibody derived from mouse antibodies.

The scientific name for any compound derived from mouse tissue is *murine*. *Humanization* refers to the use of recombinant DNA techniques to make animal-derived antibody proteins more genetically similar to those of humans. It works by binding to and inhibiting the biological activity of human vascular endothelial growth factor (VEGF). VEGF is an endogenous protein that normally promotes angiogenesis in the body.

Bevacizumab is available only in injectable form. The only recognized contraindication is severe drug allergy or allergy to other murine products. It is approved for the treatment of metastatic colon cancer, rectal cancer in combination with 5-fluorouracil (see [Chapter 44](#)), non-small cell lung cancer, ovarian cancer, and malignant glioblastoma. Bevacizumab was approved for the treatment of breast cancer; however, this indication was revoked by Health Canada as the drug was shown not to be safe or effective for that use.

Adverse reactions to bevacizumab include those affecting the cardiovascular system (hypertension or hypotension, deep vein thrombosis), central nervous system (CNS) (pain, headache, dizziness, asthenia), skin (alopecia, dry skin), metabolism (weight loss, hypokalemia), gastrointestinal (GI) tract (nausea, vomiting, diarrhea, abdominal pain, constipation, GI hemorrhage), kidneys (nephrotoxicity with proteinuria), hematopoietic system (leukopenia [see Lab Values box]), and respiratory tract (infection). More severe effects can occur in any of these systems but are much less common than those listed. Drug interactions reported to date are limited but include potentiation of the cardiotoxic effects of the anthracycline antibiotics such as doxorubicin.

hydroxyurea

Hydroxyurea (Hydrea®) is an antimetabolite that interferes with the synthesis of DNA by inhibiting the incorporation of thymidine into DNA. More specifically, it inhibits ribonucleotide reductase, which is involved in conversion of ribonucleotides to deoxyribonucleotides. It works primarily in the S and G₁ phases of the cell cycle (refer to [Figure 53.2](#) in [Chapter 52](#)), which makes it a cell cycle-specific drug. It is discussed in this chapter because it is included as a miscellaneous drug.

TABLE 53.4 Hormonal Antineoplastics: Adverse Effects

Class	Drug	Adverse Effects
Aromatase inhibitors	anastrozole	Vasodilation, hypertension, hot flashes, mood disorders, weakness, arthritis
Selective estrogen receptor modulators	tamoxifen	Hypertension, peripheral edema, mood disorders, depression, hot flashes, nausea, weakness
Progestins	megestrol acetate, medroxyprogesterone acetate	Hypertension, chest pain, headache, weight gain, hepatotoxicity, dizziness, abdominal pain
Estrogen receptor antagonists	fulvestrant	Vasodilation, pain, headache, hot flashes, nausea, vomiting, pharyngitis
Antiandrogens	bicalutamide, flutamide, nilutamide	Peripheral edema, pain, hot flashes, gynecomastia, anemia, nausea, diarrhea
Gonadotropin-releasing hormone agonists	leuprolide, goserelin acetate	Rash, pain on injection, alopecia, body odour
Antineoplastic hormone	estramustine phosphate sodium	Edema, dyspnea, leg cramps, breast tenderness, nausea, anorexia, diarrhea

It is used in the treatment of squamous cell carcinoma together with radiation to take advantage of its radiosensitizing activity. It is also used in the treatment of various types of leukemia. The drug is available only in oral form. Adverse reactions include edema, drowsiness, headache, rash, hyperuricemia, nausea, vomiting, dysuria, myelosuppression, elevated liver enzyme levels, muscular weakness, peripheral neuropathy, nephrotoxicity, dyspnea, and pulmonary fibrosis. Hydroxyurea interacts with the anti-HIV drugs zidovudine and didanosine (see [Chapter 45](#)), which can actually have a synergistic effect with hydroxyurea. Concurrent use of hydroxyurea with fluorouracil increases the risk of neurotoxic symptoms. Because hydroxyurea can reduce the clearance of cytarabine, dosage reduction of cytarabine is recommended when the two are used concurrently.

imatinib mesylate

Imatinib mesylate (Gleevec®) is the standard of care for the treatment of chronic myeloid leukemia (CML). It works by inhibiting the action of a key enzyme (bcr-abl tyrosine kinase) responsible for causing CML. Although its name sounds similar to those of various monoclonal antibody drugs, imatinib is not a monoclonal antibody but rather a targeted therapy. It is available only in oral form. Common adverse reactions include fatigue, headache, rash, fluid retention, GI and hematological effects, musculoskeletal pain, cough, and dyspnea. Potential drug interactions are numerous and involve other drugs metabolized by cytochrome P450 liver enzymes. Examples include amiodarone hydrochloride, verapamil hydrochloride, warfarin sodium, azole antifungals, antidepressants, and antibiotics. A pharmacist may be needed to review the patient's medication regimen and adjust dosages or delete medications accordingly, in collaboration with the patient's health care provider.

mitotane

Mitotane (Lysodren®) is an adrenal cytotoxic drug that is indicated specifically for the treatment of inoperable adrenal corticoid carcinoma. Mitotane modifies the peripheral metabolism of steroids as well as directly suppressing the adrenal cortex. The drug alters the extra-adrenal metabolism of cortisol in humans, leading to a reduction in measurable 17-hydroxy corticosteroids, and causes increased formation of 6-β-hydroxy cortisol. It is available only in oral form. Adverse reactions include CNS depression, rash, nausea, vomiting, muscle weakness, and

headache. Reported drug interactions include enhanced CNS depressive effects when taken concurrently with other CNS depressants (e.g., benzodiazepines). Mitotane may also increase the clearance of both warfarin sodium and phenytoin, reducing their effects. The potassium-sparing diuretic spironolactone may negate the effects of mitotane.

octreotide acetate

Octreotide acetate (Ocphyl®, Sandostatin®; see [Chapter 31](#)) is a unique medication used for the management of a cancer-related condition called *carcinoid crisis* and treatment of the diarrhea caused by vasoactive intestinal peptide-secreting tumours (VIPomas).

HORMONAL ANTINEOPLASTICS

Hormonal drugs are used in the treatment of a variety of cancers. The rationale is that sex hormones act to accelerate the growth of some common types of malignant tumours, particularly certain types of breast and prostate cancers. Therefore, therapy may involve administration of hormones with opposing effects (i.e., male versus female hormones) or drugs that block the body's sex hormone receptors. Some of the more commonly used hormonal drugs for cancers, such as breast cancer—which occur more commonly in women but also can occur in men—include the selective estrogen receptor modulator tamoxifen, the progestins megestrol acetate and medroxyprogesterone acetate, the aromatase inhibitors letrozole, anastrozole, and exemestane, and the estrogen receptor antagonist fulvestrant. For cancers that occur in men, such as prostate cancer, the following drugs are used: the antiandrogens bicalutamide, abiraterone, cyproterone, enzalutamide, apalutamide, darolutamide, flutamide, and nilutamide; and the antineoplastic hormone estramustine phosphate sodium. The most common adverse effects of these drugs used to treat female and male cancers are listed in [Table 53.4](#).

RADIOPHARMACEUTICALS AND RELATED ANTINEOPLASTICS

Antineoplastic drugs that are usually administered only by health care providers include porfimer sodium and various radioactive pharmaceuticals (radiopharmaceuticals). Porfimer sodium is used to treat esophageal or bronchial tumours that

LAB VALUES RELATED TO DRUG THERAPY

Rationales for Assessment and Monitoring of Blood Cell Counts With Antineoplastics

Laboratory Test	Normal Ranges	Rationale for Assessment
Leukocytes (WBCs)	5–10 × 10 ⁹ /L	WBCs are protection against infection and, when an infection develops, the WBCs attack and destroy the causative bacteria, viruses, or other organisms. In response to the infection, WBCs increase in number dramatically. If WBCs are decreased from antineoplastic treatment and subsequent bone marrow suppression, and if they decrease to levels below 2 × 10 ⁹ /L (leukopenia), there is a high risk for severe infection and immunosuppression.
WBC components:		The major types of WBCs are neutrophils, lymphocytes, monocytes, eosinophils, and basophils.
Neutrophils	47–77% or above 1.5 × 10 ⁹ /L	Immature neutrophils are called <i>band neutrophils</i> and their number, along with neutrophil counts, provides a picture of the patient's immune system. If neutrophils are decreased to levels of less than 0.5 × 10 ⁹ /L (neutropenia), then there is risk for severe infection. If band neutrophils are included in the WBC differential count, then an abnormally low value reinforces the risk for severe infection (see Chapter 52).
Band neutrophils	0–3%	
Nadir	See normal range of each blood cell	<i>Nadir</i> refers to the lowest levels of bone marrow cells reached. The time to reach this nadir may become shorter and the recovery time longer with successive courses of antineoplastic treatment. A general estimate of the time to nadir is 10 to 28 days. Anticipation of the nadir allows the oncologist and health care team to develop a preventative treatment plan, which may include biological response modifiers and antibiotics.

WBCs, White blood cells.

Note: Similar information on red blood cells and platelet counts is given in Chapter 52. Also note that chemotherapy may be discontinued with anemia, leukopenia, neutropenia, or thrombocytopenia. Once counts recover (sometimes more quickly with certain drugs than with others), treatment is often reinitiated.

are present on the surface mucosa. The medication is given intravenously, and administration is followed by one or more sessions of laser light therapy to the esophageal or bronchial mucosa for direct tumour lysis and manual debridement. Radiopharmaceuticals are used to treat a variety of cancers and symptoms caused by cancers. Five commonly used radioisotopes are chromic phosphate P 32 (for cancer-induced peritoneal or pleural effusions), samarium SM 153 lexidronam (for bone cancer pain), sodium iodide I 131 (for thyroid cancer and hyperthyroidism), sodium phosphate P 32 (for various leukemias and palliative treatment of bone metastases), and strontium Sr 89 chloride (for bone cancer pain). One drug used in the treatment of various forms of non-Hodgkin's lymphoma is yttrium Y 90 ibritumomab tiuxetan (yttrium 90-labelled CD20 antibody [Zevalin®]). These medications are usually administered by nuclear medicine specialists.

NURSING PROCESS

Antineoplastics are some of the most toxic drugs given to patients (see Chapter 52) and because of their toxicities, serious complications and adverse effects may occur. Nursing care must be based on a thorough knowledge of cancer, its treatment, and the subsequent effects of different treatment modalities. The nurse should also bear in mind the potential of medication errors occurring with the administration of some of these drugs, such as errors that occur from confusing drugs with “sound-alike” names (see Preventing Medication Errors: Sound-Alike Drugs: “Rubicins”). This chapter presents information about cell cycle-nonspecific, hormonal, and miscellaneous antineoplastic drugs, whereas Chapter 52 covers cell cycle-specific antineoplastic drugs.

PREVENTING MEDICATION ERRORS

Sound-Alike Drugs: “Rubicins”

The anthracycline chemotherapy drugs have the same sound-alike suffix and are often nicknamed the “rubicins.” These drugs include daunorubicin hydrochloride, doxorubicin, epirubicin hydrochloride, idarubicin hydrochloride, and valrubicin. Even though these drugs are in the same class, their uses and drug effects are quite different. Medication errors have occurred because one “rubicin” was mistaken for another. It is therefore important to refer to these drugs by their complete names rather than as a “rubicin.”

ASSESSMENT

Begin the overall assessment of patients taking any of the drugs discussed in this chapter with a thorough nursing history, medication profile, and past and present medical history. Measure and record vital signs. Document the presence of conditions that represent cautions or contraindications as well as potential drug interactions. Perform a head-to-toe physical assessment that includes attention to the following: skin turgor, including level of moisture and integrity of the skin and oral mucosa; baseline level of neurological functioning including level of consciousness, alertness, motor and sensory intactness, reflexes, and presence of any abnormal sensations; bowel sounds, bowel patterns, and inquiry into any problems such as diarrhea, constipation, nausea, vomiting, or reflux; urinary patterns and colour, amount, and odour of urine; breath sounds as well as respiratory rate, rhythm, and depth; and heart sounds. Laboratory tests that may be ordered include fluid and electrolyte levels (sodium, potassium, chloride, magnesium, calcium), red blood cell (RBC) and white blood cell (WBC) counts, hemoglobin, hematocrit, kidney and liver function tests, and serum protein-albumin levels.

BOX 53.2 Concerns in the Handling and Administration of Vesicant Antineoplastic Drugs

The handling and administration of antineoplastic drugs is of major concern because the nurse mixing and giving the drug may experience negative consequences. The pharmacy department is responsible for mixing these drugs, and preparation must be carried out carefully in an appropriate environment, with use of a laminar airflow hood and personal protective equipment (mask, gown, gloves). All health care providers should also be familiar with their practice site policies as each institution may have slightly different protocols for handling and administering specific cytotoxic and non-cytotoxic hazardous medications. Many facilities recommend taking special precautions during the care of patients who are receiving chemotherapy, such as double-flushing patients' bodily secretions in the commode and using special hampers for the disposal of all items that come into contact with the patient. Special spill kits are employed to clean up the smallest chemotherapy spills. These precautions are necessary to protect health care providers from the cytotoxic effects of these drugs. In addition, appropriate and up-to-date knowledge about these drugs is important to safe and appropriate nursing care.

All nurses giving antineoplastic drugs must be certified to administer chemotherapy and must remain current in their scope of practice and secure in their competencies related to this treatment modality. All equipment and containers must be handled appropriately once infusion is completed. Hands and any exposed areas must be washed to ensure the safety of the health care provider. The British Columbia cancer agency BC Cancer (2019) (<http://www.bccancer.bc.ca/>) and the Canadian Association of Nurses in Oncology (<http://www.cano-acio.ca/>) offer exceptional resources for individuals involved in the care of patients receiving chemotherapy.

For patients receiving alkylating drugs, bone marrow suppression (with carboplatin), pulmonary fibrosis (with busulfan), nephrotoxicity or neurotoxicity (more with cisplatin than carboplatin), and hemorrhagic cystitis (with cyclophosphamide) may occur; thus, perform an appropriate and thorough nursing assessment (see Assessment in Chapter 52). Assess deep tendon reflexes and baseline hearing level, and document the findings. Assess results of any baseline pulmonary function testing and perform a thorough respiratory assessment. High-dose cyclophosphamide may lead to hemorrhagic cystitis; therefore, document urinary patterns and any abnormal symptoms. Note hydration status before administering cyclophosphamide to avoid hemorrhagic cystitis.

One of the major adverse effects associated with the use of cytotoxic antibiotics (especially bleomycin) is pulmonary fibrosis. Medical testing (e.g., X-rays, pulmonary function tests, computed tomographic [CT] scans, magnetic resonance imaging [MRI] scans, arterial blood gas levels, and partial pressures of CO₂ and O₂) may be ordered to assess findings. When dactinomycin or daunorubicin hydrochloride are given intravenously, they are generally administered via a central line indwelling catheter device (e.g., Port-A-Cath® or MediPort®) because if they are given by peripheral IV line and extravasation occurs, there is a risk for necrosis with tissue sloughing that may erode through the layers of skin and underlying supportive structures (e.g., muscles, ligaments). See the previous discussion of extravasation as well as Table 53.2 and Box 53.2. In addition, in patients with documented cardiac disease or a history

of thoracic irradiation, administer dactinomycin, daunorubicin hydrochloride, and doxorubicin with extreme caution due to cardiovascular toxicity. CT scans and ultrasound studies may be needed before and during treatment to assess cardiac ejection fraction because of the risk of cardiotoxicity, which is often associated with cumulative doses.

Prior to the use of hormonal antineoplastic drugs, obtain a thorough medical, nursing, and medication history. Many of the drugs included in this category are discussed in depth in Chapters 35 and 36, which also discuss aspects of the nursing process related to their use. Assessment associated with the use of estrogen antagonists, such as fulvestrant, tamoxifen, and raloxifene hydrochloride, often begins with a review of the results of any tumour estrogen receptor assays, CT scans, X-rays, and other diagnostic testing. Perform a neurological assessment (see previous discussion and Chapters 35 and 52) with attention to baseline concerns of any pain, abnormal sensations, or headaches. Note any menopausal symptoms upon assessment because of the possible adverse effect of vasodilation and subsequent hot flashes. In addition, these drugs may cause nausea and vomiting, so a thorough GI assessment is beneficial.

Prior to using androgens (e.g., testosterone) in female patients, obtain a thorough gynecological history with attention to any menstrual issues or problems because of the adverse effect of menstrual irregularities. It is also important to assess the patient's body image and feelings of self-esteem because of the possible adverse effects of acne, hirsutism, and virilization in female patients as well as gynecomastia in male patients. See Chapter 36 for more information on the adverse effects of androgens.

Flutamide and nilutamide are antiandrogens and require thorough assessment of any heart diseases due to their potential to cause peripheral edema. This adverse effect could exacerbate any pre-existing heart disorder. Perform a thorough GI and gynecological assessment prior to the use of these drugs because of the possibility for nausea, diarrhea, and hot flashes. Documentation of the use of a reliable form of birth control is important because of teratogenic effects. Male sperm production may be affected (see Chapter 52), and a decline in sexual functioning or desire may occur because of these drugs' antiandrogenic effects. Before treatment, sperm can be frozen for future use in artificial insemination or other fertility treatments.

Prior to the use of gonadotropin-releasing hormone agonists, such as leuprolide and goserelin, assess patients for allergies to the drugs. Contraceptive history is important because women who are taking these drugs must use a nonhormonal contraceptive. Often, the health care provider will order laboratory tests for serum testosterone levels and prostatic acid phosphatase levels for male patients before and during therapy; an increase is normally noted during the initial week of therapy, and then levels return to baseline by 4 weeks from initiation.

For patients taking antiadrenal drugs (e.g., mitotane), in addition to performing a basic assessment, inquire about any GI disturbances because of the common adverse effects of nausea and vomiting. Miscellaneous antineoplastic drugs, glucocorticoids and mineralocorticoids may be given to prevent adrenal insufficiency and may also play a part in the

therapeutic regimen. An understanding of baseline adrenal functioning through examination of laboratory test results is important.

With the miscellaneous drug hydroxyurea, assessment of liver, kidney, neurological, and pulmonary function and baseline blood cell counts are important due to the adverse reactions associated with this drug. With use of bevacizumab, an angiogenesis inhibitor, assess cardiovascular, CNS, GI tract, and kidney functioning. Assess adverse effects of hypotension or hypertension, headache, pain, dizziness, nausea, vomiting, diarrhea, and nephrotoxicity.

◆ NURSING DIAGNOSES

- Decreased cardiac output as a result of the adverse effect of cardiotoxicity associated with cytotoxic antibiotics
- Potential risk of diarrhea as a result of the adverse effects of antineoplastic drugs
- Inadequate nutrition, less than body requirements, as a result of loss of appetite, nausea, and vomiting, due to antineoplastic therapy

◆ PLANNING

◆ Goals

- Patient's cardiac output will remain within normal limits while the patient is taking antineoplastics.
- Patient will experience minimal problems with alterations in bowel elimination (e.g., diarrhea).
- Patient will maintain adequate and balanced nutritional status while taking antineoplastics.

◆ Expected Patient Outcomes

- Patient maintains normal blood pressure and heart rate while being monitored during therapy with cytotoxic antibiotics.
 - Patient demonstrates adequate knowledge for self-monitoring of daily blood pressure and pulse rate.
 - Patient understands the importance of taking daily weights.
 - Patient adheres to a daily heart-healthy regimen of conserving energy, planning activities, and asking for assistance with care and activities as needed.
- Patient or a family member or caregiver contacts health care providers immediately upon the occurrence of shortness of breath, high or low blood pressure or pulse rate, or chest pain.
- Patient states measures to prevent or decrease the occurrence of diarrhea during antineoplastic therapy, such as avoiding spicy foods, gas-producing foods, caffeine, high-fibre foods, alcohol, and extremely hot or cold foods and beverages.
 - Patient has preventative medication, as prescribed, such as synthetic opioids (e.g., loperamide hydrochloride) or adsorbents-protectants, to be taken to help with diarrhea.
- Patient maintains a daily regimen of healthy nutritional patterns, such as maintaining adequate fluid intake, maintaining a balanced diet as tolerated, avoiding foods that are irritating to the GI tract, and taking nutritional supplements as prescribed.

◆ IMPLEMENTATION

Before initiating drug therapy with the cell cycle-nonspecific drugs, hormonal antineoplastics, and miscellaneous antineoplastic drugs, the nurse must be completely knowledgeable about the given drug, its use, and its impact on all rapidly dividing cells, whether normal or malignant (see Chapters 51 and 52 for additional information).

Always handle alkylating drugs and all other antineoplastics with caution because of their possible carcinogenic, mutagenic, and teratogenic properties (see [Box 53.2](#)). Follow institutional guidelines for administration to patients. Patients receiving alkylating drugs will more than likely experience problems related to bone marrow suppression, such as anemia, leukopenia, and thrombocytopenia (see [Chapter 52](#) for specific interventions). Most nursing interventions are focused on preventing infection, conserving energy, preventing bleeding and injury, and reducing nausea. Other nursing considerations related to these drugs include taking vital signs every 1 to 2 hours or as needed during infusion, encouraging increased fluid intake, monitoring intake and output, following orders for IV therapy for hydration, and monitoring any vomiting. Contact the health care provider if vomiting is uncontrolled.

Monitor patients constantly for abnormal peripheral sensations, especially with the use of cisplatin. Report to the health care provider any numbness or tingling of extremities and any ringing or roaring in the ears or hearing loss. Encourage patients experiencing peripheral neuropathies to avoid extremely cold temperatures or the handling of cold objects. Cisplatin is particularly nephrotoxic, so monitor kidney function closely throughout therapy. IV hydration is often required at a rate of 100 to 200 mL/hr, starting before cisplatin administration with a total of 2000 to 3000 mL/day, depending on the dose of cisplatin and if not contraindicated. Do not use aluminum needles or administration sets with many of the alkylating-like drugs (e.g., cisplatin, olaxiplatin) because aluminum can degrade their platinum compounds; ensure that the proper infusion equipment is used. Because hemorrhagic cystitis is associated with cyclophosphamide use, make sure patients' hydration is maintained to minimize this adverse effect. Pulmonary toxicity may occur with some of the alkylating drugs, particularly busulfan; therefore, constantly monitor and be alert to cough, shortness of breath, and abnormal breath sounds. Immediately report these adverse effects to the prescriber. Other alkylating drugs may be given by various routes, such as intrapericardial, intratumoral, and intravesical. Be sure to perform appropriate interventions per the manufacturer's guidelines or facility policy. Reconstitute the parenteral formulations for any of these drugs according to the manufacturer's guidelines and suggestions. Not all diluents are compatible.

One important component of nursing care with alkylating drugs and their parenteral administration is continuous monitoring of the IV infusion site for signs and symptoms of infiltration. Infiltration could lead to extravasation of the medication into the surrounding tissue. To briefly review, IV infiltration is the leakage of fluids or blood from a dislodged catheter or needle cannula from the intima of the vein and into the surrounding tissue. Signs and symptoms of infiltration include inflammation at or near the

insertion site, with swollen, taut, cool skin with pain and blanching; slowed or stopped IV infusion; and no backflow of blood into the IV tubing. The reason infiltration is of concern with alkylating drugs is that some of them are irritants and others are vesicants, carrying the potential of severe tissue damage. Therefore, if extravasation occurs with some of these drugs, the use of antidotes is required to try to prevent damage from leakage of the drug into the tissue. Specific antidotes for alkylating drugs are presented in Table 53.2. Always follow facility policy when treating extravasation of any medication. With IV infusions of antineoplastics, monitoring of the IV site and infusions is usually more frequent than with other medications, and some guidelines recommend hourly assessment. It is important to mention that the vast majority of chemotherapeutic drugs are administered via a central line indwelling catheter device (such as Port-A-Cath or MediPort). Check the device and its patency prior to the drug's administration.

Patients receiving cytotoxic antibiotics such as bleomycin may require very frequent monitoring of pulmonary function. Baseline chest X-rays may be obtained for comparison with subsequent X-rays if pneumonitis occurs. Monitor results of liver and kidney function tests throughout therapy with dactinomycin hydrochloride, daunorubicin, doxorubicin, or mitomycin hydrochloride. Assessing heart sounds, daily weights, blood pressure, and pulse rate, as well as monitoring for signs and symptoms of cardiovascular toxicities (e.g., alterations in vital signs, abnormal heart sounds, dyspnea, chest pain), is especially important with doxorubicin, idarubicin hydrochloride, and mitoxantrone. Additionally, if patients experience an increase in body weight of 1 kg or more in 24 hours or 2.3 kg or more in 1 week, notify the health care provider as this may reflect fluid retention related to heart failure. Mitomycin hydrochloride is associated with liver, kidney, and lung toxicities. Close monitoring of related systems during treatment is crucial to patient safety. As well, cytotoxic precautions and reverse isolation may be necessary, especially for patients who have neutropenia. Refer to institution policies regarding cytotoxic precautions pertaining to preparation, dispensing, packaging, transportation, storage, administration, and waste management of cytotoxic agents.

Use of hormone antagonists in the treatment of various cancers is common, particularly with breast and prostate cancer. Associated nursing interventions and patient education details related to the use of these hormone antagonists are discussed in depth in Chapters 35 and 36. Corticosteroid therapy and related nursing considerations are presented in Chapter 34.

Hydroxyurea is used sparingly but is a component of some treatment protocols. This drug is given orally. Monitor platelet and leukocyte counts of patients taking this drug due to the adverse effect of bone marrow suppression. Monitoring must be ongoing during therapy. If platelet count falls below $100 \times 10^9/L$ or leukocyte count falls below $2 \times 10^9/L$, therapy may need to be temporarily halted until counts rise toward normal values. See earlier discussion and Chapter 52 regarding nursing considerations associated with anemia, fatigue, weakness, bleeding tendencies, and infection. Additionally, hyperuricemia may precipitate gout-related symptoms (i.e., painful, swollen joints); report these to the health care provider so that the appropriate medication may be ordered. Often, a drug such as allopurinol is prescribed to help control high levels of uric acid caused by cell death from chemotherapy.

In addition to the nursing interventions discussed earlier and in Chapter 52, keep epinephrine, antihistamines, and anti-inflammatory drugs available in case of allergic or anaphylactic reactions. Each antineoplastic drug has its own peculiarities and its own set of cautions, contraindications, nursing implementations, and toxicities. Cytoprotective drugs are useful in reducing certain toxicities. For example, use of IV amifostine may help to reduce the kidney toxicity associated with cisplatin, and oral allopurinol may be given to reduce hyperuricemia (see Table 52.6 and Box 52.2). Other major concerns related to the care of patients receiving chemotherapy are the oncological emergencies that arise because of damage occurring to rapidly dividing normal cells as well as rapidly dividing cancerous cells. Some of the complications that are potential emergencies include infections, infusion reactions and allergies, stomatitis with severe ulceration, bleeding, metabolic aberrations, severe diarrhea, kidney failure, liver failure, and cardiotoxicity, including dysrhythmia or heart failure (Box 53.3).

BOX 53.3 Indications of an Oncological Emergency

- Fever or chills with a temperature higher than 38.1°C
- New sores or white patches in the mouth or throat
- Swollen tongue with or without cracks and bleeding
- Bleeding gums
- Dry, burning, “scratchy,” or “swollen” throat
- A cough that is new and persistent
- Changes in bladder function or patterns
- Blood in the urine
- Changes in GI or bowel patterns, including diarrhea lasting longer than 2 to 3 days, dyspepsia, nausea, vomiting, or constipation.
- Blood in the stool

Note: The patient must contact the health care provider immediately if any of the listed signs or symptoms occurs. If the health care provider is not available, the patient must seek medical treatment at the closest emergency department.

CASE STUDY

Chemotherapy With Alkylating Drugs

Antonia, a 50-year-old insurance auditor, is receiving cisplatin as part of treatment for ovarian cancer. She is receiving her third treatment today and has just arrived at the cancer treatment centre for her outpatient infusion. Antonia says that she felt “okay” during the time between the last treatment and today but is not looking forward to today’s treatment because of the adverse effects.

1. While the nurse prepares to start the infusion, what is important for the nurse to assess before beginning the chemotherapy?
2. What will the nurse do before the infusion to help reduce or prevent adverse effects?
3. During the infusion, Antonia mentions that she is hearing a slight “roaring” sound and that she feels a bit dizzy. What will the nurse do next?
4. After stopping the infusion, the nurse spills some of the chemotherapy solution on her arm and the floor. What is the nurse’s priority action at this time?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

◆ EVALUATION

Focus the evaluation of nursing care on determining whether goals and outcome criteria have been met, as well as on monitoring for therapeutic responses and adverse and toxic effects of antineoplastic therapy. Therapeutic responses may manifest as clinical improvement, decrease in tumour size, and decrease in metastatic spread. Evaluation of nursing care with reference to goals and outcomes may reveal improvements related to a decrease in adverse effects; decrease in the impact of cancer on the patient's well-being; increase in comfort, nutrition, and hydration; improved

energy levels and ability to carry out activities of daily living; and improved quality of life. Goals and outcome criteria can be revisited to identify specific parameters to monitor. In addition, certain laboratory studies, such as measurement of tumour markers; levels of carcinoembryonic antigens; and RBC, WBC, and platelet counts may also be used to determine how well the goals and outcome criteria have been met. As part of the evaluation, health care providers may also order additional X-rays, CT scans, magnetic resonance imaging, tissue analyses, and other studies appropriate to the diagnosis, during and after antineoplastic therapy, at time intervals related to anticipated tumour response.

PATIENT TEACHING TIPS

- Advise patients to avoid aspirin, ibuprofen, and products containing these drugs to help prevent excessive bleeding.
- Be open in discussion about the risk of alopecia (a complete discussion is presented in [Chapter 52](#)), an adverse effect of many of the antineoplastic drugs.
- Encourage patients to increase fluid intake up to 3000 mL/day, if not contraindicated, to prevent dehydration and further weakening and, in the case of cyclophosphamide therapy, to prevent or help manage hemorrhagic cystitis.
- Constipation and diarrhea may be problematic, so educate patients about ways to help manage these alterations in bowel status that may be due to antineoplastic drugs or

to opioids used for pain management. To help avoid constipation, increased intake of fluids and consumption of a balanced diet are important; however, oncologists often order either a stool softener or a mild noncramping laxative to prevent the problem. Diarrhea is generally treated with dietary restrictions and the use of antidiarrheals as ordered.

- The following are helpful online resources for patients and their family members and significant others: <http://www.cancer.ca/en/>, www.bccancer.bc.ca/, <http://wellspring.ca/>, <http://www.hc-sc.gc.ca/hc-ps/dc-ma/cancer-eng.php>, and www.oncolink.org/.

KEY POINTS

- Antineoplastics are drugs that are used to treat malignancies and are classified as cell cycle-specific drugs, cell cycle-nonspecific drugs, miscellaneous antineoplastics, and hormonal drugs.
- Cell cycle-specific drugs kill cancer cells during specific phases of the cell growth cycle, whereas the cell cycle-nonspecific drugs (discussed in this chapter) kill cancer cells during any phase of the growth cycle.
- Chemotherapy, or antineoplastic drug therapy, requires skillful and perceptive care, and the nurse must act prudently and make crucial decisions about the nursing care of patients receiving these drugs.
- Knowledge is important to ensure patient and health care provider safety and for protection from the adverse effects of antineoplastics.
- Always exercise extreme caution in the handling and administration of cell cycle-nonspecific (as well as cell cycle-specific) drugs.
- Hormonal drugs, both agonists and antagonists, are used to treat a variety of malignancies.
- Extravasation of strong vesicants (e.g., doxorubicin) may lead to severe tissue injury with complications such as permanent damage to muscles, tendons, and ligaments, and possible loss of a limb. Constantly monitor IV sites and infusions to prevent this possible complication. Checking the patency of central venous access devices is also important because the majority of chemotherapy drugs are given via this route.
- Oncological emergencies occur as a consequence of cell death and may be life-threatening. Skillful assessment and immediate intervention may help to decrease the severity of the problem or even reduce the occurrence of such emergencies.

EXAMINATION REVIEW QUESTIONS

1. A patient who is receiving chemotherapy with cisplatin has developed pneumonia. The nurse would be concerned about nephrotoxicity if which type of antibiotic was ordered as treatment for the pneumonia at this time?
 - a. A penicillin
 - b. A sulpha drug
 - c. fluoroquinolone
 - d. aminoglycoside
2. A patient has been prescribed treatment with doxorubicin (Adriamycin). The nurse must monitor closely for which potentially life-threatening adverse effect?
 - a. Nephrotoxicity
 - b. Peripheral neuritis
 - c. Cardiomyopathy
 - d. Ototoxicity

3. The nurse is teaching a patient who is about to receive cyclophosphamide (Procytox) chemotherapy. Which of the following potential adverse events will the nurse prioritize during the teaching?
 - a. Cholinergic diarrhea
 - b. Hemorrhagic cystitis
 - c. Peripheral neuropathy
 - d. Ototoxicity
4. A patient has been prescribed chemotherapy with alkylating drugs. What nursing intervention would the nurse plan to implement to prevent nephrotoxicity?
 - a. Hydrating the patient with IV fluids before chemotherapy
 - b. Limiting fluids before chemotherapy
 - c. Monitoring drug levels during chemotherapy
 - d. Assessing creatinine clearance during chemotherapy
5. A patient has been prescribed therapy with the cytotoxic antibiotic bleomycin. Which of the following would the nurse monitor in a patient for potentially serious adverse effects?
 - a. Blood urea nitrogen and creatinine levels
 - b. Cardiac ejection fraction
 - c. Respiratory function
 - d. Cranial nerve function
6. The nurse has administered bevacizumab (Avastin). Which of the following will the nurse monitor for drug-related toxicities? (Select all that apply.)
 - a. Blood pressure
 - b. Colour of the skin and sclera of the eye (for jaundice)
 - c. Blood glucose level
 - d. Urine protein level
 - e. Hearing
7. The nurse is preparing to add a dose of bevacizumab (Avastin) to a patient's IV infusion. The dose is 70 mg of bevacizumab in 100 mL of normal saline, and it is to infuse over 90 minutes. The nurse will set the infusion pump to what rate for this dose?
8. The day before a third round of chemotherapy, the nurse reads that a patient's neutrophil count is $1.65 \times 10^9/L$. The nurse anticipates the oncologist will follow which course of treatment?
 - a. The chemotherapy will be started as scheduled.
 - b. The chemotherapy will be given at a lower dosage.
 - c. The oncologist will order a neutrophil transfusion to be given first.
 - d. The chemotherapy will not be given today.

CRITICAL THINKING ACTIVITIES

1. During an infusion of carmustine, a patient dislodges the IV catheter, and infiltration of the medication occurs. What is the nurse's priority action at this time? Explain your answer.
 2. A patient has been receiving bleomycin irrigations through a chest tube for 3 days. Today he has begun to have an irregular and slow heart rhythm, as well as nausea, and says, "I'm seeing yellow hazy circles around the lights." He thinks the chemotherapy is causing these problems. The nurse reviews the patient's medications and notes that he is taking digoxin (Lanoxin®), lisinopril (Prinivil®), and simvastatin (Zocor®).

What is the nurse's priority action at this time? Explain your answer.
 3. During a prechemotherapy teaching session, a patient hears that she will be receiving a cytotoxic antibiotic as part of the medication regimen. The patient asks, "How can this drug help cancer? It's an antibiotic! Cancer is not an infection!"

What is the nurse's best answer?
- For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Biological Response–Modifying Drugs and Antirheumatic Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Describe the basic anatomy, physiology, and functions of the immune system.
2. Compare the two major classes of biological response–modifying drugs: hematopoietic drugs and immunomodulating drugs.
3. Discuss the mechanisms of action, indications, dosages, routes of administration, adverse effects, cautions, contraindications, and drug interactions of the different biological response–modifying drugs.
4. Describe briefly the pathology associated with rheumatoid arthritis.
5. Discuss the mechanisms of action, indications, dosages, routes of administration, adverse effects, cautions, contraindications, and drug interactions of the different antirheumatic drugs.
6. Develop a collaborative plan of care that includes all phases of the nursing process for patients receiving biological response–modifying drugs and for those receiving antirheumatic drugs.

KEY TERMS

Adjuvant A nonspecific immunostimulant that enhances overall immune function rather than stimulating the function of a specific immune system cell or cytokine through specific chemical reactions. (p. 884)

Antibodies Immunoglobulin molecules (see Chapter 51) that have the ability to bind to and inactivate antigen molecules by forming an antigen–antibody complex; this process serves to inactivate foreign antigens that enter the body and are capable of causing disease. (p. 874)

Antigen A biological or chemical substance that is recognized as foreign by the body's immune system. (p. 874)

Arthritis Inflammation of one or more joints. (p. 885)

Autoimmune disorder A disorder that occurs when the body's tissues are attacked by its own immune system. (p. 885)

B lymphocytes (B cells) Leukocytes of the humoral immune system that develop into plasma cells and then produce the antibodies that bind to and inactivate antigens. B cells are one of the two principal types of lymphocytes; T lymphocytes are the other. (p. 874)

Biological response–modifying drugs (BRMs) A broad class of drugs that includes hematopoietic drugs and immunomodulating drugs; often referred to as *biological response modifiers*, they alter the body's response to diseases such as cancer as well as autoimmune, inflammatory, and infectious diseases. Examples are cytokines (e.g., interleukin, interferons), monoclonal antibodies, and vaccines. They are also called *biomodulators* or *immunomodulating drugs*. Biological response–modifying drugs may be adjuvants, immunostimulants, or immunosuppressants. (p. 874)

Cell-mediated immunity (CMI) All immune responses mediated by T lymphocytes (T cells); also called *cellular immunity*. Cell-mediated immunity acts in collaboration with humoral immunity. (p. 874)

Colony-stimulating factors (CSFs) Cytokines that regulate the growth, differentiation, and function of bone marrow stem cells. (p. 876)

Cytokines Nonantibody proteins released by specific cell populations (e.g., activated T cells) on contact with antigens. Cytokines act as intercellular mediators of an immune response. (p. 875)

Cytotoxic T cells Differentiated T cells that can recognize and lyse (rupture) target cells that bear foreign antigens on their surfaces; also called *natural killer cells*. These antigens are recognized by the corresponding antigen receptors that are expressed (displayed) on the cytotoxic T cell surface. (p. 875)

Differentiation The process of cellular development from a simplified into a more complex and specialized cellular structure; in hematopoiesis, the multistep processes involved in the maturation of blood cells. (p. 876)

Disease-modifying antirheumatic drugs (DMARDs) Medications used in the treatment of rheumatic diseases that have the potential to arrest or slow the actual disease process instead of providing only anti-inflammatory and analgesic effects. (p. 874)

Hematopoiesis All of the body's processes originating in the bone marrow that result in the formation of various types of blood components (adjective: *hematopoietic*); includes the three main processes of differentiation (see earlier): erythropoiesis (formation of red blood cells, or

erythrocytes), leukopoiesis (formation of white blood cells, or leukocytes), and thrombopoiesis (formation of platelets, or thrombocytes). (p. 874)

Humoral immunity All immune responses mediated by B cells, which ultimately work through the production of antibodies against specific antigens; humoral immunity acts in collaboration with cell-mediated immunity. (p. 874)

Immunoglobulins Complex immune system glycoproteins that bind to and inactivate foreign antigens; synonymous with *immune globulins*. (p. 874)

Immunomodulating drugs (IMDs) Various subclasses of biological response–modifying drugs that specifically or nonspecifically enhance or reduce immune responses; the three major types of immunomodulators, based on mechanism of action, are adjuvants, immunostimulants, and immunosuppressants (see Chapter 50). (p. 874)

Immunostimulant A drug that enhances immune response through specific and nonspecific chemical interactions with particular immune system components; an example is interleukin-2. (p. 884)

Immunosuppressant A drug that reduces immune response through specific chemical interactions with particular immune system components; an example is cyclosporine (see Chapter 50). (p. 878)

Interferons One type of cytokine that promotes resistance to viral infections in uninfected cells and can also strengthen the body's immune response to cancer cells. (p. 877)

Leukocytes All subtypes of white blood cells; leukocytes include granulocytes (neutrophils, eosinophils, and basophils), monocytes, and lymphocytes (B cells and T cells); some monocytes also develop into tissue macrophages. (p. 875)

Lymphokine-activated killer (LAK) cells Cytotoxic T cells that have been activated by interleukin-2 and therefore have

a stronger and more specific response against cancer cells than other cytotoxic T cells. (p. 883)

Lymphokines Cytokines that are produced by sensitized T lymphocytes on contact with antigen particles. (p. 875)

Memory cells Cells involved in the humoral immune system that remember the exact characteristics of a particular foreign invader or antigen for the purpose of an expediting immune response in the event of future exposure to this antigen. (p. 874)

Monoclonal A group of identical cells or organisms derived from a single cell. (p. 874)

Plasma cells Cells derived from B cells found in the bone marrow, connective tissue, and blood. They produce antibodies. (p. 874)

Rheumatism Any of several disorders characterized by inflammation, degeneration, or metabolic derangement of connective tissue structures, especially joints and related structures. (p. 885)

T-helper cells Cells that promote and direct the actions of other cells of the immune system. (p. 875)

T lymphocytes (T cells) Leukocytes of the cell-mediated immune system; unlike B cells, they are not involved in the production of antibodies but instead occur in various cell subtypes (e.g., T helper cells, T suppressor cells, and cytotoxic T cells); they act through direct cell-to-cell contact or through production of cytokines that guide the functions of other immune system components (e.g., B cells, antibodies). (p. 874)

T-suppressor cells Cells that regulate and limit the immune response, balancing the effects of T helper cells. (p. 875)

Tumour antigens Chemical compounds expressed on the surfaces of tumour cells. They signal to the immune system that these cells do not belong in the body, labelling the tumour cells as foreign. (p. 874)

OVERVIEW OF IMMUNOMODULATORS

Over the last two decades, medical technology has developed a group of drugs whose primary site of action is the immune system. This has resulted in new additions to the class of drugs known as **biological response-modifying drugs (BRMs)**, or *biological response modifier(s)*. These drugs alter the body's response to diseases such as cancer and autoimmune, inflammatory, and infectious diseases. These drugs can enhance or restrict the patient's immune response to disease, can stimulate a patient's hematopoietic (blood-forming) function, and can prevent disease. **Hematopoiesis** is the collective term for all of the blood component-forming processes of the bone marrow. Two broad classes of BRMs are hematopoietic drugs and **immunomodulating drugs (IMDs)**. Subclasses of IMDs include interferons, monoclonal antibodies, interleukin receptor agonists and antagonists, and miscellaneous drugs. **Disease-modifying antirheumatic drugs (DMARDs)** are first-line therapy drugs used to treat rheumatoid arthritis, which is discussed later in the chapter.

IMDs therapeutically alter a patient's immune response. In cancer treatment, they make up the fourth type of cancer therapy, the others being surgery, chemotherapy, and radiation. The human immune system is most commonly viewed as the body's natural defence against pathogenic bacteria and viruses. However, it also has effective antitumour capabilities. An intact immune system can identify cells as malignant and destroy them. Normal cells are recognized as "self" and are not damaged, whereas tumour cells are recognized as "foreign" and are destroyed. People develop cancerous cells in their bodies on a regular basis. Normally, the immune system is able to eliminate these cells before they multiply to uncontrollable levels. It is only when natural immune responses fail to keep pace with these initially microscopic cancer cell growths that a person develops a true "cancer" that requires clinical intervention.

In terms of their activity against cancer cells, BRMs work by one of three mechanisms: (1) enhancement or restoration of the host's immune system defences against the tumour; (2) direct toxic effect on the tumour cells, which causes them to lyse, or rupture; or (3) adverse modification of the tumour's biology, which makes it difficult for the tumour cells to survive and reproduce.

Some IMDs are used to treat autoimmune, inflammatory, and infectious diseases. In these instances, the drug ideally functions either to reduce patients' inappropriate immune responses (in the case of inflammatory and autoimmune diseases, such as rheumatoid arthritis) or to strengthen the patient's immune response against microorganisms (especially viruses) and cancer cells. To better understand these complex drugs, a review of the physiology of the immune system is beneficial.

IMMUNE SYSTEM

The immune system is an intricate biological defence network of cells that are capable of distinguishing an unlimited variety of substances as being either foreign ("nonself") or a natural part of the host's or patient's body ("self"). When a foreign substance such as a bacterium or virus enters the body, the immune system recognizes it as being foreign and mounts an immune response

to eliminate or neutralize the invader. Tumours are not truly foreign substances because they arise from cells of normal tissues whose genetic material (deoxyribonucleic acid [DNA] and ribonucleic acid [RNA]) has somehow mutated. Tumour cells express chemical compounds on their surfaces that signal to the immune system that these cells are a threat. These chemical markers are called **tumour antigens** or *tumour markers*, and they label the tumour cells as abnormal cells. An **antigen** is any substance that the body's immune system recognizes as foreign. Recognition of antigens varies among individuals, which is why some people are more prone than others to immune-related diseases such as allergies, inflammatory diseases, and cancer. The two major components of the body's immune system are **humoral immunity**, mediated by B-cell functions (primarily antibody production), and **cell-mediated immunity (CMI)**, which is mediated by T-cell functions. These two systems act together to recognize and destroy foreign particles and cells in the blood or other body tissues. Communication between these two divisions is vital to the success of the immune system as a whole. An attack against tumour cells by antibodies produced by the **B lymphocytes (B cells)** of the humoral immune system prepares those tumour cells for destruction by the **T lymphocytes (T cells)** of the cell-mediated immune system. This is just one example of the effective way that the two divisions of the immune system communicate with each other for a collaborative immune response.

Humoral Immune System

The functional cells of the humoral immune system are the B lymphocytes. They are also called *B cells* because they originate in the bone marrow. The B cells that are capable of generating a particular antibody normally remain dormant until the corresponding antigen is detected. When an antigen binds to receptors located on the B cells, a biochemical signal is sent to the B lymphocytes. These B cells then mature or *differentiate* into **plasma cells**, which in turn produce antibodies. **Antibodies** are **immunoglobulins** (large glycoprotein molecules; *glyco* = sugar; *protein* = amino acid chain) that bind to specific antigens, forming an antigen-antibody complex that inactivates disease-causing antigens.

The immune system in a healthy individual is genetically preprogrammed to be able to mount an antibody response against literally millions of different antigens. This ability results from the individual's lifetime antigen exposure and is further developed through exposure to new antigens and then passed down through many generations. Antibodies that a single plasma cell makes are all identical. They are therefore called **monoclonal** antibodies. Since the 1980s, monoclonal antibodies have also been prepared synthetically using recombinant DNA (rDNA) technology, which has resulted in new drug therapies.

There are five major types of naturally occurring immunoglobulins in the body: immunoglobulins A, D, E, G, and M. These unique types have different structures and functions and are found in various areas of the body. During an immune response, when B lymphocytes differentiate into plasma cells, some of these B cells become **memory cells**. Memory cells "remember" the exact characteristics of a particular foreign invader or antigen, which allows a stronger and faster immune

response in the event of re-exposure to the same antigen. The cells of the humoral immune system are shown in [Figure 54.1](#).

Cell-Mediated Immune System

The functional cells of the cell-mediated (as opposed to antibody-mediated) immune system are the T lymphocytes. They are also referred to as *T cells* because they mature in the thymus. There are three distinct populations of T cells: cytotoxic T cells, T-helper cells, and T-suppressor cells ([Figure 54.2](#)). They are distinguished by the different functions they perform. **Cytotoxic T cells** directly kill their targets by causing cell lysis or rupture. **T-helper cells** are considered the master controllers of the immune system—they direct the actions of many other immune components, such as lymphokines and cytotoxic T cells. **Cytokines** are nonantibody proteins that serve as chemical mediators of various physiological functions. **Lymphokines** are a subset of cytokines. They

are released by T lymphocytes upon contact with antigens and serve as chemical mediators of the immune response. **T-suppressor cells** have an effect on the immune system that is opposite that of T-helper cells, and they serve to limit or control the immune response. A healthy immune system has approximately twice as many T-helper cells as T-suppressor cells at any given time.

The major cells involved in the destruction of cancer cells are part of the cell-mediated immune system (see [Figure 54.2](#)). The cancer-killing cells of the cellular immune system are the macrophages (derived from monocytes), natural killer (NK) cells (another type of lymphocyte), and polymorphonuclear **leukocytes** (not lymphocytes), which are also called *neutrophils*. In contrast, T-suppressor cells have an important negative influence on antitumour actions of the immune system. Overactive T-suppressor cells may be responsible for clinically significant cancer cases by permitting tumour growth beyond the immune system's control.

Fig. 54.1 Cells of the humoral (antibody-mediated) immune system. *Ig*, immunoglobulin.

BIOLOGICAL RESPONSE MODIFIERS

Therapy with BRMs combines the knowledge of several disciplines, including general biology, genetics, immunology, pharmacology, medicine, and nursing. The general therapeutic effects of BRMs are as follows:

- Enhancement of hematopoietic function
- Regulation or enhancement of the immune response, including cytotoxic or cytostatic activity against cancer cells
- Inhibition of metastases, prevention of cell division, or inhibition of cell maturation

[Box 54.1](#) lists the currently available BRM drugs used in the treatment of cancer and other illnesses that have varying levels of immune system–related pathophysiology. The drugs are classified according to biological effects.

HEMATOPOIETIC DRUGS

Hematopoietic drugs include several medications developed over the past 10 to 15 years. Within this category are two

Fig. 54.2 Cells of the cellular immune system.

erythropoietic drugs (epoetin alfa and darbepoetin alfa) and two **colony-stimulating factors (CSFs)** (filgrastim and pegfilgrastim). The one platelet-promoting drug that has been developed (oprelvekin) is not available in Canada. All of these drugs promote the synthesis of various types of major blood components by promoting the growth, **differentiation**, and function of their corresponding precursor cells in the bone marrow.

Mechanism of Action and Drug Effects

Although the hematopoietic drugs are not directly toxic to cancer cells, they do have beneficial effects in the treatment of cancer. All hematopoietic drugs have the same basic mechanism of action—they decrease the duration of chemotherapy-induced anemia and neutropenia and enable higher doses of chemotherapy to be given, decrease bone marrow recovery time after bone marrow transplantation or irradiation, and stimulate other cells in the immune system to destroy or inhibit the growth of cancer cells, as well as virus- or fungus-infected cells.

All of these drugs are produced by rDNA technology, which allows them to be essentially identical to their endogenously produced counterparts. These substances work by binding to receptors on the surfaces of specialized progenitor cells in the bone marrow. *Progenitor cells* are responsible for the production of three particular cell lines: red blood cells (RBCs), white blood cells (WBCs), and platelets. When a hematopoietic drug binds to a progenitor cell surface, the immature progenitor cell is stimulated to mature, proliferate (reproduce itself), differentiate (transform into its respective type of specialized blood component), and become functionally active. Hematopoietic drugs may

enhance certain functions of mature cell lines as well. Epoetin alfa is a synthetic derivative of the human hormone erythropoietin, which is produced primarily by the kidneys. It promotes the synthesis of erythrocytes (RBCs) by stimulating RBC progenitor cells in the bone marrow. Darbepoetin alfa is a longer-acting form of epoetin alfa. These drugs are discussed in detail in [Chapter 55](#). Filgrastim is a CSF that stimulates progenitor cells for the subset of leukocytes (WBCs) known as *granulocytes* (including basophils, eosinophils, and neutrophils). For this reason, it is also commonly called *granulocyte colony-stimulating factor* (G-CSF). Pegfilgrastim is a longer-acting form of filgrastim.

Indications

Neutrophils are the most important granulocytes for fighting infection. Infections often appear in patients who have experienced destruction of bone marrow cells as a result of cytotoxic chemotherapy. CSFs stimulate neutrophils to grow and mature and thus directly oppose the detrimental bone marrow actions of chemotherapy. Because these drugs reduce the duration of low neutrophil counts, they reduce the incidence and duration of infections. CSFs also enhance the functioning of mature cells of the immune system, such as macrophages and granulocytes. This effect increases the ability of the body's immune system to kill cancer cells, as well as virus- and fungus-infected cells. Ultimately, these properties allow patients to receive higher dosages of chemotherapy. Similar benefits affecting RBC counts occur with epoetin alfa.

The effect of hematopoietic drugs on bone marrow cells also reduces recovery time after bone marrow transplantation and

TABLE 54.1 Hematopoietic Drugs: Common Adverse Effects

Body System	Adverse Effects
Cardiovascular	Edema, thrombosis
Gastrointestinal	Anorexia, nausea, vomiting, diarrhea
Integumentary	Alopecia, rash
Respiratory	Cough, dyspnea, sore throat
Other	Fever, blood dyscrasias, headache, bone pain

radiation therapy. Dosages of chemotherapy used in bone marrow transplantation are often much higher than those used in conventional chemotherapy. Both chemotherapy and radiation therapy are toxic to the bone marrow. When one or more CSFs are administered as part of the drug therapy for bone marrow transplantation, bone marrow cell counts return to normal in a significantly shortened time. This helps increase the likelihood of successful bone marrow transplantation and therefore patient survival. Specific drug indications are listed in the Dosages table in the right column.

Contraindications

Contraindications for all the hematopoietic drugs include drug allergy. Use of epoetin and darbepoetin is contraindicated in cases of uncontrolled hypertension. The initiation or intensification of antihypertensive therapy may be required during the early phase of treatment, when hemoglobin increases. Use of filgrastim and pegfilgrastim is contraindicated in the presence of more than 10% myeloid blasts (immature tumour cells in the bone marrow), because CSFs may stimulate malignant growth of these myeloid tumour cells.

Adverse Effects

Adverse effects associated with the use of hematopoietic drugs are mild. The most common are fever, muscle aches, bone pain, and flushing. Table 54.1 lists additional adverse effects.

Interactions

Filgrastim has significant drug interactions when given with myelosuppressive antineoplastic drugs. Remember that this drug is administered to enhance the production of bone marrow cells; therefore, when myelosuppressive antineoplastics are given with filgrastim, the drugs directly antagonize each other. Typically, filgrastim is not given within 24 hours of administration of myelosuppressive antineoplastics. However, it is often given soon after this time to help prevent the WBC nadir from reaching a dangerously low level and to speed WBC recovery. It is also recommended that filgrastim be used with caution or not be given with other medications that can potentiate their myeloproliferative (bone marrow–stimulating) effects; two examples of these are lithium carbonate and corticosteroids.

Dosages

For dosage information on hematopoietic drugs, refer to the table in the right column.

DRUG PROFILES

filgrastim

Filgrastim (Neupogen®) is a synthetic analogue of human granulocyte CSF and is commonly referred to as *G-CSF*. Filgrastim promotes the proliferation, differentiation, and activation of the cells that make granulocytes. Granulocytes are the body's primary defence against bacterial and fungal infections. Filgrastim has the same pharmacological effects as those of endogenous human *G-CSF*, which is normally secreted by specialized leukocytes, known as *monocytes*, *macrophages*, and mature *neutrophils*. Filgrastim is indicated to prevent or treat febrile neutropenia in patients receiving myelosuppressive antineoplastics for nonmyeloid (non–bone marrow) malignancies. It must be given *before* a patient develops an infection, but not within 24 hours before or after myelosuppressive chemotherapeutic drugs, because administering it in this way tends to cancel out the therapeutic benefits of the filgrastim. Pegfilgrastim (Neulasta®) is a long-acting form of filgrastim that reduces the number of required injections. Both drugs are available for injection only. These drugs are usually discontinued when a patient's absolute neutrophil count (ANC) rises above $10 \times 10^9/L$. However, some health care providers will stop it when the ANC is between 1 and $2 \times 10^9/L$.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Subcut or IV	1 hr	2–6 hr	3–5 hr	12–24 hr

Dosages

Hematopoietic Drug

Drug	Pharmacological Class	Usual Dosage Range	Indications
filgrastim (Neupogen)	Colony-stimulating factor	IV/Subcut: 5–10 mcg/kg/day	Chemotherapy-induced neutropenia

IV, intravenous; Subcut, subcutaneous.

INTERFERONS

Interferons are proteins that have three basic properties: they are antiviral, antitumour, and immunomodulating. There are three different groups of interferon drugs: the α , β , and γ interferons, each with its own antigenic and biological activities. Interferons are most commonly used in the treatment of certain viral infections and certain types of cancer.

Mechanism of Action and Drug Effects

Interferons are recombinantly manufactured substances that are identical to the interferon cytokines naturally present in the human body. In the body, interferons are produced by activated T cells and by other cells in response to viral infection. Interferons

TABLE 54.2 Interferons: Adverse Effects

Body System	Adverse Effects
General	Flulike syndrome, fatigue
Cardiovascular	Tachycardia, cyanosis, electrocardiogram changes, orthostatic hypotension
Central nervous	Confusion, somnolence, irritability, seizures, hallucinations
Gastrointestinal	Nausea, diarrhea, vomiting, anorexia, taste alterations, dry mouth
Hematological	Neutropenia, thrombocytopenia
Renal and hepatic	Increased blood urea nitrogen and creatinine levels, proteinuria, abnormal liver function test results

protect human cells from attack by viruses by enabling the cells to produce enzymes that stop viral replication and prevent viruses from penetrating into healthy cells. Interferons prevent cancer cells from dividing and replicating and also increase the activity of other cells in the immune system, such as macrophages, neutrophils, and NK cells. Interferons also increase the expression of cancer cell antigens on cell surfaces, which enables the immune system to recognize cancer cells more easily and specifically mark them for destruction.

Overall, interferons have three different effects on the immune system. They can (1) restore its function if it is impaired, (2) augment its ability to function as the body’s defence, and (3) inhibit it from working. This latter function may be particularly useful when the immune system has become dysfunctional, causing an autoimmune disease. This is believed to be the case in multiple sclerosis. Two interferons (interferon beta-1a and interferon beta-1b) are specifically indicated for treatment of multiple sclerosis. Inhibiting the dysfunctional immune system prevents further damage to the body from the disease process.

Indications

The beneficial actions of interferons (antiviral, antineoplastic, and immunomodulatory) make them excellent drugs for the treatment of viral infections, various cancers, and some autoimmune disorders. Currently accepted indications for interferons are listed in the Dosages table on p. 879.

Contraindications

Contraindications to the use of interferons include known drug allergy and may include autoimmune disorders, hepatitis or liver failure, concurrent use of immunosuppressant drugs, AIDS-related Kaposi sarcoma, severe depression, and severe liver disease.

Adverse Effects

The most common adverse effects of interferons can be broadly described as flulike symptoms: fever, chills, headache, malaise, myalgia, and fatigue. The major dose-limiting adverse effect of interferons is fatigue. Patients taking high dosages become so exhausted that they are often confined to bed. Antibodies may bind to interferons and neutralize their biological effects. Other adverse effects of interferons are listed in Table 54.2.

Interactions

Drug interactions are seen with interferon alfa-2b when it is used with drugs that are metabolized in the liver via the cytochrome P450 enzyme system. The combination results in decreased metabolism and increased accumulation of these drugs, which leads to drug toxicity. There is also some evidence that using interferons together with antiviral drugs such as zidovudine enhances the activity of both drugs but may lead to toxic levels of zidovudine. Live attenuated virus vaccines may carry a higher potential risk of infection and complication for patients on immunosuppressant medications. They may also be less effective following periods of immunosuppression and should not be administered for 3 months following treatment with immunosuppressant medications.

Dosages

For dosage information on interferons, refer to the table on p. 879.

DRUG PROFILES

The three major classes of interferons are alfa, beta, and gamma (gamma products are not available in Canada), which are sometimes also written using the lower-case Greek letters α , β , and γ , respectively. The “alfa” designation is synonymous with the Greek letter “alpha,” but the “alfa” spelling is now more commonly used clinically. Interferons vary in their antigenic makeup, biological actions, and pharmacological properties. Alfas comprise the most well-known class of interferons.

Interferon products are BRMs that can be broadly classified as cytokines. Cytokines are immune system proteins that serve two essential functions: they direct the actions of and communication between the cell-mediated and humoral divisions of the immune system, and they augment or enhance the immune response. Other cytokines include tumour necrosis factor (TNF), interleukins, and CSFs.

Interferon Alfa Products

interferon alfa-2b, peginterferon alfa-2a

The most commonly used interferon products are in the interferon alfa class. They are also referred to as leukocyte interferons because they are produced from human leukocytes. One newer type of interferon alfa is peginterferon alfa-2a. The *peg* refers to the attachment of a polymer chain of the hydrocarbon polyethylene glycol (PEG). This “pegylation” process increases the size of the interferon molecule. This increased size delays the drug’s absorption, increases its half-life, and decreases its plasma clearance rate, which prolongs the drug’s therapeutic effects. In addition, pegylation is believed to reduce the immunogenicity of the interferon and thus delay its recognition and destruction by the immune system. Similarly, pegfilgrastim, mentioned previously in this chapter, is a pegylated form of filgrastim and is also longer acting.

Interferon alfa-2a is indicated for use in patients with chronic active hepatitis B or chronic hepatitis C, chronic myelogenous leukemia, multiple myeloma, non-Hodgkin lymphoma, malignant melanoma, AIDS-related Kaposi sarcoma, hairy

Dosages

Currently Available Interferons

Drug	Pharmacological Class	Usual Dosage Range	Indications
interferon alfa-2b (Intron A®)	Immunomodulator, antiviral, antineoplastic	IM/Subcut: 1–30 million units 3×/wk*	Chronic, active hepatitis B, chronic hepatitis C, chronic myelogenous leukemia, multiple myeloma, non-Hodgkin lymphoma, malignant melanoma, AIDS-related Kaposi sarcoma, hairy cell leukemia, basal cell carcinoma, condylomata acuminata
peginterferon alfa-2a (Pegasys®)	Immunomodulator, antiviral	Subcut: 180 mcg weekly for 48 wk	Chronic hepatitis C, chronic hepatitis B, HIV–HCV co-infection
interferon beta-1a (Avonex PEN®, Avonex PS®, Rebif®)	Immunomodulator	IM (Avonex): 30 mcg 1 ×/wk Subcut (Rebif): 22–44 mcg 3 ×/wk	Multiple sclerosis
interferon beta-1b (Betaseron®, Extavia®)	Immunomodulator	Subcut: 0.25 mg every other day	Multiple sclerosis

HCV, hepatitis C virus; IM, intramuscular; PS, prefilled syringe. Subcut, subcutaneous.

*Available through Health Canada's Special Access Programme.

cell leukemia, basal cell carcinoma, or condylomata acuminata. Peginterferon alfa-2a is indicated for use in patients with chronic active hepatitis B or chronic hepatitis C. Peginterferon alfa-2b is available in combination with the protease inhibitor boceprevir (see Chapter 45) and the nucleoside reverse transcriptase inhibitor ribavirin (VICTRELIS Triple®; see Chapter 45) for the treatment of chronic hepatitis C genotype 1 infection with compensated liver disease that has been previously untreated or treated unsuccessfully.

Interferons are indicated for use in patients over the age of 18 and are most commonly given by either intramuscular (IM) or subcutaneous injection, but intravenous (IV) and intraperitoneal routes have been used as well. Interferon alfa-2a is available in a multidose pen, and peginterferon alfa-2a is available in a prefilled syringe, single-use vial, and autoinjector. It is important to note that some interferons are dosed in millions of units. Although it is unacceptable to use the abbreviation MU for “millions of units,” it may be written as such. It is imperative to double-check the dose, because the health care provider's writing of “MU” may be mistaken for “mg” or “mcg.” If there is any question about the dose of any medication, double-check with the health care provider, the pharmacist, or another experienced colleague before administering the medication to the patient. Although this is true for all medications, it is especially so for interferons and other BRMs because of both their potency and their dosage variability.

Interferon Beta Products

interferon beta-1a and beta-1b

Interferon beta-1a and interferon beta-1b are the currently available interferon beta products. They interact with specific cell receptors found on the surfaces of human cells and possess antiviral and immunomodulatory activities. Both are produced by rDNA techniques and are indicated for the treatment of relapsing–remitting multiple sclerosis (to slow the progression of physical disability and decrease frequency of clinical exacerbations). Their only contraindication is drug allergy, including allergy to human albumin. Both drugs are available for injection only.

MONOCLONAL ANTIBODIES

Monoclonal antibodies are quickly becoming standards of therapy in many areas of medicine, including treatment of cancer, rheumatoid arthritis and other inflammatory diseases, and multiple sclerosis, as well as in organ transplantation. In cancer treatment, they have advantages over traditional antineoplastics in that they can specifically target cancer cells and have minimal effects on healthy cells. Monoclonal antibodies block or target an abnormal gene or protein in the cancer cell, alerting the individual's own immune system to attack and destroy the cancer cells. This characteristic reduces many of the adverse effects traditionally associated with antineoplastic drugs. There are several commercially available monoclonal antibodies used to treat cancer and rheumatoid arthritis; those most commonly used are listed in the Dosages table on p. 882. The *mab* suffix in a drug name is usually an abbreviation for “monoclonal antibody.” Muromonab is used in kidney transplantation. Canakinumab (Ilaris®) administered subcutaneously is used for the treatment of active systemic juvenile idiopathic arthritis in patients aged 2 years and older as well as cryopyrin-associated periodic syndromes. Vedolizumab (Entyvio®) is used to treat ulcerative colitis in patients who have had an inadequate response or loss of response or are intolerant to infliximab.

Mechanism of Action, Drug Effects, and Indications

Because these drugs are so diverse, specific information for each appears in the individual drug profiles provided later in this chapter.

Contraindications

The only clear contraindication to the use of monoclonal antibodies reported to date is drug allergy to a specific product. The use of monoclonal antibodies is usually contraindicated in patients with known active infectious processes, because of their immunosuppressive qualities. Although known drug allergy is a contraindication, depending on the urgency of the clinical situation, a monoclonal antibody may be the only viable treatment option for a seriously ill patient. In such situations, allergic

TABLE 54.3 Common Adverse Effects Associated With Specific Monoclonal Antibody Drugs

Drug	Adverse Effects
Adalimumab	Localized inflammatory reaction at the injection site, infectious processes such as upper respiratory tract and urinary tract infections, higher rates of various malignancies
Alemtuzumab	Rash, pruritus, nausea, vomiting, diarrhea, dyspnea, cough, muscle spasms, fever, fatigue, skeletal pain, myelosuppression
Bevacizumab	Deep vein thrombosis, hypertension, diarrhea, abdominal pain, constipation, vomiting, gastrointestinal hemorrhage, leukopenia, asthenia, headache, dizziness, dry skin, proteinuria, hypokalemia, epistaxis, weight loss
Cetuximab	Headache, insomnia, skin rash, conjunctivitis, gastrointestinal discomfort, anemia, leukopenia, dehydration, edema, weight loss, dyspnea, asthenia, back pain, fever
Golimumab	Hypertension, increased liver function tests, infection
Infliximab	Headache, rash, gastrointestinal discomfort, dyspnea, upper and lower respiratory tract infection
Palivizumab	Upper respiratory infection, otitis media, rhinitis, rash, pain, hernia, increased aspartate aminotransferase, pharyngitis
Rituximab	Fever, chills, headache; potentially fatal infusion-related events, including severe bronchospasm, dyspnea, hypoxia, pulmonary infiltrates, adult respiratory distress syndrome, angioedema. Tumour lysis syndrome (see Chapter 52) with acute kidney injury has also been reported; the drug must be stopped immediately and indicated supportive care provided if such a reaction appears imminent
Tocilizumab	Hypertension, rash, diarrhea, dizziness, anaphylaxis, infection, injection site reaction
tositumomab and iodine I-131 tositumomab	Headache, rash, gastrointestinal discomfort, muscle pains, dyspnea, pharyngitis, asthenia, fever, chills, infection
Tofacitinib	Urinary tract infections, hypertension
Trastuzumab	Fever, chills, headache, infection, nausea, vomiting, diarrhea, dizziness, headache, insomnia, rash, gastrointestinal discomfort, edema, dyspnea, rhinitis, asthenia, back pain, fever, chills, infection, cardiotoxicity

symptoms may be controlled with supportive medications such as diphenhydramine hydrochloride and acetaminophen (for fever control). All of the drugs that are TNF antagonists are contraindicated in patients with active tuberculosis or other infections. Infliximab has been shown to worsen severe cases of heart failure and is dosed at no more than 5 mg/kg and only after considering other treatment options for its indications. Use of alemtuzumab is also contraindicated in patients with active systemic infections and immunodeficiency conditions, including AIDS.

Adverse Effects

Many, if not most, patients receiving these potent drugs manifest acute symptoms that are comparable to classic allergy or flulike symptoms, such as fever, dyspnea, and chills. The primary objective is to administer the medication and control such symptoms. Because the mechanisms of action of these drugs work through augmentation or inhibition of the human immune response, they can have a variety of adverse effects—some mild, some severe—that affect several body systems. Drug-specific adverse effects with the highest reported incidence (10 to 50% or more) are listed in [Table 54.3](#). The risk of such adverse effects must be weighed against the severity of the patient's underlying illness. Many of these adverse effects may also be associated with the patient's disease process (e.g., infections) and even with other causes (e.g., headache, depression). This is especially true for the milder effects. The risk of acquiring an infection is a serious adverse effect of all of the BRM agents because they alter the normal immune response.

Interactions

Drug interactions associated with monoclonal antibodies are relatively few, and no major food interactions are listed.

Administration of adalimumab with the antirheumatic drug anakinra (an interleukin) may increase the risk of serious infections secondary to neutropenia. The clearance of natalizumab may be reduced by concurrent administration of interferon beta-1a (both used for multiple sclerosis). Coadministration of anti-TNF drugs (e.g., etanercept, anakinra) with infliximab may also increase the risk of neutropenia and infections. Etanercept is not to be given concurrently with varicella-zoster immunoglobulin (VZIG) because of undesirable drug interactions. However, etanercept may be resumed after completion of VZIG therapy. Bevacizumab is associated with increased risk of severe diarrhea and neutropenia when given concurrently with another drug used to treat colorectal cancer, irinotecan (see [Chapter 52](#)). Paclitaxel (see [Chapter 52](#)) has been shown to reduce the clearance of trastuzumab when the two are administered concurrently to treat breast cancer.

Dosages

For dosage information on the monoclonal antibodies, refer to the table on p. 882.

DRUG PROFILES

All the monoclonal antibodies are synthesized using rDNA technology. Because of the complexities of this technology, these drugs tend to be much more expensive than most other medications, with prices in the hundreds or thousands of dollars per single dose. Most of the monoclonal antibodies are used to treat various forms of cancer. Their advantage is that they offer excellent cell-killing specificity, aimed at cancer cells instead of all body cells. Nonetheless, these drugs are associated with significant adverse effects and, therefore, with risk, which must be weighed against their benefit, using expert clinical judgement.

Severe allergic inflammatory-type infusion reactions can occur; thus patients may be premedicated with acetaminophen or diphenhydramine hydrochloride to reduce the occurrence of such reactions. If reactions do occur, they may be treated with diphenhydramine hydrochloride and other drugs such as epinephrine and corticosteroids. Conventional pharmacokinetic data are not listed for most of these drugs because they do not follow standard pharmacokinetic models, owing to their unique behaviour in the body. It is known, however, that they may remain in cancerous tissues for weeks or months. Their elimination half-life is listed in the following profiles when known.

adalimumab

Adalimumab (Humira®) works through its specificity for human TNF alpha (TNF- α). TNF- α is a naturally occurring cytokine involved in normal inflammatory and immune responses. Adalimumab is indicated for the treatment of moderate to severe rheumatoid arthritis, alone or in combination with methotrexate or other DMARDs. In patients with rheumatoid arthritis, elevated levels of TNF are found in the synovial fluid in the spaces of affected joints. In addition to preventing TNF- α molecules from binding to TNF cell surface receptors—part of the rheumatoid arthritis disease process—adalimumab also modulates the inflammatory biological responses that are induced or regulated by TNF. Adalimumab is also indicated for the treatment of psoriatic arthritis, ankylosing spondylitis, Crohn's disease, ulcerative colitis, and psoriasis. Use of adalimumab is contraindicated in patients with any active infectious process, whether localized or systemic, acute or chronic.

alemtuzumab

Alemtuzumab (MabCampath®) is approved to treat B cell-mediated chronic lymphocytic leukemia. It is classified as a recombinant humanized antibody that is directed against the CD52 glycoprotein that appears on the surfaces of virtually all B and T lymphocytes. Humanization involves the insertion of human DNA sequences during drug production to make the drug better tolerated by human patients. It is used specifically in patients for whom other first-line chemotherapy treatments, including treatment with alkylating drugs and the antimetabolite fludarabine (see [Chapter 52](#)), have failed. Its contraindications are drug allergy, active systemic infection, and documented immunodeficiency conditions such as HIV-positive status. The half-life of alemtuzumab is 10 hours to 30 days. Alemtuzumab (Lemtrada®) is indicated for the management of active relapsing–remitting multiple sclerosis in adult patients who have had an inadequate response to interferon beta or other disease-modifying therapies.

belimumab

Belimumab (Benlysta®) is the first drug approved for the treatment of systemic lupus erythematosus in the past 40 years. It is a B-lymphocyte stimulator–specific inhibitor. Its most common adverse effects include nausea, diarrhea, insomnia, bronchitis, migraine, and pain in the extremities. Its most serious adverse effects include infection (sometimes fatal), anaphylaxis, and depression. It is given via IV infusion.

bevacizumab

Bevacizumab (Avastin®) was approved for the treatment of metastatic colorectal cancer in combination with 5-fluorouracil (see [Chapter 52](#)), non–small cell lung cancer, and malignant glioblastoma. It is unique in that it binds to and inhibits vascular endothelial growth factor, a protein that promotes development of new blood vessels in tumours (as well as in normal body tissues). It has no listed contraindications but may complicate surgical wound healing because of its antivascular effects. The half-life of bevacizumab is 11 to 50 days.

certolizumab pegol

Certolizumab pegol (Cimzia®) is a TNF antagonist. It is used in combination with methotrexate for the treatment of rheumatoid arthritis, alone or in combination with methotrexate for psoriatic arthritis, and for active ankylosing spondylitis. Its most common adverse effects include headache, nausea, upper respiratory infection, hypertension, and infection. A patient medication guide must be dispensed with each prescription, warning patients of potential serious infections and possible lymphoma.

cetuximab

Cetuximab (Erbix®) is approved for the treatment of metastatic colorectal cancer and squamous cell carcinoma of the head and neck. It is a recombinant monoclonal antibody made from both human and murine genetic material and is designed for concurrent use with the second-line antineoplastic drug irinotecan (see [Chapter 52](#)). It binds to epidermal growth factor on the surface of tumour cells, where it hinders cell growth through interference with cell metabolism. Cetuximab is used either in combination with irinotecan or alone in patients who are intolerant of the latter drug. It has no listed contraindications but is known to cause severe infusion reactions in up to 3% of patients receiving it. The half-life of cetuximab is 97 to 114 hours.

golimumab

Golimumab (Simponi®) is a TNF antagonist approved for the treatment of severe rheumatoid arthritis (in combination with methotrexate), psoriatic arthritis, and ankylosing spondylitis. It is also used in adult patients with moderately to severely active ulcerative colitis who have had an inadequate response to or contraindications with other treatments. Its most common adverse effects include hypertension, dizziness, high values on liver function tests, and infection. It is not to be given with other TNF antagonists. Patients taking golimumab must be monitored for infection, as with all TNF antagonists.

infliximab

Infliximab (Inflectra®, Remicade®, Remsima®) was one of the earliest monoclonal antibodies available. It antagonizes TNF- α , similarly to adalimumab. It is approved for the treatment of ankylosing spondylitis, Crohn's disease, and rheumatoid arthritis (in combination with methotrexate). It is contraindicated in patients with severe heart failure (grade III or IV on the New York Heart Association scale) because it may worsen such heart failure. Health Canada has also issued a warning regarding infliximab due to reported cases of fatal tuberculosis and fungal

infections associated with use of this drug. It is recommended that patients be tested for latent tuberculosis before infliximab is administered. The half-life of infliximab is 8 to 9 days.

natalizumab

Natalizumab (Tysabri®) is approved for the treatment of relapsing–remitting multiple sclerosis. It is a humanized monoclonal antibody derived from murine myeloma cells. Natalizumab works by binding to the α_4 subunits of integrins, proteins found on the surfaces of leukocytes (with the exception of neutrophils). These proteins are implicated in the multiple sclerosis disease process, but their exact mechanism has not been documented. However, the drug is known to inhibit the leukocyte adhesion that is mediated by these α_4 protein subunits, also believed to be part of the disease process. Natalizumab has no listed contraindications. Its half-life is 11 days. Natalizumab is associated with multifocal leukoencephalopathy, a rare and serious viral infection of the brain.

palivizumab

Palivizumab (Synagis®) is a passive immunizing agent (humanized monoclonal antibody). It is indicated for the prevention of serious lower respiratory tract disease caused by the highly infectious respiratory syncytial virus in children who are at high risk of developing the disease. The recommended dose of palivizumab administered intramuscularly is 15 mg/kg of body weight. It is administered monthly during peak times (generally November to April).

The first dose should be administered prior to the beginning of the infectious season, with subsequent doses administered monthly during the season. The mean half-life of palivizumab is 20 days.

rituximab

Rituximab (Rituxan®) specifically binds to antigen CD20. This antigen is a protein on the membranes of both normal and malignant B cells found in patients with non-Hodgkin lymphoma. Antigen CD20 is expressed in more than 90% of B-cell non-Hodgkin lymphomas. Once rituximab binds to these B cells, a host immune response causes lysis of the cells. Rituximab has become a standard drug for the treatment of patients with follicular low-grade non-Hodgkin lymphoma for whom previous therapy has failed. It is recommended that patients be premedicated with acetaminophen and diphenhydramine hydrochloride before each infusion of the drug, to reduce its well-known infusion-related adverse effects.

trastuzumab

Trastuzumab (Herceptin®, Kadcyla®) kills tumour cells by mediating antibody-dependent cellular cytotoxicity. It accomplishes this by inhibiting proliferation of human tumour cells that overexpress HER2 protein. The HER2 protein is overexpressed in 25 to 30% of primary malignant breast tumours and has been established as an adverse prognostic factor for early-stage breast cancer. Because of the relatively selective

Dosages

Monoclonal Antibodies

Drug	Pharmacological Class	Usual Dosage Range	Indications
adalimumab (Humira)	Anti-TNF- α monoclonal antibody	<i>Adults only</i> Subcut: 40 mg every other week; may advance to 40 mg weekly if indicated	Moderate to severe rheumatoid arthritis, alone or in combination with methotrexate
alemtuzumab (MabCampath)	Anti-glycoprotein CD52	IV: 3–10 mg daily until maximum dose tolerated, then 30 mg 3×/wk (alternate days) for up to 12 wk	B-cell chronic lymphocytic leukemia
alemtuzumab (Lemtrada)	Anti-glycoprotein CD52	IV: 12 mg daily for 2 treatment courses	Relapsing–remitting multiple sclerosis
belimumab (Benlysta)	B-lymphocyte stimulator–specific inhibitor	IV: 10 mg/kg at 2-wk intervals	Systemic lupus erythematosus
certolizumab pegol (Cimzia)	Anti-TNF	Subcut: 400 mg at 2-wk intervals $\times$ 2, then monthly	Rheumatoid arthritis, psoriatic arthritis, ankylosing spondylitis
bevacizumab (Avastin)	Anti-human vascular endothelial growth factor	IV: 5 mg/kg q14d	Metastatic colorectal cancer
cetuximab (Erbix)	Anti-human epidermal growth factor	IV: 400 mg/m ² loading dose, then 250 mg/m ² weekly	Metastatic colorectal cancer, squamous cell carcinoma of head and neck
infliximab (Remicade)	Anti-TNF	<i>Adults</i> IV: 3–5 mg/kg at 0, 2, and 6 wk, then every 6 wk	Ankylosing spondylitis, Crohn's disease, rheumatoid arthritis, ulcerative colitis, psoriatic arthritis
natalizumab (Tysabri)	Anti- α_4 integrin subunit	IV: 300 mg every 4 wk	Multiple sclerosis
 rituximab (Rituxan)	Anti-CD20 surface antigen	IV: 375 mg/m ² 1×/wk $\times$ 4 doses IV: 1 000 mg, 2 wk apart; SC: 1400 mg q1-3 wk as per protocol	Non-Hodgkin lymphoma Rheumatoid arthritis
trastuzumab (Herceptin)	Anti-HER2 protein monoclonal antibody	IV: Loading dose, 4–8 mg/kg IV: Maintenance dose, 2 mg/kg/wk	Breast cancer

IV, intravenous; Subcut, subcutaneous; TNF, tumour necrosis factor.

expression of HER2 on cancer cells, it has been an appealing target for antineoplastic therapy. The combination of trastuzumab and paclitaxel (Perjeta®/Herceptin) has produced encouraging results. Ventricular dysfunction and heart failure have been associated with trastuzumab. It is important to monitor for signs and symptoms of heart failure and ventricular dysfunction before and during treatment. In addition, fatal hypersensitivity reactions, infusion reactions, and pulmonary events have occurred in association with its use; therefore, careful clinical judgement, risk evaluation, and informed patient consent are called for in its use. The half-life of trastuzumab is 10 to 30 days.

INTERLEUKINS AND RELATED DRUGS

Interleukins are a natural part of the immune system and are classified as lymphokines. Lymphokines are soluble proteins that are released from activated lymphocytes such as natural killer cells. There are several known interleukins in the body (e.g., IL-1, IL-2, IL-3, IL-4, IL-5, IL-6, etc.). Currently, 36 interleukins have been identified. The pharmaceutical interleukin receptor agonists currently available are aldesleukin, tocilizumab (IL-6), and anakinra.

Mechanism of Action and Drug Effects

Interleukins cause multiple effects in the immune system, one of which is antitumour action. IL-2 is produced by activated T cells in response to macrophage-processed antigens and secreted interleukin (IL-1). It was formerly called *T-cell growth factor* because, among other actions, it aids in the growth and differentiation of T lymphocytes. The IL-2 derivative aldesleukin acts indirectly to stimulate or restore immune response. Aldesleukin binds to receptor sites on T cells, which stimulates the T cells to multiply. One type of cell that results from this multiplication is **lymphokine-activated killer (LAK) cells**. LAK cells recognize and destroy only cancer cells and ignore normal cells. Aldesleukin is currently the most widely used of the interleukin drugs. A detailed list of aldesleukin's specific immunomodulating effects appears in [Box 54.2](#).

Anakinra is a recombinant form of the natural human IL-1 receptor antagonist. It competitively inhibits the binding of IL-1

to its corresponding receptor sites, which are expressed in many different tissues and organs. Tocilizumab is a recombinant form of the natural IL-6 receptor antagonist.

Indications

Aldesleukin was previously indicated solely for metastatic kidney cell carcinoma, a malignancy that originates in the kidney tissues. It is now also approved for the treatment of metastatic malignant melanoma. Anakinra and tocilizumab are indicated for symptom control in patients with rheumatoid arthritis for whom other therapy has failed.

Contraindications

Contraindications to the administration of aldesleukin include drug allergy, organ transplantation, and abnormal results on thallium heart stress tests or pulmonary function tests. For anakinra and tocilizumab, the only usual contraindication is drug allergy.

Adverse Effects

Therapy with aldesleukin is commonly complicated by severe toxicity. A syndrome known as *capillary leak syndrome* is responsible for the severe toxicities of aldesleukin. As the name implies, capillary leak syndrome refers to a condition in which capillaries lose their ability to retain vital colloids, such as albumin and other essential components of blood vessels. Because the capillaries become “leaky,” these substances migrate into surrounding tissues. This results in massive fluid retention (10 to 15 kg), which can lead to the life-threatening problems of respiratory distress, heart failure, dysrhythmias, and myocardial infarction. Fortunately, these effects are all reversible after discontinuation of the interleukin therapy. Close patient monitoring and vigorous supportive care are essential for patients receiving aldesleukin therapy. Other adverse effects that may be associated with aldesleukin are fever, chills, rash, fatigue, hepatotoxicity, myalgia, headache, and eosinophilia.

Anakinra has a much milder adverse effect profile than that of aldesleukin; it includes local reactions at the injection site, various respiratory tract infections, and headache. Tocilizumab has a high risk of causing anaphylaxis.

Interactions

Aldesleukin, when given with antihypertensives, can produce additive hypotensive effects. Coadministration of corticosteroids with aldesleukin can reduce its antitumour effectiveness and is to be avoided. Anakinra and tocilizumab are not to be used (or need to be used cautiously) with other immune modifiers because of the resultant increased risk of serious infections.

Dosages

For dosage information on the interleukin agonists and antagonists, refer to the table on p. 884.

BOX 54.2 Interleukin-2 (aldesleukin): Drug Effects

Modulating Effects

- Proliferation of T cells
- Synthesis and secretion of cytokines
- Increased production of B cells (antibodies)
- Proliferation and activation of natural killer cells
- Proliferation and activation of lymphokine-activated killer cells

Enhancing Effects

- Enhancement of killer T-cell activity
- Amplification of the effects of cytokines
- Enhancement of the cytotoxic actions of natural killer cells and lymphokine-activated killer cells

DRUG PROFILES

The interleukins are a group of naturally occurring cytokines in the body that were originally believed to be produced by and

Dosages

Interleukins and Related Drugs

Drug	Pharmacological Class	Usual Dosage Range	Indications
aldesleukin (IL-2) (Proleukin)	Human recombinant IL-2 analogue	IV: 600 000 units/kg (0.037 mg/kg) q8h × 14 doses; rest for 9 days, repeat × 14 doses	Metastatic kidney cell carcinoma, metastatic malignant melanoma
anakinra (Kineret)	IL-1 receptor antagonist	Subcut: 100 mg/day	Rheumatoid arthritis
tocilizumab (Actemra)	IL-6 antagonist	IV: 4–8 mg/kg monthly	Rheumatoid arthritis

IV, intravenous; Subcut, subcutaneous.

TABLE 54.4 Miscellaneous Immunomodulating Drugs

Drug (Trade and Other Names)	Classification	Indications	Mechanism of Action
abatacept (Orencia)	Selective co-stimulation modulator	Rheumatoid arthritis	Inhibits T-cell activation
BCG vaccine (Immucyst®, Onco-TICE®)	Live virus vaccine, adjuvant	Localized bladder cancer	Promotes local inflammation and immune response in bladder mucosa
etanercept (Enbrel)	Tumour necrosis factor receptor antagonist	Rheumatoid arthritis (including juvenile), active ankylosing spondylitis, plaque and psoriatic arthritis	Blocks effects of tumour necrosis factor, a major inflammatory mediator
leflunomide (Arava)	Antimetabolite	Rheumatoid arthritis	Exerts anti-inflammatory effects via inhibition of cellular DNA synthesis
mitoxantrone hydrochloride	Anthracycline antibiotic (also an antineoplastic drug)	Metastatic breast cancer, relapsed leukemia	Inhibits cellular RNA and DNA synthesis and alters chromosome structure
thalidomide (Thalomid®)	Immunostimulant	Multiple myeloma	Exact mechanism unclear, but may have anti-tumour necrosis factor properties, which counter the disease process
Tretinoin* (Retin-A®, Vescanoid®)	Retinoid receptor agonist	Acute promyelocytic leukemia	Induces differentiation and maturation of leukemic cells, reducing proliferation of immature, disease-causing cells

BCG, bacille Camille-Guérin; DNA, deoxyribonucleic acid; RNA, ribonucleic acid.

*Available through Health Canada's Special Access Programme.

act primarily on WBCs. They are now recognized as multifunctional cytokines that are produced by a variety of cells but act at least partly within the lymphatic system.

aldesleukin

Aldesleukin (Proleukin®) is a human IL-2 derivative that is manufactured using rDNA technology. It is a cytokine that is produced by lymphocytes and is therefore classified as a lymphokine. Aldesleukin is currently approved only for the treatment of metastatic kidney cell carcinoma and metastatic melanoma, despite its activity against other cancers. Aldesleukin is contraindicated in patients with known drug allergy, abnormal thallium stress tests or pulmonary function tests (because of potential drug effects on cardiopulmonary function), and organ transplant (because of the immunostimulating qualities of the drug, which may cause organ rejection). It is available only for injection.

anakinra

Anakinra (Kineret®) is an IL-1 receptor antagonist that is used to control the symptoms of rheumatoid arthritis. Its only current contraindication is known drug allergy. It is available for injection only.

tocilizumab

Tocilizumab (Actemra®) is an IL-6 antagonist approved for the treatment of severe rheumatoid arthritis. It is approved for patients who have not had an adequate response to other medications. It carries a significant risk of anaphylaxis, and premedication must be given. A medication guide must be given to all patients receiving tocilizumab. Its serious adverse effects include hepatotoxicity, infections, herpes zoster reactivation, and gastrointestinal (GI) perforation. Tocilizumab is not to be given with other BRM agents. It is given as an IV infusion.

MISCELLANEOUS IMMUNOMODULATING DRUGS

In addition to the drugs in the major classes discussed thus far, there are several additional medications that can be broadly classified as miscellaneous IMDs. They work by means of various specific and nonspecific mechanisms. A special term used for **immunostimulant** drugs that work by a nonspecific mechanism is **adjuvant**. These miscellaneous medications, including some that are classified as adjuvants, are outlined in Table 54.4.

Fig. 54.3 Areas of the body affected by rheumatoid arthritis. Rheumatoid arthritis is most frequently seen in the shoulders, elbows, wrists, knees, and ankles, and it often affects the joints on both sides of the body equally.

RHEUMATOID ARTHRITIS

Rheumatism is a general term for any of several disorders characterized by inflammation, degeneration, or metabolic derangement of connective tissue structures, especially joints and related structures such as muscles, tendons, bursae, fibrous tissue, and ligaments. Rheumatoid **arthritis** is a chronic **autoimmune disorder** that commonly causes inflammation and tissue damage in joints. It can also cause anemia and diffuse inflammation in the lungs, eyes, and pericardium of the heart, as well as subcutaneous nodules under the skin (Figure 54.3). It is a painful and often disabling disease. It is diagnosed primarily on the basis of symptoms and the results of a blood test for rheumatoid factor, C-reactive protein (CRP), or erythrocyte sedimentation rate (ESR) and antinuclear antibody (ANA). Symptoms include pain, stiffness, and reduced range of motion. Treatment encompasses both pharmacological and nonpharmacological modalities, including physiotherapy and occupational therapy. There is no known cure for rheumatoid arthritis, and the goal of therapy is to alleviate current symptoms and to prevent further damage of the joints. Rheumatoid arthritis affects approximately 1 in 100 Canadians, or approximately 300 000 people in Canada (Arthritis Society, 2017) and usually appears between the ages of 25 and 50. Women are two to three times more likely than men to have rheumatoid arthritis. Smokers and those with a family history are also at risk.

Early diagnosis and treatment of rheumatoid arthritis can prevent joint damage and make remission easier to achieve. Because rheumatoid arthritis is a disease characterized by inflammation, the nonsteroidal anti-inflammatory drugs (NSAIDs) are the most commonly used drugs (see Chapter 49). Full dosages of NSAIDs are tried in the early stages of rheumatoid arthritis. Corticosteroids, also potent anti-inflammatory drugs (see Chapter 34), are also used to prevent inflammatory symptoms. Although these drugs are effective in reducing inflammation, they do not actually affect the disease itself.

BOX 54.3 Disease-Modifying Antirheumatic Drugs

abatacept
adalimumab
anakinra
certolizumab
etanercept
golimumab
hydroxychloroquine sulphate
infliximab
leflunomide
methotrexate
rituximab
sulfasalazine
tocilizumab
tofacitinib citrate

DMARDs not only provide anti-inflammatory and analgesic effects but can also arrest or slow the disease processes associated with rheumatoid arthritis. Initiation of DMARDs in the first 6 months following diagnosis can reverse loss of function in 80% of patients and induce remission in 42 to 48% of patients.

DISEASE-MODIFYING ANTIRHEUMATIC ARTHRITIS DRUGS

DMARDs are drugs that modify the disease of rheumatoid arthritis. They exhibit anti-inflammatory, antiarthritic, and immunomodulating effects and work by inhibiting the movement of various cells into an inflamed, damaged area, such as a joint. These cells (neutrophils, monocytes, and macrophages) are responsible for causing many of the deleterious effects of chronic rheumatoid arthritis. By preventing the accumulation of these inflammatory cells in the area of the diseased joint, antiarthritic drugs prevent progression of the disease. DMARDs often have a slow onset of action of several weeks, in contrast to minutes to hours for NSAIDs. For this reason, DMARDs are sometimes also referred to as *slow-acting antirheumatic drugs* (SAARDs). They were previously thought of as second-line drugs for the treatment of arthritis because they can have much more toxic adverse effects than those of the NSAIDs. However, the Canadian Rheumatology Association recommends the use of the combination of two DMARDs as first-line therapy in many patients (Bykerk, Akhavan, Hazlewood, et al., 2012). Its guidelines differentiate the two categories of DMARDs—nonbiological, or conventional, and biological. Nonbiological DMARDs include methotrexate, leflunomide, hydroxychloroquine sulphate, sodium aurothiomate, cyclosporine, azathioprine, and sulfasalazine. The guidelines recommend starting with methotrexate alone or with another DMARD in most patients. Use of other drugs, including the biological DMARDs, is generally reserved for those patients who do not respond to methotrexate or combination DMARDs. The biological DMARDs include adalimumab, anakinra, certolizumab, etanercept, golimumab, infliximab, adalimumab, abatacept, rituximab, tocilizumab, and tofacitinib. Box 54.3 lists the DMARDs. Etanercept and abatacept are discussed in this section; the others were discussed in the section on monoclonal antibodies.

Mechanism of Action, Indications, and Adverse Effects

The mechanisms of action and adverse effects of the different DMARDs vary. The individual drug profiles provide information on mechanisms of action and adverse effects. All of these drugs are indicated for the treatment of rheumatoid arthritis, and some have other uses, as previously mentioned.

Contraindications

DMARDs are not to be used in patients with active bacterial infection, active herpes zoster, active or latent tuberculosis, or acute or chronic hepatitis B or C. Etanercept, infliximab, and adalimumab are not to be used in patients with heart failure, lymphoma, or multiple sclerosis. Methotrexate, tofacitinib, and leflunomide are to be avoided during pregnancy and lactation. Tofacitinib (Xeljanz®) causes a decrease in heart rate and a prolongation of the PR interval and should not be used in individuals with heart failure, ischemic heart disease, heart block, or dysrhythmias.

DRUG PROFILES

abatacept

Abatacept (Orencia®) is a selective co-stimulation modulator; it inhibits T-cell activation. Abatacept is indicated for the treatment of rheumatoid arthritis. It is contraindicated in patients with a known hypersensitivity to it or any of its components. It should be used with caution in patients with a history of recurrent infections or chronic obstructive pulmonary disease. Its adverse effects include headaches, upper respiratory tract infections, and hypertension. Abatacept may increase the risk of infections associated with live vaccines and may decrease the response to dead or live vaccines; thus patients need to have received all immunizations prior to starting abatacept therapy. Abatacept is not to be given with anakinra or TNF-blocking drugs because of the resultant risk of serious infections, or with the herb echinacea, which has immunostimulant properties. Abatacept is dosed according to body weight and is given at 4-week intervals. It is administered intravenously, and a filter must be used. Its half-life is 8 to 25 days. The recommended dosage is 50 mg subcutaneously, weekly.

etanercept

Etanercept (Enbrel®) is an rDNA-derived TNF-blocking drug. It binds to TNF and blocks its interaction with cell surface receptors. It is indicated for the treatment of rheumatoid arthritis (including juvenile rheumatoid arthritis) and moderate to severe chronic plaque psoriasis. It is contraindicated in patients with a known hypersensitivity to it and in those with sepsis or active infections (including chronic or local infections). It should be used with caution in patients with pre-existing demyelinating central nervous system (CNS) disorders, heart failure, or significant hematological abnormalities. Some dosage forms may contain latex, so patients need to be screened for latex allergy. It has been reported to cause reactivation of hepatitis

and tuberculosis. Live vaccines should not be given with etanercept. Common adverse effects include headache, reaction at the injection site, upper respiratory tract infection, dizziness, and weakness. The drug is administered subcutaneously. Drugs with which it interacts include anakinra, which may increase the risk of infection, and cyclophosphamide, which may increase the risk of malignancy. Etanercept has not been shown to be a risk to the fetus if used during pregnancy. It is not known if the drug is excreted in breast milk, and its use is not recommended in lactating women. Its onset of action is 1 to 2 weeks, and its half-life is 72 to 132 hours.

leflunomide

Leflunomide (Arava®) is indicated for the treatment of active rheumatoid arthritis. It modulates or alters the response of the immune system to rheumatoid arthritis. It has antiproliferative, anti-inflammatory, and immunosuppressive activity. Its most common adverse effects are diarrhea, respiratory tract infection, alopecia, elevated liver enzyme levels, and rash. It is contraindicated in women who are or may become pregnant and is not to be used by nursing mothers or those with a hypersensitivity to it. Aspirin, other NSAIDs, or low-dose corticosteroids may be continued during leflunomide therapy. Leflunomide is available only for oral use. Its half-life is 14 to 15 days. Because of its long half-life, a loading dose of 100 mg per day is given for 3 days, followed by a maintenance dose of 20 mg per day.

methotrexate

Methotrexate is an anticancer drug that is commonly used for the treatment of rheumatoid arthritis in much lower dosages than those used for cancer. It is usually started at a dosage of 7.5 mg per week but can be increased to 20 mg per week. It is important to note that the drug is given once per week, not once per day. Serious medication errors, including deaths, have occurred when an order is mistranscribed and the drug is given daily instead of once a week. It is usually given orally for rheumatoid arthritis, but it can also be given by injection. Bone marrow suppression is the main adverse effect of methotrexate. Most patients are advised to take supplemental folic acid to lessen the likelihood of adverse effects. The onset of antirheumatic action is 3 to 6 weeks. The half-life of the drug is 3 to 10 hours.

tofacitinib

Tofacitinib, another immunomodulatory drug used in the management of rheumatoid arthritis, is recommended to be used in combination with methotrexate in adult patients with moderately to severely active rheumatoid arthritis who have not responded adequately to methotrexate. Tofacitinib is thought to interfere with the activity of a specific enzyme (Janus kinase), which activates other cellular components that initiate the immune response. If methotrexate is not tolerated by a patient, tofacitinib may be used alone. The recommended dosage is 5 mg administered twice daily in combination with methotrexate. Follow institutional policies for special handling of methotrexate as well as for administration to patients.

❖ NURSING PROCESS

◆ ASSESSMENT

Prior to the administration of hematopoietic drugs, assess the medication order thoroughly, as well as the specific indication for each of the drugs prescribed. With knowledge of the indication, specific laboratory value(s) may be easily determined for further assessment (e.g., WBC counts with filgrastim). After initial assessment and monitoring of baseline blood counts, measure drug response against these values. Additionally, prior to administering these medications, document baseline assessment of the following: vital signs, skin turgor and intactness, bowel sounds and patterns, and breath sounds. Assess also for any reports of pain and rate it accordingly (see discussion in [Chapter 11](#)). These areas are all important to assess when giving hematopoietic drugs because of the adverse effects of edema, nausea, vomiting, diarrhea, rash, cough, dyspnea, sore throat, fever, blood dyscrasias, headache, and bone pain. Assess potential IV and subcutaneous sites and, if appropriate, note chemotherapy-induced absolute neutrophil nadir (low point); this is important because timing of the dose is crucial to boosting blood cell counts. For example, with filgrastim, do *not* give the drug within 24 hours before or after chemotherapy. Also assess for any existing joint or bone pain because of the possible adverse effect of mild to severe bone pain with filgrastim. Specific information regarding assessment associated with use of epoetin alfa is found in [Chapter 55](#).

Before administering any of the BRMs (and other drugs included in this chapter), assess your own knowledge about these medications, with attention to the drug's action, pharmacokinetic properties, associated cautions, contraindications, drug interactions, adverse effects, and toxicities. Assess patients for the presence of any conditions that represent contraindications or cautions to drug administration as well as for use of possible interacting drugs. Assess for hypersensitivity to the drug, egg proteins, or immunoglobulin G. Furthermore, assess the following systems: (1) respiratory system, with attention to breath rate, rhythm, and depth as well as breath sounds, listening for any adventitious (abnormal) sounds; (2) cardiac system, with attention to vital signs, heart sounds, heart rate and rhythm, and oxygen saturation levels, as well as for edema or shortness of breath, presence of cyanotic discoloration around the mouth (circumoral cyanosis) or nail beds, and any chest pain; (3) CNS, with a focus on baseline mental status, as well as for any seizure-like activity or CNS abnormalities; and (4) immune system, noting ability to fight off infections and any history of chronic illnesses or suppressed immunity. Note the patient's nutritional status, height, and weight as well as results of any prescribed laboratory tests, such as complete blood count (CBC) and especially hemoglobin and hematocrit levels, serum protein and albumin levels, and immunoglobulin levels (see Nursing Process in Chapters 52 and 53). Also document the presence or absence of underlying diseases or symptoms and the success or failure of medication regimens in the past. Assess patients' ability to carry out activities of daily living (ADLs), emotional and socioeconomic status, educational level, learning needs, desire and ability to learn,

past coping strategies, and support systems. Before interferons (e.g., alfa-2b) are given, assess patients' history of drug allergies as well as any history of autoimmune disorders, hepatitis, liver failure, or AIDS. Contraindications to interferons include concurrent use of immunosuppressant drugs and Kaposi sarcoma. Determine baseline WBC and platelets counts prior to initiation of therapy because of the potential for drug-induced neutropenia and thrombocytopenia. Monitor other serum laboratory values such as blood urea nitrogen (BUN), creatinine, glomerular filtration rate (GFR), alkaline phosphatase (ALP), and aspartate transaminase (AST) before and during therapy due to the risk of problems with kidney and liver functioning. Document baseline neurological functioning, bowel status, heart sounds, pulse rate, and blood pressure (including postural readings). Significant drug interactions for which to assess include those drugs that are metabolized via the cytochrome P450 enzyme system in the liver because of the risk of subsequent drug toxicity.

With use of monoclonal antibody drugs (e.g., alemtuzumab, rituximab, trastuzumab), assess and document any history of allergic reactions. Assess for ranges of responses with these medications, including mild to severe reactions (see [Table 54.3](#)). Assessment of baseline vital signs and any signs of infection are important because of the risk of acquiring an infection when taking these drugs. Contraindications to their use include any active infectious process or HIV. There is a Health Canada warning that fatal tuberculosis or fungal infections have been associated with the use of infliximab (Remicade), so any infectious process needs to be ruled out prior to its use. Trastuzumab also has a warning associated with it due to cases of ventricular dysfunction and heart failure. Fatal hypersensitivity and infusion reactions have occurred with this drug, so prior to drug administration the health care provider needs to conduct a careful risk evaluation and provide subsequent, prudent clinical decision-making. Closely monitor the patient before, during, and after the infusion of monoclonal antibody drugs. [Table 54.3](#) provides a list of common adverse effects associated with these drugs, indicating further areas and systems to be assessed.

Prior to the use of DMARDs, perform a thorough assessment for any past or present medical conditions as well as for allergies. Compile a complete and thorough medication profile, listing prescription drugs, natural health products, and over-the-counter drugs. Assess the specific type of DMARD prescribed because there are nonbiological and biological DMARDs. Assess for contraindications to the use of DMARDs, such as active bacterial infections, active herpes, active or latent tuberculosis, and acute or chronic hepatitis B or C. Additional contraindications are presented in the earlier discussion. Because bone marrow suppression is one of the main adverse effects of DMARDs, including methotrexate, assess and monitor baseline RBC, WBC, and platelet counts before, during, and after therapy. Another important area for assessment is the medication order by the health care provider, because serious medication errors have occurred when the order for this drug has been transcribed incorrectly and the drug has been given daily instead of once weekly, as recommended.

Before initiation of therapy with leflunomide, perform a complete assessment of liver functioning and obtain baseline blood cell counts. Because of the possible adverse effects of diarrhea and respiratory infections, assess respiratory and GI functioning. A thorough respiratory assessment includes obtaining a history of past and present respiratory disorders and infections as well as noting breath sounds, any presence of sputum, and baseline respiratory rate, rhythm, and depth. Assess bowel patterns and document findings. Etanercept is to be avoided in those with sepsis and active infections, so conduct a thorough assessment of WBC counts and of any signs, symptoms, or history of infection. Because some dosage forms may contain latex, it is crucial to also assess for latex allergy. The DMARD abatacept is given based on weight; thus, an accurate weight needs to be taken before initiation of drug therapy. Additionally, assess the patient's immunization record; all immunizations must be current prior to beginning therapy with abatacept. Document the findings of baseline head-to-toe physical assessment, and note any musculoskeletal changes due to the pathology of arthritis and related changes in performance of ADLs before drug therapy is initiated, as well as throughout the therapeutic regimen.

◆ NURSING DIAGNOSES

- Potential risk for infection as a result of adverse effect of bone marrow suppression related to DMARDs and IMDs
- Inadequate nutrition, less than body requirements, as a result of the adverse effects of BRMs
- Potential risk for impaired skin integrity (rash) as a result of the adverse effects of BRMs

◆ PLANNING

◆ Goals

- Patient will remain free from infection or have minimal risk for infection during drug therapy.
- Patient's nutritional status will return to as near normal as possible after initiation of drug therapy.
- Patient's skin and mucous membranes will remain intact.

◆ Expected Patient Outcomes

- Patient states ways to minimize risk of infection, such as through maintaining proper nutrition and adequate fluid intake, as well as identifying early signs and symptoms of infection.
 - Patient understands needed dietary adjustments (e.g., increase in protein) and uses Canada's Food Guide and advice from consultation with a dietitian to meet additional nutritional demands, thus preventing malnourishment and boosting nutritional status.
 - Patient knows to take their temperature orally or via the axillary route every 4 hours during periods of increased risk of infection.
 - Patient states need to report temperature of 38.1°C or higher to the health care provider for appropriate and immediate treatment.

- Patient describes nutritional needs and daily meal planning reflecting dietary needs, such as consumption of a high-calorie, low-residue, high-protein diet, including high-energy foods with protein and complex carbohydrates, and increased intake of fluids.
 - Patient performs a 24-hour recall of food intake and can report a typical week's menus.
 - Patient understands the importance of consuming small, frequent meals in an environment conducive to eating.
 - Patient states measures to minimize GI adverse effects, such as eating small, frequent meals and avoiding spicy foods, and uses antiemetics as prescribed.
 - Patient understands the importance of energy conservation and takes frequent rests before and after meals while undergoing treatment.
- Patient's skin and mucous membranes remain intact and clean due to daily bathing, proper skin care with moisturizing products, and daily oral hygiene with gentle flossing as well as follow-up care with a dental professional.
 - Patient reports any breaks in skin, redness, irritation, areas of swelling, drainage, or pain to the health care provider.
 - Patient contacts a health care provider or dental professional with any concerns regarding poor dentition, sores in the mouth, bleeding in the mouth, or swelling of gums.

CASE STUDY

Hematopoietic Biological Response Modifiers

Pavel, a 38-year-old surveyor, is receiving a second round of chemotherapy as part of treatment for non-Hodgkin lymphoma. The oncologist is monitoring for signs of bone marrow suppression affecting the various blood cell components.

1. What symptoms would the nurse expect to see if Pavel had diminished production of platelets?

White blood cells? Explain your answers.

2. Explain the purpose of an order for filgrastim for Pavel. The nurse will need to assess him for what conditions before beginning the filgrastim?

3. The nurse notices a woman with a baby about to enter Pavel's room. The baby is fussy, and the woman wipes the baby's nose after a sneeze. What does the nurse need to do at this time?

4. Pavel asks the nurse, "When can I stop having these injections? I hate having to have another shot!" What is the best answer to his question?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

◆ IMPLEMENTATION

Administer BRMs exactly as prescribed and in keeping with manufacturer guidelines to minimize adverse effects. It is important to acknowledge that infection is a serious adverse effect of these drugs, so this risk must always be weighed against the severity of the patient's underlying illness. Patients, especially those with a low neutrophil nadir, may be placed on reverse isolation. Appropriate cytotoxic precautions will be implemented by health care providers when handling and administering drugs. Measure vital signs with special

attention to temperature. Premedication with acetaminophen and diphenhydramine hydrochloride to help minimize any allergic type of reaction may be necessary when administering any of the BRMs. With some of the BRMs, treatment with opioids, antihistamines, or anti-inflammatory drugs may be required for the management of bone pain and chills if treatment with acetaminophen or diphenhydramine hydrochloride is not successful. Antiemetics may also be needed for any drug-related nausea or vomiting and may be administered prior to the administration of the BRM. Antiemetics may need to be dosed around the clock if nausea and vomiting are problematic. Encourage patients to rest when tired, not to overexert themselves, and to contact a health care provider if they experience profound fatigue or loss of appetite. Encourage patients to drink fluids, up to 2 to 3 litres per day (unless contraindicated), in order to promote excretion of the by-products of cellular breakdown and maintain cellular hydration. Consultation with a registered dietitian may help patients learn about a nourishing diet to promote health and wellness (e.g., ensuring intake of foods high in protein and complex carbohydrates, as well as necessary minerals, vitamins, and natural health products). Discuss menu planning and grocery shopping and give specific individualized suggestions. Many grocery stores support online food shopping with pickup at the store on the same day or provide home delivery options at no or minimal cost. Inform patients of community resources (e.g., Meals on Wheels, respite care organizations) as deemed appropriate and as needed.

With hematopoietic drugs, it is important to administer the drug as ordered. Determine and rotate subcutaneous and IV sites as specified by facility policy. With filgrastim, administer the drug before a patient receiving myelosuppressive chemotherapy develops an infection, but not within 24 hours before or after a myelosuppressive chemotherapy drug is given. Once a patient's ANC reaches $1 \times 10^9/L$, discontinue the drug, as ordered and as recommended by the manufacturer. Give filgrastim and use 5% dextrose in water to dilute the product. When drugs are given subcutaneously, rotate the injection sites. See the Patient Teaching Tips for more information.

When interferons are to be given, be sure to first read the order for correct spelling and be careful not to confuse the drug with any other sound-alike, look-alike drugs. Administer interferons parenterally by either the subcutaneous, IV, or IM route, depending on the drug. For example, interferon alfa-2b is given subcutaneously, intramuscularly, or subcutaneously. Be sure to rotate sites and use accurate technique (see [Chapter 10](#)). When there are concerns regarding infection, as occurs with many of the BRMs, monitor the patient's vital signs with attention to temperature and also for the occurrence of chills and headache. Electrocardiograms (ECGs) are generally prescribed before and during treatment, so monitor the results and report any chest pain, hypotension, hypertension, or dyspnea. Make sure to always check each brand of medication for dilution directions,

as each brand has different directions. Read the package insert prior to giving any interferon. Acetaminophen may be prescribed to help with fever and headache. Encourage patients to increase their intake of fluids.

With the use of monoclonal antibodies, serious infections are a major concern, especially with belimumab, with which infection may sometimes be fatal. Constantly monitor for infection during therapy. Certolizumab, which is used for severe rheumatoid arthritis, is also associated with the risk of serious infections and possible lymphoma, which needs to be explained to patients. Continue to monitor blood counts during and after therapy with these drugs. Monitor patients for changes in blood pressure and pulse rate and for chest pain. Contact the health care provider immediately if there are significant changes in baseline parameters. Avoid use of infliximab in patients with severe heart failure. When giving this drug, it is important to monitor the patient for heart sounds, blood pressure, pulse rate, pulse oximetry reading, and ECG readings. If there are signs and symptoms of infection or changes in cardiac status, contact the health care provider immediately.

With the biological DMARD methotrexate, a test dose is usually administered to see how the patient reacts to the medication. Be aware of the warning concerning cautious administration of this drug in those with kidney disease, infection, pulmonary disease, and stomatitis. Be sure that if methotrexate is ordered for rheumatoid arthritis, it is administered weekly as ordered. For more information on methotrexate, see [Chapter 52](#). Give etanercept (yet another drug with specific warnings; see the previous discussion) subcutaneously into the thigh, abdomen, or upper arm, rotating injection sites. Give leflunomide cautiously while monitoring liver and kidney functioning; administer it orally with meals or food to minimize GI upset. Monitor daily weights because of possible edema.

◆ EVALUATION

Therapeutic responses to BRMs include a variety of responses, such as a decrease in the growth of a lesion or mass, decreased tumour size, and an easing of symptoms related to a tumour or disease process. Other therapeutic responses are an improvement in WBC and platelet counts or a return of blood counts to normal levels, and absence of infection and hemorrhage. Encourage the patient to keep a journal, as this may provide health care providers with more data from which to evaluate the patient's responses during and after therapy. Possible adverse effects for which to evaluate are presented in [Tables 54.1, 54.2, and 54.3](#). DMARDs are expected to have therapeutic results within a documented time frame (often weeks), with the patient experiencing increased ability to move joints, less discomfort, and an overall increased sense of improvement and well-being. Toxicity of these drugs may be manifested by liver, renal, and respiratory dysfunction and, for methotrexate, bone marrow suppression.

PATIENT TEACHING TIPS

- Advise patients to avoid doing hazardous tasks because of the CNS changes noted with several BRMs. Fatigue is also a common adverse effect; instruct patients to report excessive fatigue.
- Instruct patients to report to the health care provider immediately any signs of infection, such as sore throat, diarrhea, vomiting, or fever of 38.1°C or higher. Advise patients also to report excessive fatigue, loss of appetite, edema, or bleeding.
- Pregnancy is discouraged while patients are taking a BRM. Educate patients of childbearing age about contraceptive choices and the need to use contraception for up to 2 years after completion of therapy.
- Inform patients that adverse effects associated with BRMs usually disappear within 72 to 96 hours after therapy is discontinued.
- Interleukins may be self-administered; therefore, teach patients self-injection techniques and proper disposal of equipment (e.g., needles, syringes). Provide patients with

corresponding written instructions. Encourage patients to keep a daily journal to record the site of injection and an overall rating of how they feel.

- Educate patients that bone pain and flulike symptoms often occur with some of the BRMs, and the use of nonopioid or, in some cases, opioid analgesics may be required. Some patients may find relief with acetaminophen or ibuprofen.
- With the use of DMARDs, patients will experience improved joint function and decreased pain. Encourage patients to report any bleeding, excess fatigue, fever, or respiratory symptoms to the health care provider.
- Educate patients about the cost of medication and possible disbursement, which varies from province to province for treatment of multiple sclerosis. Disease-modifying therapies vary and may range from \$20 000 to \$40 000 per year ([Multiple Sclerosis, 2020](#)). Contact Multiple Sclerosis Society of Canada for information.

KEY POINTS

- Cancer treatment has traditionally involved surgery, radiation, and chemotherapy. Surgery and radiation are usually local or regional therapies. Chemotherapy is generally systemic, but it often does not completely eliminate all of the cancer cells in the body. Adjuvant therapy is frequently used to destroy undetected distant micrometastases.
- The humoral and cellular immune systems act together to recognize and destroy foreign particles and cells. The humoral immune system is composed of lymphocytes known as B cells until they are transformed into plasma cells when they come in contact with an antigen (foreign substance). Plasma cells then manufacture antibodies to that antigen.
- BRMs provide another treatment option for patients who have malignancies or for those who are receiving chemotherapy and need to boost blood cell counts. BRMs include hematopoietics, interferons, interleukins, monoclonal

antibodies, and DMARDs. Use of these drugs may augment, restore, or modify host defences against the tumour.

- Nursing management and teaching associated with the administration of BRMs focuses on the use of careful aseptic technique and other measures to prevent infection; proper nutrition, oral hygiene, and monitoring of blood counts; and management of adverse effects, including joint or bone pain and flulike symptoms.
- Do not administer filgrastim within 24 hours of a myelosuppressive antineoplastic, and follow the time frame for its use (as prescribed), whether in an inpatient or home setting.
- The recommended therapy with nonbiological DMARDs usually begins with methotrexate or leflunomide for most patients. Biological DMARDs are generally reserved for those patients whose disease does not respond to methotrexate or leflunomide. The biological DMARDs include etanercept, infliximab, adalimumab, abatacept, and rituximab.

EXAMINATION REVIEW QUESTIONS

1. The nurse is conducting a class on drugs for malignant tumours for a group of new oncology staff members. Which best describes the action of interferons in the management of malignant tumours?
 - a. Interferons increase the production of specific anticancer enzymes.
 - b. Interferons have antiviral and antitumour properties and strengthen the immune system.
 - c. Interferons stimulate the production and activation of T lymphocytes and cytotoxic T cells.
 - d. Interferons help improve the cell-killing action of T cells because they are retrieved from healthy donors.
2. The nurse is planning care for a patient who is receiving interferon therapy. Which of the following symptoms should the nurse must keep in mind for this patient?
 - a. Fatigue
 - b. Bone marrow depression
 - c. Fever
 - d. Nausea
3. The nurse has administered methotrexate as part of the treatment for rheumatoid arthritis. Which of the following should the nurse monitor for sign of bone marrow suppression?
 - a. Edema
 - b. Tinnitus
 - c. Increased bleeding tendencies
 - d. Tingling in the extremities

4. The nurse is caring for a patient who has been prescribed therapy with a myelosuppressive antineoplastic drug. The nurse reviews an order to begin filgrastim (Neupogen) after the chemotherapy is completed. Which statement correctly describes when the nurse should begin the filgrastim therapy?
 - a. It can be started during chemotherapy.
 - b. It will begin immediately after chemotherapy is completed.
 - c. It will be initiated 24 hours after chemotherapy is completed.
 - d. It will not be started until at least 72 hours after chemotherapy is completed.
5. The nurse is monitoring a patient who has been receiving aldesleukin (IL-2; Proleukin) for the treatment of malignant melanoma. Which adverse effect would be a primary concern of the nurse?
 - a. Chills
 - b. Fatigue
 - c. Headache
 - d. Fluid retention
6. The nurse is reviewing the medical history of a patient who is about to receive therapy with etanercept (Enbrel). Which conditions, if present, would be a contraindication to or caution for therapy with this drug? (Select all that apply.)
 - a. Urinary tract infection
 - b. Psoriasis
 - c. Heart failure
 - d. Glaucoma
 - e. Latex allergy
7. A patient is to receive filgrastim (Neupogen) after therapy with carmustine and radiation therapy for treatment of a brain tumour. The patient weighs 60 kg. The protocol that the oncologist has written states that the filgrastim will be dosed at 5 mcg/kg. Filgrastim comes in a 300-mcg/mL vial. What dose will the patient receive? How many millilitres will the patient be given?
8. The nurse notes in the patient's medication history that the patient is taking natalizumab (Tysabri). Based on this finding, the nurse interprets that the patient has which disorder?
 - a. Multiple sclerosis
 - b. Rheumatoid arthritis
 - c. Non-Hodgkin lymphoma
 - d. Crohn's disease

CRITICAL THINKING ACTIVITIES

1. A patient who has been receiving an alkylating chemotherapeutic drug is to receive the CSF filgrastim (Neupogen). A new nurse is preparing to start the filgrastim as soon as the chemotherapy is completed, and the charge nurse is reviewing the orders. What is the priority action of the charge nurse at this time? Explain your answer.
2. The nurse is monitoring a patient who is receiving the interleukin drug aldesleukin (Proleukin). The patient is experiencing fever, chills, fatigue, dyspnea, slight crackles, ankle edema rated as 2+, and headache. What is the nurse's priority action at this time?
3. The nurse is preparing to administer etanercept (Enbrel) to a patient with severe rheumatoid arthritis. During the assessment, the nurse notes that the patient has a history of moderate psoriasis, type 2 diabetes mellitus, and allergies to penicillin and latex. What is the nurse's priority action at this time?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Anemia Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Discuss the importance of iron, vitamin B₁₂, and folic acid to the formation of blood cells.
2. Discuss the various types of anemia-related blood products.
3. Discuss the mechanisms of action, cautions, contraindications, drug interactions, uses, dosages, and special administration techniques of the various drugs used to treat anemia, as well as measures to enhance the effectiveness and decrease the adverse effects of these drugs.
4. Develop a collaborative plan of care that includes all phases of the nursing process for patients taking drugs used to treat anemia.

KEY TERMS

Erythrocytes Another name for red blood cells (RBCs). (p. 892)

Erythropoiesis The process of erythrocyte production. (p. 893)

Erythropoietin A hormone secreted by the kidneys that increases the rate of production of red blood cells in the bone marrow in response to decreasing oxygen levels in the tissues. (p. 893)

Globin The protein part of the hemoglobin molecule (see later); the four different structural chains most often found in adults are the α_1 , α_2 , β_1 , and β_2 chains. (p. 893)

Hematopoiesis The normal formation and development of all blood cell types in the bone marrow. (p. 892)

Heme Part of the hemoglobin molecule; a nonprotein, iron-containing pigment. (p. 893)

Hemoglobin (Hgb) A complex protein-iron compound in the blood that carries oxygen to the cells from the lungs and carbon dioxide away from the cells to the lungs. (p. 893)

Hemolytic anemias resulting from excessive destruction of erythrocytes. (p. 893)

Hypochromic Pertaining to less than normal colour; usually describes a red blood cell with decreased hemoglobin content and helps further characterize anemias associated with reduced synthesis of hemoglobin. (p. 893)

Microcytic Pertaining to or characterized by smaller than normal cells. (p. 893)

Pernicious anemia A type of megaloblastic anemia usually seen in older adults and caused by inadequate intestinal absorption of vitamin B₁₂ (cyanocobalamin) due to lack of availability of intrinsic factor. (p. 893)

Reticulocytes Immature erythrocytes characterized by a meshlike pattern of threads and particles at the former site of the nucleus. (p. 893)

Spherocytes Small, globular, completely hemoglobinated erythrocytes without the usual central concavity or pallor. (p. 895)

DRUG PROFILES

epoetin alfa, p. 895

ferric gluconate, p. 897

ferrous fumarate, p. 897

ferrous sulphate, p. 897

folic acid, p. 898

iron dextran, p. 897

iron sucrose, p. 897

Key drug

ERYTHROPOIESIS

The formation of new blood cells is one of the primary functions of bones. This process is known as **hematopoiesis**, and

it includes the production of **erythrocytes** (red blood cells [RBCs]), as well as leukocytes (white blood cells) and thrombocytes (platelets). This process takes place in the myeloid tissue or bone marrow. This specialized tissue is located primarily in

the ends, or epiphyses, of certain long bones and also in the flat bones of the skull, pelvis, sternum, scapulae, and ribs.

Erythropoiesis, the process of erythrocyte formation, is the focus of this chapter and involves the maturation of a nucleated RBC precursor into a hemoglobin-filled, nucleus-free erythrocyte. Erythropoiesis is driven by the hormone **erythropoietin**, which is produced by the kidneys. Erythropoietin is also produced commercially and is used to treat anemia in certain specific circumstances and is discussed in detail later in the chapter.

When RBCs are manufactured in the bone marrow by myeloid tissue, they are released into the circulation as immature RBCs called **reticulocytes**. Once in the circulation, reticulocytes undergo a 24- to 36-hour maturation process to become mature, fully functional RBCs. After this, they have a lifespan of approximately 120 days.

More than one third of an RBC is composed of hemoglobin. **Hemoglobin (Hgb)** is composed of two parts: heme and globin. **Heme** is a red pigment. Each heme group contains one atom of iron. **Globin** is a protein chain. The four different structural globulin chains most often found in adults are the α_1 , α_2 , β_1 , and β_2 . Together, four heme groups, each linked to one protein chain of globin, make one hemoglobin molecule (Figure 55.1).

TYPES OF ANEMIA

Anemias are classified into four main types, based on underlying causes (Figure 55.2). Anemias can be caused by maturation defects, or they can be secondary to excessive RBC destruction. Two types of maturation defects lead to anemias, categorized by the location of the defect within the cell: cytoplasmic maturation defects occur in the cell cytoplasm, and nuclear maturation

Fig. 55.1 Schematic structure of a hemoglobin molecule (α , alpha; β , beta).

defects occur in the cell nucleus. Factors responsible for excessive RBC destruction can be either intrinsic or extrinsic. Anemia of chronic disease is another common type of anemia.

Figure 55.3 summarizes the types of anemias arising from cytoplasmic maturation defects. Major examples include iron-deficiency anemia and genetic disorders such as thalassemia, which result in defective globin synthesis. In each of these anemias, RBCs appear **hypochromic** (lighter red than normal) and **microcytic** (smaller than normal) on a blood smear. Cytoplasmic maturation anemias occur as a result of reduced or abnormal hemoglobin synthesis. Because hemoglobin is synthesized from both iron and globin, a deficiency in either one can lead to a hemoglobin deficiency. Some common causes of iron-deficiency anemia are blood loss, surgery, childbirth, gastrointestinal (GI) bleeding (which can be caused by nonsteroidal anti-inflammatory drug [NSAID] ingestion; see Chapter 49), menstrual blood flow, and bleeding hemorrhoids.

Figure 55.4 summarizes the types of anemias arising from nuclear maturation defects. These occur because of defects in deoxyribonucleic acid (DNA) or protein synthesis. Both DNA and protein require vitamin B₁₂ and folic acid (B₉) to be present in normal amounts for their proper production. If either of these two vitamins is absent or reduced, anemias secondary to nuclear maturation defects may develop. RBCs actually appear to be normochromic (normal in colour) but are commonly macrocytic (larger than normal) on a blood smear. One example of this type of anemia is **pernicious anemia**, which results from a deficiency of vitamin B₁₂, used in the formation of new RBCs. The usual underlying cause is failure of the stomach lining to produce intrinsic factor. Intrinsic factor is a gastric glycoprotein that allows vitamin B₁₂ to be absorbed in the intestine (see Chapter 9). Another example of anemia arising from nuclear maturation defects is the anemia caused by folic acid deficiency. Both pernicious anemia and folic acid deficiency anemia are also known as types of **megaloblastic anemia**, because they are both characterized by large, immature RBCs. Megaloblastic anemias are not caused by a lack of intrinsic factor but are usually a result of poor dietary intake. These types of anemia are most commonly seen in infancy, childhood, and pregnancy.

Figure 55.5 summarizes the types of anemias arising from excessive RBC destruction, or **hemolytic anemias**. These can occur because of abnormalities within the RBCs (intrinsic factors) or as a result of factors outside (extrinsic to) the RBCs.

Fig. 55.2 Underlying causes of anemia are red blood cell (RBC) maturation defects and factors secondary to excessive RBC destruction.

Fig. 55.3 Schematic showing common causes and results of red blood cell (RBC) cytoplasmic maturation defects. ↓, decreased.

Fig. 55.4 Schematic showing common causes and results of red blood cell (RBC) nuclear maturation defects.

Fig. 55.5 Increased red blood cell (RBC) destruction occurs as a result of intrinsic and extrinsic factors. ↑, increased; DIC, disseminated intravascular coagulation; G6PD, glucose-6-phosphate dehydrogenase.

In both cases, the erythrocytes appear on a blood smear as **spherocytes**. RBC abnormalities caused by intrinsic factors are usually the result of a genetic defect. Examples include sickle cell anemia, hereditary spherocytosis, glucose-6-phosphate dehydrogenase (G6PD) deficiency, and paroxysmal nocturnal hemoglobinuria. Examples of extrinsic mechanisms of excessive RBC destruction include drug-induced antibodies that target and destroy RBCs, septic shock that produces disseminated intravascular coagulation, and mechanical forces such as those created by intra-aortic balloon pumps, ventricular assist devices, and continuous venovenous hemodialysis (CVVHD), commonly used in critical care units.

ERYTHROPOIESIS-STIMULATING AGENTS

DRUG PROFILES

epoetin alfa

Epoetin alfa (Eprex®) is a biosynthetic form of the natural hormone erythropoietin, which is normally secreted by the kidneys in response to a decrease in RBCs. It promotes the synthesis of erythrocytes (RBCs) by stimulating RBC progenitor cells in the bone marrow. Epoetin alfa and darbepoetin alfa are used to treat anemia that is associated with end-stage kidney disease, chemotherapy-induced anemia, and anemia associated with zidovudine therapy (see [Chapter 45](#)). Epoetin alfa causes the progenitor cells in the bone marrow to manufacture large numbers of immature RBCs and greatly speed up their maturation. This medication is inadequate without appropriate body iron stores and bone marrow function. Most patients receiving epoetin alfa need to also receive an oral iron preparation. A longer-acting form of epoetin alfa, called *darbepoetin* (Aranesp®), is available that reduces the required number of injections, although one study found that there is no significant difference in overall cost between the two. Both drugs are available for injection only and can be given intravenously or subcutaneously. When they are given by the subcutaneous route, their onset of action is slower, and lower dosages can be used.

Contraindications to the use of erythropoiesis-stimulating agents (ESAs) include known drug allergy. Use of epoetin alfa and darbepoetin alfa is contraindicated in cases of uncontrolled hypertension and in patients who develop pure red cell aplasia following erythropoiesis-regulating hormone. Hemoglobin levels above 100 g/L for cancer patients and 130 g/L for patients with kidney disease have been associated with harm and should be avoided. Use in patients with head or neck cancers or patients who have a potential for thrombosis is controversial as these medications increase tumour growth and thrombosis risk. Their most frequent adverse effects include hypertension, fever, headache, pruritus, rash, nausea, vomiting, arthralgia, and injection site reaction.

In clinical trials, serious concerns about the use of ESAs became evident. When patients' hemoglobin levels were above 130 g/L, they experienced serious adverse events, including heart attack, stroke, and death. Individualized dosing is necessary to achieve and maintain hemoglobin levels within the range of 100 to 120 g/L. Patients with uncontrolled hypertension should not be treated with ESAs; blood pressure must be

controlled prior to treatment with ESAs. They are to be used cautiously in patients with a history of seizures. Patients with cancer require a target hemoglobin of less than 120 g/L to minimize adverse effects associated with ESAs. Misuse of erythropoietin by athletes hoping to increase their oxygen-carrying capacity and improve their performance places them at risk for diseases caused by increased blood viscosity (e.g., stroke, myocardial infarction). Erythropoietin is an illegal substance in the sports industry.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Subcut or IV	7–10 days	5–24 hr	4–13 hr	Variable

IRON

Iron is a mineral that is essential for the proper function of all biological systems in the body. It is stored in many sites throughout the body (liver, spleen, bone marrow). Deficiency of this mineral is the principal nutritional deficiency resulting in anemia. Individuals who require the highest amount of iron are women (particularly pregnant and menstruating women) and children, and they are the groups most likely to develop iron-deficiency anemia. Most vitamin supplements for men contain little or no iron, because men are much less likely to develop iron-deficiency anemia. Nonetheless, dietary iron is usually sufficient for both men and women in developed countries. Dietary sources of iron include meats, certain vegetables and grains, beans, dried fruits, and eggs. These forms of iron must be broken down by gastric juices before the iron can be absorbed. Orange juice, veal, fish, and ascorbic acid may assist with iron absorption. Conversely, eggs, corn, beans, and many cereal products containing chemicals known as *phytates* may impair iron absorption. Oral iron preparations are available as ferrous salts. See [Table 55.1](#) for a list of the currently available oral iron salts and their respective iron content. Profferin® is a natural health product (NHP) and is the sole supplement in Canada that contains heme-iron polypeptide. This NHP preferentially absorbs heme-iron through specific receptors throughout the small intestine. FeraMax® is a polysaccharide-iron complex that has 150 mg of elemental iron available in one capsule. Triferexx® is an NHP that contains vitamin

TABLE 55.1 Ferrous Salts: Iron Content

Ferrous Salt*	Iron Content (in 300 mg)	Number of Tablets Taken Per Day (Adults)
Ferrous gluconate	35 mg or 11.6% iron	3–4 300-mg tablets
Ferrous sulphate	60 mg or 20% iron	3–4 324-mg tablets
Ferrous fumarate	100 mg or 33% iron	2–3 300-mg tablets

*Some patients may tolerate different formulations better; however, the number of tablets that must be consumed may decrease patient adherence.

C, vitamin B₁₂, and folic acid as well as iron. When a patient cannot tolerate oral iron, if rapid replenishment is necessary, or if oral iron therapy is unsuccessful, intravenous (IV) iron may be administered (Baird-Gunning & Bromley, 2016). There are four injectable iron products available: iron dextran (Dexiron®, Infufer®), iron sucrose (Venofer®), ferric gluconate (Ferrlecit®), and ferumoxytol (Feraheme®).

Mechanism of Action and Drug Effects

Iron is an oxygen carrier in both hemoglobin and *myoglobin* (oxygen-carrying molecule in muscle tissue) and is critical for tissue respiration. Small quantities of iron are absorbed in the small intestine at a time, and non-heme iron needs to be transformed into its ferrous form and bound to a transporter to pass from the intestine into the bloodstream. Once in the bloodstream, iron is used in the bone marrow to make hemoglobin and the excess iron is stored as ferritin, primarily in the liver and some in the spleen. Iron is also a required component of a number of enzyme systems in the body and is necessary for energy transfer in the cytochrome oxidase and xanthine oxidase enzyme systems. Administration of iron corrects iron-deficiency symptoms such as anemia, dysphagia, dystrophy of the nails and skin, and fissuring or cracking of the angles of the lips, and also maintains the bodily functions described earlier.

Indications

Supplemental iron in multivitamins containing iron or iron supplements alone are indicated for the prevention or treatment of iron-deficiency anemia. In all cases of anemia, an underlying cause needs to be identified. After identification of the cause, treatment is aimed at attempting to correct the cause (e.g., chronic blood loss, such as from a peptic or duodenal ulcer, cancerous colon lesion, or Crohn's disease) rather than simply alleviating the symptoms. Iron supplementation is also used in erythropoietin therapy because it is essential for the production of RBCs.

Contraindications

Contraindications to the use of iron products include known drug allergy, hemochromatosis (iron overload), hemolytic anemia, and any other anemia not associated with iron deficiency.

Adverse Effects

The most common adverse effects associated with oral iron preparations are nausea, vomiting, diarrhea, constipation, dark stools, stomach cramps, and stomach pain. Iron is a metal in its basic form and metals may carry a charge that is magnetic or electric, which can affect muscles and nerves in the bowel, resulting in constipation (slowing down peristalsis) or diarrhea (speeding up peristalsis). Iron supplements that work quickly add more of the metal to the body, so they may cause more constipation. Slow-release forms of iron may be easier on the digestive system but may not be absorbed as effectively. Dose is also important. Excess iron intake can lead to accumulation and iron toxicity. See Table 55.2 for a more complete listing of the undesirable effects associated with iron preparations. Older individuals tend to respond to lower doses of iron supplementation,

TABLE 55.2 Iron Preparations: Adverse Effects

Body System	Adverse Effects
Gastrointestinal	Nausea, constipation, epigastric pain, black or dark stools, vomiting, diarrhea
Integumentary	Temporarily discoloured tooth enamel and eyes, pain on injection

and lower doses are associated with lower rates of adverse effects than are higher doses in this population.

Toxicity and Management of Overdose

Iron overdose is one of the most common cause of child poisoning deaths reported to Canadian poison control centres. Many iron supplements are enteric coated and resemble candy. Toxicity from iron ingestion results from a combination of corrosive effects on the GI mucosa and the metabolic and hemodynamic effects caused by the presence of excessive elemental iron.

Treatment of iron overdose is based on symptomatic and supportive measures, including suction and maintenance of the airway, correction of acidosis, and control of shock and dehydration with IV fluids, blood, oxygen, and vasopressors. Abdominal X-rays may be helpful because iron preparations are radiopaque and may be visualized on X-ray film. Serum iron concentrations may be helpful in establishing the amount ingested. A serum iron concentration of more than 54 micromol/L places the patient at serious potential for toxicity. In any case of iron overdose, consultation with a poison control centre is recommended. The GI tract is decontaminated via whole-bowel irrigation. In patients with severe symptoms of iron intoxication, such as coma, shock, or seizures, chelation therapy with IV deferoxamine mesylate should be initiated.

Interactions

The absorption of iron can be enhanced when it is given with ascorbic acid or decreased when it is given with antacids and calcium. Iron preparations can decrease the absorption of certain antibiotics, including tetracyclines and quinolones.

Dosages

For dosage information on iron preparations, refer to the table on p. 898.

DRUG PROFILES

Iron preparations are available by prescription and as over-the-counter (OTC) medications. They are contraindicated in patients with ulcerative colitis and regional enteritis, conditions involving excessive stores of iron in the body (e.g., hemosiderosis, hemochromatosis), peptic ulcer disease, hemolytic anemia, cirrhosis, gastritis, or esophagitis. Goals of therapy include maintenance of normal hemoglobin and hematocrit levels (Box 55.1), as well as improved energy levels.

BOX 55.1 Normal Hemoglobin and Hematocrit Values

Laboratory Test	Female	Male
Hemoglobin	120–160 g/L	140–180 g/L
Hematocrit	0.37–0.47 volume fraction	0.37–0.47 volume fraction

 ferrous fumarate

The ferrous fumarate iron salts (Palafer®) contain the largest amount of iron per gram of salt consumed. Ferrous fumarate is 33% elemental iron; therefore, a 300-mg tablet of ferrous fumarate provides 100 mg of elemental iron. Ferrous fumarate is available only for oral use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	3–10 days	Unknown	6 hr	Variable

 ferrous sulphate

Ferrous sulphate is the most frequently used form of oral iron. Ferrous sulphate (FeSO_4) is dosed at 300 mg two to three times a day for most adult patients. Confusion can arise with ferrous sulphate because while the typical dose is 300 mg, many commercially available products are 324 mg. The two doses are used interchangeably. To add to the confusion, each 324-mg tablet contains 65 mg of elemental iron. The adult dose of elemental iron is 50 to 100 mg given two to three times daily. Ferrous sulphate is also available as a syrup and as oral drops. Dosing for children is based on elemental iron.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	3–10 days	2 hr	6 hr	Variable

iron dextran

Iron dextran (Dexiron, Infufer) is a colloidal solution of iron (as ferric hydroxide) and dextran. It is intended for IV or intramuscular (IM) use for treatment of iron deficiency. Anaphylactic reactions to iron dextran, including major orthostatic hypotension and fatal anaphylaxis, have been reported in 0.3% of patients. As a result, a test dose of 25 mg of iron dextran is administered before injection of the full dose. Given the potential of iron dextran to cause anaphylaxis, its use has been replaced by use of the newer products, ferric gluconate and iron sucrose. Iron dextran is available only for injection.

PHARMACOKINETICS (iron dextran)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IM or IV	3–10 days	24–48 hr	48 hr	3 wk

ferric gluconate

Ferric gluconate (Ferrlecit) is an injectable iron product that is indicated for repletion of total body iron content in patients with iron-deficiency anemia who are undergoing hemodialysis. The risk of anaphylaxis is much less with ferric gluconate than with iron dextran, and a test dose is not required. Doses higher than 125 mg are associated with increased adverse events, including abdominal pain, dyspnea, cramps, and itching.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	End of infusion	7 min	1 hr	4 days

iron sucrose

Iron sucrose (Venofer) is another injectable iron product indicated for the treatment of iron-deficiency anemia in patients with chronic renal disease. It is also used for patients without kidney disease. The risk of its use precipitating anaphylaxis is much less than that associated with iron dextran, and a test dose is not required. Hypotension is its most common adverse effect resulting from infusion rate. Large doses of iron sucrose are infused over 2.5 to 3.5 hours. Low-weight older adult patients appear to be at greatest risk of hypotension. The iron products ferumoxytol (Feraheme) and Monoferric (iron isomaltoside 1 000 for injection) are also available for use in Canada. Advantageously, ferumoxytol (Feraheme) can be given undiluted as an IV push in 1 minute.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	3–10 days	Unknown	6 hr	Unknown

FOLIC ACID

Folic acid is a water-soluble B-complex vitamin. It is also referred to as *folate*, the name of its anionic form. The human body requires oral intake of folic acid. Dietary sources of folic acid include dried beans, peas, oranges, and green vegetables. Several conditions can lead to folic acid deficiency. However, because folic acid is absorbed in the upper duodenum, malabsorption syndromes are the most common cause of deficiency.

Mechanism of Action and Drug Effects

Folic acid is used for erythropoiesis and for synthesis of nucleic acids (DNA and ribonucleic acid [RNA]). Dietary ingestion of folate is required for the production of DNA and RNA. It is also essential for normal erythropoiesis. Folic acid is not active in the ingested form. It must first be converted to tetrahydrofolic acid, which is a cofactor for reactions in the biosynthesis of nucleic acids.

Indications

Folic acid is used primarily to prevent and treat folic acid deficiency. Anemias caused by folic acid deficiency can be treated by exogenous supplementation of folic acid. There is also much evidence to support the use of folic acid in the prevention of neural tube defects such as spina bifida, anencephaly, and encephalocele. It is recommended that administration begin at least 1 month before pregnancy and continue through early pregnancy to reduce the potential for fetal neural tube defects. Folic acid is also indicated for the treatment of tropical sprue, a malabsorption syndrome.

Contraindications

Contraindications to the use of folic acid include known allergy to a specific drug product and any anemia not resulting from folic acid deficiency (e.g., pernicious anemia). Folic acid is not to be used to treat anemias until the underlying cause and type of anemia have been determined. For example, administering folic acid to a patient with pernicious anemia may correct the hematological

changes of anemia (making the complete blood count [CBC] normal), while deceptively masking neurological and other symptoms of pernicious anemia that result from B₁₂ deficiency.

Adverse Effects

Adverse effects associated with folic acid use are rare. Allergic reaction or yellow discoloration of urine may occur.

Interactions

No significant drug interactions occur with folic acid. However, oral contraceptives (see Chapter 35), corticosteroids (see Chapter 34), sulfonamides (see Chapter 43), and dihydrofolate reductase inhibitors (including the antineoplastic drug methotrexate [see Chapter 52] and the antibiotic trimethoprim [see Chapter 43]) can all cause signs of folic acid deficiency but are not affected by folic acid administration.

Dosages

For dosage information on folic acid, refer to the table below.

DRUG PROFILES

folic acid

Folic acid is a water-soluble B-complex vitamin used primarily in the treatment and prevention of folic acid deficiency and

Dosages

Selected Anemia Drugs

Drug (All Are Safe to Use During Pregnancy)	Pharmacological Class	Usual Dosage Range	Indications
 epoetin alfa (Eprex)	Human recombinant hormone (erythropoietin) analogue	IV/Subcut: 2 000–40 000 units 1–3 × wk, depending on weight and indication	Chemotherapy-induced anemia; anemia associated with chronic kidney disease
ferric gluconate (Ferrlecit)	Parenteral iron salt	<i>Adults</i> IV: 10 mL (125 mg) diluted in 100 mL of 0.9% normal saline over 1 hr for 8 doses	Iron deficiency associated with hemodialysis
 ferrous fumarate/ ferrous sulphate/ferrous gluconate	Oral iron salt	<i>Adults and adolescents*</i> PO: 1 capsule = 300mg ferrous gluconate = 35mg elemental Ferrous sulfate = 60mg elemental Ferrous fumarate = 99mg elemental 105–200mg elemental target per day for anemia management	Iron-deficiency anemia
 folic acid	Water-soluble B-complex vitamin	<i>Children†</i> PO/IV/IM: 0.1–0.4 mg/day <i>Adults†</i> PO/IV/IM/Subcut: Up to 1 mg/day	Folate deficiency; tropical sprue; nutritional supplementation; pregnancy-related supplementation
iron dextran (Dexiron, Infuror)	Parenteral iron salt	<i>Children and infants†</i> IM/IV: 5–10 kg: 25 mg/day elemental iron (0.5 mL/day); greater than 10 kg: 50 mg/day elemental iron (1 mL/day) <i>Adults†</i> IM/IV: 100 mg/day elemental iron (2 mL/day)	Iron deficiency when oral iron is unsatisfactory
iron sucrose (Venofer)	Parenteral iron salt	IV: 100 mg 1–3 times weekly to a cumulative dose of 1000 mg; may give up to 500 mg as single dose on days 1 and 14	Iron deficiency in patients with chronic kidney failure

IM, intramuscular; IV, intravenous; PO, oral; Subcut, subcutaneous.

*Doses are in terms of elemental iron, not the salt itself.

†Expressed in milligrams of elemental iron. Dosages are calculated for each patient's weight according to manufacturer's label. Doses are approximate.

anemias caused by folic acid deficiency. Folic acid is available as an OTC medication in multivitamin preparations and by prescription as a single drug. It is contraindicated in patients with anemias that are neither megaloblastic nor macrocytic, including vitamin B₁₂ deficiency anemia and uncorrected pernicious anemia. Folic acid is available for both oral and injectable use.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
PO	Unknown	60–90 min	Unknown	Unknown

OTHER ANEMIA DRUGS

Cyanocobalamin (vitamin B₁₂), which is discussed in [Chapter 9](#), is used to treat pernicious anemia and other megaloblastic anemias. It can be given orally in a multivitamin preparation to treat vitamin B₁₂ deficiency and to treat pernicious anemia. Cyanocobalamin IM can be given by deep IM injection for patients with severe neurological symptoms ([BC Health, 2013](#)).

NURSING PROCESS

ASSESSMENT

Before any drug is given to treat anemia, assess the patient's past and present medical history; compile a medication profile, including all prescription and OTC drugs and NHPs the patient is taking; also assess for drug allergies. It is important to assess for and document any signs and symptoms of anemia, such as fatigue, changes in nails and skin, and fissuring or cracking of the angles of the lips. It is also necessary to assess patients for contraindications, cautions, and drug interactions prior to beginning treatment with any of the drugs used to treat anemia. ESAs (epoetin alfa and darbepoetin alfa) are used to treat anemia associated with end-stage kidney disease and chemotherapy-induced anemia. Assessment of adequate body iron stores and bone marrow function is needed prior to administration of either of these drugs. Document baseline vital signs because blood pressure may elevate as hematocrit rises; medical intervention may be needed. Assess for allergies to ESAs as well as for other contraindications, such as uncontrolled hypertension and hemoglobin levels greater than 100 g/L for patients with cancer and greater than 130 g/L for patients with kidney disease.

With iron products, significant contraindications include hemochromatosis, hemolytic anemia, and any other anemia that is not resulting from iron deficiency. Food and drug interactions affecting the absorption of iron preparations include ascorbic acid (increased absorption) and antacids (decreased absorption); iron preparations can decrease absorption of other drugs, such as tetracyclines and quinolones. Laboratory studies that may be ordered before, during, and after therapy include RBC counts, hemoglobin and hematocrit levels, reticulocyte counts, bilirubin levels, and baseline levels of folate or B-complex vitamins. Perform a nutritional assessment with a focus on the amount of iron in the patient's diet. A 24-hour recall of all food

intake with serving sizes may be beneficial. A nutritional and dietary consultation may also be ordered. In addition, asking questions about the patient's energy levels, ability to carry out activities of daily living (ADLs), overall immunity to illnesses, and state of health may provide valuable information.

PHARMACOKINETIC BRIDGE TO NURSING PRACTICE

Iron preparations provide perfect examples of how pharmacokinetic properties can affect drug dosing and efficacy. Oral iron is available in a variety of salt forms, such as ferrous fumarate, ferrous sulphate, and ferric gluconate. Although quite similar in mechanism of action, the specific salt forms are associated with different pharmacokinetics and offer varying amounts of elemental iron. The ferrous fumarate iron salts contain high proportions of iron per gram of salt consumed. For example, each 100 mg of ferrous fumarate provides 33 mg of elemental iron, whereas each 300-mg tablet of ferrous sulphate contains 65 mg of elemental iron. Even though the pharmacokinetics of the different oral iron salts are similar, the amount of elemental iron per 100 mg varies significantly. Because of these varying amounts of elemental iron, the iron salts must not be exchanged for one another and must be given with caution to avoid medication errors. Other pharmacokinetic properties of oral iron products, such as absorption and excretion, must be understood because unabsorbed iron—though harmless—turns the stool black and may mask melena (blood in the stool). It is recommended that oral iron be taken with orange juice (because vitamin C helps the body to absorb more iron) or water but not with milk or antacids because of subsequent decreased drug absorption ([Zeller & Verhovsek, 2017](#)).

NURSING DIAGNOSES

- Activity intolerance resulting from fatigue and lethargy associated with anemias
- Imbalanced nutrition, less than body requirements, resulting from inadequate food intake
- Constipation as a result of adverse effects of iron products

PLANNING

Goals

- Patient will maintain or regain typical level of activity (as recommended by the health care provider).
- Patient will attain adequate nutritional status through the use of pharmacological and nonpharmacological measures.
- Patient will remain free from or will experience minimal constipation as an adverse effect of iron products.

Expected Patient Outcomes

- Patient is able to tolerate a gradual increase in activity as ordered (e.g., performing ADLs, walking 10 minutes per day with increases as tolerated) while on drug therapy for anemia.
- Patient reports improved energy levels and decreased shortness of breath or activity intolerance during drug therapy.

- Patient improves dietary intake as recommended, with the help of Canada's Food Guide (<http://www.hc-sc.gc.ca/fn-an/food-guide-aliment/index-eng.php>) and its suggestions of appropriate amounts of fruits and vegetables, grains and starches, and meats and other protein sources.
- Patient increases daily intake of iron through consumption of foods such as green leafy vegetables, eggs, and beans.
- Patient implements measures to minimize constipation, such as increasing intake of roughage, fibre, fruits, vegetables, and fluids.
- Patient reports any unresolved constipation to health care provider once the above measures have been implemented.
- Patient takes medication for management of constipation, such as bulk-forming laxatives, as prescribed.

◆ IMPLEMENTATION

Do not administer ESAs with any other product and do not shake the vial containing the drug. Prolonged, vigorous shaking may denature the glycoprotein, rendering it biologically inactive. During treatment, always monitor blood pressure and give vitamin B₁₂ supplements orally as prescribed. Instruct the patient to dilute liquid dosage forms of iron products according to manufacturer instructions and to sip them through a plastic straw to avoid discoloration of tooth enamel. Other oral forms of iron need to be given with a large quantity of fluids but not with antacids or milk, and preferably not with meals because of the risk of decreased absorption of the drug. However, most individuals find that they do need to take oral iron products with meals or food because of the commonly encountered adverse effect of GI distress. If antacids or milk products are used, schedule them at least 1 to 2 hours before or after the oral dosage of iron. Iron products are generally packaged in a light-resistant, airtight container. Instruct patients to remain in an upright or sitting position for up to 30 minutes after taking oral dosage forms of iron products and related drugs to help minimize esophageal irritation or corrosion. Warn patients that the use of iron products will turn their stools from brown to a black, tarry colour. Patients taking epoetin alfa may also be taking oral iron preparations. See the Patient Teaching Tips for more information and the Special Populations: Older Adults: Iron Products box.

If a patient cannot tolerate oral iron, IV iron (e.g., iron dextran, iron sucrose, or ferric gluconate) may be prescribed. A test dose of iron dextran may be ordered, with the remaining dose given 1 hour later if no adverse reaction occurs. Intramuscularly administered iron must be given deep in a large muscle mass using the Z-track method (see [Chapter 10](#)). IV iron dextran must be given after the IV line has been flushed with 10 mL of normal saline and must be administered with the recommended amount of diluent and at the recommended drip rate. Keep epinephrine and resuscitative equipment available in case of an anaphylactic reaction (to iron or any drug that has an increased risk of causing anaphylaxis). In addition, it may be necessary for the patient to remain recumbent for 30 minutes after the IV injection to prevent drug-induced orthostatic hypotension. Encourage the patient to move slowly and purposefully during this time.

SPECIAL POPULATIONS: OLDER ADULTS

Iron Products

- Instructions on how to take oral forms of iron are crucial to safe administration. Implement a variety of teaching strategies to reinforce all verbal and written instructions. Make sure education is individualized, especially for patients with alterations in sensory perception. Caution patients not to make changes in their medication regimens, such as doubling doses or discontinuing a drug, without a health care provider's order.
- Provide older adults and their family members or caregivers with instructions about foods that are high in iron and how to include these foods in their menu planning. Instruct patients to preserve vegetables' content of vitamins and minerals by steaming them and not overcooking them through excessive boiling.
- Remind older patients that GI upset may occur with many drugs, including vitamins and iron. Iron products can be taken with food or a snack to help decrease GI upset.
- To facilitate proper diet, always educate older adults, as well as their spouses, family members, other significant others, and caregivers about appropriate community resources (e.g., Meals on Wheels, senior citizen community centres, public recreation centres).

◆ EVALUATION

Focus the evaluation of therapeutic responses to drugs used for anemia on ensuring that goals and expected patient outcomes are met as well as on monitoring therapeutic and adverse effects. Therapeutic responses to ESAs may take 2 to 6 weeks, so monitor for increased energy, appetite, and sense of well-being. Adverse effects of ESAs may include heart attack, stroke, and possible death if ESAs are used in patients with a hemoglobin level greater than 130 g/L. Therapeutic responses to iron products include improved nutritional status, increased weight, increased activity tolerance and well-being, and absence of fatigue. Adverse effects of iron products include nausea, constipation, epigastric pain, black and tarry stools, and vomiting. Signs of toxicity include nausea, diarrhea, hematemesis, pallor, cyanosis, shock, and coma.

CASE STUDY

Erythropoiesis-Stimulating Agents

Justine, a 37-year-old middle-school teacher, is receiving a second round of chemotherapy as part of treatment for ovarian cancer. Chemotherapeutic drugs may lead to the adverse effect of bone marrow suppression of various blood cell components.

Two weeks after this round of chemotherapy, Justine's hemoglobin level is 79 g/L (pretherapy value was 110 g/L), and her hematocrit is 0.28 (pretherapy value was 0.34). The following orders are received: epoetin alfa (Eprex) 150 units/kg subcutaneously three times a week; ferrous sulphate, 300 mg orally daily.

1. What is the purpose of the order for ferrous sulphate?
 2. What conditions will the nurse assess for before beginning the epoetin alfa therapy?
 3. The nurse needs to monitor Justine closely. What assessment findings would be of most concern during this therapy?
 4. After 5 weeks, Justine's hemoglobin level is 114 g/L and her hematocrit is 0.33. The next dose of epoetin alfa is due today. What action will the nurse take?
- For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

PATIENT TEACHING TIPS

- Educate patients taking ESAs about the possible need to take oral iron supplements. These supplements are often needed to ensure adequate body iron stores, which are needed for the drug therapy to be effective.
- Encourage patients to take iron products cautiously and to be aware of the potential for poisoning if these drugs are taken in greater amounts than recommended. Patients should be aware that oral iron products need to be taken in their original dosage form and without alteration (e.g., without crushing).
- Instruct patients to take iron products exactly as ordered. Parenteral dosage forms may cause anaphylaxis and orthostatic hypotension. Recommend to patients that oral dosage forms of iron be taken with at least 120 to 180 mL of water or juice to help minimize GI upset and increase absorption.
- Patients should be aware that oral dosage forms of iron are not interchangeable, and prescription forms of these products may be different from one another. Products contain different iron salts and also come in different dose amounts.
- Instruct patients to remain upright for up to 30 minutes after taking an oral iron product to prevent esophageal irritation or corrosion. Remind patients that iron products may turn their stools a black, or dark colour.
- Encourage patients to maintain a diet high in iron, including foods such as dark green, leafy vegetables, dried fruits, beans, meats, and eggs.
- Remind patients to store iron tablets out of reach of children because of the risk of iron poisoning.

KEY POINTS

- Epoetin alfa (Eprex) is indicated for anemias associated with end-stage kidney disease and chemotherapy and requires careful use. Always check for route of administration, as this drug has a slower onset of action when given by the subcutaneous route as compared to the IV route.
- ESAs are inadequate without adequate body iron stores.
- Iron and folic acid are important in the treatment of many disorders and diseases (e.g., malignancies) to achieve RBC and hemoglobin formation that is as adequate as possible and to help prevent nutritional deficits that can affect all body systems, particularly the immune system.
- Drugs for anemia are often used in the treatment of pernicious anemia, malabsorption syndromes, hemolytic anemia, hemorrhage, and kidney and liver diseases.

EXAMINATION REVIEW QUESTIONS

1. When administering oral iron tablets, the nurse must keep in mind that which substance, other than water, is the most appropriate to give with these tablets?
 - a. Pudding
 - b. An antacid
 - c. Milk
 - d. Orange juice
2. The nurse is teaching a patient about oral iron supplements. Which statement is correct?
 - a. "You need to take this medication on an empty stomach or else it won't be absorbed."
 - b. "It is better absorbed on an empty stomach, but if that causes your stomach to be upset, you can take it with food."
 - c. "Take this medication with a sip of water, and then lie down to avoid problems with low blood pressure."
 - d. "If you have trouble swallowing the tablet, you may crush it."
3. The nurse is administering an IV dose of iron dextran. For which potential adverse effect is it most important for the nurse to monitor at this time?
 - a. Anaphylaxis
 - b. GI distress
 - c. Black, tarry stools
 - d. Bradycardia
4. The nurse is assessing a patient who is to receive folic acid supplements. It is important to rule out which condition before giving the folic acid?
 - a. Malabsorption syndrome
 - b. Pernicious anemia
 - c. Tropical sprue
 - d. Pregnancy
5. A patient with renal failure has severe anemia, and there is an order for darbepoetin alfa (Aranesp). Upon assessment, which condition listed will the nurse consider a contraindication to use of this medication?
 - a. Uncontrolled hypertension
 - b. Diabetes mellitus
 - c. Hypothyroidism
 - d. Angina
6. When iron sucrose is administered, which nursing interventions are correct? (Select all that apply.)
 - a. Administer a test dose before giving the full dose.
 - b. Give via deep IM injection into a large muscle mass using the Z-track method.
 - c. Administer large doses over 2.5 to 3.5 hours, intravenously.
 - d. Monitor the patient for hypertension.
 - e. Monitor the patient for hypotension.

7. The order reads: “Give epoetin alfa (Eprex), 3 500 units Sub-cut, three times a week.” The medication is available in a vial that contains 4 000 units/mL. How many millilitres will the nurse draw up for the ordered dose? Round to hundredths.
8. A woman who is planning to become pregnant asks the nurse when she should start to take folic acid supplements. What is the nurse’s best response?
 - a. “There is no evidence to support the use of folic acid during pregnancy.”
 - b. “You should start taking it at least 1 month before you become pregnant and continue it throughout early pregnancy.”
 - c. “You need to start it as soon as you discover you are pregnant.”
 - d. “You should take it only during the last trimester of your pregnancy and not any earlier.”

CRITICAL THINKING ACTIVITIES

1. The nurse is administering an IV dose of iron dextran. A test dose has just been given. What important action will the nurse take next? Explain your answer.
2. A 27-year-old female patient has decided that she wants to start a family. She asks the nurse, “Are there any vitamins I need to take now to make sure I’m healthy?” What is the nurse’s best answer?
3. A patient has been receiving epoetin alfa (Eprex) three times a week, during his dialysis treatments for chronic kidney

failure. This morning, as the nurse prepares to give him a dose, he states, “I’ve felt strange today, and last night I had a little chest pain, but it went away after a few minutes, so I didn’t call the nurse.” Will the nurse give the dose of epoetin alfa at this time? Explain your answer. What is the nurse’s priority action at this time?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Dermatological Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Discuss the normal anatomy, physiology, and functions of the skin.
2. Describe different disorders, infections, and conditions commonly affecting the skin.
3. Identify various dermatological drugs used to treat these disorders, infections, and conditions, and describe the various classifications of these drugs.
4. Discuss the mechanisms of action, indications, contraindications, cautions, other drug interactions, application techniques, and adverse effects associated with various topical dermatological drugs.
5. Develop a collaborative plan of care that includes all phases of the nursing process for patients using topical dermatological drugs.

KEY TERMS

Acne vulgaris A chronic inflammatory disease of the pilosebaceous glands of the skin, involving lesions such as papules and pustules (pimples or comedones; referred to in this chapter as *acne*). (p. 907)

Actinic keratosis A slowly developing, localized thickening of the outer layers of the skin resulting from long-term, prolonged exposure to the sun; also called *solar keratosis*. (p. 913)

Atopic dermatitis A chronic skin inflammation seen in patients with hereditary susceptibility. (p. 904)

Basal cell carcinoma The most common form of skin cancer; it arises from epidermal cells known as *basal cells* and is rarely metastatic. (p. 904)

Carbuncles Necrotizing infections of skin and subcutaneous tissue caused by multiple furuncles (boils); they are usually caused by the bacterium *Staphylococcus aureus*. (p. 906)

Cellulitis An acute, diffuse, spreading infection involving the skin, subcutaneous tissue, and sometimes muscle as well; it is usually caused by infection of a wound with *Streptococcus* or *Staphylococcus* species bacteria. (p. 906)

Dermatitis Any inflammation of the skin. (p. 904)

Dermatophytes Any of the common groups of fungi that infect skin, hair, and nails; these fungi are most commonly from the genera *Microsporum*, *Epidermophyton*, and *Trichophyton*. (p. 908)

Dermatosis Any abnormal skin condition. (p. 904)

Dermis The layer of the skin just below the epidermis, consisting of papillary and reticular layers and containing blood and lymphatic vessels, nerves and nerve endings, glands, and hair follicles. (p. 904)

Eczema A pruritic, papulovesicular dermatitis occurring as a reaction to many endogenous and exogenous agents;

characterized by erythema, edema, and an inflammatory infiltrate of the dermis and accompanied by oozing, crusting, and scaling. (p. 904)

Epidermis The superficial, avascular layers of the skin, made up of an outer, dead, cornified portion and a deeper, living, cellular portion. (p. 904)

Folliculitis Inflammation of a follicle, usually a hair follicle; a *follicle* is defined as any sac or pouchlike cavity. (p. 906)

Furuncles Painful skin nodules caused by *Staphylococcus* organisms that enters the skin through the hair follicles; also called *boils*. (p. 906)

Impetigo A pus-generating, contagious superficial skin infection, usually caused by *Staphylococci* or *Streptococci*; it generally occurs on the face, is most commonly seen in children, and may be recognized by honey-coloured crusts. (p. 906)

Papules Small, circumscribed, superficial, solid elevations of the skin that are usually pink and less than 0.5 to 1 cm in diameter. (p. 906)

Pediculosis An infestation with lice of the family *Pediculidae*. (p. 911)

Pruritus An unpleasant cutaneous sensation that provokes the desire to rub or scratch the skin to obtain relief. (p. 908)

Psoriasis A common, chronic squamous cell dermatosis with polygenic (multi-gene) inheritance and a fluctuating pattern of recurrence and remission. (p. 904)

Pustules Visible collections of pus within or beneath the epidermis. (p. 906)

Scabies A contagious disease caused by *Sarcoptes scabiei*, the itch mite, characterized by intense itching of the skin and injury to the skin (excoriation) resulting from scratching. (p. 912)

Tinea A fungal skin disease caused by a dermatophyte and characterized by itching, scaling, and, sometimes, painful lesions; infections with any of various dermatophytes that occur on several sites; also called *ringworm*. (p. 908)

Topical antimicrobials Substances applied to any surface that either kill microorganisms or inhibit their growth or replication. (p. 905)

Vesicles Small sacs containing liquid; also called *cysts*. (p. 906)

DRUG PROFILES

* Full generic name is given in parentheses. For the purposes of this text, the more common, shortened name is used.

SKIN ANATOMY AND PHYSIOLOGY

The skin is the largest organ of the body. It covers the body and serves several functions, including protection, sensation, temperature regulation, excretion, absorption, and metabolism. It acts as a protective barrier for the internal organs. Without skin, harmful external forces such as microorganisms and chemicals would gain access to and damage or destroy many of the body's delicate internal organs. Part of this protection includes the skin's ability to maintain a surface pH of 4.5 to 5.5. This weakly acidic environment discourages the growth of microorganisms that thrive at a more alkaline pH. The skin also has the ability to sense changes in temperature, pressure, or pain—information that is then transmitted along nerve endings. The temperature of the environment changes continuously; despite this, the body maintains an almost constant internal temperature, due in large part to the skin, which plays a major role in the regulation of body temperature. Heat loss and conservation are regulated in coordination with the blood vessels that supply blood to the skin and by means of perspiration. The skin is also able to excrete fluid and electrolytes through sweat glands. In addition, it stores fat, synthesizes vitamin D, and provides a site for drug absorption.

The skin is made up of two layers: the **dermis** and the **epidermis** (Figure 56.1). The outer skin layer, the epidermis, is composed of four layers. From the outermost to innermost layer, these are the stratum corneum, stratum lucidum, stratum granulosum, and stratum germinativum. The respective functions of these layers are described in Table 56.1.

None of these layers has a direct blood supply of its own. Instead, nourishment is provided through diffusion from the dermis below. The dermis lies between the epidermis and subcutaneous fat and differs from the epidermis in many ways. It is approximately 40 times thicker than the epidermis. Traversing the dermis is a rich supply of blood vessels, nerves, lymphatic tissue, elastic tissue, and connective tissue, which provide extra support and nourishment to the skin. Also contained in the dermis are the exocrine glands—the eccrine, apocrine, and sebaceous glands—and the hair follicles. The functions of the various types of exocrine glands are explained in Table 56.2.

Below the dermis is a layer of loose connective tissue called the *hypodermis*. It helps make the skin flexible. It is also here that subcutaneous fat tissue is located, which provides thermal insulation and cushioning or padding. It is also the source of nutrition for the skin.

Reactions or disorders of the skin are common and numerous. A **dermatosis** is any abnormal skin condition. Dermatoses include a variety of types of **dermatitis** (skin inflammation). Among these are conditions such as **atopic dermatitis**, **eczema**, and **psoriasis**. In addition, there are also a variety of skin cancers, including **basal cell carcinoma**, squamous cell carcinoma, and melanoma.

TOPICAL DERMATOLOGICAL DRUGS

Drugs that are administered directly to the site are called *topical dermatological drugs*. These drugs are available in a variety of prescription and over-the-counter (OTC) formulations that are suitable for specific indications. Each formulation has certain characteristics that make it beneficial for particular uses. For example, ointments have an oil base that makes them stickier than creams and better for smaller areas, whereas creams have a water base that makes them better for larger surfaces. Gels promote penetration of the active ingredient. Lotions are similar to creams but are lighter. More information on the formulations of dermatological drugs, as well as their characteristics and some examples are provided in Table 56.3. Note that the focus of this chapter is primarily on topically administered medications. Because so many topical drugs are available, the scope of this chapter is limited to some of the more commonly used medications. Systemically administered drugs (transdermal delivery systems) are also used to treat several skin disorders and are cross-referenced throughout this chapter.

There are many therapeutic categories of dermatological drugs. Some of the most common ones are the following:

- Antibacterial drugs
- Antifungal drugs
- Anti-inflammatory drugs
- Antineoplastic drugs
- Antipruritic drugs (for itching)

Fig. 56.1. Microscopic view of the skin. The epidermis, shown in longitudinal section, is raised at one corner to reveal the ridges in the dermis. (From Jarvis, C. (2008). *Physical examination and health assessment* (5th ed.) (p. 222). St. Louis, MO: Saunders.)

TABLE 56.1 Epidermal Layers

Layer	Description
Stratum corneum ("horny layer," so named because keratin is the same protein that makes up the horns of animals)	This is the outermost layer, consisting of dead skin cells that are made of a converted water-repellent protein known as <i>keratin</i> ; it is the protective layer for the entire body. After it is desquamated, or shed, the layer is replaced by new cells from below.
Stratum lucidum ("clear layer")	This is the layer where keratin is formed; it is translucent and contains flat cells.
Stratum granulosum ("granular layer")	Cells die in this layer; granulated cells are located here, which gives this layer the appearance for which it is named.
Stratum germinativum ("germinative layer")	New skin cells are made in this layer; it contains melanocytes, which produce melanin, the skin colour pigment.

TABLE 56.2 Exocrine Glands of the Skin

Gland	Function
Sebaceous	Large, lipid-containing cells that produce oil or film that covers the epidermis; protects and lubricates skin, and is water repellent and antiseptic
Eccrine	Sweat glands that are located throughout the skin surface; help regulate body temperature and prevent skin dryness
Apocrine	Mainly in axillae, genital organs, and breast areas; emit an odour; believed to be scent or sex glands

- Antiviral drugs
- Burn drugs
- Debriding drugs (promote wound healing)
- Emollients (skin softeners)
- Keratolytics (cause softening and peeling of the stratum corneum)
- Local anaesthetics
- Sunscreens
- Topical vasodilators

ANTIMICROBIALS

Topical antimicrobials are antibacterial, antifungal, and antiviral drugs that, as the name implies, are applied topically. Although topical antimicrobials have many of the same properties as systemic forms, there are differences in terms of their absorption, distribution, toxicities, and adverse effects. Also, many topically administered drugs can have systemic effects because they reach the circulation after being absorbed by the tissues.

TABLE 56.3 Dermatological Drug Formulations: Characteristics and Examples

Formulation	Characteristics	Examples
Aerosol foam	Can cover large area; useful for drug delivery into a body cavity (e.g., vagina, rectum) or hairy areas	Proctofoam®, contraceptive foams
Aerosol spray	Spreads thin liquid or powder film; covers large areas; useful when skin is tender to touch (e.g., burns)	Solarcaine®, Tinactin®
Bar	Similar to a bar of soap; useful as a wash with water	PanOxyl® (benzoyl peroxide)
Cleanser	Nongreasy; used as an astringent (oil remover) or wash with water	Neutrogena Ultra Sheer®
Cream	Contains water and can be removed with water; not greasy or occlusive; usually white semisolid; good for moist areas	hydrocortisone cream (Cortamed®), Benadryl® cream
Gel/jelly	Contains water and possibly alcohol; easily removed and good lubricator; usually clear, semisolid substance; useful when lubricant properties are desirable	K-Y® jelly, Benzamycin®, Erysol®
Lotion	Contains water, alcohol, and solvents; may be a suspension, emulsion, or solution; good for large or hairy areas	Calamine® lotion, Lubriderm® lotion, Kwellada-P® lotion
Oil	Contains little if any water; occlusive, liquid; not removable with water	Lubriderm® bath oil
Ointment	Contains no water; not removable with water; occlusive, greasy, and semisolid; desirable for dry lesions because of occlusiveness	petrolatum (Vaseline®), zinc oxide ointment, A+D ointment
Paste	Similar properties to those of the ointments; contains more powder than ointments; excellent protectant properties	zinc oxide paste (Balmex®)
Pledget (pad)	Moistened pad is applied to or wiped over affected area	chlorhexidine gluconate
Powder	Slight lubricating properties; may be shaken on affected area; promotes drying of area where applied	Tinactin powder, Desenex® powder
Shampoo	Soapy liquid for washing hair and skin	ketoconazole (Nizoral®)
Solution	Nongreasy liquid; dries quickly	Various skin care products
Stick	Spreads thin chalky or viscous liquid film; often better for smaller areas	Benadryl Itch Relief
Tape	Moist occlusive formulation; consistent topical drug delivery; useful when small, straight areas require drug application	Various products

GENERAL ANTIBACTERIAL DRUGS

Common skin disorders caused by bacteria are **folliculitis**, **impetigo**, **furuncles**, **carbuncles**, **papules**, **pustules**, **vesicles**, and **cellulitis**. The bacteria responsible are most commonly *Streptococcus pyogenes* and *Staphylococcus aureus*. Dermatological antibacterial drugs are used to treat or prevent these skin infections. The most commonly used drugs are bacitracin, polymyxin, and neomycin. Unfortunately, because of the high incidence of infection with methicillin-resistant *S. aureus* (MRSA), mupirocin is now also commonly used.

DRUG PROFILES

bacitracin

Bacitracin (Baximycin®, Bioderm®) is a polypeptide antibiotic that is applied topically for the treatment or prevention of local skin infections caused by susceptible aerobic and anaerobic Gram-positive organisms such as staphylococci, streptococci, anaerobic cocci, corynebacteria, and clostridia. It works by inhibiting bacterial cell wall synthesis, which leads to cell death. It can be either bactericidal or bacteriostatic, depending on the causative organism. Bacitracin's antimicrobial spectrum is broadened in several available combination drug products. Most of these contain neomycin or polymyxin B (see later in this chapter).

Adverse reactions to bacitracin are usually minimal; however, reactions ranging from skin rash to allergic anaphylactoid reactions have occurred. If itching, burning, inflammation, or other signs of sensitivity occur, discontinue bacitracin. This drug is available in ointment form and it is usually applied to

the affected area one to three times daily. It is also available in systemic and ophthalmic (see [Chapter 57](#)) formulations.

neomycin and polymyxin B

Neomycin and polymyxin B are two additional broad-spectrum antibiotics that are available together in the nonprescription product known as Neosporin®. Neosporin cream is a combination of these two drugs alone, whereas Neosporin ointment also contains bacitracin. Several brand name and generic combinations of these three topical antibiotics are available, and all are commonly used as topical antiseptics for minor skin wounds. Although neomycin/polymyxin B is still a popular OTC product, there is evidence that use of the drug can increase the likelihood of future allergic reactions of the skin.

mupirocin

Mupirocin (Bactroban®) is an antibacterial product available only by prescription. It is used on the skin for treatment of staphylococcal and streptococcal impetigo. It is applied topically three times daily to treat colonization with MRSA. Adverse reactions are usually limited to local burning, itching, or minor pain.

silver sulfadiazine

Silver sulfadiazine (Flamazene®) has proved both effective and safe in the prevention and treatment of infections in burns. A major concern for individuals with burns is infection at the burn site. However, because increased systemic absorption of a drug can occur in compromised skin areas, to avoid causing dangerous systemic effects, topical burn drugs must not be too potent or toxic. This is especially true when large burned areas must be treated, because the drug may be applied over a large surface

area of skin and therefore may be absorbed in high quantities. Conversely, the blood supply to burned areas is often drastically reduced, so systemically administered antibiotics either cannot reach the site or do so only in quantities too low to be effective. Therefore, the only way of administering these drugs to ensure that they reach the burn site is to apply them topically.

Silver sulfadiazine is a synthetic antimicrobial drug produced when silver nitrate reacts with the chemical sulfadiazine. It appears to act on the cell membranes and cell walls of susceptible bacteria and is used as an adjunct in the prevention and treatment of infection in second- and third-degree burns and less frequently for cellulitic or eczematous extremities. The adverse effects of silver sulfadiazine are similar to those of other topical drugs and include pain, burning, and itching. This drug should not be used in patients who are allergic to sulfonamide drugs. It is available only as a 1% cream and is applied topically to cleansed and debrided burned areas once or twice daily, using a sterile-gloved hand.

ANTIACNE DRUGS

Acne vulgaris is the most common skin infection. Its precise cause is unknown and somewhat controversial. Likely causative factors include heredity, stress, drug reactions, hormones, and bacterial infections. Common bacterial causes include *Staphylococcus* species (spp.) and *Propionibacterium acnes*. Some of the most commonly used antiacne drugs are benzoyl peroxide, clindamycin, erythromycin, tetracycline, isotretinoin, and the vitamin A acid known as *retinoic acid*. Many other drugs are also used in the treatment and prevention of acne, including systemic formulations of the antibiotics minocycline, doxycycline, and tetracycline (see Chapter 43). Some health care providers also prescribe oral contraceptives (see Chapter 35) for female patients with acne, because in some controlled studies estrogen has been shown to have beneficial effects against acne, especially hormone-driven acne.

DRUG PROFILES

benzoyl peroxide

The microorganism that most commonly causes acne, *P. acnes*, is an anaerobic bacterium; that is, it needs an environment that is poor in oxygen to grow. Benzoyl peroxide is effective in combating such infection because it slowly and continuously liberates active oxygen in the skin, resulting in antibacterial, antiseptic, drying, and keratolytic actions. These actions create an environment that is unfavourable for the continued growth of the *P. acnes* bacteria and they soon die. Drugs such as benzoyl peroxide that soften scales and loosen the outer horny layer of the skin are referred to as *keratolytics*.

Benzoyl peroxide generally produces signs of improvement within 8 to 12 weeks; clinical worsening may occur during the initial 2 to 4 weeks of use. Adverse effects tend to be a result of dose (including overuse) and include peeling skin, red skin, or a sensation of warmth. Blistering or swelling of the skin is generally considered an allergic reaction to the product and is an indication to stop treatment. Overuse of this drug and also of tretinoin is common in adolescent patients who are attempting to quickly cure their acne. The result can be painful, reddened

skin, which usually resolves upon return to use of these medications as prescribed.

Benzoyl peroxide is available in multiple topical dosage forms, including as a cleansing bar, liquid, lotion, mask, cream, gel, and cleanser. It is also available in various combination drug products. It is usually applied topically one to four times daily, depending on the dosage form and the health care provider's instructions. There have been no studies to determine the effects of benzoyl peroxide during pregnancy, but the benefits of using this drug during pregnancy are considered to outweigh the risk.

clindamycin phosphate

Clindamycin phosphate (Clindets®, Dalacin®) is a topical form of the systemic antibiotic clindamycin described in Chapter 44. It is most commonly prescribed for acne inflammatory lesions. Adverse reactions associated with this topical drug are usually limited to minor local skin reactions, including burning, itching, dryness, oiliness, and peeling. The drug is available in cream, gel, lotion, suspension, and pledget formulations. Clindamycin is usually applied once or twice daily. Combination therapy (e.g., benzoyl peroxide) may prevent bacterial resistance. It is safe to use during pregnancy.

isotretinoin

Isotretinoin (Accutane®, Clarus®, Epuris®) is an oral product indicated for the treatment of severe recalcitrant cystic acne. Isotretinoin inhibits sebaceous gland activity and has antikeratinizing (anti-skin-hardening) and anti-inflammatory effects. Isotretinoin is one of relatively few acne medications that are not to be used during pregnancy. This means that it is a proven human *teratogen*, or chemical that is known to induce birth defects. It is imperative that female patients of childbearing age be counselled and agree not to become pregnant during use of the drug. Given these teratogenic effects, in 2005, the US Food and Drug Administration (FDA) approved stringent guidelines regarding the prescription and use of this medication. Canada quickly followed the United States' lead with a risk management program called the Accutane Pregnancy Prevention Program (PPP). This program requires that women of childbearing age taking isotretinoin receive education about the teratogenicity of the drug and sign a form indicating that they have been educated through the PPP, understand the need for contraception, and will undergo pregnancy testing before, during, and after drug therapy (Government of Canada, 2016). The risk management program features the following: a toll-free number that both patients and health care providers can call for information; suggestions for an expanded health care providers' checklist, including lists of potentially interacting medications and natural health products; a website with information regarding isotretinoin and contraception; improved education for health care providers and pharmacists; and information about the introduction of generic forms of isotretinoin. In addition, there have been case reports of suicide and suicide attempts by patients receiving isotretinoin. It has not been determined if the drug increases the potential for suicide or if psychosocial sequelae from severe acne are to blame for increased suicide risk. As such, more research is required in order to definitively

link isotretinoin as a direct cause of depression in this population (Singer, Tkachenko, Sharma, et al., 2019). Regardless, it is important to advise patients to report any signs of depression to their health care providers. Follow-up treatment may be needed, and simply stopping the drug may be insufficient. Despite these rather strong concerns, this drug does prove to be helpful in treating severe cases of acne. Isotretinoin is available only for oral use.

tretinoin

Tretinoin (retinoic acid, vitamin A acid; Retin-A®, Stieva-A®) is a derivative of vitamin A that is used to treat acne and ameliorate dermatological changes (e.g., fine wrinkling, mottled hyperpigmentation, roughness) associated with photodamage (sun damage). The drug appears to act as an irritant to the skin, in particular the follicular epithelium. Specifically, it stimulates the turnover of epidermal cells, which results in skin peeling. While this is occurring, the free fatty acid levels of the skin are reduced, and horny cells of the outer epidermis cannot then adhere to one another. Without fatty acids and horny cells, comedones, or pimples, cannot exist.

Topically administered tretinoin has been shown to enhance the repair of skin damaged by ultraviolet radiation (e.g., sunlight, tanning beds, and tanning lights). It does this by increasing the formation of fibroblasts and collagen, both of which are needed to rebuild skin. The drug may also reduce collagen degradation by inhibiting the enzyme collagenase that breaks down collagen. Tretinoin's main adverse effects are local inflammatory reactions, which are reversible when therapy is discontinued. Common adverse effects are excessively red and edematous blisters, crusted skin, and temporary alterations in skin pigmentation. Tretinoin is available in many topical formulations, including creams, gels, and a liquid. Because of its potential to cause severe irritation and peeling, it may initially be applied only once every 2 or 3 days, in the evening due to photosensitivity. Treatment often starts with a low-strength product.

Retin-A Micro® is approved for the treatment of acne vulgaris. This particular acne product contains tretinoin inside a synthetic polymer called a *microsponge delivery system*. This system is made of round microscopic particles of synthetic polymer. The microspheres act as reservoirs for tretinoin, allowing the skin to absorb small amounts of the drug over time. Retin-A Micro is currently available only in gel form. The potential benefits of all topical forms of tretinoin are considered to outweigh their risks when used during pregnancy. They are not to be confused with the oral capsule form of tretinoin (alitretinoin) used to treat leukemia, which is not to be used during pregnancy because of the risk of harm to the fetus. Another antiacne retinoid is adapalene, available in a topical gel or cream.

ANTIFUNGAL DRUGS

A few fungi produce keratinolytic enzymes, which allow them to live on the skin. Topical fungal infections are primarily caused by *Candida* spp. (candidiasis), **dermatophytes**, and *Malassezia furfur* (tinea versicolor). These fungi are found in moist, warm environments, especially in dark areas such as the feet or groin.

Candidal infections are commonly caused by *Candida albicans*, a yeastlike opportunistic fungus present in the normal flora of the mouth, vagina, and intestinal tract. Two significant factors that commonly predispose a person to a candidal infection are immunodeficiency disorders and broad-spectrum antibiotic therapy, which promotes an overgrowth of nonsusceptible organisms in the natural flora of the body. Because these infections favour warm, moist areas of the skin and mucous membranes, they most commonly occur orally (e.g., thrush in infants), vaginally, and cutaneously, in sites such as beneath the breasts and in diapered areas. They may also cause nail infections.

Dermatophytes comprise a group of three closely related genera consisting of *Epidermophyton* spp., *Microsporum* spp., and *Trichophyton* spp. that use the keratin found on the skin to feed their growth. They produce superficial mycotic (fungal) infections of keratinized tissue (hair, skin, and nails). Infections caused by dermatophytes are collectively called **tinea**, or *ringworm*, infections. The name *ringworm* comes from the fact that the infection sometimes assumes a circular pattern at the site of infection. Tinea infections are further identified by the body location where they occur: tinea pedis (foot), tinea cruris (groin), tinea corporis (body), and tinea capitis (scalp). Tinea infections of the foot are also known as *athlete's foot* and those of the groin as *jock itch*.

Fungi usually invade the stratum corneum, which is the dead layer of desquamated (shed) cells. Inflammation occurs when fungi invade this layer; sensitivity (e.g., itching) occurs when they penetrate the epidermis and dermis.

Many of the fungi that cause topical infections are difficult to eradicate. The organisms are slow growing, and antifungal therapy may be required for periods ranging from several weeks to as long as 1 year. However, many topical antifungal drugs are available for the treatment of both dermatophyte infections and those caused by yeast and yeastlike fungi. Some of these drugs, their dosage forms, and their uses are listed in [Table 56.4](#). Systemically administered antifungal drugs are sometimes used for skin conditions as well. These drugs were discussed in [Chapter 47](#).

The most commonly reported adverse effects of topical antifungals are local irritation, **pruritus**, burning sensations, and scaling. Ciclopirox and clotrimazole are safe to use during pregnancy; ketoconazole and miconazole may have an adverse effect on the fetus but their benefits may outweigh the risks of use during pregnancy. Hypersensitivity is the one contraindication to the use of any of these drugs.

DRUG PROFILES

clotrimazole

Clotrimazole (Canesten®) is available over the counter. It is available as a cream for the treatment of dermatophytoses (e.g., athlete's foot), superficial mycoses, and cutaneous candidiasis. Similar topical preparations (cream and vaginal tablets) are also available for intravaginal administration in the treatment of vulvovaginal candidiasis, commonly called a *yeast infection*,

TABLE 56.4 Topical Antifungal Drugs

Drug	Trade Names	Dosage Forms	Uses
ciclopirox	Loprox®, Stieprox Shampoo®	1% cream and lotion, 1.5% shampoo, 8% lotion (for nails)	Candidiasis, dermatophytoses, tinea versicolor
clotrimazole	Canesten Combi-Pak	1% vaginal cream, 200- and 500-mg vaginal tabs	Candidiasis
	Clotrimaderm, Clotrimazole	1% and 2% topical creams	Candidiasis; dermatophytoses; tinea versicolor
	Lotriderm®	Cream (1% clotrimazole, 0.05% beclamethasone dipropionate)	Dermatophytoses
ketoconazole	Ketoderam cream®	2% cream	Candidiasis, dermatophytoses, tinea versicolor
	Nizoral®	2% shampoo	Dermatophytoses, tinea versicolor
miconazole nitrate	Micatin	2% cream, powder spray	Candidiasis, dermatophytoses, tinea versicolor
	Micozole	2% cream	Candidiasis, dermatophytoses, tinea versicolor
	Monistat	100-, 400-, and 1 200-mg vaginal ovules	Candidiasis
	Monistat Pak	2% cream; 100-, 400-, and 1 200-mg vaginal suppository	Candidiasis
nystatin	Flagylstatin®	Cream, ovule	Candidiasis
	Nyaderm®		
terbinafine hydrochloride	Lamisil®	1% cream and spray	Dermatophytoses
tolnaftate	Tinactin, others	1% cream, solution, gel, powder, and spray	Dermatophytoses

and vaginal trichomoniasis. Clotrimazole is available in many topical formulations: a 1% cream; 1%, 2%, and 10% vaginal creams; and 200- and 500-mg vaginal tablets. Different dosages and dosage forms are used for the treatment of different fungal infections. Clotrimazole is safe to use during pregnancy.

miconazole nitrate

Miconazole nitrate (Micatin®, Micozole®, Monistat®) is a topical antifungal drug that is available in several OTC products (e.g., cream, prefilled applicators or suppositories, ovules). It inhibits the growth of several fungi, including dermatophytes and yeast, as well as Gram-positive bacteria, and is commonly used to treat dermatophytoses, superficial mycoses, cutaneous candidiasis, and vulvovaginal candidiasis. It is present in many remedies for athlete's foot, jock itch, and yeast infections.

For the treatment of athlete's foot, jock itch, ringworm, and other susceptible fungal infections, miconazole is applied sparingly to a cleansed, dry, infected area twice daily in the morning and evening. For the treatment of yeast infections, one 400-mg ovule suppository should be inserted in the vagina once daily at bedtime for 3 consecutive days. Also available is a dual pack, which contains one 100-mg suppository and 2% cream. The suppository is administered intravaginally once daily at bedtime for 7 days and the cream is applied to the itchy, irritated area. One-day regimens for vaginal candidiasis are also available (e.g., Monistat 1 Vaginal Ovule 1 200 mg × 1 day or Combi Pak 1 200 mg/2% cream × 1 day). The most common adverse effects of topically administered miconazole are vulvovaginal burning and itching, pelvic cramps and rash, urticaria, stinging, and contact dermatitis. Miconazole is available in a variety of topical formulations: a 2% cream; a 2% vaginal cream; and a 100- and 400-mg vaginal suppository. It is also available as a 1 200-mg vaginal suppository for

one-time dosing. If used during pregnancy, miconazole may have adverse effects on the fetus; however, the benefits of its use may outweigh the risks.

ANTIVIRAL DRUGS

Topical antivirals are now used less frequently than in years past, because systemic antiviral drug therapy has generally been shown to be superior for controlling such viral skin conditions. Nonetheless, two antiviral ointments are described here. As is the case with systemic drug therapy, these products are best used early in an outbreak of viral skin lesions. Topical antivirals are more likely to be used for acute outbreaks, whereas systemic drugs are used for acute outbreaks and for ongoing prophylaxis against outbreaks. Viral infections are difficult to treat because they live in the body's healthy cells and use their cell mechanisms to reproduce; the same is also true for topical viral infections. Infections caused by herpes simplex types 1 and 2 and human papillomavirus (which causes anogenital warts) are particularly serious and are becoming more common.

The only topical antiviral drug currently available to treat such viral infections is acyclovir (Zovirax®). It works by comparable mechanisms as described for similar antiviral drugs in [Chapter 45](#). Acyclovir acts by inhibiting the viral enzymes necessary for deoxyribonucleic acid (DNA) synthesis. Acyclovir is available as a 5% topical cream, which is applied four to six times daily for up to 10 days. A finger cot or rubber glove should be worn for application of the ointment to prevent the spread of infection. The medication's most common adverse effects are stinging, itching, and rash. If used during pregnancy, acyclovir may have adverse effects on the fetus; however, the benefits of its use may outweigh the risks.

TOPICAL ANAESTHETICS

Topical anaesthetics are drugs that are used to numb the skin. They accomplish this by inhibiting the conduction of nerve impulses from sensory nerves, thereby reducing or eliminating the pain or pruritus associated with insect bites, sunburn, and allergic reactions to plants such as poison ivy, as well as many other uncomfortable skin disorders. They are also used to numb the skin before a painful injection (e.g., insertion of an intravenous line in a patient). Topical anaesthetics are available as ointments, creams, sprays, liquids, and gels, and are discussed in [Chapter 12](#). A lidocaine/prilocaine combination drug (EMLA®) and lidocaine alone (Betacaine®, Lidodan®) are topical anaesthetic drugs that are used frequently, especially in pediatric patients. EMLA is applied 1 hour before a procedure, whereas lidocaine alone is effective within 30 minutes.

TOPICAL ANTIPRURITICS AND ANTI-INFLAMMATORIES

Topical antipruritic (anti-itching) drugs contain antihistamines or corticosteroids. Many exert a combined anaesthetic and antipruritic action when applied topically. The antihistamines and their therapeutic effects are covered in [Chapter 37](#). Topical antihistamines are not used to treat the following conditions because of systemic absorption and subsequent toxicity: chicken pox, widespread poison ivy lesions, and other lesions involving large body surface areas.

The most commonly used topical anti-inflammatories are the corticosteroids (see [Chapter 34](#)). They are generally indicated for the relief of inflammatory and pruritic dermatoses. When topically administered corticosteroids are used, many of the undesirable systemic adverse effects associated with the use of the systemically administered corticosteroids are avoided. The beneficial drug effects of topically administered corticosteroids are their anti-inflammatory, antipruritic, and vasoconstrictive actions.

The many different available dosage forms of the various corticosteroids vary in their relative potency, and this often guides their selection in the treatment of various conditions. For instance, corticosteroids that are fluorinated (which increases their potency) are used for the treatment of dermatological disorders such as psoriasis. Also, the vehicle in which the corticosteroid is contained may alter its vasoconstrictor properties and therapeutic efficacy. Ointments are generally the most penetrating, followed next by gels, creams, and lotions. Propylene glycol also enhances the penetration of a corticosteroid and its vasoconstrictor effects. Most corticosteroids are available in many topical formulations, which provides a variety of options. The currently available topical corticosteroids, along with their respective potencies, are listed in [Table 56.5](#).

Adverse effects of topical corticosteroids include skin reactions such as acne eruptions, allergic contact dermatitis, burning sensations, dryness, itching, skin fragility, hypopigmentation, purpura, hirsutism (usually facial), folliculitis, roundness and

swelling of the face, and alopecia (usually of the scalp). Another adverse effect is the opportunistic overgrowth of bacteria, fungi, or viruses as a result of the immunosuppressive effects of this class of drugs. *Tachyphylaxis* (weakening of drug effect over time) may also occur with these drugs, especially with long-term use or overuse. The usual adult dosage of these drugs is one or two applications daily as a thin layer over the affected area. Less potent topical corticosteroids are used in children, following the same dosing schedule. If used during pregnancy, corticosteroids may have adverse effects on the fetus; however, their benefits may outweigh the risk. They are contraindicated in patients with a hypersensitivity to them. Because many of these products are available orally as well as topically, the potential exists for both to be administered simultaneously. This is not recommended and is potentially harmful. The combined use of topical and oral preparations of the same drug can lead to toxicity.

ANTIPSORIATIC DRUGS

Psoriasis is a common skin condition in which areas of the skin become thick, reddened, and covered with silvery scales. Psoriasis is actually a result of a disordered immune system, although it is generally referred to as a skin condition. It is believed to involve *polygenic* (multi-gene) inheritance. Psoriasis has a fluctuating pattern of recurrence and remission. Flare-ups can be triggered by infection, stress, changes in climate, excessive alcohol intake, or dry skin. Although there are many subtypes, the most classic one is known as *plaque psoriasis* and typically manifests as large, dry, erythematous scaling patches of the skin that are often white or silver on top. Commonly affected skin areas include the nails, scalp, genitals, and lower back. Treatment for mild to moderate cases usually begins with a topical corticosteroid. When this therapy is not successful, topical antipsoriatic drugs are used. In addition to these topical drugs, there are recently developed systemically administered antipsoriatic drugs. A thorough discussion of these drugs is beyond the scope of this chapter on topical medications; those given by systemic injection include etanercept (Enbrel®) and adalimumab (Humira®), which are given subcutaneously. Etanercept is discussed in more detail in the chapter on biological response-modifying drugs (see [Chapter 54](#)). In addition, the antineoplastic anti-metabolite methotrexate (see [Chapter 52](#)) may be used for its antipsoriatic properties. The newest injectable drug used to treat psoriasis, ustekinumab (Stelara®), is an interleukin-12 inhibitor and is indicated for plaque psoriasis. It is given subcutaneously, and its most serious adverse effect is increased risk of infection.

DRUG PROFILES

tazarotene

Tazarotene is a receptor-selective retinoid. It is thought to normalize epidermal differentiation, reducing the influx of inflammatory cells into the skin. Synthetic retinoids are vitamin A

TABLE 56.5 Commonly Used Topical Corticosteroids (in Order of Decreasing Potency)

Range of Potency*	Corticosteroid
1. High potency	betamethasone dipropionate (cream, ointment, and lotion), clobetasol 17-propionate, halobetasol propionate (cream and ointment)
2. Moderate potency*	amcinonide, beclomethasone dipropionate (cream), betamethasone valerate (0.1% cream, ointment, and lotion), desoximetasone (0.05% cream), fluocinolone acetonide (cream and lotion), mometasone furoate, triamcinolone acetonide (0.5% cream and ointment)
3. Mild potency*	desonide, fluocinolone (0.01% solution), triamcinolone (0.1% cream), hydrocortisone

*Skin penetration and, thus, potency are enhanced by the vehicle containing the steroid. In decreasing order of effectiveness are ointments, gels, creams, and lotions.

analogues and are thought to play a role in skin cell differentiation and proliferation. Tazarotene is available in gel form and is approved for the treatment of stable plaque psoriasis and mild to moderately severe facial acne. Like isotretinoin, tazarotene is not recommended for use during pregnancy, and a negative pregnancy test 2 weeks before starting therapy is required for female patients.

tar-containing products

Drug products containing coal tar derivatives were among the first medications used to treat psoriasis and are still used today for this purpose. Tar derivatives are known to have antiseptic, antibacterial, and antiseborrheic properties, and they work to soften and loosen scaly or crusty areas of the skin. *Seborrhea* is excessive secretion of *sebum*, a normal skin secretion containing fat and epithelial cell debris. Tar-containing products are available in a variety of shampoo forms (for scalp psoriasis), as well as solution, oil, ointment, cream, lotion, gel, and even soap forms for bathing. These products typically contain 1 to 10% coal tar. Adverse reactions usually include minor skin burning, photosensitivity, and other irritations. These products may be applied from one to four times daily or once or twice weekly as prescribed.

calcipotriol

Calcipotriol (Dovonex®) is a synthetic vitamin D₃ analogue that works by binding to vitamin D₃ receptors in skin cells known as *keratinocytes*, the abnormal growth of which contributes to psoriatic lesions. Calcipotriol helps to regulate the growth and reproduction of keratinocytes. The most common adverse reaction to this drug is minor skin irritation. However, more serious reactions can occur in some cases, including worsening of psoriasis, dermatitis, skin atrophy, and folliculitis. Calcipotriol is usually applied twice daily. Its usefulness in pregnancy may outweigh its associated risks. Dovobet® is a combination product containing calcipotriene and betamethasone dipropionate, a topical steroid.

MISCELLANEOUS DERMATOLOGICAL DRUGS

There are many other topically applied drugs. Those discussed in this section are the topical ectoparasiticides (scabicides and pediculicides), hair growth drugs, antineoplastics, and immunomodulating drugs. Many of these drugs are available both over the counter and by prescription. Aloe vera and tea tree oil preparations (see the Natural Health Products box) are also available over the counter.

NATURAL HEALTH PRODUCTS

Aloe (*Aloe vera*)

Overview

The dried juice of the leaves of the aloe plant contain anthranoids, which give aloe a laxative effect when it is taken orally. For thousands of years, the topical application of the plant has been known to aid in wound healing.

Common Uses

Wound healing, treatment of constipation

Adverse Effects

Diarrhea, nephritis, abdominal pain, dermatitis when used topically

Potential Drug Interactions

Digoxin, antidysrhythmics, diuretics, corticosteroids

Contraindications

Contraindicated in patients who are menstruating or have kidney disease; can increase menstrual blood flow and also cause acute kidney injury

Tea Tree Oil (*Melaleuca alternifolia*)

Overview

Tea tree oil is extracted from the evergreen leaves of the *Melaleuca alternifolia* tree, a cultivated tea tree that is native to Australia, New Zealand, and Southeast Asia. The oil contains over 100 components. Tea tree oil is thought to disrupt the cell membranes of fungi. Its exact mechanism of action is not fully understood.

Common Uses

Treatment of minor cuts, burns, acne, athlete's foot, mild fungal nail infections

Adverse Effects

Dermatitis when used topically, eye irritant

Potential Drug Interactions

None well identified

Contraindications

Tea tree oil must not be taken orally.

DRUG PROFILES

Ectoparasiticide Drugs

Ectoparasites are insects that live on the outer surface of the body. The drugs used to kill them are called *ectoparasiticide* drugs. Lice are transmitted from person to person by close contact with infested individuals, clothing, combs, or towels. A parasitic infestation on the skin with lice is called **pediculosis**, and such infestations go by one of three different names, depending on the location of the infestation:

Pediculosis pubis: pubic lice, or “crabs”; infestation by *Phthirus pubis*

Pediculosis corporis: body lice; infestation by *Pediculus humanus corporis*

Pediculosis capitis: head lice; infestation by *Pediculus humanus capitis*

Common findings in infested persons include itching; eggs of the lice (called nits) attached to hair shafts; lice on the skin or clothes; and, in the case of pubic lice, sky blue macules (discoloured skin patches) on the inner thighs or lower abdomen. Pediculoses are treated with a class of drugs called *pediculicides*. A second common parasitic skin infection known as **scabies** is caused by the itch mite *Sarcoptes scabiei*. Scabies is transmitted from person to person by close contact, such as by sleeping next to an infested person. The scabies mite causes irritation and itching by boring into the horny layers of skin located in cracks and folds. Itching seems to occur most commonly in the evening. The drugs used to treat these infestations are called *scabicides*.

Treatment of these parasitic infestations should begin with identification of the source of infestation to prevent reinfestation. Next, the clothing and personal articles of the infested person must be decontaminated. This is best accomplished by washing them in hot, soapy water or by dry cleaning them. All close contacts of the person should also be treated to prevent reinfestation.

Many of the ectoparasitocidal drugs that have been used to treat lice have been removed from the market in Canada because of resistance, lack of efficacy, and potential for neurotoxicity. Crotamiton (Eurax®) is an ectoparasitocidal drug with an unclear mechanism of action; it is a scabicide and also an antipruritic. It is applied to the entire body, with particular attention paid to skin folds and creases and under nailbeds; after 48 hours, the patient showers. Crotamiton produces a counterirritation; upon evaporation from the skin, the drug produces a cooling effect, which distracts the patient from the itching. Permethrin 5% (Kwellada-P® lotion, Nix® dermal cream) and 1% (Kwellada-P crème rinse, Nix crème rinse) as well as pyrethrins (e.g., piperonyl butoxide) are still in use (applied as directed and repeated in 7 to 10 days).

Another treatment for head lice is dimeticone 50% (Nyda®), a pediculicide that does not contain any neurotoxic chemicals and is effective in killing head lice and their eggs. It is safe for use in children 2 years and older. Dimeticone penetrates the tracheas of lice and the breathing holes of their eggs, blocking their oxygen supply and suffocating them through all stages of their development. Because of this mode of action, resistance to the drug does not occur. It is sprayed onto dry hair, massaged in, and left for 30 minutes. The dead lice are then removed with a lice comb. Once the hair dries (after 8 hours), it is shampooed.

Hair Growth Drugs

minoxidil

Minoxidil (Loniten®) is a vasodilating drug that is administered systemically to control hypertension (see [Chapter 23](#)). Topically, minoxidil (Rogaine®) has the same vasodilating effect, but when used in this way it is applied to the scalp to stimulate hair

growth. The vasodilation it causes is one possible explanation for how it promotes hair growth. It may also act at the level of the hair follicle, possibly stimulating hair growth directly.

Minoxidil can be used in men who are experiencing baldness or hair thinning. It is not approved by Health Canada for use in women under 18 years of age or in women who are pregnant or breastfeeding. Treatment involves administering the drug to the affected (balding or thinning) area twice daily, usually morning and evening. It generally takes 4 months before results are seen. Systemic absorption of topically applied minoxidil may occur, with possible adverse effects, including tachycardia, fluid retention, and weight gain. Local effects may include skin irritation, and the drug is not to be applied to skin that is already irritated, nor used concurrently with other topical medications applied to the same site. Note that the beneficial effects of this drug can be reduced by heat, including the use of a blow dryer.

The systemically administered drug finasteride (Proscar®, 5 mg) is used to treat benign prostatic hyperplasia, as discussed in [Chapter 36](#). A lower-strength version known as Propecia® (1 mg) is also used to treat male-pattern alopecia. Finasteride is not to be used during pregnancy because it is known to have adverse effects on the fetus, and women are not to handle this drug without gloves or crush this drug, thereby making it airborne.

Sunscreens

Sunscreens are topical products used to protect the skin from damage caused by the ultraviolet radiation of sunlight. There are numerous specific sunscreen products on the market. None requires a prescription for use. Each is composed of typically three to five various chemical ingredients that work together to provide ultraviolet protection and, usually, a moisturizing effect as well. Common examples of these ingredients are titanium dioxide, octyl methoxycinnamate, homosalate, and parabens. Sunscreens are rated with a sun protection factor (SPF) rating, which is a number ranging from 2 to 50 (and even higher in some newer products) in order of increasing potency of ultraviolet protection. [Health Canada \(2017\)](#) recommends the use of sunscreens with an SPF of 30 or greater to reduce the risk of skin cancer and early skin aging. Most sunscreens come in lotion, cream, or gel form. A smaller number of lip balms are also available. It is important for sunscreens to have both ultraviolet A and ultraviolet B protection. Sunscreen is not to be used on infants.

Antineoplastic Drugs

Although related statistics of nonmelanoma skin cancer are not reported by Canadian cancer registries, it is considered the most common cancer diagnosed in Canadians ([Canadian Cancer Society, 2020a](#)). There are two types of nonmelanoma skin cancer: basal cell carcinoma and squamous cell carcinoma. Basal cell carcinoma and squamous cell carcinoma make up 75 to 80% and 20% of all skin cancers, respectively ([Canadian Cancer Society, 2020b](#)). The most common cause of skin cancer is exposure to the sun and use of tanning beds. Early detection and prevention (with the use of sunscreen) are of the utmost importance.

fluorouracil

Various premalignant skin lesions and basal cell carcinomas may be treated with the topically applied form of the antineoplastic drug fluorouracil (Efudex®). As noted in [Chapter 52](#), this drug is an antimetabolite that acts by interfering with key cellular metabolic reactions, destroying rapidly growing cells such as premalignant and malignant cells. It is also used topically in the treatment of solar or [actinic keratosis](#) and superficial basal cell carcinomas of the skin, often in addition to local surgical excision. More aggressive skin cancers (squamous cell carcinoma and malignant melanoma) are not treated with fluorouracil but are usually treated with more aggressive interventions, such as surgery, radiation therapy, or systemic chemotherapy (see [Chapters 52 and 53](#)).

The adverse effects associated with the topical use of this antineoplastic drug are generally limited to local inflammatory reactions such as dermatitis, stomatitis, and photosensitivity. More serious effects include swelling, scaling, pain, pruritus, burning, soreness, tenderness, suppuration, scarring, and hyperpigmentation.

Fluorouracil is available as a topical cream. It can be applied with a nonmetallic applicator, clean fingertips, or gloved fingers. If the fingers are used, they need to be washed thoroughly immediately after application. The 1% fluorouracil cream is used for the treatment of multiple actinic keratoses of the head and neck. The cream is applied twice daily to the lesions. Superficial basal cell carcinoma may be treated with 5% fluorouracil, administered twice daily for at least 2 to 6 weeks. Another topical drug used for actinic keratoses and basal cell carcinomas is the immunomodulator imiquimod, discussed in the following section.

Immunomodulators

▶ pimecrolimus

Pimecrolimus (Elidel®) is available in a cream form for use in treating atopic dermatitis. Atopic dermatitis is caused by a hereditary susceptibility to pruritus and is often associated with allergic rhinitis, hay fever, and asthma. This drug works through a mechanism similar to that of the immunosuppressant drug tacrolimus (Advacraf®) used to prevent rejection of transplanted organs, which was discussed in [Chapter 50](#). A topical form of tacrolimus (Protopic®) is also used and has similar actions and indications. Adverse reactions to both drugs are usually limited to minor skin irritations.

imiquimod

Imiquimod (Aldara P®, Vyloma®) is an immunomodulating drug that has demonstrated efficacy in treating actinic keratoses, basal cell carcinoma, and anogenital warts. Its exact mechanism of action is unknown, but it is believed to somehow enhance the body's immune response to these conditions. It is applied two to five times per week, as prescribed, depending on the condition being treated. Adverse reactions to imiquimod include mild skin reactions such as burning, induration (hardness), irritation, pain, and bleeding, which can occur both locally (at the site of medication administration) and at skin areas remote from the site of administration. More severe adverse skin reactions include edema, erosion or ulceration, scaling, scabbing,

exudation, and vesicle formation. Systemic reactions, likely a result of systemic immunomodulating effects, include cough, upper respiratory infection, musculoskeletal reactions (e.g., back pain), and lymphadenopathy. This drug is available only in cream form.

WOUND CARE DRUGS

Although superficial skin wounds usually require minimal interventions, deeper skin wounds often require more deliberate care to promote optimal healing. Such care includes addressing systemic factors (e.g., body nutritional status) that are critical to tissue repair. Vitamin C (ascorbic acid) and zinc have been shown to improve wound healing when they are given orally. Topical wound care medications are one of the fundamental steps of wound care, referred to in the literature as *preparation of the wound bed*. When medications are required for wound care, consult with a wound care specialist. Wound *débridement* is removal of nonviable tissue and elimination of bacteria by suitable cleansing or surgical intervention. Drugs containing papain or a combination of papain and urea are commonly used as topical débriding drugs. [Table 56.6](#) lists information regarding selected currently available wound care products.

SKIN PREPARATION DRUGS

The skin must be disinfected before undergoing any invasive procedure. Isopropyl alcohol (70%) is most commonly used to prepare the skin before minor procedures such as drawing blood or giving injections. Isopropyl alcohol has been shown to lower the bacterial count on the skin for 20 to 40 minutes after application. Other drugs that are used to prepare the skin include povidone-iodine, chlorhexidine (Dexidin®, Hibitane®), and benzalkonium chloride (Agentquat®). Benzalkonium chloride is a surface-active drug that works by denaturing microorganisms or essentially destroying their proteins. Chlorhexidine acts by disrupting bacterial membranes and inhibiting cell wall synthesis. It is used primarily by health care providers as a surgical scrub or handwashing agent. Chlorhexidine 2% and 70% alcohol swabs are also used to reduce skin microbial levels when used to cleanse an arterial or central line. Povidone-iodine is an antiseptic that kills bacteria, fungi, and viruses. It is used for the prevention or treatment of topical infections associated with surgery, burns, and minor cuts and scrapes, and for relief of minor vaginal infections. It is the most widely used antiseptic.

There is no need to screen for iodine or shellfish allergies with its use—immunoglobulin E antibody-mediated seafood allergies are not linked to iodine; such allergies are to specific proteins in fish and shellfish, which do not contain iodine. Some debate exists when screening for shellfish or seafood allergy during radiocontrast media (RCM) administration, despite evidence that the allergy is not related to potential for RCM ([Kaur, Schend, Virant, et al., 2018](#)). Povidone-iodine is available in many different dosage forms. See [Table 56.7](#) for more information on selected skin preparation drugs.

TABLE 56.6 Selected Wound Care Products

Product Name	Advantages	Disadvantages	Contraindications
acetic acid (vinegar)	Low cost; antiseptic	Cytotoxic	Allergy
sodium hypochlorite (Clorox® bleach solution, 0.65%; Dakin's Solution®, 0.5%)	Aids débridement; reduces microbial count	Partly toxic and irritating to healing tissue	Clean, noninfected wounds
collagenase (Santyl®)	Good for patients taking anticoagulants or in whom surgery is contraindicated; selectively removes necrotic tissue; does not harm normal tissue; satisfactory for infected wounds	Requires health care provider's order; not for use with other common wound care products such as silver sulfadiazine; expensive	Clean wounds with granulation tissue and signs of healing but with limited areas of necrosis; product allergy
iodine (Iododerm®)	Slow-release; safe for viable cells; absorbs exudates; promotes wound healing	Partly toxic to fibroblast cells; stains tissue	Iodine allergy

TABLE 56.7 Skin Preparation Drugs

Drug	Effective Against	Adverse Effects
isopropyl alcohol	Bacteria, fungi, virus	Excessive dryness of skin
chlorhexidine (Dexidin, Hibitane)	Bacteria, fungi	Central nervous system toxicity in newborns and burn patients
povidone-iodine	Bacteria, fungi, virus	Staining of skin, irritation and pain at wound sites; retards or reverses the granulation process
benzalkonium chloride (Agentquat)	Bacteria, fungi	Chemical burns if left in contact with skin for too long

Assess the patient's overall health status and hygiene practices, including whether the patient has experienced any trauma and whether there is any history of immunosuppression. Remember that the skin of young children and older adults is more fragile and permeable to certain topical dermatological preparations. These characteristics also lead to a higher risk of systemic absorption from the skin. It is important to note other possible situations that may result in a drug effect that is less than therapeutic, such as the use of topical drugs over an area containing pus or debris. Use of natural health products, such as topical aloe vera, also requires thorough assessment and notation of any allergies, contraindications, cautions, and drug interactions (see the Natural Health Products box on p. 911).

❖ NURSING PROCESS

◆ ASSESSMENT

Before administering any dermatological preparation, assess patients for any allergies (including allergies to all drug ingredients), contraindications, cautions, and drug interactions. Topical antibacterials are associated with a wide range of reactions because of the sensitivity of patients to antibiotics, even when in a different dosage form; therefore, if a patient is allergic to a systemic antibacterial, the patient will also be allergic to its topical dosage forms. Assess the results of any culture and sensitivity testing that was ordered before giving an antibacterial, to ensure appropriate identification of effective drugs. Before administering any type of topical medication (e.g., antimicrobial, corticosteroid, antiacne drug), always consider the concentration of the medication, length of exposure to the skin, condition of the skin, size of the affected area, and hydration of the skin. All of these factors have a significant influence on the action of the medication. Additionally, assess the medication order for not only the correct drug but also the prescribed route. Inspect the skin or affected area thoroughly under an adequate light source. Palpate the area with a gloved hand. In dark-skinned patients, an erythematous area may not be visible but may be palpated as an area of warmth. Accompany physical assessment of the skin with a documented assessment of surrounding structures, including lymph nodes.

◆ NURSING DIAGNOSES

- Reduced skin integrity resulting from specific diseases, reactions, conditions, or breaks in skin barrier
- Inadequate knowledge resulting from lack of experience with and exposure to use of topical drugs

◆ PLANNING

◆ Goals

- Patient's skin will remain intact and healed in appearance, and skin integrity will be maintained.
- Patient will demonstrate adequate knowledge about the use of dermatological medication.
- Patient will remain adherent to the drug regimen.

◆ Expected Patient Outcomes

- Condition of patient's skin improves daily as stated by the patient, with less redness, drainage, discomfort, itching, or rash.
- Patient states the rationale for treatment, adverse effects of the specific dermatological preparation, and symptoms associated with the dermatological preparation that should be reported to the health care provider.
- Patient demonstrates how to apply the medication in keeping with the health care provider's orders, with specific attention to the requirements for emollient, lotion, solution, spray, cream, gel, and ointment dosage forms.

- Patient experiences improvement in the condition of affected area(s) and demonstrates continued adherence to the medication regimen.
- Patient applies or self-administers the medication, as prescribed or directed and at the recommended frequency.

◆ IMPLEMENTATION

When a wound has been noted, a wound assessment and treatment flow sheet should be implemented and filled out each time wound care has been completed. In general, before any topical medication is applied, cleanse the affected site of any debris, drainage, and residual medication, taking care to follow any specific directions, such as removing water- or alcohol-based topical preparations with soap and water. Always begin (and end) by performing hand hygiene and maintain standard precautions/routine practices (see Box 10.1). Store all dosage forms of medication as recommended. Wear gloves, not only to prevent contamination from secretions but also to prevent absorption of the medication through the skin. Apply topical drugs using a gloved hand, tongue depressor, or cotton-tipped applicator. Shake or mix lotions and solutions thoroughly before use and apply them evenly (see Chapter 10). Wash hands before and after application of the medication. Apply any dressings as ordered, paying special attention to directions concerning occlusive, wet, or wet-to-dry dressing changes. It is important to note, however, that most topical dermatological drugs do not require the use of a dressing once the medication is applied. The medication order may also indicate that any dressing or coverage of the affected area is to be avoided. When medications are used for wound care, there is usually a step-by-step protocol for application of a cleansing agent, a possible debridement drug, and a rinsing solution, as well as final application of an antibacterial, antifungal, burn, antiseptic, or other solution that may have been ordered. Provide comprehensive patient education regarding wound care and use of topical dermatological drugs to ensure safe and effective treatment. If home health care is needed after discharge, arrangements need to be in place before the patient returns home. Document information about the site of drug application, including drainage (colour and amount), swelling, temperature, odour, skin colour, and pain or other sensations. Also record the type of treatment rendered and the response with each treatment or application, as well as a comparative before-and-after assessment. Some health care agencies have procedures for taking pictures of wounds to assess for improvement in healing. Patients should be encouraged to continue this documentation when they are able to do so.

Follow the manufacturer's guidelines regarding the use of any dermatological preparation, because each medication has a different type of base solution. Specific application procedures may be required for different dosage forms. It is also important to follow any instructions or orders regarding other treatments around the affected area, such as the use of an occlusive or wet dressing (see earlier in the chapter). Medicated areas may also need to be protected from exposure to air or sunlight. Strict adherence to the proper method of application and dosage of any dermatological preparation

is important to its effectiveness. Doubling of the next dose following a missed dose is not recommended. After the medication administration process is complete, dispose of all contaminated dressings, gloves, and equipment properly. Maintain safety, comfort, and privacy for the patient at all times. See the Patient Teaching Tips for more information. Also see Table 56.6 for information about specific drugs for wound care and their advantages and disadvantages.

◆ EVALUATION

Begin evaluation by monitoring to ensure that goals and expected outcomes are being met. Therapeutic responses to the various dermatological preparations include improved condition of skin; healing of lesions or wounds; decrease in the size of the lesions with eventual resolution; and decrease in swelling, redness, weeping, itching, or burning in the affected area. Notify the health care provider if a therapeutic response is not observed within an appropriate time frame (anywhere from 48 to 72 hours or longer, depending on the drug, the disorder or skin problem, and the acute or long-term nature of the condition) or if signs and symptoms worsen or new ones appear. Adverse effects for which to evaluate include increased severity of symptoms, such as increased redness, swelling, pain, and drainage; fever; or any other unusual problems at the affected area. Adverse effects may range from slight irritation of the site where the topical drug has been applied, to an allergic reaction, to toxic systemic effects.

CASE STUDY

Medications for Wound Care

Akule, a 16-year-old student, was clearing brush with his father when he cut his hand. His mother washed the wound and told him to apply cream. Akule checked the family medicine cabinet and applied clotrimazole (Clotrimaderm) cream, the only cream in the cabinet.

Two days later, the wound is not better and is painful. Akule's mother takes him to the clinic to have the wound checked. The nurse finds that the laceration wound is deep but does not have any drainage. The

wound is irrigated with normal saline, bacitracin is applied, and the wound is closed with adhesive strips and then covered with a loose gauze dressing. The nurse gives Akule instructions on how to care for the wound and tells him that this wound care is to be done twice a day for 1 week. In addition, the nurse suggests that Akule take vitamin C and zinc supplements for the next month and instructs him not to use the clotrimazole ointment on the wound.

1. Why did the nurse apply bacitracin instead of clotrimazole? Explain your answer.
2. What is the purpose of the vitamin C and zinc supplements?
3. The next day, Akule discovers a rash that covers both his arms and legs. The rash is itchy, and his skin is red with small bumps. He knows that there was poison ivy in the brush and wants something to stop the itching. What will be suggested?
4. The next evening, as he takes off the dressing to clean his wound, Akule finds that the area is swollen and more inflamed, with tiny red bumps around the wound. There is no drainage. What do you think has happened, and what will be done?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

PATIENT TEACHING TIPS

- Advise patients to keep the skin clean and dry or clean and moist, as prescribed. Provide instructions to patients and caregivers about maintaining adequate general hygiene, cleanliness, and hydration, as well as proper nutrition, during drug therapy.
- Ensure that patients have a thorough understanding of how to prepare skin for the application of medication and any other instructions.
- Apply dressings to the affected area as directed, if indicated or ordered. Perform dressing application after medication use, and properly dispose of contaminated dressings or equipment. Emphasize the need for thorough hand hygiene before and after application of medication with a gloved hand, cotton-tipped applicator, or tongue depressor. Demonstrate proper techniques to all individuals involved in the care of patients. Always emphasize the importance of adherence to the drug regimen. Teach patients to use a thin layer of drug product; only the product that actually touches the skin has any benefit.
- Encourage patients to notify their health care provider of any unusual or adverse reactions or if the original condition worsens or fails to improve within a designated period of time.
- Counsel all female patients of childbearing age about the teratogenic hazards associated with fetal exposure to certain dermatological drugs. All sexually active women must use contraception during treatment with any teratogenic drug and for at least 1 month after its discontinuation.
- Educate patients about ways to prevent exposure to the sun through the use of sunscreen and protective clothing, as well as avoidance of overexposure. Use of tanning beds creates potential for skin cancer as well, so share with patients appropriate and accurate information regarding their use and associated risk. Sunscreen must also be applied with use of tanning beds in order to reduce the damage from the ultraviolet radiation.
- Vitamin D deficiency may be an issue for some sunscreen users and for those who live at higher latitudes or are not exposed to sunlight. As adequate oral intake of vitamin D is difficult to achieve without supplementation, many people with minimal exposure to sunlight do not activate vitamin D and have reduced vitamin D levels.
- Patients should be taught how to self-assess all skin moles or lesions and monitor for any unusual changes in colour, size, texture, or shape, which should be reported to a health care provider.

KEY POINTS

- Dermatological drugs are used to treat topical infections.
- Common skin disorders caused by bacteria are folliculitis, impetigo, furuncles, carbuncles, and cellulitis.
- The bacterium most commonly responsible for acne is *Propionibacterium acnes*.
- The fungi that are responsible for causing topical fungal infections are *Candida* spp., dermatophytes, and *Malassezia furfur*.
- The most common topical fungal infections are *Candida* infections, for example, yeast infections.
- One of the most common topical viral infections is infection with herpes simplex virus types 1 and 2.
- Topical anaesthetics are used therapeutically to numb the skin. Indications for topical anaesthetics include insect bites, sunburn, poison ivy, and prevention of pain from injections.
- Corticosteroids are some of the most widely used topical drugs and are indicated for relief of topical inflammatory and pruritic disorders.
- Beneficial effects of corticosteroids include anti-inflammatory, antipruritic, and vasoconstrictor actions. Some of the negative effects of potent corticosteroid use or prolonged use of weaker corticosteroids include dermal atrophy and adrenal insufficiency.
- Adverse and toxic reactions to dermatological drugs can and do occur; therefore, administer these drugs cautiously and follow the health care provider's orders and manufacturer's guidelines. This is crucial to ensure safe and effective treatment.
- Patient education about each medication, its administration, and its effectiveness is important to ensure adherence to the treatment regimen.

EXAMINATION REVIEW QUESTIONS

1. The nurse is assessing the skin of an adolescent patient who has been using a benzoyl peroxide product for 2 weeks as part of treatment for acne. Which assessment findings indicate that the patient is having an allergic reaction and will need to stop treatment?
 - a. Reddened skin over the treatment area
 - b. Blistering skin over the treatment area
 - c. Peeling skin over the treatment area
 - d. Sensation of warmth when the product is applied
2. When considering the variety of OTC topical corticosteroid products the nurse is aware that which type of preparation is generally most penetrating and effective?
 - a. Gel
 - b. Lotion
 - c. Spray
 - d. Ointment
3. The nurse is monitoring for an allergic reaction to topical bacitracin, which would be evident by the presence of which symptom(s)?

- a. Petechiae
 - b. Thickened skin
 - c. Itching and burning
 - d. Purulent drainage
4. When the nurse is teaching a patient about the mechanism of action of tretinoin, which statement by the nurse is correct?
 - a. “This medication acts by killing the bacteria that cause acne.”
 - b. “This medication actually causes skin peeling.”
 - c. “This medication acts by protecting your skin from ultra-violet light.”
 - d. “This medication has anti-inflammatory actions.”
 5. When the nurse is providing wound care with Dakin’s Solution for a patient who has a stage III pressure wound, the patient exclaims, “I smell bleach! Why are you putting bleach on me?” What is the nurse’s best explanation?
 - a. “This is a dilute solution and acts to reduce the bacteria in the wound so that it can heal.”
 - b. “This solution is used instead of medication to promote wound healing.”
 - c. “This solution is used to dissolve the dead tissue in your wound.”
 - d. “Don’t worry; we would never use bleach on a patient!”
 6. The nurse is instructing a parent on the use of dimeticone for treatment of a child’s head lice. Which statement by the parent indicates a need for further education?
 - a. “I will spray his hair, then rinse out the shampoo immediately.”
 - b. “I will leave the medication on his hair for 30 minutes before rinsing.”
 - c. “After the hair is dry, I will shampoo and dry his hair.”
 - d. “When the hair is dry, I will comb the hair to remove the nits.”
 7. The nurse is performing wound care on a burned area of a patient’s arm using silver sulfadiazine cream. Which actions by the nurse are correct? (Select all that apply.)
 - a. Applying the cream over the previous layer to avoid disturbing the wound bed
 - b. Gently cleansing the wound to remove wound debris and the previous layer of cream
 - c. Using clean gloves to apply the ointment
 - d. Using sterile gloves to apply the ointment
 - e. Always covering the wound with a dressing after applying the cream
 - f. Performing hand hygiene before and after the procedure
 8. The nurse is reviewing the use of topical anaesthetic drugs. Which of these is an appropriate use for the lidocaine/prilocaine combination cream known as EMLA?
 - a. To reduce the discomfort of insect bites
 - b. To reduce the pain of sunburn
 - c. To relieve the itching associated with poison ivy
 - d. To reduce pain before a needle insertion

CRITICAL THINKING ACTIVITIES

1. A 22-year-old woman with severe acne is receiving counseling before taking isotretinoin (Accutane) therapy. She has read the related warnings from Health Canada online and was shocked and concerned to learn that two negative pregnancy tests are required before starting therapy and that a pregnancy test must be performed monthly during therapy. What is the nurse’s best answer to her concerns?
2. A child is being discharged after a minor surgical procedure. The child’s mother has been instructed to use a povidone-iodine OTC antiseptic to cleanse the area. The mother

expresses concern that her child has a sensitivity to shellfish and that she read on the Internet that this antiseptic should not be used in individuals who have an allergy or sensitivity to shellfish. What is the nurse’s best response?

3. A 6-year-old child is sent home from school with head lice. His mother is worried that the lice will spread to her two younger children. You are her neighbour and a nurse. She asks what she can do to prevent the spread of lice.

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Ophthalmic Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Discuss the anatomy and physiology of the structures of the eye and the impacts of glaucoma and other disorders and disease processes on these structures.
2. List the various classifications of ophthalmic drugs, with examples of specific drugs in each class.
3. Discuss the mechanisms of action, indications, dosage forms, application techniques, adverse effects, cautions, contraindications, and drug interactions of the various ophthalmic drugs.
4. Develop a collaborative plan of care that includes all phases of the nursing process for patients receiving ophthalmic drugs.

KEY TERMS

Accommodation The adjustment of the lens of the eye for variations in distance. (p. 921)

Anterior chamber The bubblelike portion of the front of the eye between the iris and the cornea. (p. 921)

Aqueous humour The clear, watery fluid circulating in the anterior and posterior chambers of the eye. (p. 920)

Canal of Schlemm A tiny, circular vein at the angle of the anterior chamber of the eye through which the aqueous humour is drained and ultimately funnelled into the bloodstream; also called *Schlemm's canal*. (p. 921)

Cataract An abnormal, progressive condition of the lens of the eye, characterized by loss of transparency and resultant blurred vision. (p. 921)

Ciliary muscles The circular muscles between the anterior and posterior chambers behind the iris; connected to the suspensory ligaments that control the lens curvature. (p. 921)

Closed-angle glaucoma that occurs as a result of a narrowed anatomical angle between the lens and cornea; also called *narrow-angle glaucoma*, *congestive glaucoma*, and *pupillary closure glaucoma*. (p. 922)

Cones Photoreceptive (light-receiving) cells in the retina of the eye that enable a person to perceive colours and play a large role in central (straight-ahead) vision. (p. 921)

Cornea The convex, transparent, anterior part of the eye. (p. 920)

Cycloplegia Paralysis of the ciliary muscles, which prevents the accommodation of the lens to variations in distance. (p. 921)

Cycloplegics Drugs that paralyze the ciliary muscles of the eye. (p. 921)

Dilator muscle A muscle that constricts the iris of the eye but dilates the pupil; also called *dilator pupillae*. (p. 921)

Glaucoma An abnormal condition of elevated pressure within the eye because of obstruction of the outflow of aqueous humour. (p. 922)

Intraocular pressure (IOP) The internal pressure of all fluids of the eye against the tunics (retina, choroid, and sclera). (p. 921)

Iris The round, muscular portion of the eye that gives the eye its colour and serves as an aperture controlling the amount of light passing through the pupil. (p. 919)

Lacrimal ducts Small tubes that drain tears from the lacrimal glands into the nasal cavity. (p. 920)

Lacrimal glands located at the medial corners of the eyelids that produce tears. (p. 920)

Lens The transparent, curved structure of the eye that is located directly behind the iris and pupil and is attached to the ciliary body by ligaments. (p. 921)

Lysozyme An enzyme with antiseptic actions that destroys some foreign organisms; it is normally present in tears, saliva, sweat, and breast milk. (p. 920)

Miotics Drugs that constrict the pupils. (p. 921)

Mydriatics Drugs that dilate the pupils. (p. 921)

Open-angle glaucoma A type of glaucoma that is often bilateral, develops slowly, is genetically determined, and does not involve a narrowing of the angle between the iris and the cornea; also called *chronic glaucoma*, *wide-angle glaucoma*, and *simple glaucoma*. (p. 922)

Optic nerve A major nerve that connects the posterior end of each eye to the brain, to which it transmits visual signals. (p. 921)

Pupil A circular opening in the iris of the eye, located slightly to the nasal side of the centre of the iris; the pupil lies behind the anterior chamber of the eye and the cornea and in front of the lens. (p. 920)

Retina The innermost layer of the eye, containing both rods and cones that receive visual stimuli and transmit them to the optic nerve. (p. 921)

Rods Photoreceptive (light-receiving) elements arranged perpendicularly to the surface of the retina; rods are especially sensitive to low-intensity light and are responsible

for black-and-white and peripheral (to-the-side) vision.
(p. 921)

Sphincter pupillae A muscle that expands the iris while constricting or narrowing the diameter of the pupil.
(p. 920)

Tears Watery saline or alkaline fluid secreted by the lacrimal glands to moisten the conjunctiva (see [Figure 57.1](#)).
(p. 920)

Uvea The fibrous tunic beneath the sclera that includes the iris, the ciliary body, and the choroid of the eye (see [Figure 57.1](#)); also called *tunica vasculosa bulbi* or the *uveal tract*.
(p. 920)

Vitreous humour A transparent, semigelatinous substance contained in a thin membrane filling the cavity behind the lens; also called the *corpus vitreum* or *vitreous body*.

* Full generic name is given in parentheses. For the purposes of this text, the more common, shortened name is used.

OCULAR ANATOMY AND PHYSIOLOGY

The eye is the organ responsible for the sense of sight. The structures of the eye are illustrated in [Figure 57.1](#), all of which are needed for accurate eyesight. Each eyeball is nearly spherical and approximately 2.5 cm in diameter. Each eye is recessed into a small frontal

skull cavity known as the *orbit*. The exposed anterior (front) portion of the eye is covered by three layers: the protective external layer (cornea and sclera), a vascular middle layer known as the *uvea* (includes the choroid, iris, and ciliary body), and the internal layer, known as the *retina*. All of these layers are protected by the eyelid, which serves as an external protection device.

Each eye is held in place and moved by six muscles controlled by cranial nerves III, IV, and VI. These muscles include the *rectus* and *oblique* muscles. There are four types of rectus muscles: inferior, superior, medial, and lateral. There are two types of oblique muscles: inferior and superior. These muscles are shown in [Figure 57.2](#). (The medial rectus muscle is hidden from view in this figure but is directly across from the lateral rectus muscle.) The levator palpebrae superioris muscle opens the eyelid (see later in this chapter). This muscle rests on top of the superior rectus muscle. There are several other important structures that are either part of or adjacent to the eye. The structures and the purpose of each are as follows:

- **Eyebrow:** Rows of short hairs above (superior to) the upper eyelid. The eyebrow protects the eye from direct light, falling dust or other small particles, and perspiration coming from the forehead.
- **Eyelid:** The layer of muscle and skin lined interiorly by the conjunctiva. The conjunctiva also covers the outer anterior surface of the eye, which includes the cornea. The eyelid is movable and can open or close. It protects the eye when closed and allows vision when open. The eyelid is raised by contraction of the levator palpebrae superioris muscle and is lowered by relaxation of this muscle (see [Figure 57.2](#)).
- **Cornea:** The convex (outward-projecting), transparent, anterior portion of the eye. It can be thought of as a window that sits in front of the lens and allows the passage of light.
- **Eyelashes:** Two or three rows of hairs that are located on the edge (margin) of the eyelid. They help prevent small particles from falling into the eye when it is open.
- **Palpebral fissure:** The space between the upper and lower eyelids when the eyelids are open but relaxed.
- **Sclera:** A tough, white coat of fibrous tissue that surrounds the entire eyeball except for the cornea. It helps maintain the shape of the eye. Commonly called the *white* of the eye, the sclera is nonvascular and allows light to pass through it to the lens.
- **Choroid:** One of the middle-layer structures of the eyeball that contains the blood vessels supplying the eye; it also absorbs light.
- **Ciliary body:** The structure that supports the ciliary muscles that control the curvature of the lens via attached suspensory ligaments.

Fig. 57.1 Horizontal section through the left eyeball, looking from the top down. (Modified from Patton, K. T., & Thibodeau, G. A. (2010). *Anatomy and physiology* (7th ed.). St. Louis, MO: Mosby.)

Fig. 57.2 Extrinsic muscles of the right eye, lateral view. (Modified from Patton, K. T., & Thibodeau, G. A. (2010). *Anatomy and physiology* (7th ed.). St. Louis, MO: Mosby.)

- **Conjunctiva:** The mucous membrane that lines the eyelids and also covers the exposed anterior surface of the eyeball.
- **Iris:** The coloured (pigmented) muscular apparatus behind the cornea.
- **Pupil:** The variable-sized opening in the centre of the iris that allows light to enter into the eyeball when the eyelids are open. The pupil is the most posterior part of the front portion of the eye through which light passes to the lens and the retina (the cornea is the front part of this window).
- **Medial canthus:** The site of union of the upper and lower eyelids near the nose.
- **Lacrimal caruncle:** A small, red, rounded elevation covered by modified skin at the medial angle of the eye; the site of the lacrimal glands (see later in the chapter).

- **Lateral canthus:** The site of union of the upper and lower eyelids away from the nose.

Lacrimal Glands

The eye is kept moist and healthy by an intricate network of connected canals, ducts, and sacs that work together. The **lacrimal glands** produce tears that bathe and cleanse the exposed anterior portion of the eye. **Tears** are composed of an isotonic, aqueous solution that contains an enzyme called **lysozyme**, which acts as an antibacterial to help prevent eye infections. Tears drain into the nasal cavity through the **lacrimal ducts**.

Layers of the Eye

Overall, the eye can be thought of as having three separate anatomical layers. The fibrous outer layer of the eye has two parts that are continuous with each other: the sclera and the cornea. The sclera is a tough, fibrous layer that protects and maintains the shape of the eye. The **cornea** is a nonvascular, transparent portion of the outer layer that allows light to enter the eye. It is located at the extreme front of the eye and is continuous with the sclera. It is pain sensitive (a protective function) and obtains nutrition from **aqueous humour**, the clear, watery fluid that circulates in the anterior and posterior chambers of the eye. The vascular middle layer of the eye is composed of the iris (to the anterior), ciliary body, and choroid (to the posterior). These three structures are collectively called the **uvea**. The iris gives colour to the eye and has an adjustable opening in the centre called the **pupil**. The main function of the iris is to regulate the amount of light that enters the eye by causing the size of the pupil to vary. Pupil size is controlled by two smooth muscles.

Fig. 57.3 Different nervous systems control pupil size.

The **sphincter pupillae** muscle is controlled by the parasympathetic nervous system and constricts the diameter of the pupil (an action called *miosis*; Figure 57.3). In contrast, the pupil is opened (an action called *mydriasis*) by a radial smooth muscle called the **dilator muscle**. It is composed of radiating fibres, like spokes of a wheel, which converge from the circumference of the iris toward its centre. Sympathetic nervous system impulses control this muscle (see Figure 57.3).

The anterior portions of both the retina and choroid merge to become the ciliary body, which produces aqueous humour. This is the clear, watery fluid that circulates in both the anterior and posterior chambers and should not be confused with tears. Aqueous humour contributes, along with **vitreous humour**, to the **intraocular pressure (IOP)** of the eye. This is the internal pressure of all fluids against the tunics (retina, uvea, sclera) of the eye. Given the small size of the eye, any change in the volume of aqueous humour present can lead to increased or reduced IOP. Normally, the aqueous humour is removed from the **anterior chamber** via the **canal of Schlemm** at a rate that balances out its production by the ciliary body. The ciliary body also provides support for the suspensory ligaments to which the lens is attached. The **lens** is the transparent, crystalline structure of the eye, located directly behind the iris and the pupil. It has a biconvex (ellipsoid) shape and is held in place by suspensory ligaments that are attached to the **ciliary muscles**. Contraction of the ciliary muscles changes the shape of the lens. This function is important for visual accommodation (see below) as well as the focusing of light (and visual images) onto the retina. The ciliary muscle is controlled by the parasympathetic nervous system through the oculomotor nerve (cranial nerve III). The lens divides the interior of the eyeball into posterior (rear) and anterior (forward) chambers. The larger chamber behind the lens is filled with a jellylike fluid called the **vitreous body**. The lens is transparent to allow light to pass through it easily. A loss of lens transparency results in a visual condition called a **cataract**. A cataract is a grey–white opacity that can be seen within the lens. If cataracts are untreated, sight may eventually be completely lost. At the onset of a cataract, vision is blurred and may be further worsened by the glare of bright lights. *Diplopia*, or double vision, may also develop.

Before light rays reach the retina, they are focused into a sharp image by the lens of the eye. The elasticity of the lens enables it to change its shape and focusing power. This process is called **accommodation** and is facilitated by the ciliary body. Paralysis of accommodation is called **cycloplegia**. **Mydriatics** are drugs that dilate the pupil (e.g., apraclonidine). Drugs that constrict the

Fig. 57.4 Drug classes and their effects on pupil size.

pupil are called **miotics** (e.g., acetylcholine, pilocarpine). Drugs that paralyze the ciliary body are called **cycloplegics**, but they also have mydriatic properties (e.g., atropine sulphate, cyclopentolate) (Figure 57.4). All of these medications are used to facilitate visualization of the inner eye during ophthalmic examinations.

The third and inner layer of the eye is a thin, delicate layer known as the **retina**. It contains light-sensitive photoreceptors called **rods** and **cones**. The basic function of the retina is to receive the light image formed by the lens and to convert it via the rods and cones into the neural signals that support vision. **Rods** produce black-and-white vision, including shades of grey, and are especially sensitive in low light; **cones** are responsible for colour vision (Figure 57.5). In addition, rods are more active in providing peripheral (to-the-side) vision, whereas cones are more active in central (straight-ahead) vision. In the posterior central part of the retina, the nerve fibres of retinal cells join to form the **optic nerve**. The function of the optic nerve is to connect the retina with the visual centre of the brain, located within the occipital lobe that extends above and behind the cerebellum. It is this portion of the brain that interprets incoming visual stimuli.

TREATMENT OF EYE DISORDERS

Some of the minor ailments that affect the eye can be treated with over-the-counter (OTC) medications, but persistent, painful conditions generally require prescription medications. Medications used to treat disorders of the eye can be divided into several major drug groups: antiglaucoma drugs, antimicrobials, anti-inflammatory drugs, topical anaesthetics, diagnostic drugs, antiallergic drugs, and lubricants and moisturizers. There are also a variety of combination drug products that include two or more medications from different subclasses. The reader can assume the therapeutic indications for and drug effects of these combination products are the same as those of the single-ingredient drug products corresponding to their individual components. The focus of this chapter is on commonly used therapeutic medications.

A multitude of products is also available for use in the care of contact lenses, including contact lens–cleaning enzymes, irrigating solutions, and eye washes. Their use is straightforward, and they carry limited risk. Complicated surgical drugs are

Fig. 57.5 Function of rods and cones in relation to colour vision.

Fig. 57.6 How increased aqueous humour can result in reduced vision. IOP, intraocular pressure.

Fig. 57.7 Main structures of the eye and an enlargement of the canal of Schlemm showing an aqueous flow. (A) Flow in a normal eye. (B) In closed-angle glaucoma, the closure of the anterior angle prevents aqueous humour from exiting through the canal of Schlemm, which leads to increased intraocular pressure. (C) In open-angle glaucoma, the anterior angle remains open, but the canal of Schlemm is obstructed by tissue abnormalities. (Modified from McKenry, L. M., Tessier, E., & Hogan, M. A. (2006). *Mosby's pharmacology in nursing—revised and updated* (22nd ed.). St. Louis, MO: Mosby.)

Dosages Selected Prostaglandin Analogues			
Drug	Pharmacological Class	Usual Dosage Range	Indications
 latanoprost (Xalatan, Xalatan)	Prostaglandin	1 drop every day in the evening	Open-angle glaucoma and ocular hypertension in patients who are intolerant of or whose condition is uncontrolled by other drugs

beyond the scope of this chapter. The reader is advised to refer to manufacturer’s packaging information for details about any unfamiliar product encountered in clinical practice.

GLAUCOMA

Glaucoma is a group of eye disorders that damage the optic nerve. In most cases, this is due to increased IOP that is caused by abnormally elevated levels of aqueous humour. Glaucoma occurs when the aqueous humour is not drained through the canal of Schlemm as quickly as it is formed by the ciliary body. The accumulated aqueous humour creates a backward pressure that pushes the vitreous humour against the retina. Continued pressure on the retina destroys its neurons, which leads to reduced vision and eventual blindness (Figure 57.6). Unfortunately, glaucoma is often without early symptoms, and many patients are not diagnosed until some permanent sight loss has occurred.

Two major types of glaucoma are discussed in this chapter: **closed-angle glaucoma** and **open-angle glaucoma**. Figure 57.7 shows the pathophysiology of each and provides an enlarged view of the involved eye structures. Table 57.1 lists additional characteristic features of each type. Glaucoma can be a primary illness (occurring on its own), or it can be secondary to another eye condition or injury (e.g., post-traumatic glaucoma). Congenital glaucoma can also occur in infants. The visual and optic nerve changes typical of glaucoma can also occur in the absence of increased IOP (normotensive glaucoma). There are a few other less common forms of glaucoma (e.g., pigmentary glaucoma, pseudoexfoliative glaucoma) that are beyond the scope of this chapter.

ANTIGLAUCOMA DRUGS

Treatment of glaucoma involves reducing IOP by either increasing the drainage of aqueous humour or decreasing

TABLE 57.1 Glaucoma: Types and Characteristics

	Closed-angle	Open-angle
Synonyms	Narrow-angle glaucoma, congestive glaucoma, and pupillary closure glaucoma	Chronic glaucoma, wide-angle glaucoma, and simple glaucoma
Chronicity	Acute (can cause rapid vision loss)	Chronic
Relative incidence	Less common	More common
Nature of angle	Narrow	Larger
Most common age of onset and race	30 yr or older, White	30 yr or older, Black
Major symptoms	Blurred vision, severe headaches, eye pain	Blurred vision, occasional headaches
Treatment	Topical or systemic drugs, surgery	Topical or systemic drugs, surgery

TABLE 57.2 Antiglaucoma Eye Drop Drug Effects on Aqueous Humour

Prostaglandin agonists	+++	0

its production. Some drugs may do both. Drug therapy can delay and possibly even prevent the development of glaucoma. Glaucoma eye drops are colour-coded according to medication class to aid the patient in their identification. However, this may not be standard across Canada and may often change. Drug classes of eye drops used to reduce IOP include the following:

- Direct-acting cholinergics (also called *miotics* and *parasympathomimetic drugs*)
- Indirect-acting cholinergics (also called *miotics*, *cholinesterase inhibitors*, and *parasympathomimetic drugs*)
- Adrenergics (also called *mydriatics* and *sympathomimetic drugs*)
- Antiadrenergics (β -blockers; also called *sympatholytic drugs*)
- Carbonic anhydrase inhibitors
- Osmotic diuretics
- Prostaglandin agonists

See Table 57.2 for a comparison of the effects of these drugs on the aqueous humour.

Cholinergic Drugs

There are two categories of ophthalmic parasympathomimetic drugs, more concisely referred to as *cholinergic drugs*: direct-acting and indirect-acting. Some examples of direct-acting cholinergics include acetylcholine, carbachol, and pilocarpine. Indirect-acting cholinergics are also called

cholinesterase inhibitors, and an example of this type of drug is echothiophate (currently not available in Canada). Because one primary drug effect of these drugs is pupillary constriction or miosis (see later), they are also commonly called *miotics*.

Mechanism of Action and Drug Effects

Acetylcholine is the neurochemical mediator of nerve impulses in the parasympathetic nervous system. It stimulates parasympathetic, or cholinergic, receptors located in the brain and throughout the body along parasympathetic nerve branches. This stimulation results in several effects on the eye: miosis (pupillary constriction), vasodilation of blood vessels in and around the eye, contraction of ciliary muscles, drainage of aqueous humour, and reduced IOP. Ciliary muscle contraction promotes aqueous humour drainage by widening the space where the drainage occurs. Miosis promotes aqueous humour drainage by causing the iris to stretch, which also serves to widen this space.

Both direct- and indirect-acting miotics have effects similar to those of acetylcholine, but their actions are more prolonged (Figure 57.8). The direct-acting miotics are able to directly stimulate ocular cholinergic receptors and mimic acetylcholine. Indirect-acting miotics work by binding to and inactivating the cholinesterases acetylcholinesterase and pseudocholinesterase, the enzymes that break down acetylcholine. As a result, acetylcholine accumulates and acts longer at cholinergic receptor sites. This action leads to drug effects that include miosis, ciliary muscle contraction, enhanced aqueous humour drainage, and reduced IOP by an average of 20 to 30% (Figure 57.9). Drug-induced miotic effects may be less pronounced in individuals with dark eyes (e.g., brown or hazel) than in those with lighter eyes (e.g., blue or green). This difference occurs because the pigment of the iris also absorbs the drug (which reduces its therapeutic effects), and dark eyes have more pigment.

Indications

The direct- and indirect-acting miotics are used for open-angle glaucoma, closed-angle glaucoma, and convergent strabismus (“cross-eye”; a condition in which one eye points toward the other) and in ocular surgery. They are also used to reverse the effect of mydriatic (pupil-dilating) drugs following ophthalmic examination. Specific indications may vary for different drugs, as shown in Table 57.3.

Fig. 57.8 Cholinergic response of miosis to parasympathomimetics. *ACh*, acetylcholine; *PSNS*, parasympathetic nervous system.

Fig. 57.9 The therapeutic effects of direct- and indirect-acting parasympathomimetics on glaucoma. *IOP*, intraocular pressure.

TABLE 57.3 Miotics: Indications

Miotic Drug	Indications
acetylcholine	Need for complete and rapid miosis after cataract lens extraction, iridectomy
carbachol	Open-angle glaucoma
pilocarpine	Open-angle glaucoma, secondary glaucoma after iridectomy, cycloplegic reversal

Contraindications

Contraindications to the use of miotics include known drug allergy and any serious active eye disorder in which induction of miosis might be harmful.

Adverse Effects

Most of the adverse effects associated with the use of cholinergics and cholinesterase inhibitors (miotics) are local and limited to the eye. Adverse effects are more likely to occur with indirect-acting miotics because they have longer-lasting effects. These effects include blurred vision, drug-induced myopia (nearsightedness), and accommodative spasms. Such effects are secondary to contraction of the ciliary muscle. Miotic drugs also cause vasodilation of blood vessels supplying the conjunctiva, iris, and ciliary body, which may lead to vascular congestion and ocular inflammation. Other undesirable effects include temporary stinging upon drug instillation, reduced nighttime or low-light vision, conjunctivitis, lacrimation (tearing), twitching of the eyelids (blepharospasm), and eye or brow pain. Systemic effects are uncommon with miotic drugs but are also more likely to occur with indirect-acting miotics (cholinesterase inhibitors). See Chapters 21 and 22 for more information on the systemic effects of these drugs.

Interactions

Drug interactions are unlikely with miotics because of the local actions of these drugs. When miotic drugs are given with topical adrenergics, antiadrenergics (e.g., β -blockers), or carbonic anhydrase inhibitors, additive lowering effects on IOP can be seen. Systemic cholinergic drugs can theoretically have additive cholinergic effects when given with miotics. Indirect-acting miotics may also potentiate the effects of the neuromuscular blocker succinylcholine (see Chapter 12).

Dosages

For recommended dosages of selected miotic drugs, refer to the table on p. 925.

DRUG PROFILES

Direct-Acting Miotics

Direct-acting ophthalmic cholinergics include acetylcholine chloride (Miochol E®), carbachol (Miostat®), and pilocarpine (Akarpine®, Diocarpine®, Isopto Carpine®, Minims®). Indirect-acting ophthalmic drugs, which are also called *cholinesterase inhibitors*, are not available in Canada.

acetylcholine chloride

Acetylcholine chloride (Miochol E) is a direct-acting cholinergic drug that is used to produce miosis during ophthalmic surgery. It is a pharmaceutical form of the naturally occurring neurotransmitter in the body. It has a rapid onset and may begin to work almost immediately. It is administered directly into the anterior chamber of the eye before and after securing one or more sutures.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Ocular	Instant (seconds)	Instant	3 min	20 min (up to 6 hr)

pilocarpine hydrochloride

Pilocarpine hydrochloride (Akarpine, Diocarpine, Isopto Carpine, Minims) is a direct-acting cholinergic drug that is used as a miotic in the treatment of glaucoma. Pilocarpine is available in different strengths as an ophthalmic gel or solution.

PHARMACOKINETICS (IMMEDIATE-RELEASE FORMULATION)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Ocular	10–30 min	30–60 min	Unknown	4–8 hr

Fig. 57.10 Mechanism of mydriasis.

Sympathomimetics (Mydriatics)

Sympathomimetic drugs are used for the treatment of glaucoma and ocular hypertension. These drugs include the α -receptor agonists brimonidine (Alphagan P®, Combigan®, Simbrinza (Brinzolamide/Brimonidine), Lumify) and apraclonidine (Iopidine®).

Mechanism of Action and Drug Effects

Sympathomimetic drugs mimic the sympathetic neurotransmitters norepinephrine and epinephrine. They stimulate the dilator muscle to contract by means of α - or β -receptor interaction. This stimulation results in increased pupil size or *mydriasis* (Figure 57.10). Dilation is seen within minutes of instillation of the ophthalmic drops and lasts for several hours, during which time the IOP is reduced (Figure 57.11). α -Receptor stimulation reduces IOP by enhancing aqueous humour outflow through the canal of Schlemm. Production of aqueous humour by the ciliary body is also reduced. Both of these effects appear to be dose dependent.

Indications

Apraclonidine stimulates the α_2 -receptors, which oppose these effects, and thus corrects the surgery-induced elevation in IOP. Brimonidine also has primarily α_2 activity but is used to lower IOP in patients with open-angle glaucoma or ocular hypertension.

Contraindications

Contraindications for the sympathomimetic ophthalmic drugs include known drug allergy.

Adverse Effects

Adverse effects of the sympathomimetic mydriatics are primarily limited to ocular effects and include burning, eye pain, and lacrimation. Such effects are usually temporary and may subside as the patient grows accustomed to the medication. Other ocular effects may include conjunctival hyperemia, localized melanin deposits in the conjunctiva, and release of pigment granules from the iris. Although systemic effects associated with the use of sympathomimetic mydriatics are uncommon, they are theoretically possible, especially with the use of larger doses or prolonged drug therapy. They include cardiovascular effects such as extrasystoles, tachycardia, and hypertension. Other effects that patients may experience are headache, presyncope, fatigue, anxiety, sleep disturbances, and also may exacerbate rosacea.

Interactions

With sufficient topical absorption, sympathomimetic mydriatics have the potential to react with other drugs. Cardiac dysrhythmias are potentiated when mydriatic drugs are given with halogenated anaesthetics, cardiac glycosides, thyroid hormones, or tricyclic antidepressants. Monoamine oxidase inhibitors (MAOIs) are contraindicated with the use of apraclonidine.

Dosages

For dosage information on sympathomimetic drugs, refer to the table on p. 926.

Fig. 57.11 Ocular effects of α - and β -stimulation. IOP, intraocular pressure.

Dosages Selected Miotics

Drug	Pharmacological Class	Usual Dosage Range	Indications
acetylcholine chloride (Miochol E)	Direct-acting cholinergic	0.5–2 mL preoperatively	Need for surgical miosis
 pilocarpine hydrochloride (Akarpine, Diocarpine, Isopto Carpine, Minims)	Direct-acting cholinergic	Solution: 1–2 drops tid–qid Gel: 1.25-cm ribbon into lower conjunctival sac at bedtime (use any other eye drops at least 5 min before gel)	Chronic open-angle and closed-angle glaucoma; acute closed-angle glaucoma; preoperative and postoperative intraocular hypertension; need for reversal of drug-induced mydriasis

DRUG PROFILES

Sympathomimetic ophthalmic drugs include dipivefrin, apraclonidine hydrochloride (Iopidine), and brimonidine tartrate (Alphagan, Alphagan P). These drugs are used for glaucoma, ocular hypertension, and ocular surgery.

apraclonidine hydrochloride

Apraclonidine hydrochloride (Iopidine) is structurally and pharmacologically similar to the α_2 -stimulant clonidine. It reduces IOP 23 to 39% by stimulating α_2 - and β_2 -receptors. It also prevents ocular vasoconstriction, which reduces ocular blood pressure as well as aqueous humour formation. Apraclonidine is used primarily to inhibit perioperative IOP increases, rather than to treat glaucoma. Brimonidine (Alphagan, Alphagan P) is a similar drug but is used primarily for glaucoma.

PHARMACOKINETICS (APRACLONIDINE)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Ocular	1 hr	3–5 hr	8 hr	12 hr

dipivefrin hydrochloride

β -Adrenergic Blockers

The antiglaucoma β -adrenergic blockers that reduce IOP include the β_1 -selective blocker betaxolol, and nonselective β_1 - and β_2 -blockers levobunolol hydrochloride and timolol.

Mechanism of Action and Drug Effects

The ophthalmic β -blockers reduce both elevated and normal IOP. They do so by reducing aqueous humour formation. In addition, timolol may produce a minimal increase in aqueous outflow.

Indications

Ophthalmic β -blockers are used to reduce elevated IOP in various conditions, including chronic open-angle glaucoma and ocular hypertension. They may also be used alone or in combination with a topical miotic (e.g., pilocarpine), topical dipivefrin, or systemic carbonic anhydrase inhibitors. When used in combination, these drugs may have an additive IOP-lowering effect. They may also be used to treat some forms of closed-angle glaucoma.

Contraindications

Contraindications for ophthalmic β -blockers include known drug allergy and any ocular condition in which β -receptor blockade might be harmful.

Adverse Effects

The adverse effects of antiglaucoma β -blockers are primarily limited to ocular effects. The most common ocular effects are transient burning and discomfort. Other adverse effects include blurred vision, pain, photophobia, lacrimation, blepharitis, keratitis (inflammation of the cornea), and decreased corneal sensitivity. Because these drugs are administered topically, few, if any, systemic effects are expected following their application. Theoretical systemic effects include bradycardia, bronchospasm, headache, and dizziness, as described for systemic β -blockers in Chapter 20. However, ophthalmic β -blockers have not been shown to affect glucose metabolism.

Interactions

Drug interactions with systemic drugs are unlikely because of the primarily localized nature of ophthalmically administered drugs. Theoretically, ophthalmic β -blockers can have additive therapeutic or adverse effects when given with systemically administered β -blockers or other cardiovascular drugs (e.g., calcium channel blockers).

Dosages

For dosage information on β -adrenergic blockers, refer to the table on p. 927.

DRUG PROFILES

The currently available ophthalmic β -blocking drugs are betaxolol hydrochloride (Betoptic®), levobunolol hydrochloride (Betagan®), and timolol maleate (Timoptic®, Timoptic XE®). These drugs are used for glaucoma and ocular hypertension.

betaxolol hydrochloride

Betaxolol hydrochloride (Betoptic) is a β_1 -selective β -blocker. It is one of the most potent and selective β -blocking drugs. Its ability to decrease aqueous humour formation and reduce IOP has made it an excellent drug for the treatment of ocular disorders such as open-angle glaucoma and ocular hypertension.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Ocular	30 min	2 hr	Unknown	More than 12 hr

timolol maleate

Timolol maleate (Timoptic, Combigan, Azarga, Cosopt, Xalacom, Duotrav PQ) differs slightly from the other ophthalmic

Dosages Selected Ophthalmic Sympathomimetics

Drug	Pharmacological Class	Usual Dosage Range	Indications
apraclonidine hydrochloride (Iopidine)	Direct-acting	0.5% solution: 1–2 drops tid	Short-term adjunctive therapy for glaucoma not controlled by other drugs
Brimonidine	Direct-acting	1 drop q6–8hrs	Open angle glaucoma or ocular hypertension

β -blockers in that it may increase the outflow of aqueous humour as well as decrease its formation. The drug acts at both β_1 - and β_2 -receptors and is indicated for the treatment of open-angle glaucoma and ocular hypertension. It is available in various liquid forms, both with and without preservatives. Preservative-free products were developed for patients with allergies to benzalkonium chloride, a commonly used preservative. Timolol is also available in a gel-forming solution (with preservatives). These gel-forming products (Timoptic XE®) are longer acting and allow for once-daily dosing, a convenience over the twice-daily dosing that many patients require with the other timolol formulations.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Ocular	30 min	1–2 hr	4 hr	24 hr

Carbonic Anhydrase Inhibitors

Ophthalmic carbonic anhydrase inhibitors include brinzolamide (Azarga®, Azopt®) and dorzolamide (Cosopt®, Trusopt®). These two drugs are available only in topical ophthalmic form. Systemic carbonic anhydrase inhibitors are sometimes used as adjunct drug therapy for glaucoma and are described in Chapter 29. Both drugs are also sulfonamides and are chemically similar to the sulfonamide antibiotics (see Chapter 43). They are to be used with caution in patients who are allergic to sulfa antibiotics.

Mechanism of Action and Drug Effects

Carbonic anhydrase inhibitors work by inhibiting the enzyme carbonic anhydrase, which results in decreased IOP by reduction of aqueous humour formation.

Indications

Ophthalmic carbonic anhydrase inhibitors are used primarily for the management of glaucoma, including both open-angle and closed-angle glaucoma; they may also be used preoperatively to control IOP.

Contraindications

Contraindications to the use of carbonic anhydrase inhibitors include known drug allergy and any ocular condition with which their use might be considered harmful in the judgement of an ophthalmologist. Allergy to sulfonamide antibiotics is a precaution, not a contraindication; however, patients need to be educated regarding the possibility of cross-reaction.

Adverse Effects

When given in eye drop form, carbonic anhydrase inhibitors can cause stinging, burning, and eye discomfort. Orally, these drugs can cause a tingling sensation in the feet, some memory loss, nausea, fatigue, and urinary frequency. Systemic absorption of these drugs does occur (e.g., causing a bitter taste in 25%), although systemic adverse effects are rare. The same adverse effects listed for sulfonamide antibiotics in Chapter 43 can theoretically occur with these drugs. Patients with allergies to sulfonamides may develop cross-sensitivities to the carbonic anhydrase inhibitors.

Interactions

The systemic use of carbonic anhydrase inhibitors can result in several significant drug interactions, and the ophthalmic carbonic anhydrase inhibitors have a theoretical (but less likely) potential for these interactions. See Chapter 29 for information on systemic drug interactions.

Dosages

For dosage information on the carbonic anhydrase inhibitor dorzolamide, refer to the table on p. 928.

DRUG PROFILE

There are currently two ophthalmic carbonic anhydrase inhibitors: brinzolamide (Azopt) and dorzolamide (Cosopt, Trusopt). Brinzolamide is available in combination with timolol (Azarga).

dorzolamide hydrochloride

Dorzolamide hydrochloride (Trusopt) is indicated for the treatment of elevated IOP associated with either ocular hypertension or open-angle glaucoma. Dorzolamide is available in combination with timolol (Cosopt). It is available only as an ophthalmic solution. The other drug in this class, brinzolamide, has comparable indications, dosages, and pharmacokinetics.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Ocular	Rapid	Variable	3–4 mo	8–12 hr

Osmotic Diuretics

Osmotic diuretic drugs may be administered intravenously, orally, or topically to reduce IOP. The osmotic diuretics that

Dosages Selected Ophthalmic β -Blockers

Drug	Pharmacological Class	Usual Dosage Range	Indications
 betaxolol hydrochloride (Betoptic)	Direct-acting	1–2 drops bid	Chronic open-angle glaucoma; ocular hypertension
 Timolol maleate (Timoptic, Timoptic XE®)	Direct-acting	Solution: 1 drop bid Gel-forming solution: 1 drop daily	Open-angle glaucoma; ocular hypertension

Dosages Ophthalmic Carbonic Anhydrase Inhibitors

Drug	Pharmacological Class	Usual Dosage Range	Indications
 dorzolamide hydrochloride (Trusopt)	Carbonic anhydrase inhibitor	1 drop BID-TID	Open-angle glaucoma; ocular hypertension

Fig. 57.12 Mechanism and ocular effects of osmotic diuretics. *IOP*, intraocular pressure.

are most commonly used for this purpose are glycerin and mannitol.

Mechanism of Action and Drug Effects

Osmotic diuretics reduce ocular hypertension by causing the blood to become hypertonic in relation to both intraocular and spinal fluids. This creates an osmotic gradient that draws water from the aqueous and vitreous humours into the bloodstream, which causes a reduction in volume of intraocular fluid; the result is a decrease in IOP (Figure 57.12). Systemic (nonocular) effects of these drugs are discussed in Chapter 29.

Indications

Ocular uses for osmotic diuretics include treatment of acute glaucoma episodes and reduction of IOP before or after ocular surgery. Typically, glycerin is used first; if the treatment is unsuccessful, mannitol is tried.

Contraindications

Osmotic diuretics are contraindicated in patients with known drug allergy, significant anuria, acute pulmonary edema, cardiac decompensation, or severe dehydration, because they can worsen all of these conditions.

Adverse Effects

The most frequent adverse effects to osmotic diuretics are nausea, vomiting, and headache. The most significant adverse effects are fluid and electrolyte imbalances. Other effects are possible irritation and thrombosis at the injection site. Other potential adverse effects are listed in Table 57.4.

Interactions

The only significant drug interaction associated with osmotic diuretics is increased lithium excretion associated with mannitol.

Dosages

For dosage information on mannitol, refer to the table on p. 926.

DRUG PROFILES

Osmotic diuretics include mannitol and glycerin. Mannitol is normally reserved for acute reduction of IOP during glaucoma

TABLE 57.4 Osmotic Diuretics (Mannitol): Adverse Effects

Body System	Adverse Effects
Cardiovascular	Edema, thrombophlebitis, hypotension, hypertension, tachycardia, angina-like chest pains, fever, chills
Central nervous	Dizziness, headache, convulsions, rebound increased intracranial pressure, confusion
Electrolytes	Fluid and electrolyte imbalances, acidosis, dehydration
Eyes, ears, nose, throat	Loss of hearing, blurred vision, nasal congestion
Gastrointestinal	Nausea, vomiting, dry mouth, diarrhea
Genitourinary	Marked diuresis, urinary retention, thirst

crises and preoperative reduction of IOP in ophthalmic surgery. Glycerin is a component of OTC eye drops used to moisturize dry and irritated eyes.

mannitol

Mannitol (Osmitol®) is used only by intravenous infusion to reduce elevated IOP when the pressure cannot be lowered by other treatments. Mannitol is effective in treating acute episodes of closed-angle, absolute, or secondary glaucoma and in lowering IOP before intraocular surgery. Mannitol does not penetrate the eye and may be used when irritation is present.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
IV	30–60 min	1 hr	15–100 min	1.5–6 hr

Prostaglandin Agonists

The newest class of drugs used to treat glaucoma is the prostaglandin agonists. There are currently three drugs in this class: latanoprost (Xalacom®, Xalatan®), travoprost (Travatan Z®), bimatoprost (Lumigan®), and Latanoprostene Bunod (Vyzulta®).

Mechanism of Action and Drug Effects

Prostaglandins reduce IOP by increasing the outflow of aqueous fluid between the uvea and sclera as well as via the usual exit through the trabecular meshwork (see Figure 57.7). A single

Dosages Selected Osmotic Diuretics

Drug	Pharmacological Class	Usual Dosage Range	Indications
mannitol (Osmitol)	Organic alcohol	IV: 1.5–2 g/kg infused over at least 30 min; for preoperative use give 1–1.5 hr before surgery	Acute reduction of elevated intraocular pressure

TABLE 57.5 Common Ocular Infections

Infection	Description
Blepharitis	Inflammation of the eyelids
Conjunctivitis	Inflammation of the conjunctiva (the mucous membrane lining the back of the eyelids and the front of the eye except the cornea); it may be bacterial or viral and is often associated with common colds. When caused by <i>Haemophilus</i> organisms, it is commonly called <i>pink eye</i> ; it is highly contagious but usually self-limiting.
Hordeolum (sty)	Acute localized infection of the eyelash follicles and the glands of the anterior lid; it results in the formation of a small abscess or cyst.
Keratitis	Inflammation of the cornea caused by bacterial infection; herpes simplex keratitis is caused by viral infection.
Uveitis	Infection of the uveal tract or the vascular layer of the eye, which includes the iris, ciliary body, and choroid
Endophthalmitis	Inflammation of the inner eye structure caused by bacteria

dose of a prostaglandin agonist lowers IOP for 20 to 24 hours, which allows a regimen involving only a single daily dosage. Drug effects are primarily limited to these ocular effects.

Indications

Prostaglandin agonists are used in the treatment of glaucoma.

Contraindications

Contraindications to the use of prostaglandin agonists are known drug allergy, history of uveitis, cystoid macular edema, herpes simplex keratitis, and complicated cataract surgery.

Adverse Effects

Prostaglandin agonists are generally well tolerated. Adverse effects include the sensation of a foreign body in the eye, punctate epithelial keratopathy (dotted appearance of cornea), stinging, conjunctival hyperemia (“bloodshot” eyes), blurred vision, itching, and burning. Systemic effects occur in a small percentage of patients and include skin reactions, upper respiratory infections, and headache. There is one unique adverse effect associated with all prostaglandin agonists: in some people with hazel, green, or bluish-brown eye colour, prostaglandin agonists will cause their iris to darken because of melanin deposits, even if the medication is discontinued; as well, they can cause thickening, darkening, and lengthening of eyelashes (Harasymowycz, Birt, Gooi, et al., 2016). This adverse effect appears to be cosmetic only, with no known ill effects on the eye.

Interactions

Concurrent administration of prostaglandin agonists with any other eye drops containing the preservative thimerosal may result in precipitation. It is recommended that such medications be administered at least 5 minutes apart.

Dosages

For dosage information on the prostaglandin agonist latanoprost, refer to the table on p. 922.

DRUG PROFILE

latanoprost

Latanoprost is a prodrug of a naturally occurring prostaglandin known as *prostaglandin F_{2α}*. When it is administered, it is converted by hydrolysis (with water from ocular fluids) to prostaglandin F_{2α}, which in turn reduces IOP. Latanoprost is available only in eye drop form. About 3 to 10% of patients treated with latanoprost (Xalacom, Xalatan) have shown increased iris pigmentation after 3 to 4.5 months of treatment.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Ocular	3–4 hr	8–12 hr	17 min	24 hr

ANTIMICROBIAL DRUGS

A variety of infections can occur in the eye; many are self-limiting. However, some infections require the use of ophthalmic antimicrobials to be eliminated. Topical antimicrobials used to treat ocular infections include antibacterial, antifungal, and antiviral drugs. All require a prescription; however, some eye antibiotic drops are available over the counter in lower doses. Many of these drugs are also available for systemic administration for treatment of infections elsewhere in the body. The most commonly used antimicrobials from the main antimicrobial drug classes are discussed in this chapter. Some common eye infections may require antibiotic therapy and are listed in Table 57.5. The choice of a particular ophthalmic antimicrobial drug should be based on the following:

- Clinical experience
- Sensitivity and characteristics of the organisms most likely to cause the infection
- Characteristics of the infection
- Sensitivity and response of the patient
- Laboratory results (cultures and sensitivities)

Mechanism of Action and Drug Effects

Topical antimicrobials used to treat infections of the eye work to destroy the invading organism. Their specific antimicrobial actions are similar to those described for systemically administered drugs, which are discussed in Chapters 43, 44, 45, and 47. The effects of the drugs used to treat ocular infections are focused on the microorganism invading the eye. Some antimicrobials destroy the causative organism, whereas others simply inhibit the organism's growth, allowing the body's immune system to fight the infection.

Indications

The indication for ophthalmic antimicrobials is known or suspected infection with one or more specific microorganisms. Empirical treatment is based on reasonable clinical evaluation of presenting signs and symptoms. Topical use of antimicrobials helps prevent antimicrobial drug resistance that could arise from unnecessary systemic use. However, systemic antimicrobials may be administered to treat more severe ocular infections.

Contraindications

Contraindications to the use of antimicrobials include known drug allergy or a prior severe adverse drug reaction.

Adverse Effects

The most common adverse effects of ophthalmic antibiotics are local and transient inflammation, burning, stinging, urticaria, dermatitis, angioedema, and drug hypersensitivity. Topical application of antimicrobial drugs may also interfere with the growth of the normal bacterial flora of the eye, which may encourage the growth of other, more harmful organisms. If large doses are given, systemic adverse effects are possible.

Interactions

Systemic drug interactions with ophthalmic antimicrobials are unlikely because of their primarily local effects. One possible interaction involves the concurrent use of corticosteroids (e.g., dexamethasone). Corticosteroids have immunosuppressive effects that may impede the therapeutic effects of ophthalmic antimicrobials.

Dosages

For dosage information on ophthalmic antimicrobials, refer to the table on p. 932.

DRUG PROFILES

Aminoglycosides

Aminoglycosides (see Chapter 44) are antimicrobials that destroy bacteria by interfering with protein synthesis in bacterial cells, which leads to bacterial death. Aminoglycosides used to treat ocular infections include gentamicin (Diogen®) which is no longer available in Canada, and tobramycin (Tobrex®). Adverse effects include swollen eyelids, mydriasis, and local erythema. Systemic reactions are rare because of poor topical absorption. Overgrowth of nonsusceptible organisms, which can lead to eye infections that are resistant to treatment, is a possibility with the use of aminoglycosides.

tobramycin

Tobramycin (Tobrex®) is effective against a wide variety of Gram-negative and Gram-positive organisms. It is particularly useful against *Pseudomonas*, *Escherichia coli*, *Proteus*, *Enterobacter*, and *Klebsiella* organisms. Gram-positive organisms that are effectively destroyed by tobramycin include staphylococci and streptococci that have developed resistance to other antibiotics. Tobramycin is available as an ophthalmic ointment and a solution.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Ocular	Variable	Immediate	Unknown	6–12 hr

Macrolide Antibiotics

Macrolide antibiotics include erythromycin, azithromycin, and other drugs (see Chapter 43). Erythromycin is currently the only macrolide available for ophthalmic use.

erythromycin

Erythromycin is a macrolide antibiotic indicated for the treatment of various ophthalmic infections. Erythromycin eye ointment is indicated for the treatment of neonatal conjunctivitis caused by *Chlamydia trachomatis* and for the prevention of eye infections in newborns that may be caused by *Neisseria gonorrhoeae* or other susceptible organisms.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Ocular	Variable	Immediate	Unknown	Variable

Polypeptide Antibiotics

Bacitracin and polymyxin B are polypeptide antibiotics. These drugs are rarely used systemically because of their potent nephrotoxic effects. They are bactericidal antimicrobials that inhibit protein synthesis in susceptible organisms, which leads to cell death. They are most commonly used in the treatment of surface infections caused by Gram-positive bacteria.

bacitracin zinc/polymyxin B sulphate

Bacitracin is an ophthalmic antimicrobial drug used to treat various eye infections. It is available as a single-ingredient product and as a combination product with polymyxin. Such combination products have a broader spectrum of activity than the individual drugs on their own. Bacitracin is available in ointment form.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Ocular	Variable	Immediate	Unknown	Variable

Quinolones

Quinolone antibiotics are effective broad-spectrum antibiotics. They are discussed in detail in Chapter 44. They are bactericidal, destroying a wide spectrum of organisms that are often difficult to treat. Currently, four ophthalmic quinolones are available: ciprofloxacin (Ciloxan®), gatifloxacin (Zymar®), moxifloxacin hydrochloride (Vigamox®), ofloxacin (Apo-Ofloxacin®) and besifloxacin (Besivance).

Significant adverse effects of ophthalmic quinolones include the formation of corneal precipitates during treatment for bacterial keratitis. Other reactions include corneal staining and corneal infiltrates. Systemic reactions are limited because of poor topical absorption; those that occur are usually taste disorders and nausea. Ophthalmic quinolones have no significant drug interactions with other drugs.

ciprofloxacin hydrochloride

Ciprofloxacin hydrochloride (Ciloxan) is a synthetic quinolone antibiotic. It is available in ointment and solution forms. Ciprofloxacin is indicated for the treatment of bacterial keratitis and conjunctivitis caused by susceptible Gram-positive and Gram-negative bacteria. One notable adverse reaction to ophthalmic ciprofloxacin is the appearance of white, crystalline precipitates within any corneal lesions. This has occurred in approximately 17% of patients, within 1 to 7 days of starting therapy. In all cases to date, the condition has been self-limiting, has not required drug discontinuation, and has not adversely affected clinical outcome.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Ocular	Variable	Immediate	1–2 hr	Variable

Sulfonamides

Sulfonamides are synthetic bacteriostatic antibiotics that work by blocking the synthesis of folic acid in susceptible bacteria. Sulfacetamide sodium 10.0% and prednisolone acetate 0.2% (Blephamide®) is used to treat conjunctivitis and other ocular infections caused by susceptible bacteria.

The adverse effects of ophthalmic sulfonamides are primarily limited to local reactions and include local irritation and stinging. Sulfonamide/Prednisone combination use can result in the overgrowth of nonsusceptible organisms. No significant topical toxic effects have been reported with its use.

sulfacetamide sodium / prednisolone acetate

Sulfacetamide sodium/Prednisone combination (Blephamide®) is the most commonly used ophthalmic sulfonamide antibacterial drug. It is available in solution form and is a sulfacetamide combination product with prednisolone. As with all corticosteroids, Blephamide® can activate, enhance, and even mask infection. Blephamide® should be discontinued if the infection does not respond to treatment.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Ocular	Variable	Immediate	Unknown	Variable

Antivirals

The sole available antiviral ophthalmic drug is trifluridine (Viroptic®).

trifluridine

Trifluridine (Viroptic; 1% ophthalmic drops) is a pyrimidine nucleoside. Trifluridine inhibits viral replication by blocking the synthesis of viral deoxyribonucleic acid (DNA) by inhibiting viral DNA polymerase, an enzyme required for DNA synthesis. It is used for ocular infections (keratitis and keratoconjunctivitis) caused by types 1 and 2 of the herpes simplex virus. Significant adverse effects include secondary glaucoma, corneal punctate defects, uveitis, and stromal edema (edema in the tough, fibrous, transparent portion of the cornea known as the *stroma*). The drug exhibits no appreciable topical absorption, and no significant drug interactions have been reported.

ANTI-INFLAMMATORY DRUGS

Many of the same anti-inflammatory drugs used systemically may also be used ophthalmically to treat ocular inflammatory disorders and ocular surgery-related pain and inflammation. These drugs include both nonsteroidal anti-inflammatory drugs (NSAIDs) and corticosteroids and are listed in Box 57.1.

Mechanism of Action and Drug Effects

Corticosteroids and NSAIDs, as discussed in Chapters 34 and 49, respectively, act to reduce inflammatory responses. When tissues are damaged, the membranes of affected cells release phospholipids, which are broken down by several different enzymes within the arachidonic acid metabolic pathway. Phospholipase is one of the first enzymes involved, and its activity is inhibited by corticosteroids. A second enzyme, cyclo-oxygenase, is the site of action of the NSAIDs (see Chapter 49); its inhibition reduces the pain, erythema, and other manifestations associated with inflammation.

BOX 57.1 Ophthalmic Anti-Inflammatory Drugs

NSAIDs	Corticosteroids
diclofenac sodium (Voltaren Ophtha®)	dexamethasone (AK-Dex®, Diodex, Dioptril®, Maxidex)
flurbiprofen sodium (Ocufen®)	fluorometholone (Flarex®, FML®)
ketorolac tromethamine (Acular®)	loteprenol etabonate (Alrex®, Lotemax®)
	prednisolone acetate (Diopred®)
	rimexolone (Vexol®)

Dosages Selected Ophthalmic Antimicrobials

Drug	Pharmacological Class	Usual Dosage Range	Indications
Antibacterial Drugs			
 bacitracin (AK-Tracin®)	Miscellaneous antibiotic	Solution: 1–2 drops every 1–4 hr	Bacterial ocular infections
 ciprofloxacin (Ciloxan)	Quinolone	Solution: 1–2 drops every 2 hr for 2 days, and then 2 drops every 4 hr for 5 days Ointment: 12 mm ribbon tid for 2 days, then 12 mm ribbon daily for 5 days	
 erythromycin (AK-Mycin®)	Macrolide	Ointment: 13 mm ribbon 2–6 times/day	
 tobramycin (Tobrex®)	Aminoglycoside	Solution: 1–2 drops every 2–4 hr Ointment: 1.25 cm ribbon 2–3 times/day	
 Sulfacetamide sodium / prednisolone acetate (Blephamide®)	Sulfonamide	Solution: 1 drop 3–4 times/day	
Antiviral Drug			
trifluridine (Viroptic)	Antiviral	Initially 1 drop every 2 hr while awake (max 9 drops/day); may later decrease to 5 drops/day	Viral ocular infections: keratitis, keratoconjunctivitis due to HSV types 1 and 2

HSV, herpes simplex virus.

Note: Dosages vary based on the type and severity of infection.

Indications

Corticosteroids and NSAIDs are applied topically for the symptomatic relief of many ophthalmic inflammatory conditions. They may be used to treat corneal, conjunctival, and scleral injuries from chemical, radiation, or thermal burns or from the penetration of foreign bodies. They are used during the acute phase of the injury process to prevent fibrosis and scarring that results in visual impairment. Corticosteroids produce a greater immunosuppressant effect than the NSAIDs. Consequently, NSAIDs are often preferred as initial topical therapy for such injuries. NSAIDs are also used in the symptomatic treatment of seasonal allergic conjunctivitis.

Corticosteroids and NSAIDs are used prophylactically before ocular surgery to prevent or reduce intraoperative miosis. They are also used prophylactically after ocular surgeries, such as cataract extraction, glaucoma surgery, and corneal transplantation, to prevent inflammation and scarring.

Contraindications

Corticosteroids and NSAIDs are contraindicated in cases of known drug allergy. In addition, they are not to be used for minor abrasions or wounds because they may suppress the ability of the eye to resist bacterial, viral, or fungal infections. This is especially true of corticosteroids, which have stronger immunosuppressant effects than NSAIDs.

Adverse Effects

The most common adverse effect of corticosteroids is transient burning or stinging on application. The extended use of corticosteroids may result in cataracts, increased IOP, and optic nerve damage. If large doses are given, systemic absorption is possible. Systemic adverse effects of corticosteroids and NSAIDs are discussed in Chapters 34 and 49, respectively.

DRUG PROFILES

Corticosteroids and NSAIDs used to treat ophthalmic inflammatory disorders are listed in [Box 57.1](#). The ophthalmic formulations of these drugs share many of the characteristics of their systemic drug counterparts. However, the ophthalmic derivatives have limited systemic absorption; therefore, the majority of their therapeutic and toxic effects are restricted to the eye. Potential benefits of the use of corticosteroids and NSAIDs during pregnancy may outweigh the possible risk to the fetus.

Corticosteroid

dexamethasone

Dexamethasone (AK-Dex, Diodex, Dioprol) is a synthetic corticosteroid that is available in many ophthalmic formulations. It is used to treat inflammation of the eye, eyelids, conjunctiva, and cornea, and it may also be used in the treatment of uveitis, iridocyclitis, allergic conditions, and burns, as well as in the removal of foreign bodies. Dexamethasone is available in ointment, suspension, and solution forms.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Ocular	Variable	Immediate	Unknown	Variable

ketorolac tromethamine

Ketorolac tromethamine (Acular) is an NSAID used to reduce ocular inflammation caused by trauma, such as ocular surgery, as well as inflammation secondary to external agents, such as

allergens and bacteria. Ketorolac is contraindicated in patients with known drug allergy. It is available in solution form. Ketorolac may delay eye wound healing and lead to corneal epithelial breakdown where patients exhibit symptoms including pain, foreign body sensation, sensitivity to light, and blurred vision (Watson & Leung, 2018). Therefore, the eye needs to be consistently monitored through the duration of therapy.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Ocular	Rapid	Immediate	Unknown	4–6 hr

TOPICAL ANAESTHETICS

Topical anaesthetic ophthalmic drugs are local anaesthetics that are used to alleviate eye pain. The currently available topical anaesthetic used for ophthalmic purposes is tetracaine. Benoxinate hydrochloride is another topical anaesthetic available only in combination with fluorescein sodium (see later).

Mechanism of Action and Drug Effects

As described in Chapter 12, local anaesthetics stabilize the membranes of nerves, which results in a decrease in the movement of ions into and out of the nerve endings. When nerves are stabilized in this way, they cannot transmit signals about painful stimuli to the brain. Usually, the application of topical anaesthetic drugs to the eye results in local anaesthesia in less than 30 seconds.

Indications

Ophthalmic anaesthetic drugs are used to produce anaesthesia for short corneal and conjunctival procedures. They prevent pain during surgical procedures and certain painful ophthalmic examinations, including removal of embedded foreign objects. As they are an anaesthetic they are recommended only for short-term use and are not recommended for self-administration and should only be given by health-care professionals.

Contraindications

Contraindications to local ophthalmic anaesthetics include known drug allergy.

Adverse Effects

Adverse effects are rare with ophthalmic anaesthetic drugs and are limited to local effects such as stinging, burning, redness, lacrimation, and blurred vision. Systemic toxicity is rare but can theoretically lead to central nervous system (CNS) stimulation or CNS or cardiovascular depression.

Interactions

Because of their limited systemic absorption and short duration of action, ophthalmic anaesthetic drugs have no significant drug interactions.

DRUG PROFILES

There is currently one drug available for this purpose: tetracaine hydrochloride (Minims®).

tetracaine hydrochloride

Tetracaine hydrochloride is a local anaesthetic of the ester type (see Chapter 12). It is applied as an eye drop to numb the eye for various ophthalmic procedures. Tetracaine begins to act in about 25 seconds and lasts for approximately 15 to 20 minutes. Additional drops are applied as needed. It is currently available only in solution form. Potential benefits of use during pregnancy may outweigh the possible risk to the fetus.

PHARMACOKINETICS

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-Life	Duration of Action
Ocular	Less than 30 sec	1–5 min	Short	10–20 min

DIAGNOSTIC DRUGS

DRUG PROFILES

Cycloplegic Mydriatics

atropine sulphate

Atropine sulphate (Isopto Atropine 1%®, Dioptic's Atropine Solution®) solution is used as a mydriatic and cycloplegic drug. The drug dilates the pupil (mydriasis) and paralyzes the ciliary muscle (cycloplegic refraction), which prevents accommodation. It is used to assist in an eye examination or to treat uveal tract inflammatory states. The usual dose for uveitis (inflammation of the choroid, iris, or ciliary body) in children and adults is one to two drops of the solution two to three times daily. The dose for an eye examination is one drop of solution, ideally 1 hour before the procedure. Potential benefits of use during pregnancy may outweigh the possible risk to the fetus.

cyclopentolate hydrochloride

Cyclopentolate hydrochloride solution (Cyclogyl®) is used primarily as a diagnostic mydriatic and cycloplegic drug. Unlike atropine, it is not used to treat uveitis. The usual adult dose is one to two drops (0.5% or 1%). This is repeated in 5 to 10 minutes if needed. The dose for children is the same as that for adults. The drug effects usually subside within 24 hours. Other cycloplegic mydriatics are homatropine (Isopto Homatropine®) and tropicamide (Mydracil®). Both are topical ophthalmic solutions with indications similar to those of atropine and cyclopentolate, except that tropicamide, like cyclopentolate, is generally used for diagnostic purposes only and not for treatment of inflammatory states. Potential benefits of the use of cycloplegic mydriatics during pregnancy may outweigh the possible risk to the fetus.

Ophthalmic Dye

fluorescein sodium

Fluorescein sodium (AK-Fluor®) is an ophthalmic diagnostic dye used to identify corneal defects and to locate foreign objects in the eye. It is also used in fitting hard contact lenses. After the instillation of fluorescein sodium, various defects are highlighted in either bright green or yellow-orange, and foreign objects have a green halo around them. Dose determination and drug administration may be carried out by an ophthalmologist, an optometrist, or a health care provider in family practice. Potential benefits of the use of fluorescein sodium during pregnancy may outweigh the possible risk to the fetus.

ANTIALLERGIC DRUGS

DRUG PROFILES

Antihistamines

olopatadine hydrochloride

Olopatadine hydrochloride (Patanol®, Pataday) is an ophthalmic antihistamine used to treat symptoms of an allergic conjunctivitis (hay fever), which can be seasonal or nonseasonal. It works by competing with histamine for receptor sites. Histamine normally produces ocular symptoms such as itching and tearing. Another ophthalmic antihistamine is ketotifen (Zaditor®). These drugs have mechanisms of action, therapeutic and adverse effects, and drug interactions similar to those of the systemic antihistamines described in Chapter 37, although systemic effects are less likely to occur with ophthalmic administration than with systemic administration. Recommended dosages for olopatadine hydrochloride are given in the Dosages table below. Potential benefits of its use during pregnancy may outweigh the possible risk to the fetus.

Mast Cell Stabilizers

cromolyn sodium

Cromolyn sodium (Opticrom®) is an antiallergic drug that inhibits the release of inflammation-producing mediators from sensitized inflammatory cells called *mast cells*. It is used in the treatment of vernal keratoconjunctivitis (springtime inflammation of the cornea and conjunctiva). Other mast cell stabilizers with similar effects are nedocromil sodium (Alocril®) which is no longer available in Canada and lodoxamide (Alomide®). Recommended dosages for cromolyn can be found in the table below. There are no controlled studies in pregnant women that show that these drugs cause a risk to fetuses.

Decongestants

tetrahydrozoline hydrochloride

Tetrahydrozoline hydrochloride (Allergy Eye Drops®, Visine®) is an ophthalmic decongestant. It works by promoting vasoconstriction of blood vessels in and around the eye. This reduces the edema associated with allergic and inflammatory processes. It is specifically indicated to control redness, burning, and other minor irritations. Other ophthalmic decongestants include phenylephrine hydrochloride, oxymetazoline hydrochloride (Visine Workplace®), and naphazoline (Clear Eyes®). Recommended dosages for tetrahydrozoline are given in the table below. Potential benefits of its use during pregnancy may outweigh the possible risk to the fetus.

Lubricants and Moisturizers

artificial tears

An array of products is available over the counter to provide lubrication or moisture for the eyes. These products are helpful to patients with dry or otherwise irritated eyes. Artificial tears are isotonic and contain buffers to adjust pH. In addition, they contain preservatives for microbial control and may contain viscosity agents. Corneal contact time of topical ophthalmic solutions increases with the viscosity of the formulations. Selected OTC brand names include GenTeal®, Isopto Tears®, Murine®, Akwa Tears®, Refresh®, and Tears Plus®. Many similar products are also available on the market, as solutions (eye drops) and as lubrication ointments. They are often dosed to patient comfort as needed. Restasis® is an ophthalmic form of the immunosuppressant drug ciclosporin (see Chapter 50). It is also used to promote tear production in those with the condition technically known as *keratoconjunctivitis sicca* (dry eyes). It can be used together with artificial tears if the drugs are given 15 minutes apart. There are no controlled studies in pregnant women that show that this drug causes a risk to fetuses.

❖ NURSING PROCESS

◆ ASSESSMENT

Before administering an ophthalmic drug according to the health care provider's orders, perform a baseline assessment of the patient's eye and its structures. Document normal and abnormal findings, including any redness, swelling, pain, excessive tearing, eye drainage or discharge, decrease in visual acuity, or other unusual symptoms. Assess patients for any

Dosages Ophthalmic Antiallergics

Drug	Pharmacological Class	Usual Dosage Range	Indications
cromolyn sodium (Opticrom)	Mast cell stabilizer	1–2 drops in affected eye(s) 4–6 times daily	Vernal (springtime) conjunctivitis and keratitis (corneal inflammation)
olopatadine (Patanol 0.1%) (C)	Antihistamine	1–2 drops in affected eye(s) 2 times per day at an interval of 6–8 hr	Allergic conjunctivitis
olopatadine (Pataday 0.2%) (C)	Antihistamine	1 drop in affected eye(s) once a day	Allergic conjunctivitis
tetrahydrozoline (Murine Plus®, others)	Decongestant	1–2 drops in affected eye(s) up to 4 times daily	Redness, burning, or other minor irritation

hypersensitivity to medications or chemicals and for any drug- or disorder-related contraindications, as well as possible drug interactions. It may be necessary to perform a visual acuity test (e.g., using a Snellen chart) after a suspected injury and subsequent treatment. Focus the nursing history on past or present systemic disease processes and exposure to any chemicals that could be topical irritants to the eye, skin, or mucous membranes, including past and present work-related and environmental exposures. Also, complete a medical history to identify all medications the patient is taking.

◆ NURSING DIAGNOSES

- Acute pain as a result of an eye disorder, infection, or inflammatory eye condition
- Reduced knowledge resulting from lack of information about the eye disorder and associated medication therapy
- Potential for injury (to eyes) resulting from improper use of medication or improper instillation procedures

◆ PLANNING

◆ Goals

- Patient will remain free from eye pain.
- Patient will demonstrate adequate knowledge as a result of use of ophthalmic medication, including its application and adverse effects.
- Patient will remain free from injury (to eyes) as a result of therapy.

◆ Expected Patient Outcomes

- Patient minimizes eye pain as a result of the eye disorder by applying warm or cold compresses as prescribed, using nonaspirin analgesics as directed, and properly applying prescribed ophthalmic medication.
- Patient identifies rationale for use of ophthalmic medication and adverse effects associated with each medication, as well as signs and symptoms to be reported to the health care provider, such as drainage, redness, increase in eye pain, or decrease in visual acuity.
- Patient minimizes self-injury as a result of the adverse effects of therapy by creating a safe environment in the home, including reducing clutter and removing any unused rugs or furniture; installing more lighting, especially night lights; and using assistive devices as needed, if vision is altered.

◆ IMPLEMENTATION

Always inspect ophthalmic solutions, and administer only clear, unexpired products (e.g., drops, ointments, solutions) to eyes. Shake all solutions and mix their contents thoroughly. Do not use any solutions with particulate matter. One of the most important standards to follow during the instillation of drops or ointment is to avoid touching the eye with the tip of the dropper or container to prevent contamination of the product. Remove any excess medication promptly and apply pressure to the inner canthus for 1 minute (or other specified

duration). Applying pressure to the inner canthus after the instillation of medication is needed to prevent or decrease systemic absorption and subsequent systemic adverse effects. Apply ointments and any other ophthalmic topical drug dosage forms to the conjunctival sac and never directly onto the eye (cornea). To facilitate the instillation of ophthalmic medication, tilt the patient's head back and have the patient look up at the ceiling during administration. Several ophthalmic drugs with different actions may be ordered; give each drug exactly as prescribed and within the specified time period. Ointments may cause a temporary blurring of vision because of the film that bathes the eye. This film will decrease once the drug is absorbed, and vision will then become clearer. Always refer to the medication order, as well as an authoritative drug resource, for specific instructions and guidelines about application techniques, the length of time to apply pressure to the inner canthus, and any other specific instructions. See Chapter 10 regarding ophthalmic drug administration. Follow directions for the use of antiviral ophthalmic preparations closely. Administer topical anaesthetics (for use in removal of a foreign body or treatment of eye injury) as ordered. Repeated and continuous use of such medications is not recommended because of the related risk of delayed wound healing, corneal perforation, permanent corneal opacification, and vision loss. When there is an abrasion or other injury to the eye and appropriate medications are ordered, patching of the affected eye is recommended. This helps prevent further injury resulting from loss of the blink reflex due to overuse of topical anaesthetics. Include education regarding any possible change in eye colour caused by medication. For example, latanoprost can change hazel, green, or bluish-brown eyes permanently to brown. See the Patient Teaching Tips for more information regarding use of ophthalmic medications.

◆ EVALUATION

Therapeutic responses to miotics include decreased aqueous humour of the eye with resultant decreased IOP and decreased signs, symptoms, and long-term effects associated with glaucoma. β -Adrenergic blockers are therapeutic if their use produces a decrease in IOP. Possible adverse effects for which to assess with their use include weakness, eye irritation, rash, bradycardia, hypotension, and dysrhythmias (see Chapter 20). Therapeutic responses to antibiotic and antiviral ophthalmic drugs include elimination of an infection or condition and resolution of symptoms, as well as prevention of complications. Therapeutic responses to ophthalmic anaesthetics include prevention or relief of pain associated with an injury; their adverse effects may include CNS excitation (e.g., dizziness, tremors, restlessness, nervousness) if they are systemically absorbed. Anti-inflammatory ophthalmic solutions result in a decrease in allergic reactions, including a decrease in itching, tearing, redness, and eye discharge. A potential complication as a result of the use of these solutions is swelling of the conjunctiva (chemosis). Further monitoring of patients taking these medications includes re-evaluation of goals and expected outcomes.

CASE STUDY

Eye Trauma

Paul, a 31-year-old construction worker, is being seen in the emergency department because of a possible eye injury. He was working without eye protection, and a gust of wind sprayed metal shavings into his face. The health care provider has instilled fluorescein sodium and has noted areas in the eyeball with green halos around them.

1. What is the purpose of the fluorescein sodium, and what is indicated by the green halos?

2. Paul is sent to an ophthalmologist for further treatment. What eye medication do you expect will be used for the next procedure?

3. After the procedure, Paul receives a prescription for dexamethasone ophthalmic ointment, which is to be administered three times a day. What specific patient teaching will the nurse share with Paul?

4. How could this injury have been prevented?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

PATIENT TEACHING TIPS

- Educate patients about the correct administration technique for the drugs they are taking. A recommended teaching strategy involves conducting a demonstration and requiring return demonstrations by patients.
- Encourage patients to use solutions only if they are clear and unexpired. Patients should keep solutions in containers for direct application and should keep eyedroppers sterile by avoiding touching the tip of the eyedropper or container to the surface of the eye.
- Educate patients receiving indirect-acting cholinergics about their adverse effects, such as blurred vision, bronchospasm, nausea, vomiting, bradycardia, hypotension, and sweating.
- With the use of any ophthalmic drug, instruct patients to report to the health care provider any severe stinging, burning, itching, or redness of the eye; excessive tearing or excessive dryness of the eye; puffiness of the eye or eyelids; discharge from the eye; fever; eye pain; or loss of or change in vision.
- Antiadrenergic drugs should be instilled as ordered. Once these drugs (and many other drugs used in the eye) are instilled, instruct patients to apply pressure to the inner canthus with a tissue or 2 × 2 gauze pad for 1 full minute or as directed. Application of pressure to the inner canthus helps minimize systemic drug absorption and decrease the risk of systemic adverse effects. Advise patients to report to their health care provider immediately any blurred vision, difficulty breathing, wheezing, sweating, flushing, or loss of sight.
- Photosensitivity is an expected adverse effect of mydriatics; therefore, when these drugs are administered, encourage patients to wear sunglasses while in sunlight to help minimize eye discomfort and headaches.
- With the use of topical anaesthetics, advise patients to avoid rubbing or touching the eye while it is numb, because eye damage may result. An eye patch may be worn, if prescribed, to protect the eye because of loss of the blink reflex.
- Instruct patients to use ophthalmic drugs as prescribed and never to overuse them. Stress that products with expiration dates that have passed are not to be used and are to be discarded appropriately. Remind patients that ophthalmic medications are to be stored in a cool environment.
- Advise patients never to stop medications without consulting their health care provider first because of the possibility of adverse reactions.
- Inform patients that contact lenses must not be worn while ophthalmic drugs are being instilled and for the duration of therapy, as the lenses may lead to further irritation.
- Ophthalmic ketorolac, an anti-inflammatory drug, may delay eye wound healing and lead to corneal epithelial breakdown. Instruct patients to report these problems if present or suspected.

KEY POINTS

- Glaucoma is a disorder of the eye caused by inhibition of the normal flow and drainage of aqueous humour. Treatment helps reduce IOP either by increasing the drainage of aqueous humour or decreasing its production.
- Drugs that increase aqueous humour drainage are direct-acting cholinergics, indirect-acting cholinergics, and β -blockers.
- A large proportion of inflammatory diseases of the eye are caused by viruses, and many ophthalmic antimicrobials are available to treat bacterial and viral infections of the eye. Common ocular infections include conjunctivitis, hordeolum (sty), keratitis, uveitis, and endophthalmitis.
- Anti-inflammatory ophthalmic drugs include corticosteroids and are used to inhibit inflammatory responses to mechanical forces, chemicals, and immunological reactions.
- Topical anaesthetics are used to prevent pain to the eye and are beneficial during surgery, ophthalmic examinations, and removal of foreign bodies.
- Administer all ophthalmic preparations exactly as ordered. Always apply them into the conjunctival sac. Safe and accurate application or instillation technique also includes avoiding contact of the eyedropper or tube with the eye, to prevent contamination of the drug.
- Patients need to report to their health care provider any increase in symptoms, such as fever or eye pain or drainage.

EXAMINATION REVIEW QUESTIONS

1. The ophthalmologist has given a patient a dose of ophthalmic atropine drops before an eye examination. Which statement by the nurse accurately explains to the patient the reason for these drops?
 - a. "These drops will cause the surface of your eye to become numb so that the doctor can do the examination."
 - b. "These drops are used to check for any possible foreign bodies or corneal defects that may be in your eye."
 - c. "These drops will reduce your tear production for the eye examination."
 - d. "These drops will cause your pupils to dilate, which makes the eye examination easier."
2. When assessing a patient who is receiving a direct-acting cholinergic eye drop as part of treatment for glaucoma, the nurse anticipates that the drug affects the pupil in which way?
 - a. It causes mydriasis, or pupil dilation.
 - b. It causes miosis, or pupil constriction.
 - c. It changes the colour of the pupil.
 - d. It causes no change in pupil size.
3. During patient teaching regarding self-administration of ophthalmic drops, which statement by the nurse is correct?
 - a. "Hold the eye dropper over the cornea and squeeze out the drop."
 - b. "Apply pressure to the lacrimal duct area for 5 minutes after administration."
 - c. "Be sure to place the drop in the conjunctival sac of the lower eyelid."
 - d. "Squeeze your eyelid closed tightly after placing the drop into your eye."
4. When a nurse is providing teaching about eye medications for glaucoma, the nurse tells the patient that miotics help glaucoma by which mechanism of action?
 - a. Decreasing intracranial pressure
 - b. Decreasing intraocular pressure
 - c. Increasing tear production
 - d. Causing pupillary dilation
5. Following assessment of a patient with glaucoma who has newly prescribed carbonic anhydrase inhibitor eye drops, the nurse would report to the health care provider a history of which condition?
 - a. Allergy to sulfa drugs
 - b. Decreased kidney function
 - c. Diabetes mellitus
 - d. Hypertension
6. The nurse is preparing to administer ketorolac (Acular) eye drops. The patient asks, "Why am I getting these eye drops?" Which is the correct answer by the nurse?
 - a. "These drops will reduce the pressure inside your eye as part of treatment for glaucoma."
 - b. "These drops are for a bacterial eye infection."
 - c. "These drops will relieve your dry eyes."
 - d. "These drops work to reduce the inflammation in your eyes."
7. A patient has undergone an eye procedure during which ophthalmic mydriatics and anaesthetic drops were used. The nurse gives which instructions to the patient prior to discharge? (Select all that apply.)
 - a. "Do not rub or touch the numb eye."
 - b. "You may reinsert your contact lenses before you leave."
 - c. "Be sure to wear sunglasses when you go outside."
 - d. "Your pupils will appear very tiny until the medication wears off."
 - e. "Report any increase in eye pain or drainage to the ophthalmologist immediately."
8. The nurse is administering sympathomimetic ophthalmic drops. Which therapeutic drug effect will these drops have on the patient's eyes?
 - a. Miosis
 - b. Reduced intraocular pressure
 - c. Reduced inflammation
 - d. Increased lubrication

CRITICAL THINKING ACTIVITIES

1. A patient has a prescription for latanoprost (Xalatan). What is the most important piece of information that the nurse needs to tell the patient *before* the patient starts taking this medication?
2. A patient with type 2 diabetes has a new prescription for an ophthalmic β -blocker for treatment of glaucoma. Two days later, the patient calls the office and tells the nurse, "I looked up this drug on the Internet, and it says that this type of drug can mess up my blood sugar levels. I don't want to take the drops if that happens." What is the nurse's best response?
3. The nurse is assessing the eyes of a patient who had ocular surgery a week earlier. The patient has been receiving ketorolac tromethamine (Acular) ophthalmic solution. What is the priority action when the nurse assesses the eyes of this patient?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

Otic Drugs

OBJECTIVES

After reading this chapter, the successful student will be able to do the following:

1. Describe the anatomy of the ear, including the outer, middle, and inner ear.
2. Name the various categories of ear disorders and explain their causes and signs and symptoms.
3. List various types of otic preparations and their indications.
4. Discuss the mechanisms of action, dosages, cautions, contraindications, drug interactions, and specific application techniques of the otic drugs.
5. Develop a collaborative plan of care that includes all phases of the nursing process for patients receiving otic drugs.

KEY TERMS

Cerumen A yellowish or brownish waxy excretion produced by modified sweat glands in the external auditory canal; also called *earwax*. (p. 941)

Otitis externa Inflammation or infection of the external auditory canal. (p. 939)

Otitis media Inflammation or infection of the middle ear. (p. 939)

DRUG PROFILES

carbamide peroxide, p. 941

Key drug

OVERVIEW OF EAR ANATOMY

The ear is made up of three parts: the outer, middle, and inner ear. The outer ear is composed of the *pinna* (outer projecting part of the ear, also called the *auricle*) and the *external auditory* (or acoustic) *meatus* (also called the *external auditory canal* or simply the *ear canal*), which is the passageway to the tympanic membrane (or *eardrum*). The middle ear is composed of the *tympanic cavity*, the space enclosed by the tympanic membrane at one end and the oval window at the other. Within the middle ear are three tiny bones—the *malleus* (from the Latin for hammer), *incus* (anvil), and *stapes* (stirrup)—which together create a connection from the tympanic membrane to the oval window of the inner ear. Also, within the middle ear is the *auditory tube*, or *eustachian tube*, which connects the middle ear to the nasopharynx. The inner ear includes the *cochlea*—the sensory organ for hearing—and the *semicircular canals*—the sensory organ for balance. The ear and its associated structures are illustrated in [Figure 58.1](#).

Disorders of the ear can be categorized according to the portion of the ear affected. Outer ear disorders are generally the result of physical trauma or infection. Physical trauma usually consists of localized infections of the hair follicles, often causing the development of boils, and lacerations or scrapes to the skin. Foreign objects and infection or inflammation associated with

water sports are the usual sources of such trauma. In adults, the condition is also more likely to manifest as otitis externa involving the ear canal and external tympanic membrane. These disorders tend to be self-limiting and heal with time. Other examples of outer ear disorders are bacterial and fungal infections, earwax accumulation, contact dermatitis, seborrhea, and psoriasis, as evidenced by itching, local redness, inflammation, weeping, or drainage. Infections affecting the external auditory canal are known as **otitis externa**. (See discussion of otitis media below for symptoms.) These conditions usually respond to the same topical medications used for any other localized skin disorders, as discussed in Chapter 56. However, symptoms such as drainage, pain, and dizziness are sometimes also the first signs of a more serious underlying condition (e.g., head trauma, meningitis) and warrant prompt medical evaluation. Medications for disorders affecting the outer ear (ear canal) and middle ear are the focus of this chapter. Diseases of the inner ear can necessitate highly specialized medical practices that are beyond the scope of this chapter.

The most common disorders affecting the middle ear are bacterial and fungal infections and inflammation. Such disorders are often self-limiting, and treatments are usually successful. If problems persist or are left untreated, however, more serious problems such as hearing loss may result. Infections affecting the middle ear are known as **otitis media**. Otitis media is a common disease of infancy and early childhood. Children younger than 2 years are physiologically predisposed to acute otitis media because their eustachian tubes are shorter, of smaller calibre, and more horizontal compared with those of adults. Otitis media is often preceded by an upper respiratory tract infection.

Fig. 58.1 Structure of the ear.

It may also occur in adults, but it is then generally associated with trauma to the tympanic membrane. Common symptoms of both otitis media and otitis externa are pain, fever, malaise, pressure, a sensation of fullness in the ears, and reduced hearing. If the condition is left untreated, tinnitus (ringing in the ears), nausea, vertigo, mastoiditis, and temporary or permanent hearing loss may occur.

Otitis media is the second most common infection in children. Approximately 75% of Canadian children will have an episode of otitis media before starting school ([Canadian Paediatric Society, 2016](#)). Medical management of otitis media is debated among the medical community, primarily because of the increased incidence of antibiotic resistance. Given these concerns, treatment of otitis media has significantly changed over the last decade. The most recent Canadian guidelines were published in 2016 by the Infectious Diseases and Immunization Committee of the Canadian Paediatric Society. A growing number of health care providers do not recommend antibiotic treatment in children with mild otitis media with no fever or temperature under 39°C for 24 hours. More emphasis is now given to observation, close follow-up, and use of analgesics, as otitis media usually resolves spontaneously. Many parents have concerns regarding treatment with only these components. If a decision is made to treat with an antibiotic, amoxicillin should be the first-line drug for most children, as it has excellent middle ear penetration. If a patient fails to respond to treatment within 48 to 72 hours, the patient must be reassessed. If no antibiotics were given initially, they should be started, or the initial antibiotic may need to be changed. Antibiotics are discussed in Chapters 43 and 44.

TREATMENT OF EAR DISORDERS

Some of the minor ailments that affect the outer or middle ear can be treated with over-the-counter (OTC) medications, but

persistent, painful conditions generally require prescription medications. Drugs used to treat ear conditions are known as *otic drugs*, and most are topically applied to the ear canal. Because of this, they generally are not involved in drug interactions. Adverse effects are uncommon and usually do not extend beyond localized irritation. Otic drugs are normally only contraindicated in cases of known drug allergy. Classes of otic drugs include the following:

- Antibacterials (antibiotics)
- Antifungals
- Anti-inflammatory drugs
- Local analgesics
- Local anaesthetics
- Corticosteroids
- Wax emulsifiers

More serious cases of ear disorders may require treatment with systemic drugs such as antimicrobial drugs, analgesics, anti-inflammatory drugs, and antihistamines. These medications have been discussed in detail in previous chapters dealing with the respective drug classes.

ANTIBACTERIAL AND ANTIFUNGAL OTIC DRUGS

Antibacterial and antifungal otic drugs are often combined with steroids to take advantage of the anti-inflammatory, antipruritic, and antiallergic effects of the latter drugs. These drugs are used to treat outer and middle ear infections. Because they all work and are dosed similarly, available products are profiled together below. Systemic antibiotics are also commonly prescribed for these conditions (e.g., amoxicillin; see Chapter 43), either alone or in addition to the otic drugs described in the following sections. [Tables 58.1 and 58.2](#) list several commonly used products and their component amounts. These drugs are used during pregnancy when potential benefits outweigh the risks to the fetus.

DRUG PROFILES

Antibacterial Products

Spor-HC Otic Suspension® is a three-drug combination that includes hydrocortisone and two antimicrobials: neomycin sulphate (an aminoglycoside; see Chapter 44) and polymyxin B sulphate. Hydrocortisone is the steroid most commonly used in otic drugs, although there is one preparation (Ciprodex®) containing both ciprofloxacin (a fluoroquinolone; see Chapter 44) and dexamethasone sodium phosphate. There is also a single-drug dexamethasone sodium phosphate (AK-Dex®) formulation. The purpose of the steroid component is to reduce the inflammation and itching associated with ear infections. An additional combination product comprises flumethasone pivalate and clioquinol (Locacorten®). All of these products are used for the treatment of bacterial otitis externa or otitis media caused by susceptible bacteria, such as *Staphylococcus aureus*, *Escherichia coli*, *Klebsiella* species, and others. Neomycin sulphate, polymyxin B sulphate, and hydrocortisone acetate otic preparations are contraindicated in patients with a perforated eardrum, because of the related risk of ototoxicity; ciprofloxacin and dexamethasone can be used with perforated eardrums. Their usual dosage is four drops, three to four times daily. With some otic drugs, as a means of dosing, it is recommended to saturate a retrievable cotton or tissue wick with the drug and let this wick soak inside the ear canal. The wick can be periodically remoistened with additional drug or removed and followed by further ear drops inserted directly into the ear canal. Follow specific instructions on drug packages or use the method recommended by the health care provider or pharmacist.

Antifungal Products

Fungal infections account for about 4% of ear infections. Antifungal otic drugs are used primarily for otitis externa. These drugs may also have antibacterial and antiviral properties. In Canada, the preparation used as an antifungal is clioquinol 1%, flumethasone pivalate 0.02% (Locacorten Vioform ear drops). Flumethasone pivalate is a corticosteroid with anti-inflammatory, antipruritic, and vasoconstrictive properties, and clioquinol is an antimicrobial. Polyethylene glycol is the vehicle that softens the cerumen and ensures prolonged contact of the active ingredients with the surface of the ear canal. It is contraindicated for use in patients with a perforated eardrum.

Earwax Emulsifiers

An additional common ear problem is the accumulation and eventual impaction (hardening) of earwax, or **cerumen**, which can also contribute to or complicate the infectious and inflammatory conditions described earlier. Products that soften and help to eliminate earwax are referred to as *earwax emulsifiers*. Cerumen is a natural product of the ear and is produced by modified sweat glands in the ear canal. It can vary in form and appearance from patient to patient, from almost liquid, to firm and solid, to dry and flaky. Its colour varies depending on its composition and can vary from dark brown to light yellow. Glandular secretions, sloughed skin

TABLE 58.1 Common Antibacterial Otic Products

Steroid Component	Antibiotic Component	Trade Name
hydrocortisone acetate 1%	3.5 mg/mL of neomycin sulphate and 10 000 units/mL polymyxin B sulphate	Spor-HC Otic® Suspension
dexamethasone 0.1%	ciprofloxacin hydrochloride 0.3%	Ciprodex® Ciloxan®
dexamethasone sodium phosphate 0.1%		AK-Dex®, Diodex® solution 0.1%
0.5 mg Dexamethasone	5 mg Framycetin sulphate, 0.05 mg Gramicidin	Sofracort

TABLE 58.2 Common Antifungal Otic Products

Ingredients	Trade Name
clioquinol 1%, flumethasone pivalate 0.02%	Locacorten Vioform ear drops

Neomycin, polymyxin B, and hydrocortisone otic preparations are contraindicated in patients with a perforated eardrum. In addition, aminoglycoside antibiotics (i.e. Tobrex) can cause ototoxicity. (See Chapter 44).

cells, normal bacteria on the surface of the ear canal, and water may all be present in earwax. Ears are considered to be self-cleaning. Once earwax dries, the movement of the jaw helps to move the cerumen out. However, it can occasionally build up and become impacted, which results in pain and temporary partial hearing loss. As we know from chemistry, a nonpolar substance is one that is not water soluble. Such a substance is said to be emulsified when it is chemically or physically converted to a more water-soluble form. *Earwax emulsifiers* loosen impacted cerumen, which allows it to be flushed out of the ear canal through irrigation with water. Often the simple application of olive, mineral, or almond oil is sufficient to soften wax.

carbamide peroxide

Carbamide peroxide (Murine® Ear Wax Removal System Otic) is a commonly used earwax emulsifier. It is combined with other components (e.g., glycerin, a lubricant) that help soften and lubricate cerumen prior to irrigation. Carbamide peroxide slowly releases hydrogen peroxide and oxygen when exposed to moisture. The release of oxygen imparts a weak antibacterial action to this otic drug. In addition, the *effervescence* (foaming) resulting from the release of oxygen has the mechanical effect of emulsifying impacted cerumen to release it from the walls of the ear canal. Earwax emulsifiers are not to be used without a health care provider's recommendation when ear drainage, tympanic membrane rupture, or significant pain or other irritation is present. After allowing the drug to dissolve the earwax, one can remove the cerumen by gently flushing the ear canal with warm water from a bulb syringe. Some earwax removal products include this syringe in the package. This drug is used

during pregnancy when potential benefits outweigh the risks to the fetus.

❖ NURSING PROCESS

◆ ASSESSMENT

Before administering any of the otic preparations, assess baseline hearing or auditory status, if deemed appropriate, and document the findings. Assessment of the outer and middle ear via otoscope can be undertaken to detect infection, cerumen buildup, or the presence of a foreign body. Assess the patient's symptoms, past and present medical history, and use of prescription drugs, OTC drugs, and natural health products. Document any drug or food allergies. A baseline understanding of the anatomy of the ear, especially anatomical variations in patients of different age groups, is needed to ensure that proper application technique is used. Contraindications, cautions, and drug interactions for otic drugs, chemicals, or solutions have been discussed previously in the treatment section; always assess the patient for these and document the findings. In addition, if the patient has a perforated eardrum, this is a contraindication to the use of otic drugs.

◆ NURSING DIAGNOSES

- Acute pain as a result of ear infection or ear disorder
- Inadequate knowledge as a result of lack of experience with otic drugs and their method of administration
- Nonadherence as a result of a lack of motivation or lack of understanding for the need of frequent ear drop instillation, as ordered

◆ PLANNING

◆ Goals

- Patient will remain free from pain and other symptoms related to the ear disorder.
- Patient will demonstrate adequate knowledge about the treatment regimen and the use, application, and adverse effects of otic drugs.
- Patient will remain adherent to the medication regimen, as prescribed.

◆ Expected Patient Outcomes

- Patient experiences minimal to no discomfort with the use of prescribed medication.
 - Patient uses measures to enhance comfort, such as the use of warm compresses, as prescribed, as well as of non-narcotic analgesics, as directed.
 - Patient reports immediately to the health care provider any increase in ear pain and other symptoms once therapy is initiated.
- Patient states rationale for the use of otic medication and ways to increase the drug's effectiveness, such as ensuring accurate application or instillation and afterward remaining supine or sitting with the affected ear upward for a short period (see Chapter 10).

- Patient instills medication as prescribed, regarding dosage, frequency, and duration of therapy.

◆ IMPLEMENTATION

Instill otic preparations only after the ear has been thoroughly cleansed and all cerumen has been removed (by irrigation if necessary, or as ordered). Ear drops, solutions, and ointments need to be at room temperature prior to instillation. Administration of solutions that are too cold may cause a vestibular type of reaction involving vomiting and dizziness. If a solution has been refrigerated, allow it to warm to room temperature. Higher temperatures may affect the potency of these solutions. When administering ear drops to adults, hold the pinna *up* and back; when administering them to children younger than 3 years of age, hold the pinna *down* and back. Allow a period of time for adequate coverage of the ear once the medication has been administered. Gentle massage to the tragus area of the pinna may also help increase coverage of the medication after the solution is given. See the Patient Teaching Tips and also Chapter 10 for more information on ear drop instillation.

◆ EVALUATION

The therapeutic effects of otic drugs are gauged by evaluating whether goals and objectives have been met. Therapeutic effects of otic drugs include a decrease in pain, redness, and swelling in the ear; a reduction in fever; and resolution of any other signs and symptoms associated with the ear disorder. Improvement in hearing may also be an anticipated therapeutic effect. Monitor the ear canal for the occurrence of rash or any signs of local irritation, such as redness and heat at the site. Evaluate the patient for adverse effects with each application or instillation and report any unusual appearance of the pinna and ear canal immediately to the health care provider.

CASE STUDY

Ear Medications

Raluca is 8 years old and loves to swim in the neighbourhood pool. Lately, she has had a feeling of fullness in her left ear, and yesterday she told her mother that her ear is hurting and itching and that she feels "awful." Her mother took her temperature and found that it was 38.3°C. She called the pediatrician's office for an appointment, and Raluca is seen

the next morning. After examining Raluca, the pediatrician says that Raluca has otitis media in her left ear and some earwax buildup in both ears. The pediatrician removes some of the earwax manually, writes a prescription for oral antibiotics for Raluca, and gives instructions to use an earwax emulsifier. The nurse meets with Raluca and her mother to review the instructions.

1. Raluca's mother asks, "Why is the antibiotic a suspension? It seems to me that if she has an ear infection, she should take ear drops!" What is the nurse's best response?
2. Raluca's mother also asks, "What will happen if this ear infection does not get better?" What is the nurse's best response?
3. Raluca reports that her ear "really hurts and itches." What can be given to her for this problem? How will it be given?

For answers, see <http://evolve.elsevier.com/Canada/Lilley/pharmacology/>.

PATIENT TEACHING TIPS

- Provide thorough instructions to patients about the proper use of ear drops and the instillation of any medication into the ear. Warn patients that dizziness may occur after application of the medication, requiring the patient to remain supine or sitting during instillation and for a few minutes thereafter.
- Medication to be applied to the ear must be at room temperature. This may be achieved by running warm water over the medication bottle, but care must be taken to prevent getting water in the container, damaging the label so that the directions become unreadable, or making the solution too warm to use. Advise patients not to heat the medication; for example, a microwave oven must not be used for warming because ear drops that are overheated may lose potency. If the pharmacy indicates that the drug should be kept in a refrigerator, instruct the patient to take it out of the refrigerator up to 1 hour before it is to be instilled so that it can warm up to room temperature. Most otic medications are stored at room temperature.
- Instruct patients to lie on the side opposite that of the affected ear for about 5 minutes after instillation of otic drugs. A small cotton ball may be inserted gently into the ear canal to keep the drug in place, but it should not be forced into the ear or jammed down into the ear canal.
- Instruct patients to avoid the use of Q-tips® or cotton swabs to clean the ears (except for the outer margins of the outer ear), as well as to refrain from undergoing ear candling procedures and from using an oral jet irrigator in the ears. These practices can push cerumen deeper into the ear canal from where it cannot be removed. This can result in the accumulation of fungi, bacteria, and viruses, leading to pain and infection, hearing loss, or a ruptured eardrum.

KEY POINTS

- Otic drugs may include the following ingredients, either alone or in combination (depending on the health care provider's order): corticosteroids, antibacterials, antifungals, anti-inflammatories, and wax emulsifying compounds. Many of the anti-infective drugs are combined with corticosteroids (in solution) to take advantage of the additional anti-inflammatory, antipruritic, and antiallergic effects of the steroids.
- Some ear infections require additional drug therapy with systemic dosage forms of corticosteroids, antibiotics, antifungals, and anti-inflammatory drugs.
- Some disorders of the ear are self-limiting to a degree, but appropriate treatment is important to prevent local and systemic complications. If left untreated, ear infections and disorders may lead to partial or complete hearing loss.
- Cerumen, or earwax, is a natural product of the ear and is normally produced by modified sweat glands in the auditory canal; emulsifying otic drugs (such as carbamide peroxide) loosen and help remove this wax.
- Single drugs and combination drug products are used to treat many ear conditions, and it is important to know the indications for and specific information about these drugs to ensure their safe use.

EXAMINATION REVIEW QUESTIONS

1. While teaching a patient about treatment of otitis media, the nurse should mention that untreated otitis media may lead to which condition?
 - a. Mastoiditis
 - b. Throat infections
 - c. Fungal ear infection
 - d. Decreased cerumen production
2. During a teaching session about ear drops, the patient tells the nurse, "I know why an antibiotic is in this medicine, but why do I need to take a steroid?" Which is the nurse's best answer?
 - a. "The steroid will help to soften the cerumen."
 - b. "The steroid reduces itching and inflammation."
 - c. "The steroid also has antifungal effects."
 - d. "This medication helps to anesthetize the area to decrease pain."
3. The nurse is preparing to administer ear drops. Which technique for administering ear drops is correct?
 - a. Warm the solution to 37.7°C before using.
 - b. Position the patient so that the unaffected ear is accessible.
 - c. Massage the tragus before administering the ear drops.
 - d. Gently insert a cotton ball into the outer ear canal after the drops are given.
4. The nurse is discussing treatment of earwax buildup with a patient. Which statement about earwax emulsifiers is true about these drugs?
 - a. They are useful for treatment of ear infections.
 - b. They loosen impacted cerumen so that it may be removed by irrigation.
 - c. They are used to rinse out excessive earwax.
 - d. They enhance the secretion of earwax.
5. During an examination, the nurse notes that a patient has a perforated tympanic membrane. There is an order for ear drops. Which action by the nurse is most appropriate?
 - a. Give the medication as ordered.
 - b. Check the patient's hearing, and then give the drops.
 - c. Hold the medication, and check with the health care provider.
 - d. Administer the drops with a cotton wick.

6. The nurse is preparing to administer ear drops and finds that the bottle has been stored in the medication room refrigerator. Which is the best action by the nurse?
 - a. Remove the bottle from the refrigerator, and administer the drops.
 - b. Heat the bottle for 5 seconds in a microwave oven before administering the drops.
 - c. Let the bottle sit in a cup of hot water for 15 minutes before administering the drops.
 - d. Remove the bottle from the refrigerator 1 hour before the drops are due to be given.
7. The nurse is preparing to administer carbamide peroxide to an adult patient with impacted cerumen. Which actions by the nurse are correct? (Select all that apply.)
 - a. Have the patient lie on his side with the affected ear up.
 - b. Chill the medication before administering it.
 - c. Pull the pinna of the ear down and back.
 - d. Pull the pinna of the ear up and back.
 - e. Gently irrigate the ear with warm water to remove the softened earwax.
8. A child is in the clinic with a severe case of otitis media. The prescriber has decided to treat it with an antibiotic. Which of the following antibiotics does the nurse anticipate will be prescribed as a first-line drug for this condition?
 - a. tetracycline
 - b. penicillin
 - c. amoxicillin
 - d. ciprofloxacin

CRITICAL THINKING ACTIVITIES

1. A nurse is explaining about wax emulsifiers to a patient who has decreased hearing because of impacted cerumen. The patient asks, "How can this help me? What will this medication do for me?" What is the nurse's best answer?
 2. When discussing ear drop administration with a patient, the patient says, "I'll keep these in the refrigerator so that they'll be cold when I give them to myself." What is the nurse's best response?
 3. The nurse is observing while the mother of an infant administers ear drops to the infant for the first time. The mother says, "When I give the drops, I will pull the ear up and back like this, give the drops, and then massage the earlobe." What is the nurse's priority action at this time?

APPENDIX: PHARMACEUTICAL ABBREVIATIONS

Abbreviation	Translation
DRUG DOSAGE	
g or Gm	Gram
gtt	Drop
L	Litre
mEq	Milliequivalent
min	Minute
mL	Millilitre
tbsp	Tablespoon
tsp	Teaspoon
mcg	Microgram
DRUG ROUTE	
ID	Intradermal
IM	Intramuscular
IV	Intravenous
NG	Nasogastric
PO	Per os (orally; by mouth)
subcut	Subcutaneous
SL	Sublingual
DRUG ADMINISTRATION	
ac	Before meals
ad lib	As desired, freely
bid	Twice a day
hr	Hour
NPO	Nothing by mouth
pc	After meals
prn	Pro re nata (when needed)
qh	Every hour
qid	Four times a day
Rx	Prescribe or take
stat	Immediately
tid	Three times a day

ANSWERS TO REVIEW QUESTIONS

CHAPTER 1

CHAPTER 32

1. b, 2. d, 3. d, 4. c, 5. b, 6. a, c, 7. 100 mcg, 8. a, d

CHAPTER 33

1. a, 2. c, 3. c, 4. c, 5. a, 6. b, 7. a, b, c, f

CHAPTER 34

1. b, 2. c, 3. b, 4. a, 5. c, 6. b, c, e, 7. 1.25 mL, 8. 100 mg.

CHAPTER 35

1. c, 2. b, 3. d, 4. a, 5. c, 6. a, e, 7. 0.25 mL, 8. c.

CHAPTER 36

1. b, 2. c, 3. a, 4. d, 5. c, 6. b, e, 7. 0.5 mL per dose, 8. c.

CHAPTER 37

1. a, 2. c, 3. b, 4. c, 5. d, 6. b, c, d, f, 7. 4 mL, 8. a.

CHAPTER 38

1. a, 2. a, 3. b, 4. c, 5. b, 6. a, c, e 7. Approximately 33 days (200 divided by 6 puffs per day), 8. 45 mL.

CHAPTER 39

1. d, 2. c, 3. b, 4. b, 5. a, 6. a, c, 7. 200 mL/hour, 8. c.

CHAPTER 40

1. c, 2. d, 3. a, b, c, e 4. a, 5. b, 6. d, 7. a, c, 8. b.

CHAPTER 41

1. b, 2. c, 3. d, 4. a, c, e, 5. 0.5 mL, 6. b, 7. b, c. e.

CHAPTER 42

1. d, 2. a, 3. b, 4. b, 5. c, 6. c, d, 7. 690 mL, 8. a, b, d.

CHAPTER 43

1. b, 2. c, 3. a, 4. d, 5. c, 6. a, d, e, 7. 4000 mg/day; 1000 mg/dose, 8. b.

CHAPTER 44

1. c, 2. c, 3. a, 4. d, 5. c, 6. c, d, 7. 167 mL/hour.

CHAPTER 45

1. d, 2. c, 3. a, 4. d, 5. c, 6. b, d, e, 7. 900 mg; no, the dose exceeds the 800 mg maximum per dose

CHAPTER 46

1. c, 2. b, 3. a, 4. d, 5. d, 6. b, d, f, 7. 625 mg/dose; no, maximum dose is 300 mg

CHAPTER 47

1. b, 2. c, 3. d, 4. c, 5. b, 6. a, b, e, 7. 5 mL, 8. d.

CHAPTER 48

1. d, 2. b, 3. b, 4. a, 5. a, 6. a, c, e, 7. 500 mg; yes, 8. b.

CHAPTER 49

1. a, 2. b, 3. d, 4. d, 5. c, 6. a, b, d, 7. 112.5 mg per dose, 8. c.

CHAPTER 50

1. d, 2. b, 3. d, 4. c, 5. a, 6. a, d, f, 7. 1.5 mg/day, 8. c.

CHAPTER 51

1. b, 2. c, 3. a, 4. b, 5. c, 6. c, e, f, 7. 4.8 mg per dose, 8. d.

CHAPTER 52

1. a, 2. b, 3. d, 4. b, 5. c, 6. b, d, e, 7. 27 000 units; yes, 8. a, e.

CHAPTER 53

1. d, 2. c, 3. b, 4. a, 5. c, 6. a, d, 7. 67 mL/hour (66.66 rounds to 67), 8. a.

CHAPTER 54

1. b, 2. a, 3. c, 4. c, 5. d, 6. a, c, e, 7. 300 mcg; 1 mL, 8. a.

CHAPTER 55

1. d, 2. b, 3. a, 4. b, 5. a, 6. c, e, 7. 0.88 mL (rounded from 0.875),
8. b.

CHAPTER 56

1. b, 2. d, 3. c, 4. b, 5. a, 6. a, 7. b, d, f, 8. d.

CHAPTER 57

INDEX OF GLOSSARY TERMS

A

Ablation, 531
 Absorption, 655
 Accommodation, 918, 921
 Acetylcholine (ACh), 263, 350–351
 Acetylcholinesterase (AChE), 350–351
 Acne vulgaris, 903
 Acquired disease, 67–68
 Acquired immune deficiency syndrome (AIDS), 40, 731–732
 Acrocyanosis, 338, 340
 Actinic keratosis, 903
 Action potential, 423, 425f
 Action potential duration (APD), 423, 426, 426f
 Active immunization, 815, 817–819
 Active immunizing drugs, 815
 Active transport, 47–48
 Acute coronary syndrome (ACS), 394
 Acute pain, 164, 167–168
 Acute therapy, 29
 Addiction, 30, 164, 171, 308–309
 Addison's disease, 563, 565, 568b–569b, 654–655
 Additive effects, 14, 31
 Adherence, 1, 3–4
 Adjunct anaesthetics, 195–196
 Adjunctive drugs, 262, 268
 Adjuvant, 872, 876b, 884
 Adjuvant analgesic drugs, 164, 166
 Adolescents, 49, 49t, 90b
 Adrenal (Addisonian) crisis, 563, 570, 632
 Adrenal cortex, 563–564, 564b
 Adrenal medulla, 563
 Adrenergic agonists, 325–326
 Adrenergic drugs (sympathomimetics), 228–229, 229t, 325–326, 606
 Adsorption, 23b, 644, 821
 Adverse drug event (ADE), 14, 31–33, 55b, 75–76, 76f
 Adverse drug reactions (ADRs), 14, 75–76, 76f
 Adverse effects, 14, 30
 Aerobic, 753
 Affective disorders, 278
 Affective domain, 88–89
 Afferent arterioles, 485–486, 487f
 Affinity, 28
 Agonist-antagonists, 29f, 164, 172–173
 Agonists, 14, 29f, 164, 338–339
 Akathisia, 278, 295
 Akinesia, 262, 264
 Albuminuria, 53
 Aldosterone, 411, 485–486, 563–564

Alkylation, 859–860
 Alleles, 67–68
 Allergen, 621–622
 Allergic asthma, 621–622
 Allergic reactions, 14, 32, 75–76, 76f, 608–609, 811–812
 Alopecia, 839, 850, 853–854, 856b
 Alpha-adrenergic receptors, 325–326
 Alpha₁ blockers, 371, 376, 379
 Alternative medicine, 98, 102
 Alveoli, 621–622
 Alzheimer's disease, 52b, 350, 352–353, 356b
 Amphetamines, 228, 231, 308
 Anabolic activity, 596
 Anabolic steroids, 597
 Anabolism, 679–680
 Anaesthesia, 195
 Anaesthetics, 195
 Analeptics, 228, 236–238
 Analgesic ceiling effect, 164, 172–173
 Analgesics, 164
 Analogue, 832, 841
 Anaplasia, 832, 837
 Anaplastic cells, 837
 Androgenic activity, 596
 Androgens, 596
 Angina, 338, 342
 Angina pectoris, 394
 Antacids, 640
 Antagonistic effects, 14, 31
 Antagonists, 14, 29f, 164, 173, 176t, 338–339, 606, 876b
 Anterior chamber (ocular), 918, 921
 Anterior pituitary gland (adenohypophysis), 520, 521t
 Anthelmintic drugs, 774
 Antibiotics, 691
 Antibodies, 621–622, 731, 733, 815–817, 819, 872, 874
 Antibody titre, 815, 819
 Anticholinergics (parasympatholytics), 361, 606
 Anticoagulants, 444, 447–453
 Antidiarrheal drugs, 654
 Antiemetic drugs, 667–668
 Antiepileptic drugs, 244, 246
 Antifibrinolytic drugs, 444, 447, 458–460, 459t–460t
 Antigens, 606, 608–609, 621–622, 731, 733, 815, 819, 872, 874
 Antihistamines, 606
 Antihypertensive drugs, 371, 374
 Antilipemic drugs, 469
 Antimalarial drugs, 774

Antimetabolites, 764–765
 Antimicrobial stewardship, 691, 695
 Antimuscarinic drugs, 361
 Antineoplastic drugs, 832, 837
 Antiprotozoal drugs, 774
 Antiretroviral drugs, 731, 734
 Antiretroviral therapy (ART), 741–742
 Antiseptics, 691, 693–694, 694t
 Antiserum, 815, 819
 Antithrombin III (AT-III), 444, 447–448
 Antitoxins, 815, 819
 Antitubercular drugs, 753–755
 Antitussives, 606
 Antivenins, 815, 819
 Antiviral drugs, 731–752
 Anxiety, 278, 280
 Apolipoproteins, 469–470
 Aqueous humour, 918, 920–921
 Arrhythmia, 423
 Arthritis, 872, 885
 Artificially acquired passive immunity, 819
 Ascites, 485
 Asthma, 621–622
 Asthma attack, 621–622
 Asystole, 423
 Atherogenesis, 471
 Atherosclerosis, 394, 471
 Atony, 350, 352
 Atopic dermatitis, 903–904
 Atrial fibrillation, 408, 413–414, 423, 427–430, 428t–429t
 Attention deficit hyperactivity disorder (ADHD), 229
 Autoimmune diseases, 804
 Autoimmune disorders, 872, 885
 Autoinduction, 244
 Automaticity, 408, 411, 424, 426
 Autonomic functions, 325–326
 Autonomic nervous system, 325–326, 375, 375f
 AV nodal re-entrant tachycardia, 430
 Azole antifungals, 765–766

B

B lymphocytes (B cells), 804, 872, 874, 875f
 Bacillus, 753–754
 Bactericidal antibiotics, 691–692, 698, 754
 Bacteriostatic antibiotics, 691, 697
 Balanced anaesthesia, 173–174, 196
 Basal cell carcinoma, 903–904, 912
 Benign prostatic hyperplasia (BPH), 596–598
 Benign tumours, 832–834, 834t
 Benzodiazepines, 214

Note: Page numbers followed by *f* indicate figures, *t* indicate tables, and *b* indicate boxes.

Benzodiazepines and Other Targeted Substances Regulations, 36, 38t, 39
 Beriberi, 111, 119
 Beta-adrenergic receptors, 325–326
 Beta-lactam, 691, 698
 Beta-lactamase, 691, 698
 Beta-lactamase inhibitors, 691
 Bias, 36, 41
 Bifunctional, 859–860
 Bioavailability, 14, 19
 Biogenic amine hypothesis (BAH), 278, 285–286, 286f
 Biological antimicrobial drugs, 815, 817
 Biotransformation, 14, 24–25
 Bipolar disorder (BPD), 278, 280
 Bivalent vaccines, 815, 824
 Blast cells, 837
 Blinded investigational drug study, 36, 41
 Blood, 500
 Blood-brain barrier, 14, 24
 Body mass index (BMI), 230
 Booster shots, 815, 819
 Bradykinesia, 262, 264
 Breakthrough pain, 164, 171
 Bronchodilators, 621, 624–629, 627t
 Bundle branch blocks, 430

C

Cachexia, 835
Canada Health Act, 36, 42
 Canada Vigilance Program, 82
 Canal of Schlemm, 918, 921
 Cancer, 832–833
 Carbuncles, 903, 906
 Carcinogens, 33, 33b, 832, 836
 Carcinomas, 832, 834, 834t
 Cardiac Arrhythmia Suppression Trial (CAST), 423, 434b
 Cardiac output (CO), 371–373, 373f
 Cardiometabolic syndrome, 278, 283b, 295, 473, 474b
 Cardioprotective effects, 380
 Cardioversion, 423, 427
 Casein, 679, 682, 753
 Catabolism, 596, 679
 Cataplexy, 229–230
 Cataract, 918, 921
 Catecholamines, 325–326
 Cell cycle-nonspecific antineoplastic drugs, 832, 838–839
 Cell cycle-specific antineoplastic drugs, 832, 838–839
 Cell-mediated immunity (CMI), 731, 733, 804, 815, 817, 836, 872, 875, 875f
 Cellulitis, 903, 906
 Central nervous system (CNS) stimulants, 228–229
 Central pain, 164, 168–169
 Central pontine myelinolysis, 510
 Centrally acting adrenergic drugs, 376
 Cerumen, 939, 941
 Cheese effect, 267

Chemical name, 14, 16, 17f
 Chemoreceptor trigger zone (CTZ), 667, 668f
 Chemotherapy, 838
 Chief cells, 640–641
 Chloasma, 574
 Cholesterol, 469
 Cholinergic crisis, 350, 353
 Cholinergic receptors, 350–351, 351f, 375
 Cholinergic-blocking drugs, 361–370
 Chorea, 262, 264
 Chromatin, 67, 69
 Chromosomes, 67–68
 Chronic bronchitis, 623–624
 Chronic obstructive pulmonary disease (COPD), 621–622
 Chronic stable angina, 394
 Chronotropic drugs, 408
 Chylomicrons, 469–470, 470t
 Ciliary muscles, 918, 921
 Circulating tumors, 834
 Classic migraine, 230
 Clinical judgement, 2
 Clinical reasoning, 2
 Clones, 832–833
 Clonic seizures, 245–246
 Closed-angle glaucoma, 918, 922, 922f, 923t
 Clot, 444
 Coagulation, 444–445, 446f
 Coagulation cascade, 444–445, 446f
 Coenzymes, 111, 121f
 Cognitive domain, 88
 Cogwheel rigidity, 271
 Collecting ducts, 485–486, 487f
 Colloid oncotic pressure (COP), 500–501, 502f
 Colloids, 500, 504–506, 505t
 Colonization, 691
 Colony-stimulating factors (CSFs), 872, 875–876
 Common migraine, 230
 Community-acquired infection, 691
 Complementary medicine, 98, 102
 Concentration-dependent killing, 715
 Conduction blocks, 427
 Cones, 918, 921, 922f
 Constipation, 654
 Contraindication, 14, 29
Controlled Drugs and Substances Act (CDSA), 36, 39
 Controlled substances, 36, 39
 Conventional medicine, 98, 102
 Convulsions, 244
 Cornea, 918–919
 Coronary arteries, 394
 Coronary artery disease (CAD), 394, 471–472, 472b, 480b
 Corpus luteum, 574–575
 Cortex, 563
 Corticosteroids, 563, 606
 Critical thinking, 1–2
 Cross-sensitivity, 702

Crystalloids, 500, 502–504, 503t, 505t
 Culture, 47
 Cushing's syndrome, 563–565
 Cycloplegia, 918, 921
 Cycloplegics, 918
 Cytochrome P450 enzymes, 14
 Cytokines, 872, 875, 878
 Cytopathic effect, 732–733
 Cytotoxic T cells, 872, 875, 875f

D

Decongestants, 606, 612
 Deep vein thrombosis (DVT), 444, 447
 Deficient knowledge, 3b
 Definitive therapy, 691, 694
 Dehydration, 500, 502, 503t

 codeine sulphate, 178b, 181t–182t
 colchicine, 797, 797b

colistimethate sodium [**Coly-Mycin**], 724–725, 724t, 725b
 collagenase [**Santyl**], 914t
 conjugated estrogens [**C.E.S. Tablets, Congest, Premarin**], 33, 576–577, 579t
 corticotropin [**Cortrosyn**], 521, 521t, 564
 cromolyn sodium [**Opticrom**], 934, 934t
 crochamiton [**Eurax**], 912
 cyanocobalamin (vitamin B₁₂), 112t–113t, 115t, 122–123, 122f, 123t
 cyclobenzaprine hydrochloride [**Novo-Cycloprine, Rive-Cycloprine**], 222t, 222b
 cyclopentolate hydrochloride solution [**Cyclogyl**], 933
 cyclophosphamide [**Procytox**], 860, 862, 862t
 cyclosporin [**Cyclosporin, Neoral, Sandimmune**], 402t, 806t–807t, 807–809, 809b, 810t, 812b
 cyproheptadine hydrochloride, 609t
 cytarabine (ara-C) [**Cytosar, Depocyt**], 843t, 844, 845t

D

dabigatran etexilate mesylate [**Pradaxa**], 448–449, 452t, 462
 dacarbazine, 860
 dactinomycin hydrochloride, 863, 869
 dalteparin [**Fragmin**], 447–448
 danaparoid sodium [**Orgaran**], 449
 danazol [**Cyclomen**], 589
 dantrolene sodium [**Dantrium**], 222t
 dapagliflozin [**Forxiga**], 551
 darbepoetin alfa [**Aranesp**], 876, 895
 darifenacin hydrobromide [**Enablex**], 365–366
 darunavir ethanolate [**Prezista**], 742t, 744
 daunorubicin hydrochloride, 863, 866b, 867
 delavirdine mesylate [**Rescriptor**], 742t
 denosumab [**Prolia, Xgeva**], 583–584
 desflurane [**Suprane**], 196t
 desipramine hydrochloride, 285t
 desloratadine [**Aerius, Allernix**], 608
 desmopressin acetate (DDAVP), 444, 459t, 460b
 dessicated thyroid [**Thyroid**], 529, 531t
 desvenlafaxine succinate [**Pristiq**], 291
 dexamethasone [**AK-Dex, Diodex, Dioptrol**], 846, 932, 932b
 dexamethasone sodium succinate, 566–567, 566t
 dextlansoprazole [**Dexilant**], 646–647
 dexmedetomidine hydrochloride [**Precedex**], 197t, 200
 dextran, 505–506, 506b
 dextroamphetamine sulphate, 231
 dextromethorphan hydrobromide [**Benylin DM-E, Buckley's, Dimetapp-DM, Robitussin-DM, Vicks**], 614, 615b, 616t

- diazepam [**Diastat**, **Diazemuls**, **Valium**], 197t, 216t, 218, 281t, 284t, 284b
- dibucaine hydrochloride [**Nupercainal**], 201t
- diclofenac sodium [**Voltaren Ophtha**], 791b, 931b
- dicyclomine hydrochloride [**Bentylol**, **Protylol**], 365, 366t
- didanosine (enteric coated) [**Videx EC**], 742t
- diethylstilbestrol, 577b
- diflunisal, 791b, 793–794
- digoxin immune Fab [**Digifab**], 413
- digoxin [**Lanoxin**], 413, 413t
- dihydroergotamine mesylate [**DHT**, **Migranal**], 234t
- diltiazem hydrochloride [**Apo-Diltiaz TZ**, **Cardizem CD**, **Tiazac**, **Taztia XT**], 400, 400t–401t, 432t, 434b, 438t, 440t
- dimenhydrinate [**Dinate**, **Gravol**, **Nauseatol**], 609t, 671
- dimeticon 50% [**Nyda**], 912
- dinoprostone [**Prostin E₂**, **Cervidil**, **Prepidil**], 587–588, 588t, 588b
- diphenhydramine hydrochloride [**Aller-Aide**, **Allernix**, **Benadryl**, **Nadryl**, **Sleep-Eze**, **Unisom**], 220, 265t, 607b, 609t–610t, 611, 671, 846
- diphenoxylate hydrochloride, 655t, 656
- diphenoxylate hydrochloride/atropine sulphate [**Lomotil**], 656, 657t
- diphtheria and tetanus toxoids with acellular pertussis vaccine adsorbed [**DTaP**], 821
- diphtheria toxoids, 821
- dipivefrin hydrochloride, 925–926, 926t
- dipyridamole, 455
- disopyramide, 432t
- disulfiram [**Antabuse**], 316
- divalproex sodium [**Depakene**, **Provallex**, **Epival**], 247t, 249t–250t, 251b, 255t–256t, 259, 285t, 777t
- dobutamine hydrochloride, 329t, 331, 332t, 412
- docetaxel [**Taxotere**], 845–846, 846t
- docusate sodium [**Colace**], 660–661, 662t, 664
- donepezil hydrochloride [**Aricept**], 353–354, 355b
- dopamine hydrochloride, 331, 332t
- dorzolamide [**Cosopt**, **Trusopt**], 927, 928t
- doxazosin mesylate [**Cardura**], 340t, 379b, 598
- doxepin hydrochloride [**Silenor**, **Sinequan**], 285t
- doxorubicin hydrochloride, liposomal [**Caelyx**, **Myocet**], 864t, 866b
- doxorubicin hydrochloride [**Adriamycin PFS**], 863–864, 863b, 864t
- doxycycline hyclate [**Apprilon**, **Atridox**, **Doxycin**, **Doxytab**, **Periostat**, **Vibramycin**], 709, 709t, 709b
- doxylamine succinate [**Unisom-2**], 220
- doxylamine succinate/pyridoxine hydrochloride [**Diclectin**], 673
- dronedrone hydrochloride [**Multaq**], 432t, 434b
- dulaglutide [**Trulicity**], 553
- duloxetine hydrochloride [**Cymbalta**], 285t, 290t, 298b
- dyclonine hydrochloride [**Sucrets**], 201t
- ## E
- edrophonium chloride [**Tensilon**], 354
- efavirenz [**Sustiva**], 742t
- efavirenz/emtricitabine/tenofovir fumarate [**Atripla**], 742t
- eletriptan hydrobromide [**Relpax**], 235
- emtricitabine [**Emtriva**], 742t
- emtricitabine/rilpivirine hydrochloride/tenofovir disoproxil fumarate [**Complera**], 742t
- enalapril sodium [**Vasotec**], 380t, 381–382
- enfuvirtide [**Fuzeon**], 742t, 744–745, 744b
- enoxaparin sodium [**Lovenox**], 447–448, 451b–452b, 452t
- Ensure**, 681b, 682
- entacapone [**Comtan**, **Stalevo**], 265t, 269t, 270b
- ephedrine, 626t
- epinephrine [**Allerject**, **EpiPen**], 625f, 626t
- epinephrine hydrochloride [**Adrenalin Chloride**], 329t, 331, 332t, 626t
- epirubicin hydrochloride, 863, 866b
- eplerenone [**Inspira**], 385, 493t
- epoetin alfa [**Eprex**], 876, 895, 895b, 898t
- eptifibatide [**Integrilin**], 455, 456t, 458b
- ergocalciferol, 117
- ergonovine maleate, 588, 588t, 588b
- eribulin mesylate [**Halaven**], 845
- ertapenem [**Invanz**], 704–705, 704b–705b
- Erwinase**, 848
- erythromycin [**EES**, **Erythro-EC**, **AK-Mycin**, etc.], 402t, 707–708, 707t, 930, 930b, 932t
- escitalopram hydrochloride [**Ciprallex**, **Ciprallex Meltz**], 285t, 291
- esmolol hydrochloride [**Brevibloc**], 340t, 344b, 345t, 434b
- esomeprazole trihydrate [**Nexium**], 646–647
- esterified estrogens [**Estragyn**], 576, 579t
- estradiol transdermal [**Climara**, **Divigel**, **Estrogen**, **Sandoz Estradiol Derm**, **Oesclim**], 577, 579t
- estradiol vaginal dose forms [**Estring**, **Premarin**, **Vagifem**], 577
- estradiol vaginal ring [**Estring**], 577
- estradiol valerate, 577, 579t
- estrogen [**Estradot**], 589
- estrone [**Folliculinum**, **Estrone Vaginal Cream**], 577
- estropipate [**Ogen**], 577
- etanercept [**Enbrel**], 884t, 886
- ethacrynic acid, 489b
- ethambutol hydrochloride [**Etibi**], 757, 757t, 757b, 759t
- ethinyl estradiol [**Alesse**, **Alysena**, **Aviane**, etc.], 577
- ethinyl estradiol-levonorgestrel [**Ovral**], 582
- ethopropazine hydrochloride [**Parsitan**], 265t
- ethosuximide [**Zarontin**], 251b, 255t–256t
- etidronate disodium/calcium carbonate [**Didrocal**, **Etidrocal**], 583–584, 585t
- etodolac, 791b
- etonogestrel/ethinyl estradiol vaginal ring [**NuvaRing**], 583t
- etoposide [**VePesid**], 846, 846t–847t
- etravirine [**Intelence**], 742t
- everolimus [**Afinitor**, **Afinitor Disperz**], 809
- exenatide [**Byetta**], 553
- ezetimibe [**Ezetrol**], 476b, 479t
- ## F
- famciclovir, 736
- famotidine [**Pepcid**, **Pepcid AC**], 608, 646, 646b, 647t
- febuxostat [**Uloric**], 796–797
- felodipine [**Plendil**, **Renedil**], 400t
- fenofibrate, 18, 478
- fenoterol [**Duovent UDV**], 626t
- fentanyl [**Abstral**, **Duragesic Mat**, **Fentanyl Citrate Injection**], 178b, 181t–182t, 190t, 197t
- ferric gluconate [**Ferrlecit**], 895–897, 897b, 898t
- ferrous fumarate [**Palafer**], 897, 897b, 898t
- ferrous sulphate, 897, 897b, 898t
- ferumoxytol [**Feraheme**], 895–897
- fesoterodine fumarate [**Toviaz**], 365–366
- feverfew (*Chrysanthemum parthenium*), 188b, 208b
- fexofenadine hydrochloride [**Allegra**], 608, 609t–610t, 616
- fidaxomicin [**Dificid**], 705–706
- filgrastim [**Neupogen**], 847–848, 877
- finasteride [**Propecia**, **Proscar**], 597–598, 599t–600t, 600b, 912
- finingolmod hydrochloride [**Gilenya**], 806t, 809
- flecainide acetate [**Tambocor**], 432t, 434b
- fluconazole [**Diflucan**], 768, 768b, 769t
- flucytosine, 765
- fludarabine phosphate [**Fludara**], 843t, 844, 845t
- fludrocortisone 21-acetate [**Florinef**], 565, 568b–569b, 569t
- flumazenil, 217, 217t
- flunitrazepam [**Rohypnol**], 313
- fluorescein sodium [**AK-Fluor**], 934
- 5-fluorocytosine [**5-FC**], 765
- fluorouracil (5-FU), 843t, 844, 845t
- fluorouracil (5-FU) topical [**Efudex**], 913
- fluoxetine hydrochloride [**Prozac**], 285t, 290t, 291, 298b
- fluphenazine, 293t

flurazepam hydrochloride [**Dalmane, Som-Pam**], 216t
 flurbiprofen sodium [**Ocufen**], 791b, 931b
 flutamide [**Euflex**], 598, 867
 fluticasone propionate [**Flonase, Flovent Diskus, Flovent HFA**], 632, 632b, 633t
 fluticasone/salmeterol xinafoate [**Advair Diskus, Advair Inhalation Aerosol**], 632
 fluvastatin sodium, 473–474
 fluvoxamine maleate [**Luvox**], 285t, 291
 folic acid, 898t, 899b
 fondaparinux sodium [**Arixtra**], 448–449, 451b, 452t, 456b
 formoterol [**Foradil, Oxeze**], 626
 fosamprenavir calcium [**Telzir**], 742t
 fosinopril sodium, 380t
 fosphenytoin [**Cerebyx**], 247t, 251b, 255t–256t
 fresh frozen plasma, 507
 frovatriptan succinate [**Frova**], 235
 furosemide [**Lasix**], 489, 489b

G

gabapentin [**Neurontin**], 247t, 251b, 255t–256t, 259
 galantamine [**Reminyl**], 353
 gamma-hydroxybutyric acid (GHB), 313
 ganciclovir hydrochloride [**Cytovene, Valcyte**], 737t, 738, 738b, 739t
 gatifloxacin [**Zymar**], 931
 gemcitabine hydrochloride [**Gemzar**], 843t, 844, 845t
 gemfibrozil, 476b, 478, 479t
 gentamicin sulphate [**Diogent, Gentak**], 718t–719t, 719, 719b, 930, 930b, 932t
 glatiramer acetate [**Copaxone**], 806t, 809, 810t
 gliclazide [**Diamicron, Diamicron MR**], 549, 551, 552b, 554t
 glimepiride [**Amaryl**], 549, 554t
Glucema, 681b
 glucose, 489, 537–538
 glyburide [**Diabeta**], 549
 glycerin [**Glycerin Suppository**], 661, 662t
 glycopyrrolate, 197t, 364–365, 366t
 glycopyrronium bromide [**Seebri Breezhaler**], 627
 golimumab [**Simponi**], 880t, 881
 gonadotropin-releasing hormone (Gn-RH) agonists, 865t
 goserelin acetate [**Zoladex**], 598
 granisetron hydrochloride [**Granisetron HCL**], 673, 676
 griseofulvin, 765
 guaifenesin [**Balminil, Bronchophan, Robitussin, etc.**], 615, 616t

H

Haemophilus influenzae type B (Hib) vaccine [**Act-HIB**], 821–822, 827
 haloperidol, 287, 293t, 298t, 303

halothane [**Halothane**], 196t, 198t
 heparin sodium, 451b, 452t, 453b
 hepatitis B immunoglobulin [**HBIG; HepaGam B, HyperHEP B**], 825
 hepatitis B virus vaccine (inactivated) [**Recombivax HB, Engerix-B**], 822
 heroin, 309
 hetastarch, 505
 homatropine [**Isopto Homatropine**], 933
 human antithrombin III [**Thrombate**], 448–449
 human papillomavirus (HPV) vaccines [**Gardasil, Cervarix**], 824
 hydantoins, 249t–250t, 251b, 256–257, 259
 hydralazine hydrochloride [**Apresoline**], 384t, 384b
 hydralazine/isosorbide dinitrate, 412
 hydrochlorothiazide [**Uroside**], 493–494, 494b–495b
 hydrocodone bitartrate, 614
 hydrocortisone sodium succinate [**Solu-Cortef**], 521, 566t, 569b
 hydromorphone [**Dilaudid**], 178, 190t
 hydroxychloroquine sulphate [**Plaquenil**], 777–780, 778t–779t, 778b
 hydroxyurea [**Hydrea**], 864–865
 hydroxyzine hydrochloride [**Atarax**], 197t, 281t, 609t
 hypertonic solution, 501, 502f

I

ibuprofen [**Motrin, Advil, others**], 233b–234b, 791b, 795, 795b, 796t
 ibutilide fumarate [**Corvert**], 432t, 434b, 440t
 idarubicin hydrochloride, 863, 866b
 ifosfamide, 860
 imatinib mesylate [**Gleevec**], 865
 imipenem/cilastatin [**Primaxin**], 704
 imipramine hydrochloride, 285t
 imiquimod [**Aldara, Vyloma**], 913
 immune globulin [**GamaSTAN S/D**], 825
 indinavir sulphate [**Crixivan**], 737t, 742t, 744, 744b
 indomethacin [**Indocid P.D.A., Nu-Indo**], 791b, 794, 794b, 796t
 infliximab [**Inflectra, Remicade, Remsima**], 880t, 881–882, 882t
 influenza virus vaccine (seasonal) [**Agriflu, Fluad, Fluviral, Fluzone, Influvac, Intanza, Vaxigrip**], 822–823
 influenza virus vaccine (attenuated trivalent) [**FluMist**], 822
 influenza virus vaccine (attenuated quadrivalent) [**FluMist Quadrivalent**], 822
 insulin aspart [**NovoRapid**], 543t, 545–546
 insulin detemir [**Levemir**], 543t, 546, 546b
 insulin glargine [**Apidra, Basaglar, Lantus**], 543t, 545–546
 insulin isophane suspension [**Humulin N, Novolin ge NPH**], 546, 546b

insulin lispro [**Humalog**], 543t, 545–546
 interferon alfa-2a, 878–879
 interferon alfa-2b [**Intron A**], 878–879, 879t
 interferon beta-1a [**Avonex PEN, Avonex PS, Rebif**], 879, 879t
 interferon beta-1b [**Betaseron, Extavia**], 879t
 iodine [**Iodosorb**], 914t
 iodine-131, 531
 iodine-131 tositumomab, 880t
 ipratropium bromide [**Atrovent, Ipratvent**], 627–628, 627t, 628b
 irinotecan hydrochloride [**Camptosar**], 848, 848t
 iron dextran [**Dexiron, Infufer**], 895–897, 897b, 898t
 iron sucrose [**Venofer**], 895–897, 897b, 898t
Isocal, 681b
 isoflurane [**Forane**], 196t, 198t, 199
 isoniazid [**Isotamine**], 753–755, 757–758, 757t, 758b, 759t
 isoniazid/pyrazinamide/rifampin [**Rifater**], 758
 isopropyl alcohol, 913, 914t
 isosorbide dinitrate [**ISDN**], 397, 398t, 405
 isosorbide-5-mononitrate [**Imdur**], 397, 398t, 405
 isotretinoin [**Accutane, Clarus, Epuris**], 907–908
 itraconazole, 766

J

Jevity, 681b

K

ketamine hydrochloride [**Ketalar**], 199
 ketoconazole [**Ketoderm cream, Nizoral**], 909t
 ketoprofen [**Apo-Keto-E**], 791b
 ketorolac tromethamine [**Acular, Toradol**], 791b, 795, 795b, 796t, 931b, 932–933, 933b

L

labetalol hydrochloride [**Trandate**], 340t, 344b, 345t
 lacosamide [**Vimpat**], 247t
 lactulose, 661
 lamivudine [**3 TC, Heptovir**], 742t
 lamivudine/zidovudine [**Combivir**], 742t
 lamotrigine [**Lamictal**], 247t, 251b, 255t–256t, 259, 285t
 lansoprazole [**Prevacid, Prevacid FasTab**], 644, 646–647, 648b, 649t
 latanoprost [**Xalacom, Xalatan**], 928–929, 929b
 leflunomide [**Arava**], 884t, 886
 leuprolide acetate [**Eligard, Lupron**], 598
 levetiracetam [**Keppra**], 247t, 251b, 255t–256t, 259
 levodopa, 266

levodopa-benserazide hydrochloride [**Prolopa**], 269t
 levodopa-carbidopa [**Duodopa**, **Sinemet**, **Sinemet CR**, **Parcopa**], 265t, 267, 269t
 levofloxacin [**Levaquin**], 720t–721t, 721, 721b
 levonorgestrel [**Min-Ovral**, **Mirena**, **Next Choice**, **Norlevo**, **Option 2**], 580
 levonorgestrel/ethinyl estradiol [**Alesse**, **Alysena**, **Avian**, **Esme**, **Min-Ovral**, **Ovima**, **Portia**, **Ortho7/7/7**, **Triquilar**, **Seasonale**], 583t
 levothyroxine sodium [**Eltroxin**, **Euthyrox**, **Synthroid**], 530, 530b, 531t
 lidocaine, transdermal, 184b
 lidocaine [**Bactine**, **Betacaine**], 201t
 lidocaine hydrochloride [**Xylocaine**], 201t, 203, 432t, 434b, 438t, 440t
 linagliptin [**Tradjenta**], 550
 linagliptin/metformin ER [**Jentadueto**], 554t
 linezolid [**Zyvoxam**], 722, 722b, 724t, 726–727
 liothyronine sodium [**Cytomel**], 530, 531t
 lipid emulsions [**Intralipid**, **Liposyn**], 685, 685f
 liraglutide [**Victoza**], 553
 lisdexamfetamine dimesylate [**Vyvanse**], 231
 lisinopril [**Prinivil**, **Zestril**], 380t, 413b
 lithium, 288t, 292b
 lithium carbonate [**Carbolith**, **Lithane**], 285t, 290t
 lithium citrate, 285t
 lomustine, 860
 loperamide hydrochloride [**Imodium**], 656, 657t
 lopinavir/ritonavir [**Kaletra**], 742t
 loratadine [**Claritin**], 607b, 608, 609t–610t, 611
 lorazepam [**Ativan**], 216t, 218b, 281t, 284t, 284b
 losartan potassium [**Cozaar**], 382, 383b
 lovastatin, 473–474
 loxapine hydrochloride [**Loxapac**], 293t
 loxapine succinate [**Xylane**], 293t
 lurasidone hydrochloride [**Latuda**], 284, 293t

M

magnesium citrate, 659t
 magnesium hydroxide [**Phillips' Milk of Magnesia**], 661
 magnesium phosphate, 659t
 magnesium sulphate, 659t
 mannitol [**Osmitrol**], 490, 490b, 928, 928b
 maprotiline hydrochloride, 285t, 288t
 maraviroc [**Celsentri**], 737t, 742t, 744, 744b
 marihuana, 104–105, 106b, 319
MCT Oil, 681b
 measles, mumps, and rubella (MMR) vaccine (M-M-R, Priorix), 823
 mebendazole [**Vermox**], 783, 783t

meclizine hydrochloride [**Bonamine**], 674t
 medroxyprogesterone [**Depo-Provera**, **Medroxy**, **Provera**], 580, 580b, 581t, 583t
 mefenamic acid [**Ponstan**], 791b
 mefloquine hydrochloride [**Lariam**], 778, 778t–779t, 778b
 megestrol acetate [**Megace**], 580, 580b, 581t
 megestrol [**Megace**], 580
 melatonin, 215
 meloxicam [**Mobicox**], 791b
 melphalan, 860
 memantine hydrochloride [**Ebixa**], 354
 meningococcal B vaccine [**Bexsero**], 823
 menotropins, 586
 meperidine hydrochloride [**Demerol**], 179b, 181t–182t, 190t
 mepivacaine hydrochloride [**Carbocaine**, **Isocaine**], 201t, 203
 mercaptopurine [**6-MP**], 843t
 meropenem [**Merrem**], 704–705, 704b–705b
 metformin hydrochloride [**Glucophage**, **Glumetza**], 552, 552b, 554t
 methadone hydrochloride [**Metadol**], 179b, 181t–182t
 methamphetamine hydrochloride, 231
 methotrexate (MTX) [**Metoject**], 843t, 845t
 methylcellulose, 660, 662t
 methyl dopa, 379
 methylenedioxymethamphetamine (MDMA, ecstasy, or E), 312
 methylgonovine maleate, 590–591
 methyl naltrexone bromide [**Relistor**], 659
 methylphenidate hydrochloride [**Concerta**, **Ritalin**, **Ritalin SR**], 231–232, 233t
 methylprednisolone sodium succinate [**Medrol**, **Solu-Medrol**], 566t, 568b–569b, 569t, 632, 632b, 633t
 metoclopramide hydrochloride [**Metonia**, **Metoclopramide OMEGA**], 672, 674t
 metolazone [**Zaroxolyn**], 494, 494b
 metoprolol tartrate [**Lopressor**], 340t, 344b, 345t, 399, 399t, 434b, 440t
 metronidazole [**Flagyl**], 722–723, 723b, 724t, 781–782, 782b
 micafungin sodium, 765
 miconazole nitrate [**Micatin**, **Micozole**, **Monistat**, **Monistat Pak**], 909, 909t
Microlipid, 681b
 midazolam, 197t, 218b
 midazolam hydrochloride, 216t
 midodrine hydrochloride, 332, 332t
 mifepristone [**Mifegymiso**], 587
 milnacipran, 182
 milrinone lactate, 412, 413t
 mineral oil [**Mineral Oil**], 661, 662t
 minoxidil [**Minox**, **Rogaine**, **Loniten**], 599t, 912
 mirtazapine [**Remeron**], 288t, 290t, 298b
 misoprostol, 649, 649b
 mitomycin hydrochloride, 863
 mitotane [**Lysodren**], 865

mitoxantrone hydrochloride, 863, 864t, 884t
 modafinil [**Alertec**], 233t, 235
Moducal, 681b
 monovalent conjugate meningococcal vaccines [**Men-C**, **Menjugate**, **NeisVac-C**], 823
 montelukast sodium [**Singulair**], 630, 630t, 630b
 morphine hydrochloride [**Doloral syrup**], 181t–182t
 morphine sulphate [**Kadian**, **M.O.S. Sulphate**, **MS Contin**, **MS IR**, **Statex**], 178, 181t–182t, 190t, 197t
 moxifloxacin hydrochloride [**Avelox**, **Vigamox**], 720t, 931
 mupirocin [**Bactroban**], 906
 mycophenolate mofetil [**CellCept**], 806t, 810t
 mycophenolate sodium [**Myfortic**], 806t, 810t

N

nabumetone, 791b, 792t, 795
 nadolol [**Nadol**], 340t, 399
 nadroparin calcium [**Fraxiparine**], 447–448, 448t
 nalbuphine hydrochloride, 190t
 naloxone hydrochloride, 165b, 172t, 176t, 180b, 181t–182t, 190t, 311
 naltrexone hydrochloride [**ReVia**], 165b, 180b, 181t–182t, 311
 naltrexone-buprenorphine hydrochloride [**Suboxone**], 311
 naltrexone-hydromorphone hydrochloride [**Targin**], 311
 nandrolone deconate, 597, 599t
 naproxen sodium [**Aleve**, **Anaprox**, **Naprelan**, **Naproxen**, **Naprosyn**], 101t, 791b
 naratriptan hydrochloride [**Amerge**], 229t, 235
 natalizumab [**Tysabri**], 873b, 882, 882t
 nateglinide [**Starlix**], 549, 552
 nebivolol hydrochloride [**Bystolic**], 340t, 372b, 379, 399
 nelfinavir mesylate [**Viracept**], 742t, 744
 neomycin sulphate, 18, 718t
 neomycin/polymyxin B [**Neosporin**], 906
 neostigmine methylsulfate [**Prostigmin**], 351b
 nevirapine [**Viramune**, **Viramune XR**], 732b, 737t, 742t, 744, 745b, 746t, 749
 niclosamide, 783
 nicotine gum [**Nicorette**], 99, 100b, 317t
 nicotine transdermal patch [**Nicoderm**, **Habitrol**], 100b, 317t
 nicotinic acid [**Niaspan**], 469b, 477, 477t, 478b, 479t, 481
 nifedipine [**Adalat XL**], 400t
 nilutamide [**Anandron**], 598, 598b, 865, 865t, 867
 nimodipine [**Nimotop**], 383, 400t

oxaliplatin, 838f, 840b, 860

oxandrolone, 597, 599t

oxaprozin tiaprofenic acid, 791b

oxazepam [**Oxepam**], 216t, 281t

oxcarbazepine [**Trileptal**], 244b–245b, 247t–250t, 251b, 255t–256t, 259, 268t, 285t

oxybutynin chloride [**Ditropan**, **Oxytrol**, **Gelnique**], 361b–362b, 365, 366t, 368

oxycodone hydrochloride [**OxyContin**, **OxyNeo**, **Oxy IR**], 165b, 174, 180b, 181t–182t, 190t

oxycodone-acetaminophen [**Percocet**], 31, 180b, 183

oxycodone-aspirin [**Ratio-Oxycodone**], 180b

oxycodone-naloxone [**Targin**], 180b

oxycodone-phenyltoloxamine [**Tussionex**], 180b

oxymetazoline hydrochloride [**Claritin**, **Dristan**, **Drixoral**, **Sinufirin**, **Vicks**], 607b, 612–613, 613b, 616t

oxytocin, 77t, 520b, 521t, 575b, 586–588, 588t, 588b, 592

P

packed red blood cells, 501b, 506t–507t, 507

paclitaxel [**Abraxane**], 102t, 833b, 840b, 845–846, 846t–847t

paliperidone [**Invega**], 278, 293t

palivizumab [**Synagis**], 873b, 876b, 880t, 882

palonosetron hydrochloride [**Aloxi**], 668t, 672

pancuronium bromide, 195b, 204t, 205, 206t

pantoprazole sodium [**Panto**, **Pantoloc**], 644, 646–647, 648b, 649t

paromomycin sulphate, 718t, 719, 780–781, 780t–781t, 783t

paroxetine hydrochloride [**Paxil**, **Paxil CR**], 285t, 291, 848t

pazopanib hydrochloride, 864

pegaspargase [**Oncaspar**], 833b, 848–849, 849t, 855

pegfilgrastim, 876b, 877

peginterferon alfa-2a [**Pegasys**], 873b, 876b, 878–879, 879t

peginterferon alfa-2b, 873b, 876b

pemetrexed disodium, 841, 844

penicillin G, 692b, 699t, 700, 700b

penicillin V potassium [**Pen VK**], 692b, 700, 700b, 701t

pentamidine isethionate, 780–783, 780t–782t

Pentaspán, 505

pentazocine, 38t, 180b, 190t–191t

pentobarbital sodium, 197t

pentoxifylline, 448–449, 448t

Peptamen, 681b

perampanel [**Fycompa**], 255t–256t

perindopril erbumine [**Coversyl**], 380t

perphenazine, 293t

phenelzine sulfate [**Nardil**], 285t

phenobarbital, 247t, 255t–256t

phentermine, 234t

phentolamine mesylate [**Rogitine**], 340t

phenylephrine hydrochloride [**Neo-Synephrine**], 332, 332t

phenytoin [**Dilantin**, **Tremytoine**], 247t, 249t–250t, 255t–256t

pilocarpine hydrochloride [**Akarpine**, **Salagen**, **Diocarpine**, **Isopto Carpine**, **Minims**], 351b

pimecrolimus [**Elidel**], 913

pimozide [**Orap**], 293t

pindolol [**Visken**], 340t

pioglitazone hydrochloride [**Actos**], 554t

piperacillin sodium, 692b, 699t

piroxicam, 791b

Polycose, 681b

polyethylene glycol [**Klean-Prep**, **Pegalex**], 662t

Portagen, 681b

potassium chloride, 77t

povidone-iodine, 913, 914t

pramipexole dihydrochloride monohydrate [**Mirapex**], 265t

pravastatin sodium, 473–474

praziquantel [**Biltricide**], 783, 783t

prazosin hydrochloride [**Minipress**], 340t

prednisolone sodium phosphate, 566t

prednisone [**Winpred**], 566t, 569t

pregabalin [**Lyrica**], 247t, 251b, 255t–256t, 259

prilocaine hydrochloride, 203

prilocaine/lidocaine (EMLA), 201t

primaquine phosphate, 778t–779t

Primene, 681b

primidone, 247t, 255t–256t

procainamide hydrochloride, 432t

procarbazine hydrochloride, 860

prochlorperazine, 293t, 674t

procyclidine hydrochloride, 265t

progesterone [**Crinone**, **Prometrium**], 580

progestins, 865t

promethazine hydrochloride [**Histanil**], 197t, 609t, 674t

ProMod, 681b

propafenone hydrochloride [**Rythmol**], 432t, 438t, 440t

propofol [**Diprivan**], 195b

propranolol hydrochloride [**Inderal**], 340t, 345t

psyllium hydrophilic mucilloid [**Metamucil Preparations**], 662t

pyrantel pamoate [**Combantrin**], 783, 783t

pyrazinamide [**Tebrazid**], 757t, 759t

pyridostigmine bromide [**Mestinon**], 351b, 355b

pyrilamine, 609t

Q

quetiapine fumarate [**Seroquel**], 293t

quinapril hydrochloride [**Accupril**], 380t

quinidine sulfate, 432t, 438t, 440t

quinupristin/dalfopristin [**Synercid**], 724t

R

rabeprazole sodium [**Pariet**], 646–647

raloxifene hydrochloride [**Evista**], 585t

raltegravir potassium [**Isentress**], 737t, 742t

ramipril [**Altace**], 380t

ranitidine hydrochloride [**Zantac**], 100b, 608, 640b, 647t

rasagiline mesylate [**Azilect**], 265t

regular insulin [**Humulin R**, **Novolin ge Toronto**], 543t

remifentanyl hydrochloride, 197t

repaglinide [**GlucoNorm**], 549, 554t

Rh0(D) immunoglobulin [**RhoGAM**, **WinRho**], 825–826

ribavirin [**Virazole**], 736t–737t, 739t

rifabutin [**Mycobutin**], 757t, 759t

rifampin [**Rifadin**, **Rofact**], 757t, 759t

risedronate sodium [**Actonel DR**], 585t

risperidone [**Risperdal**], 293t, 298t
 ritonavir [**Norvir**, **Norvir Sec**], 742t, 744
 rituximab [**Rituxan**], 840b, 873b, 876b, 880t, 882, 882t, 885b
 rivaroxaban [**Xarelto**], 445b, 448–449, 448t–449t, 451b
 rivastigmine hydrogen tartrate [**Exelon**], 351b, 352–354
 rizatriptan benzoate [**Maxalt**], 229t, 235
 rocuronium bromide [**Zemuron**], 204t
 rofecoxib [**Vioxx**], 40, 795
 roflumilast [**Daxas**], 632
 romidepsin, 864
 ropinirole [**ReQuip**], 262b, 264, 265t, 266, 267t–269t, 272, 276
 rosiglitazone mesylate [**Avandia**], 549–550
 rosiglitazone/metformin [**Avandamet**], 548, 554t
 rosuvastatin calcium [**Crestor**], 473–474, 476
 rotavirus oral vaccine [**RotaTeq**, **Rotarix**], 825

sodium polystyrene sulfonate [**Kayexalate**, **Solystat**], 509
 sodium supplements, 509–511
 solifenacin succinate [**Vesicare**], 362b
 somatotropin [**Humatrope**], 524t
 somatropin [**Serostim**], 524t
 somatropin [**Gentropin**, **Humatrope**, **Norditropin**, **Simplex**, **Nutropin**, **Omnitrope**, **Saizen**, **Serostim**], 522t, 523, 523b
 sorafenib tosylate, 864
 sotalol hydrochloride [**Rolosol**], 340t, 345t, 345b, 432t, 434b, 438t, 440t
 spironolactone [**Aldactone**], 492, 492b, 493t
 stavudine [**Zerit**], 742t
 streptokinase (SK), 457
 streptomycin, 757t
 streptomycin sulphate, 718t, 753b, 758
 streptozocin, 840b, 860
 strontium Sr 89 chloride, 865–866
 succinylcholine [**Quelicin**], 205
 sucralose, 640b
 sufentanil citrate, 197t
 sulfacetamide sodium [**AK-Sulf**, **Diosulf**], 931, 931b, 932t
 sulfamethoxazole/trimethoprim [**Apo-Sulfatrim**, **Protrim**, **Sepra**, **Teva-Trimel**], 698, 698t, 698b
 sulfasalazine, 885b
 sulfipyrazole, 796
 sulfoxazole acetyl/erythromycin ethylsuccinate, 697
 sumatriptan [**Imitrex**, **Imitrex DF**], 233t–234t, 236
 sunitinib malate, 864
Sustacal, 681b

T

tacrolimus [**Advagraf**, **Prograf**], 806t–807t, 809, 809b, 810t
 tacrolimus topical [**Protopic**], 913
 tadalafil [**Cialis**, **Adcirca**], 396, 599t
 tamsulosin hydrochloride [**Flomax**], 338b, 340t, 598, 600t
 tar-containing products, 904b
 tazarotene, 910–911
 tazobactam, 698
 tdap vaccine [**Adacel**], 821
 tdap-IPV vaccine [**Adacel-Polio**, **Boostrix-Polio**], 821
 temazepam [**Restoril**], 216t
 temozolomide, 840b, 860
 tenecteplase [**TNKase**], 458t
 teniposide, 840b
 tenofovir disoproxil fumarate [**Viread**], 737t, 742t, 745, 745b
 tenofovir disoproxil fumarate/emtricitabine [**Retrovir**], 742t
 terazosin hydrochloride [**Hytrin**], 340t, 598
 terbinafine hydrochloride [**Lamisil**], 768, 768b, 769t, 909t

terbutaline sulphate [**Bricanyl**], 624–625, 626t
 teriparatide, 584
 testosterone [**Androderm**, **AndroGel**], 596, 599t–600t, 600b
 testosterone cypionate [**Depo-Testosterone**], 600t
 tetanus immunoglobulin [**Hypertet S/D**], 826
 tetanus toxoids, 821
 tetracaine hydrochloride [**Pontocaine**, **Minims**], 201t, 203, 933, 933b
 tetrahydrocannabinol (THC), 669–670, 672
 tetrahydrozoline hydrochloride [**Allergy Eye Drops**, **Visine**], 934, 934t
 thalidomide [**Thalomid**], 884t
 theophylline [**Theolair**, **Uniphyll**], 629
 thiamazole, 532t
 thioguanine (6-TG), 843t
 thiopental [**Pentothal**], 196t
 thiothixene [**Navane**], 293t
 13-valent conjugate vaccine [**Pneu-C-13 or Prevnar 13**], 823–824
 ticagrelor [**BRILINTA**], 457t
 ticlopidine hydrochloride, 455
 tigecycline [**Tyagcil**], 709, 709t, 709b
 timolol maleate [**Betimol**, **Timoptic**, **Tim-AK**], 340t, 926–927, 927t, 927b
 tinzaparin sodium [**Innohep**], 447–448, 448t
 tiotropium bromide monohydrate [**Spiriva**], 627
 tipranavir [**Aptivus**], 742t
 tirofiban hydrochloride [**Aggrastat**], 455
 tizanidine hydrochloride, 222t
 tobramycin sulphate, 718t–719t, 719, 719b
 tocilizumab [**Actemra**], 880t, 884, 884t
 tofacitinib, 880t, 886
 tolnaftate [**Tinactin**], 909t
 tolterodine tartrate [**Detrol**], 365, 366t
 tolvaptan [**Samsca**], 510–511, 511b
 topiramate [**Topamax**], 247t, 251b, 255t–256t, 285t
 topotecan hydrochloride [**Hycamtin**], 848, 848t
 tositumomab, 880t
 tramadol hydrochloride [**Ultram**], 181t–182t, 183b
 trandolapril [**Mavik**], 380t
 tranexamic acid [**Cyklokapron**], 459t
 tranlycypromine sulfate [**Parnate**], 285t
 trastuzumab [**Herceptin**, **Kadcyla**], 880t, 882–883, 882t
 trastuzumab/paclitaxel [**Perjeta/Herceptin**], 882–883
Travasol, 681b
 travoprost [**Travatan Z**], 928
 trazodone hydrochloride [**Oleptro**, **Trazorel**], 285t, 288t, 290t, 298b
 treprostinil sodium [**Remodulin**], 386
 tretinoin [**Retin-A**, **Stieva-A**, **Vesanoid**], 884t, 908
 triamcinolone acetonide, 566t

triamterene, 492, 492b
 triamterene/hydrochlorothiazide, 493t
 triazolam, 216t
 trichlormethiazide, 493
 trifluoperazine hydrochloride, 293t
 trifluridine [**Viroptic**], 931, 932t
